Before seeking to interview the patients we tried to reduce the mass of documentary information to some sort of order. This included placing each case in one of five diagnostic categories (as explained under "Diagnosis"), a procedure which we termed "diagnosis in retrospect." We also formed an opinion from the documents whether we considered the prognosis with treatment to be "good" or "moderately good," a procedure we termed "prognosis in retrospect." Briefly, the factors which weighed with us mostly in making this prognosis were: (1) intelligence (low, average, high); (2) attitude to life and previous adjustment (poor, average, good); (3) duration of symptoms (over 10 years, 1-10 years, under 1 year); and (4) effect of symptoms on function (very serious, serious, slight). We also had to define the terms we were using—for example, distributive analysis—and, lastly, we drew up a form for use at the time of the forthcoming interviews. Our results and conclusions were eventually arrived at through analysing the completed forms.

Types of Psychotherapy

The various types of psychotherapy used by us were divided into two main groups: (1) Superficial—by which we mean advice, explanation, suggestion, persuasion, reassurance, and encouragement. (2) Distributive analysis—by which we mean that more use was made of analytical principles and that certain experiences in the patient's life were dealt with on analytical lines.

Abreactions with the use of injections or carbon dioxide were occasionally employed, chiefly in conjunction with the main methods just defined. What is described as superficial therapy was given in 45% of the cases, and distributive analysis in 49%, while 6% were treated mainly by abreactive methods.

We based our therapy on the assumption that if a person is tackling his life problems badly and producing neurotic

symptoms as a result, then a change of attitude is necessary, and this change is best brought about by increased insight derived from some form of psychotherapy.

A few further notes are necessary in order to give some idea of our broad views on psychotherapy and our procedure in selection and technique. As part of every psychiatric consultation we try to assess how much we can help the patient by out-patient psychotherapy. This includes an opinion on the extent to which the patient can accept insight and, having accepted it, on whether he or she will be able to act on it.

The aim of our treatment has been the attainment of a suitable degree of insight and the positive encouragement of self-discipline. At some stage in treatment practical advice is often given in a friendly way.

For various reasons, including the length of the waiting-list and the time at our disposal, we aim at a course of about six to eight sessions, and in this series of cases it was unusual for any patient to have had more than 12 interviews. (Recently our practice has changed a little in this respect so that very occasionally we may treat a patient for a year or more.) The interviews are weekly and last about 45 minutes, but may vary from 15 minutes to an hour or more. The average number of interviews in this series worked out at 6.8 per patient, only two patients being given as many as 20 sessions. We decided to consider the discharge date as being the last occasion on which the patient had a regular interview at not longer than monthly intervals.

In choosing a patient for psychotherapy we kept four different considerations in mind, any one of which justified placing the patient's name on the waiting-list: (1) A severe illness, where there was no other form of therapy available; (2) the possibility of removal of symptoms; (3) the possibility of helping the patient to adjust to his symptoms; (4) the possibility of assisting the patient to adjust to future stresses of a similar nature to those causing the present breakdown. Finally, as we have already stated, we attach particular importance to assessment of the degree to which the patient can accept insight and act on it.

A patient who is severely ill and likely to be helped, even if only to a limited extent, is worth accepting, if no better form of treatment is available. One would not insist on the likelihood of cure to justify selection in this type of case.

It goes without saying that the removal of symptoms is a desirable change, but one is not always sure that there may not be a recurrence later in the face of repeated stress of a similar type. If the patient deals with later stress and cures himself or herself of a relapse, this would be regarded as a good result. (In several cases where there had been a relapse a further interview proved well worth while.)

It is not always possible to remove the symptoms while treatment is being given, but if the patient can be helped to live with his symptoms it is likely that the reduced anxiety will allow a gradual improvement. When we saw some patients after a length of time we were surprised how much they had improved in the interval as the result of discussions or advice given during the psychotherapy.

It is generally agreed that the shorter types of psychotherapy tend to be somewhat authoritarian in character. When using suggestion and persuasion one tries to get a patient to abandon his own method of dealing with his problems—namely, with neurotic symptoms or reactions—and accept instead a solution which appears preferable. If the solution one offers the patient does not seem preferable to him he will refuse it, and part at least of the skill in this type of psychotherapy lies in the manner in which the therapist tackles this difficulty. Some of the issues presented are quite straightforward, and most people would agree on the lines upon which advice shall be given; but many are highly controversial, and in these there is a danger of moralizing with the patient. It appears to us that there is no objection to giving the patient specific advice if one is asked for it, but it must always be borne

in mind that far more good advice is given in the world than is ever acted upon. Needless to say, when one is actively trying to influence a patient one's own personal integrity is especially important. We would like to observe at this point that psychiatrists give fewer dramatic instructions to their patients than any other breed of doctor. It is rare for us to advise a patient to get married or have a baby, and if occasionally we do give advice of this nature we do not do it lightly.

In our follow-up interviews one of the most striking revelations was the realization of the profound influence a psychotherapist has on his patient's attitude to life even after only a few hours of treatment. This teaches us afresh the need for the most careful consideration of all the many facets of every case; and once again we realized the problems presented in the selection of doctors interested in a training in psychotherapy.

While treatment progresses it is often borne in upon us that, though the ability to accept insight depends upon emotional and intellectual factors, the will to change a pattern of reaction depends greatly on the patient's philosophy of life. In many instances the patients fail to make satisfactory improvement because we ourselves fail to assess this philosophical "disease" (or "atrophy") adequately. We are not at all sure whether our credentials as psychotherapists entitle us to tackle problems of this nature as part of treatment, but we have come to realize that the experience of psychotherapy is often a most valuable education to the patient and inevitably affects his or her philosophy in an indirect way. Unfortunately, if we fight shy of tackling the philosophical issue it happens all too often that nobody else will do it.

These few paragraphs will, we hope, give some idea of our problems in selection and treatment. We may not have always selected the most suitable patients, but we have had definite ideas and are prepared to modify them as time goes on.

Diagnosis

We grouped the 235 cases into five main categories:

Mainly Anxiety States.—This label was also used for certain psychosomatic cases and tension states; 39.6% of our patients were so classed.

Mainly Hysterical States and Anxiety Hysteria.—This term was used for the majority of phobic and anxiety states with hysterical symptoms, as well as for the more classical types of hysteria; 42.6% came under this heading.

Obsessional States.—This was used for the patients with classical obsessional states, which therapeutically we considered a very different problem from the obsessional personalities with anxiety symptoms; 6.4% of our patients were true obsessives.

Psychopathic Personalities, which accounted for 2.5% of the series.

Other Diagnoses.—This group totalled 8.9% and included psychoses, mild depressive states, etc., as well as the diagnostically difficult group of schizoid personalities.

This procedure of "diagnosis in retrospect" may be open to criticism, but it gives a more accurate diagnosis than that made at the first consultation, and it enabled us to separate off the few misdiagnosed patients who turned out to be paranoid schizophrenics. Furthermore, it made for simplicity when considering results of treatment.

Immediate Results of the Psychotherapy

From the case notes we also assessed the immediate results of treatment (that is, the state of the patient at the time of actual termination of treatment) on a four-point scale—namely, much improved, improved, not improved, and treatment broken off. The results are shown in the Table.

Like Curran we omitted, as being too difficult to define, the category "slightly improved" which is used by some authors.

Details of Results on Discharge and at Time of Follow-up

Diagnosis	Total	Condition on Discharge				Condition at Time of Follow-up			
		Much Improved	Improved	Not Improved	Psychotherapy Broken Off	Much Improved	Improved	Not Improved	Not Traced or Died
Anxiety states	93	41 (44.1%)	39 (41.9%)	5 (5.4%)	8 (8.6%)	48 (51.6%)	26 (28%)	7 (7.5%)	12 (12.9%)
Hysterical	100	31 (31%)	36 (36%)	16 (16%)	17 (17%)	31 (31%)	35 (35%)	21 (21%)	13 (13%)
Obsessional	15	7 (46.7%)	7 (46.7%)	1 (6.7%)	—	7 (46.7%)	6 (40.0%)	1 (6.7%)	1 (6.7%)
Psychopathic states	6	—	2 (33.3%)	2 (33.3%)	2 (33.3%)	1 (16.7%)	3 (50%)	1 (16.7%)	1 (16.7%)
Other diagnoses	21	7 (33.3%)	6 (28.6%)	4 (19%)	4 (19%)	7 (33.3%)	6 (28.6%)	6 (28.6%)	2 (9.5%)
	235	86 (36.6%)	90 (38.3%)	28 (11.9%)	31 (13.2%)	94 (40%)	76 (32.3%)	36 (15.3%)	29 (12.3%)

Other Treatment

It was also known to us, before we interviewed the patients, which of them had had any out-patient electroplexy during or since psychotherapy, or had been admitted to hospital for conditions of psychiatric importance. The frequency and effect of this additional treatment had to be taken into account as there were as many as 25 cases, which represented 10.5% of the whole series. When examined in detail, of the nine who had out-patient electroplexy, eight were improved, and the final results of our psychotherapy were influenced to this extent. In-patient treatment rarely helped anyone who had not already improved with psychotherapy, and, in fact, the 16 who were later admitted to hospital included a quarter of our "not improved" category.

Information Available at Follow-up

It should now be clear that at the time of interviewing the patient we had, in addition to the individual psychotherapy notes, the following information on each case: the date of last regular interview, number of regular interviews, type of psychotherapy, diagnostic category, condition on discharge (that is, immediate result of treatment), information regarding physical treatments such as out-patient electroplexy or in-patient treatment of psychiatric importance, and prognostic category.

Questionnaire Used at Interview

We were now ready to interview the patients, and we decided to adopt to some extent Curran's excellent questionnaire. In the course of the interview each patient was asked:

1. Have you regained your former health? (an answer "yes" or "almost" was required for a "much improved" classification).
2. Do you still suffer from symptoms which trouble you? If so, what symptoms?
3. Have you been able to go back to work or carry on with your work in a satisfactory manner?
4. Are you happier than before treatment?
5. Did the treatment help you? If so, in what way?

The essence of the patient's remarks was recorded verbatim. To those unable to attend, a standard letter with stamped addressed envelope was sent with these questions included in the letter. If the follow-up was carried out by a social worker she asked the same questions.

At the interview the difficulties in assessing the results were less than we anticipated, and any doubt was usually between the categories "improved" and "much improved" rather than between "improved" and "not improved." When the follow-up was carried out by means other than personal interview the information was carefully considered, and if it was regarded as inadequate for an assessment to be made the patient was classed as "not traced."

Of the total group, 59% were interviewed by their original therapist, 14% were followed up by letter, 15% by a social worker, and 12% (including two deaths, both from non-psychiatric causes) were untraced. In all, 88% were contacted. In Luff and Garrod's series none was seen by a doctor, follow-up was largely by letter from the patient or the patient's general practitioner, and 30% were untraced. In Curran's series none was seen by a doctor, and

only 40% were followed up at all. The percentage of patients traced in our series is much higher than in either of the above-quoted investigations, but we have the advantage that we work in a much more static community. Most of our untraced patients belonged to Service families, who are, of course, subject to frequent changes of station.

It may be noted that Luff and Garrod argue that their group of untraced patients have probably done as well as the traced group. Our untraced patients were regarded as a representative sample of the group as a whole.

Results and Comments

It remains now to consider our results of treatment at the time of the follow-up study, together with one or two other statistical details. Of our series, 44% were male and 56% female. Only 6% were over 50 years of age. Of Luff and Garrod's cases 9.6% were over 50. We may have been rather diffident at taking on the older patients. As already mentioned, the grouping into diagnostic categories shows that 39.6% fell into the mainly anxiety group; 42.6% into the mainly hysterical group; 6.4% had obsessional states; 2.5% were psychopathic personalities; and 8.9% belonged to "other diagnoses." One-third of our patients had been given a good prognosis and two-thirds a moderately good prognosis. Our follow-up revealed that 50% improved to the extent anticipated, 26% did less well, and 24% better than was expected.

We gave the anxiety states a better prognosis than the hysterics, and this was confirmed by our results. It is interesting that Luff and Garrod, who were apparently much more strict in the diagnosis of hysteria, came to the same conclusion. Of their anxiety states 80% were "relieved" as compared with 86% of ours. On review, their percentage dropped to 64%, while ours over a somewhat shorter period rose to 91%. It is noteworthy that their number of "much improved" anxiety states also increased. Their "relieved" rate for hysterical states was 50%, which remained at 50% after three years. Our figure was 67% on discharge and increased later to 76%. These rates we realize are embarrassingly high; but our opinion, based on so many personal interviews, is that these patients did in fact continue to improve after the termination of psychotherapy. It may be that the untraced patients, who reduced the size of the series slightly during the final review, were the less improved patients, but there is no indication that this is so. Of the obsessionals, 13 out of 14 followed up had improved, and this was consistent with our prognosis.

As a bald statement of results conveys little meaning unless prefaced by some explanatory remarks, we have left our results for the total series to the end. Of our 235 patients we know that 40% of the total are now "much improved," a further 32% are "improved," 15% are "not improved," 12% are untraced, and two patients have died. If, as in the other series, our untraced patients are excluded, our results are 45.5% much improved, 37% improved (making a total of 82.5% "relieved"), and 17.5% "not improved."

Summary

The purpose of this investigation was twofold: firstly, to examine the psychotherapeutic methods used by three consultants working independently in the same National Health Service out-patient department of psychological

medicine and to report on the aims of treatment; secondly, to follow up a series of out-patients so treated.

Out of a total of 3,226 consecutive referrals during the five-year period 1948-52 235 patients received a course of psychotherapy.

The types of psychotherapy used were: (1) superficial for 45% of the cases, and (2) distributive analysis for 49%; the remaining 6% were treated mainly by abreactive methods. The average number of sessions given to each patient was seven.

We followed up these patients early in 1954. No patient was followed up who had not been discharged for at least 15 months, and in about 35% the follow-up period was at least two and a half years. 59% were interviewed by the original therapist, 15% by a social worker, and only 10% were untraced. The method of follow-up is described in detail.

It was found that of our 235 patients 40% were "much improved," 32% were "improved," and 15% were "not improved"; the remainder were either untraced or had died.

It is our opinion that results of this order can be expected from short courses of psychotherapy in a provincial out-patient department provided that a careful selection of cases is first made.

VAGAL RESECTION IN TREATMENT OF DUODENAL ULCER

BY

A. A. MacKELVIE, M.D., F.R.C.S.Ed.

Consultant Surgeon, Stirling and Clackmannan Hospitals Group

Vagal resection for the treatment of duodenal ulcer has not been generally accepted in this country. It is not the purpose of this paper to discuss the theoretical grounds for its use, nor to review the voluminous literature on the subject, but to present the results obtained since late 1947 in one surgical unit. Pollock (1952) collected a large series, including 1,314 cases of duodenal ulcer, from various centres.

Present Investigation

As no large series from one source has been reported on in Britain, it seems worth while analysing the results of a series of 473 consecutive cases (401 male, 72 female) up to the end of 1955. These were entirely unselected. Every duodenal ulcer case referred to us for surgical treatment was treated as detailed below. The only exceptions were (1) those who refused surgical treatment; (2) those seen first with severe haemorrhage which it was impossible to control by any means other than a direct attack on the site of haemorrhage in the ulcer; and (3) those first seen with acute perforation requiring immediate operation—simple closure of the perforation was done. If persistence of ulceration or recurrence of ulceration or symptoms occurred the cases were dealt with in the routine manner and then included in the series. These exceptions comprised less than 2% of the total.

Table I shows the age incidence and the duration of symptoms. Perforation had occurred in 17% and notable haemorrhage in 17%. Medical treatment before

TABLE I.—Age Incidence and Duration of Symptoms in 473 Cases

operation had been given at home in 76% and in hospital in 19%. Over 50% had had symptoms for more than five years, and over a third had had either a perforation or noteworthy haemorrhage before operation.

The normal routine before operation was: history; physical examination; barium-meal x-ray examination; gruel fractional test meal; and a Hollander (1946) insulin test meal. After operation the gruel fractional test meal and the insulin test meal were repeated. Routine post-operative x-ray examination was not possible in all cases; it was made in many, including every case with any post-operative symptoms. Pre- and post-operative weights were recorded.

For various reasons the full investigation outlined was impossible to carry out in every case, but in over 92% of cases the data were adequate for assessing the completeness or otherwise of the nerve section.

Operation

The patient is brought to the theatre with a naso-gastric Ryle tube in position. The surgical approach is through an upper left paramedian incision, the rectus muscle being retracted laterally. After inspection, including confirmation of the presence of the duodenal ulcer, a Balfour self-retaining retractor is inserted. The left lobe of the liver is then detached from the diaphragm by cutting the suspensory ligament, close to the liver, care being taken not to damage the left inferior phrenic vein. The left lobe of the liver can then be folded and held gently to the right with a Deaver retractor. The stomach is packed down as far as possible with two packs, the upper one being placed between stomach and spleen and retracted downwards and to the left with a Deaver retractor. This exposes adequately the lower inch (2.5 cm.) of the oesophagus. The peritoneum over the oesophagus is cut transversely, the left forefinger inserted, and the opening in the peritoneum enlarged up and down. With the left fore- and mid-fingers behind and the thumb in front it is easy to identify the oesophagus with its Ryle tube.

By "burrowing" behind and around the oesophagus from right to left the two fingers emerge at the left of the oesophagus, where they pick up a gauze tractor, one end of which is pulled back around the oesophagus. During the "burrowing" process if slight traction is kept on the oesophagus it is easy to feel the right vagus behind and include it in the tissues picked up. The two ends of the gauze tractor are caught together in an artery forceps on which an assistant makes firm traction. The vagus nerves are readily palpated as taut cords. Each in turn is isolated from the oesophagus; two fingers are inserted between the nerve and the oesophagus and spread widely to free at least 2 in. (5 cm.) of nerve from the oesophagus. The nerve trunk is then caught with long Kocher artery forceps and the nerve stripped cranially as far as possible. A section of the nerve is then resected, at least 2 in. (5 cm.) being removed.

When each nerve has been thus dealt with it is found that the lower 2-3 in. (5-7.5 cm.) of the oesophagus is more mobile and can be pulled up with the gauze tractor to allow careful inspection. Any structures resembling nerve twigs are seized with diathermy forceps and sectioned after coagulation; usually these "nerve fibres" are small blood vessels emptied by the traction, and coagulation before section expedites operation. By pulling first on one side, then on the

other, of the gauze tractor the oesophagus can be rotated easily and sufficiently to allow complete inspection of the entire circumference of its lower reaches. It is essential to be painstakingly careful in the search for any branches of the nerves and to be certain that two nerves have been found and dealt with, the right nerve in particular being occasionally missed in picking up the tissues in the original "burrowing" procedure. When the nerve section has been completed, bleeding points are coagulated by diathermy and the left lobe of the liver is unfolded and replaced *in situ*, where it will adhere to its original support. The use of lighted retractors has not been found an advantage. Adequate field lighting can be obtained by tilting the normal theatre operating lamp.

The gastro-enterostomy has always been of the retrocolic no-loop isoperistaltic type and performed with clamps in the standard manner. The opening is always made at the lowest part of the stomach, and the size of the opening made is small, the aim being to achieve an anastomotic opening equal in calibre to the normal pylorus. A large gastro-enterostomy stoma is likely to lead to dumping syndrome sequelae.

If pyloroplasty is carried out the essentials are to remove a diamond-shaped area at the pylorus, including compulsorily a segment of pyloric sphincter, and where possible the ulcer itself. The resultant gap is sutured transversely in two layers. While the production of an adequate channel is necessary, the resection of part of the pyloric sphincter is regarded as the essential step in this operation.

Difficulties during operation have been rare. In two cases the oesophagus was holed during isolation. The gap was repaired without untoward sequelae. In two cases the pleura was opened without any serious complication. Before the necessity to take great care not to inflict venous damage was appreciated one patient died of severe uncontrollable haemorrhage from tearing of the left inferior phrenic vein from the inferior vena cava in freeing the liver. We now prefer to omit this step if any difficulty appears probable in freeing the liver safely.

Immediate Post-operative Results

The total mortality from operation was 2.1%. The 10 fatalities were: one anaesthetic death; one immediate death from haemorrhage as described; one death three days after operation from acute cardiac failure; one death five days after operation from perforation of the duodenal ulcer (at operation the ulcer was noted to be near perforation; it would have been wise to make a direct attack on the ulcer or at least to sew omentum over the danger area); two deaths six days after operation from paralytic ileus; three deaths from pulmonary embolus, on the fourth, seventh, and seventh days after operation; and one death six days after operation from "pseudomembranous enterocolitis." There has been no death in the last 200 consecutive cases up to the writing of this report.

Post-operative complications have been few. In the early part of the series post-operative chest complications—almost invariably a right lower segmental collapse—occurred, but pre- and post-operative breathing exercises supervised by physiotherapists have practically eliminated these. Surprisingly, ileus has been uncommon.

Dysphagia has occurred in less than 2% of cases and has been without exception of short duration.

Results at Follow-up

Cases have been followed up by return visits to out-patient clinics at intervals after operation of one month, three months, six months, and annually thereafter, unless symptoms necessitated more frequent visits. Early in the series patients were admitted for insulin test meals annually, but this practice was discontinued as a routine. A questionnaire was sent out to all cases in late 1955. If the form was not returned and the patient could not be traced information

was sought from the family doctor. By these means enough information has been obtained to allow of a final assessment of results.

From the results in the several groups certain general points emerge. (1) Complete vagal resection as shown by insulin test meals remains complete permanently. Insulin test meals negative immediately after operation have remained negative to our knowledge for as long as eight years after operation. (2) Complete vagal resection was achieved in only 86% of cases, complete section was doubtful in 7%, and failure to achieve complete section occurred in 7%. With increasing experience we think complete section is now made in over 90% of cases. We believe that incomplete section of the two vagi explains some—perhaps all—of the unsatisfactory results which have been published. To make a complete section requires experience and great care. (3) In 365 cases note was taken of whether the vagus nerves showed any branching. It was found that the left nerve alone was branched in 21% of cases, the right alone in 6%; both nerves were branched in 43%, and in only 30% of cases were both nerves single cords. This emphasizes the need for careful technique to achieve complete section.

At first vagal resection alone was practised. It became evident early in the series that this operation was not wholly satisfactory, and since 1950 the operation of choice has been vagal resection and posterior gastro-enterostomy. In a small number of cases pyloroplasty has been combined with vagal resection, sometimes by choice to compare a number of these cases with those having gastro-enterostomy, sometimes because some local condition precluded gastro-enterostomy. Table II shows the operations performed and the year of operation.

TABLE II.—Operations Performed in 473 Cases

Vagal resection and pyloroplasty ..				12				1	6	19
Vagal crush ..		1	2	1						4

Vagal Resection Alone

Vagal resection alone was the operation in 118 cases. There was one death from anaesthetic causes in the series. Of the 117 survivors one died of intercurrent disease six years after his original operation but had had no dyspepsia or other digestive troubles until his death from secondary renal carcinoma; one died of aneurysm four years after operation, having had no digestive complaints in the interim; and 10 cases were either insufficiently followed up or could not be traced. This leaves for consideration of results 105 of the original 118.

Of these, 23 required gastro-enterostomy for symptoms secondary to the vagal resection, such as gross gastric retention, with foul flatulence and diarrhoea. Six further cases await gastro-enterostomy. In all these cases the vagal section appeared complete. Thus in 28% of cases vagal resection alone has been a failure, and the necessity to relieve gastric retention by a second operation in so many cases condemns it.

In the 23 cases in which secondary gastro-enterostomy was required the duodenal ulcer was healed at the time of the second operation. All have remained well and symptom-free since their second operation. They are not included in the 332 cases whose primary operation was vagal resection and gastro-enterostomy.

In four of the remaining 76 patients who had vagal resection alone recurrence of the duodenal ulcer occurred; in all four the vagal section was not complete. One case developed a gastric ulcer within three years of operation. While some of the results have been unexceptionally good a considerable percentage of patients have troublesome flatulence and diarrhoea, and uncomfortable fullness after meals.

These indifferent results and the high rate of secondary gastro-enterostomy required forced us to the alternative of adding gastro-enterostomy to the original nerve resection.

Vagal Resection with Gastro-enterostomy

Vagal resection combined with retrocolic gastro-enterostomy was performed in 332 cases. In assessing results the classification suggested by Visick (1948) has been adopted: grade 1, cases having no gastric symptoms; grade 2, cases with preventable minor symptoms; grade 3, cases whose symptoms are not preventable but cause no interference with their activities; grade 4, symptoms preventing full enjoyment of life; and grade 5, failures.

In assessing the results grade 1 cases have been restricted entirely to those without any symptoms; in grade 2 are placed those with minor symptoms such as occasional flatulence, fullness after large meals, slight occasional indigestion after dietary indiscretion, and, on rare occasions, a loose bowel movement not amounting to diarrhoea. In grade 3 are included those with some occasional bilious vomiting, or occasional diarrhoea or intermittent discomfort relieved by alkalis. In grade 4 are those with dumping or hypoglycaemic syndromes, those with troublesome diarrhoea, and those with troublesome bilious vomiting. In grade 5 are stomal ulcers, recurrent duodenal ulcers, and those who fail to derive any benefit from operation.

The results of a total of 332 cases show that nine died from operation, an operative mortality of 2.7%. Of 324 survivors, seven died of intercurrent disease unrelated to the operation or ulcer and were free of dyspepsia, etc., to the date of death. Of the remainder, 10 have not been included in the assessment of final results as they have been followed up for less than a year; all were symptom-free at the time of writing. Nine cases could not be traced. This leaves 298 cases followed up adequately for assessment. Of these, 238 are grade 1, 31 grade 2, 8 grade 3, 13 grade 4, and 8 grade 5.

All the 31 in grade 2 have very minor symptoms, are satisfied with the result, and consider the operation has been of decided benefit and well worth while. The eight in grade 3 are also pleased with their present position as compared with their pre-operative state. Their symptoms are not of serious consequence and do not incommode them to any noticeable degree. Therefore one can say that the results in 93% of cases are satisfactory.

Of the 13 in grade 4, five have considerable trouble from dumping; three have a marked hypoglycaemic syndrome (one persisting seven years after operation); two suffer from bilious vomiting to a troublesome degree, probably due to fault in the gastro-enterostomy; two have persisting diarrhoea; and one has had partial gastrectomy elsewhere. This last patient was very neurotic and when first seen was referred to the psychiatric department, whose report was unfavourable. His duodenal ulcer persisted and operation was eventually undertaken. For a time after operation he remained well. He then again complained of symptoms similar to those before operation. Repeated investigation revealed no organic basis for his complaints. He then went elsewhere, where again after a period, and after an unfavourable psychiatric report, laparotomy was undertaken. His duodenal ulcer was healed and his gastro-enterostomy stoma healthy. Partial gastrectomy was done. He is not yet symptom-free. It was an error to operate on his duodenal ulcer in the first instance.

Among the eight in grade 5 the duodenal ulcer has recurred in five, of whom four obviously failed to have complete nerve sections, as shown by positive insulin responses after operation; the one case with a negative insulin response had one post-operative test meal only, and section may be incomplete. One case has had no relief of symptoms: ulceration has persisted, and a positive insulin response indicates failed section. Two cases have developed stomal ulcers. In both, vagal section was incomplete. In one the left nerve was known to have been missed during operation, but anaesthetic

difficulties prevented prolongation of search for the nerve. When his stomal ulcer developed, the vagal section was completed at a second operation two years after his primary surgery. Prompt healing of the stomal ulcer occurred, and the patient has been in excellent health and symptom-free for the past five years. In the second case a large stomal ulcer was found at the second operation four months after the first; vagal resection was repeated, but the post-operative insulin meal was still positive after the second operation. Apparent healing of the stomal ulcer occurred, with disappearance of symptoms, disappearance of the ulcer on x-ray examination, a negative faecal occult blood test, and a gain in weight. In just over a year the symptoms recurred and partial gastrectomy was undertaken elsewhere.

There has been a gain in weight in 70% of cases, the average being 8.3 lb. (3,765 g.); 5% have shown no change in weight; 25% have lost an average of 6.4 lb. (2,900 g.).

We have not found any case in which pulmonary tuberculosis developed after operation: no such case is known to the local tuberculosis service. Also no case has shown evidence of anaemia.

The 277 patients in the first three grades are well satisfied. They are no longer on diet and do not require to restrict themselves in any way so far as food is concerned. From this they derive much psychological benefit. The great majority have returned to their pre-operative occupations; those who have taken lighter jobs have been more than balanced by those who have found themselves capable of heavier work after operation. There has been almost no loss of working-time from digestive causes since their return to work after operation, a feature which is noted with gratitude by numbers in replying to the questionnaire.

Other Operations

Vagal crush was done in four cases. In all four a negative post-operative insulin test meal became positive within 12 months, with a return of pain and dyspepsia. The operation appears to have no useful place.

Vagal resection was combined with pyloroplasty in 19 cases. In all of them the results have been excellent. 80% have gained an average of 10.5 lb. (4,760 g.), 10% have lost 4 lb. (1,815 g.), and 10% have not changed their weight.

Conclusions

In the treatment of duodenal ulceration, operations on the vagal nerves alone, either by resection or by crushing, do not give good results. When vagal resection is combined with posterior gastro-enterostomy excellent results are obtained in over 90% of cases, with a mortality rate around 2%. It seems likely that equally good results may be obtained by vagal resection combined with pyloroplasty. The results are at least as good as those after partial gastrectomy, and the operative mortality is probably appreciably lower. These good results, added to the fact that partial gastrectomy is not excluded as a further possible operative treatment for failure in resistant cases, indicate that the combined operation should be the method of first choice in the treatment of duodenal ulceration.

SEGMENTAL LESIONS IN DRUG-TREATED PRIMARY TUBERCULOSIS IN YOUNG CHILDREN

BY

J. B. RYDER, M.D., M.R.C.P.

Mountain Sanatorium, Hamilton, Ontario

A considerable volume of experience concerning the effects of specific drug treatment on the course of primary tuberculosis in the child has now accumulated.

While it is generally recognized that the mortality rate has been favourably influenced, particularly since the introduction of isoniazid (Lincoln, 1954), and largely as a result of a decrease in the frequency and severity of the haematogenous complications, it appears to be the general consensus of opinion that in tuberculosis of the mediastinal lymph nodes neither the symptoms nor the associated bronchoscopic appearances show a specific response to drug treatment (Lincoln *et al.*, 1955). In a small series (Todd, 1955) it has also been shown that there is no statistically significant improvement in the speed of radiological resolution. Lincoln *et al.* (1955) state: "No known drug or combination of drugs has demonstrated an obvious effect on the resolution of primary pulmonary tuberculosis."

A carefully controlled series of children is at present being studied at Bellevue Hospital (Lincoln *et al.*, 1955) in order to assess the results of antimicrobial treatment, and should provide more conclusive evidence when the results are available, as previous studies, apart from that of Todd (1955), have not employed controls.

It has been suggested (Bentley, 1955) that drug treatment may even be detrimental to complete recovery in uncomplicated hilar adenitis in young children by leading to an increased frequency of segmental lesions with their associated risk of bronchiectasis in later life. His impression was mainly based on a small group of eleven children under 2 years of age. Nine of these were treated with isoniazid and P.A.S., and five of them developed segmental lesions. Two similar conservatively treated cases recovered uneventfully. On the basis of these findings he expressed the opinion that "great care should be exercised before starting a small child with obviously enlarged tuberculous mediastinal glands on a course of antibiotics, and particularly on isoniazid."

It has consequently been thought desirable to review the cases of uncomplicated tuberculous mediastinal lymphadenitis in children treated with drugs in this institution since 1951, with special emphasis on those aged 2 years and under, from the standpoint of the frequency of development of segmental lesions.

Plan of Investigation

Cases of primary pulmonary tuberculosis in children admitted to this institution since 1951 were studied, in addition to cases at present in the institution who had had a minimum of three months' drug treatment. From these, cases of uncomplicated mediastinal glandular enlargement treated with drugs from the outset were selected for study. Variations in posture and respiratory phase, with their resultant distortion of the normal mediastinal outline, often create difficulties in the diagnosis of enlarged mediastinal glands in the young child. Because of this, cases were selected on two main criteria: (1) the demonstration of an obviously enlarged mediastinal gland on two or more films,

and in many cases their reduction in size during treatment; and (2) the development of foci of calcification in mediastinal shadows whose enlargement had been doubtful. In the absence of areas of calcification to date it has been necessary to exclude a number of cases of doubtful hilar enlargement at present progressing favourably on drugs.

It was possible to collect a total of 50 cases. Of these, 20 were aged 2 years or under. The mean age of the older group was 6.3 years, the oldest child being aged 10. The racial breakdown was as shown in Table I.

TABLE I

	0-2 Years	3-10 Years	Total
Eskimo	9	12	21
Indian	2	6	8
White	9	12	21

Treatment consisted of streptomycin, P.A.S., and isoniazid in varying combinations. Streptomycin was given in a dose of 0.25-0.5 g., bi-weekly, depending on age. The dosage of P.A.S. varied from 2-8 g. daily, depending on age. Isoniazid was employed in a daily dosage of 5 mg. per kg. The combinations used are shown in Table II.

TABLE II

Drug Combinations	S.M., P.A.S.	S.M., P.A.S., I.N.H.	P.A.S., I.N.H.
No. of cases	12	14	24

S.M. = streptomycin. I.N.H. = isoniazid.

Treatment has been completed in 16 patients who have been discharged. Nineteen are continuing treatment, having had more than six months to date. The remaining 15 have been under treatment for periods varying from three to six months. The frequency with which segmental lesions appeared is shown in Table III. All these lesions occurred

TABLE III

Age	No. of Cases	Uneventful Recovery	Segmental Lesions
2 years and under	20	18	2
Over 2 years	30	28	2
Total	50	46	4

within three months of admission, except one which first became evident at six months. One occurred in a patient treated with streptomycin and P.A.S. One occurred in a patient on streptomycin, P.A.S., and isoniazid, and two occurred in patients on P.A.S. and isoniazid.

Discussion

The natural frequency with which segmental lesions occur in primary tuberculosis in childhood is not clearly established. They usually become evident at tuberculin conversion or in the early subsequent months. Because of this any series of cases of tuberculous mediastinal lymphadenitis diagnosed early will show a higher incidence of subsequent segmental lesions than a similar series diagnosed at a later stage in their natural history, when many of the cases predisposed to segmental lesions will have already developed them.

The increased efficiency of diagnostic services may therefore lead to an apparent increase in the frequency of segmental lesions mainly because of earlier diagnosis. It has been stated (Bentley *et al.*, 1954) that approximately 5-10% of children will develop a segmental lesion following primary infection.

The risk of developing a segmental lesion is believed to be appreciably greater in young children with primary infection, although again no precise figures exist. Grzybowski (personal communication) has quoted a figure of 15-18% as an approximate estimate of the total frequency of segmental

lesions in infants under the age of 2 years, based chiefly on a review of the High Wood figures (Bentley *et al.*, 1954).

Misgivings about the possible hazards of drug treatment in tuberculous mediastinal lymphadenitis have been expressed (Bentley, 1955), as mentioned previously. He also records the development of segmental lesions in 10% of a group of 80 children of all ages suffering from tuberculous mediastinal lymphadenitis treated with drugs, and he points out that this compares unfavourably with an incidence of 4% in 202 children of all ages with uncomplicated tuberculous mediastinal lymphadenitis studied at High Wood between 1942 and 1946, although he admits that much of the apparent increase in the drug-treated series may result from earlier diagnosis and admission. Cases were classified, mainly on the radiological condition found on admission, as showing uncomplicated mediastinal lymphadenitis or segmental lesions in the earlier series, and there was an average waiting period of three months before admission, during which interval the majority of the segmental lesions might be expected to appear. As a result, cases of uncomplicated mediastinal lymphadenitis classified as such at the time of admission would represent a selected group much less prone to the development of segmental lesions after admission.

In a recent article dealing with the treatment of tuberculosis in children with isoniazid (Plettenburg, 1955) the development of lobar atelectasis in 29 children, mostly of "crawler" age, is recorded. The total number of children in the group with hilar lymph node tuberculosis in whom this complication appeared is not recorded. Treatment consisted of isoniazid in a dose of 10 mg. per kg. and streptomycin in an unstated dosage. Four of these children died after bronchoscopy carried out in order to remove caseous material and granulation tissues from the bronchi.

The results obtained in the present relatively small series of cases, although they cannot take the place of an adequately controlled large-scale trial, do not suggest that specific chemotherapy in young children is likely to increase greatly the natural hazard of the development of segmental lesions. The latter occurred in only two cases in the group 2 years and under, and the overall incidence of 8% does not appear excessive in view of the low mean age of the group treated. In all four cases the lesions involved segmental areas in upper lobes, and no case of massive lobar consolidation or collapse was noticed. Three cases have run their course to a residual area of fibrosis and final stability has not yet been reached in one. No haematogenous complications occurred and no deaths were encountered.

The hazards of primary infection in the young child are well recognized. Haematogenous complications occurred in 10% of children under 2 years of age (Bentley *et al.*, 1954). The risk of meningitis or miliary tuberculosis among children under 5 years has been estimated at 4% (Cammock and Miller, 1953). The known risks in the group 2 years and under lend support to the current practice of advocating antimicrobial therapy for them, and the results in the present series do not suggest that there is at present strong enough reason to withhold the benefits of drug treatment, even in the child with obvious enlargement of the mediastinal glands.

Summary and Conclusions

A series of 50 cases of tuberculous mediastinal lymphadenitis in children were studied.

The influence of antimicrobial treatment on the development of segmental lesions was investigated.

There is no obvious increase in the natural frequency of segmental lesions as a result of antimicrobial treatment.

There appears to be no definite reason to abandon the current practice of administering specific drug treatment to children aged 2 years and under suffering from primary tuberculous infection even in the presence of obvious mediastinal glandular enlargement.

ADDENDUM.—Since this article was submitted for publication, eight further cases have completed a minimum of three months' treatment. Three were aged 2 years or under, and five were over 2 years. Segmental lesions appeared in two of these cases within three months, one occurring in each age group.

It does not appear that these additional cases increase the frequency of segmental lesions in drug-treated cases beyond the range of their natural incidence in the respective age groups.

PENETRATING ULCER OF THE TONGUE

BY

GORDON F. CASSIE, M.B., F.R.C.S.

Ashford Hospital, Middlesex

Penetrating ulcer of the tongue is of fundamental importance, in that it resembles carcinoma very closely. It has been appearing infrequently in the surgical clinics of this hospital recently, thus stimulating a search for information about the subject. No record of this disease has been found in any standard British textbook on surgery, medicine, pathology, oral medicine, or pathology. No reference has been found in the last ten years of the *Index Medicus*. Thoma (1949) mentions briefly what he calls decubitus (traumatic) ulcer of the tongue. Butlin and Spencer (1900) described traumatic ulcers of the tongue due to rough teeth, commented upon the difficulty in diagnosis, and indicated that complete excision may produce a dramatic cure.

Details

The lesion is a deep ulcer (Fig. 1), oval or circular, with sloping or slightly rolled edge and yellow slough base. It feels hard, but induration does not spread into the muscle. It is painful when eating and has usually been present for two to four months before advice is sought. The picture is typical of carcinoma, except that deep induration is absent and the cervical glands, if enlarged, are tender.

The ulcer seems to occur after middle age, affecting the same age groups as carcinoma. The frequency is impossible to assess at present, because most out-patient notes are not indexed with diagnosis. In this hospital in the last five years penetrating ulcer and carcinoma have occurred with equal frequency. The posterior aspect of the lateral border of the tongue seems to be the most commonly affected site, but it may develop in the central area.

Chronic irritation by adjacent teeth is the most obvious cause, but this cannot explain Case 3, in which the central

FIG. 1.—Penetrating ulcer of the tongue (Case 2).

area was affected and the dentures had been worn for 20 years. This area is not in contact with the upper incisors during speech or mastication. There would appear to be a special response by the tongue to irritation in advanced age groups.

The diagnosis must be made by biopsy, as the ulcer may usually be confidently diagnosed as carcinoma on first examination. The Wassermann and Kahn tests are necessary to exclude syphilis, and tuberculosis will be eliminated by histological section. There is no difficulty in differentiating penetrating ulcer from acute ulcers such as peptic, aphthous, and herpetiform. Microscopy shows an abrupt termination of normal epithelium at the edge of the ulcer and diffuse infiltration of the subepithelium and muscle by inflammatory cells (Fig. 2). There may be acanthosis of the epithelium at the edge, especially when healing is occurring.

FIG. 2.—Low-power view of biopsy in Case 2. This shows abrupt termination of epithelium and heavy infiltration with inflammatory cells.

The course is difficult to estimate in view of the small number of cases observed, but at present it can be said that healing will occur in one to three months if treatment is begun at once. The condition does not seem to be premalignant, but prolonged follow-up is obviously essential.

Treatment.—Any likely mechanical irritating factor such as a rough tooth or filling must be abolished. A course of parenteral penicillin should be given. The ulcer may be completely excised by diathermy, but healing will take much longer and the area may produce a patch of acanthosis resembling leucoplakia.

Case Histories

Case 1.—A woman aged 70 attended surgical clinic on November 13, 1951, complaining of painful ulcer on left side of tongue for two months. Tonsillar gland on that side enlarged and tender. Good general health. Several teeth in poor state, one almost opposite the ulcer. W.R. and Kahn, negative. November 28: Excision of ulcer by diathermy. Histology: Hyperplasia of epithelium at edge of lesion and heavy infiltration by inflammatory cells. No evidence of malignancy. January 21, 1952: Ulcer healed. Follow-up until July 10, 1955, shows persistence of soft whitish area which does not appear to be true leucoplakia.

Case 2.—A woman aged 75 attended surgical clinic on January 26, 1955, having had a painful ulcer on the right side of tongue for two months (Fig. 1). Raised edge and yellow slough. No enlarged glands. Good general health. Several teeth present in poor state, one being opposite the ulcer. W.R. and Kahn, negative. Biopsy performed on February 1. Histology: Floor of ulcer composed of granulation tissue heavily infiltrated by polymorphs; no evidence of malignancy (Fig. 2). A course of parenteral penicillin was given and dental clearance performed. March 9, 1955: Ulcer completely healed.

Case 3.—A man aged 63 attended surgical clinic on May 3, 1955, complaining of painful ulcer, $1\frac{1}{2}$ by $\frac{1}{4}$ in. (3.8 by 1.9 cm.), in centre of tongue for four months. Slightly raised edge and yellow slough. No enlarged glands. Good general health. Edentulous; no irritating factor present on upper denture, which had been worn for 20 years. W.R. and Kahn, negative. Biopsy performed on May 6. Histology: The loose fibrous tissue underlying the acanthotic stratified squamous epithelium is heavily infiltrated by chronic inflammatory cells. No evidence of malignancy or gumma. May 30: Ulcer healed.

Discussion

Penetrating ulcer of the tongue deserves widespread recognition and inclusion in standard textbooks of medicine and surgery, because it resembles carcinoma exactly and the two conditions seem to occur with equal frequency. Irritation by a mechanical factor is likely to be the cause of the ulcer, but this response of the tongue epithelium occurs only in later age groups. It is significant that at this hospital the lesion has not been seen in younger age groups, for a much higher percentage of them are dentulous. Biopsy of all such ulcers is imperative. The only salient clinical differences between penetrating ulcer and carcinoma are that pain is a constant complaint in the former and that deep induration is usual in the latter.

So far as can be determined at present, successful treatment involves a course of parenteral penicillin and removal of any irritating factor. In the present state of our experience the lesion is not pre-cancerous, but more widespread appraisal of the disease and prolonged follow-up should provide a final decision in some years.

Summary

A penetrating ulcer of the tongue with an incidence similar to carcinoma is described and illustrated. A plea is made for more widespread recognition of this lesion, which is quite distinct from the small acute "dental" ulcers often seen at the edge of the tongue.

I am grateful to Mr. N. M. Matheson for his advice and to Mr. O. D. Morris for access to records of patients under his care. I am indebted to Miss M. Nicholson for Fig. 1 and to Mr. A. Vinten for Fig. 2.

The Australian Government has appointed a committee of inquiry into the future of the Australian universities. The inquiry arises out of a request by the Vice-Chancellors who approached the Government. This, according to an official source, is the first comprehensive inquiry to be made into the needs of Australian universities. The committee has been asked to indicate ways in which the universities might be organized so as to ensure that their long-term pattern of development is in the best interests of the nation, and in particular to inquire into such matters as the role of the university in the Australian community; the extension and co-ordination of university facilities; technological education at university level; and the financial needs of universities and appropriate means for their provision. It is hoped that the committee will pay attention to what Australian universities could reasonably be expected to do, how they might be organized to do this, and how their activities should be financed; and that it will examine the adequacy of the Commonwealth scholarship scheme. The committee's chairman is Sir KEITH MURRAY, chairman of the British University Grants Committee, and among its members is Sir CHARLES MORRIS, Vice-Chancellor of Leeds University. The committee will carry out its inquiry in July, August, and September.

Medical Memorandum

Allergic Basis for Migraine: A Lesson from Loa loa

It is not uncommon to suspect that attacks of migraine in a particular patient may have an allergic basis, usually on the somewhat insecure grounds of a history of other known allergic phenomena in that patient or the near relatives. Proof is rarely obtained; a particular allergen is rarely incriminated; and though when antihistamines were first discovered there were hopeful reports of their efficacy in the treatment of migraine, yet they have, in general, proved most disappointing.

That a direct relationship between allergy and migraine may, however, exist is illustrated in an unusually convincing manner by the following case.

CASE REPORT

A 44-year-old woman was first seen on October 2, 1954, complaining of an intense recent aggravation of a long-standing tendency to migraine. She was admitted to hospital on October 12. From the age of 14 she had suffered from very infrequent attacks of severe headache, preceded either by loss of the right half of her field of vision or by an altitudinous hemianopia. The headaches were accompanied by vivid teichopsia in either field. Occasionally the teichopsia was the only ocular phenomenon, and at times it occurred without accompanying headache. On two occasions the left arm had become numb prior to the onset of the headache. She had had many years of complete freedom, and the attacks were so rare as never to interfere with her activities.

Ten months before admission she went to Nigeria and remained there for eight months. One week after arriving there she developed an intensely irritating rash which spread over the body from above downwards and lasted one week. Seven weeks before admission she felt a pricking sensation at the left ankle, which rapidly became greatly swollen, hot and tense, and over the next few days the swelling extended to involve the whole left leg, lasted ten days, and then subsided without any residual disability. Since this episode she had had repeated localized swellings, affecting either arm or leg, measuring several inches in diameter, appearing and subsiding spontaneously and painlessly over a three-day period. In addition she noticed areas of an urticarial nature about 1 in. (2.5 cm.) in diameter, appearing several times a day and lasting about 24 hours. The day before admission she developed one of the typical large swellings on the right arm.

In the weeks since these swellings appeared her migrainous episodes had become both severe and very frequent, so that she had attacks every day and sometimes several short attacks during one day, in between which she would have transient hemianopia without subsequent headache. It was on account of the severity of these symptoms that she sought medical advice.

On examination no abnormality was found in the central nervous, respiratory, cardiovascular, or gastro-intestinal systems. On the right upper arm there was an area of greyish-white brawny oedema, measuring 6 by 4 in. (15 by 10 cm.), and clearly outlined by an erythematous margin. The swelling was hot but not tender; it did not pit on pressure; there was no lymphangitis or enlargement of regional lymph nodes. The appearances were those of a Calabar swelling. On the left arm, leg, and buttock were small urticarial areas about the size of a florin.

Investigations.—X-ray films of chest and skull were normal. The cerebrospinal fluid was purposely not examined. Red blood count was normal. White blood counts, carried out daily, showed from 6,400 to 16,300 leucocytes per c.mm., of which the eosinophil count ranged from

1,400 to 7,800 per c.mm. (direct count). Blood smears were examined at various times of the day and night, and, by the courtesy of Professor Macgrath, midday thick films were examined at the Liverpool School of Tropical Medicine. No *Acanthocheilonema perstans* or *Loa loa* microfilariae were seen.

While awaiting admission to hospital the patient was given promethazine hydrochloride, 25 mg., three times a day, and this was continued while awaiting supplies of diethylcarbamazine dihydrogen citrate ("hetrazan"). From the first dose of promethazine there was a dramatic cessation of the migrainous symptoms and the urticarial areas on the skin ceased to appear. The antihistamine was continued throughout her subsequent full course of diethylcarbamazine and she had no further headache and no reaction to that drug until the last day of a three-weeks course, when on 300 mg. three times a day. On this day she felt giddy and was abnormally drowsy for six hours. The diethylcarbamazine was discontinued and she returned to normal rapidly. During the period of the treatment she had one typical Calabar swelling on the left thigh, lasting two days.

The patient remained perfectly well. Within three months her white blood count was normal, with no eosinophils, and 18 months after discharge she had been entirely free from headache, hemianopia, or any form of swelling.

COMMENT

Microfilariae were not seen in this patient's blood. Nevertheless, the history of having lived in Nigeria, the typical Calabar swellings, the smaller more transient urticarial areas, and the very high eosinophilia make the diagnosis of loasis almost beyond doubt.

It was, however, a striking fact that the patient came complaining, not of the swellings, but of the intensity and frequency of her attacks of migraine.

Neurological complications in the course of loasis are not unknown, and van Bogaert and his collaborators (1955) give an extensive review of the literature on this aspect and describe in detail a fatal case of encephalitis. They consider that many of the reported neurological manifestations are allergic in origin and that the pathological findings in their case are consistent with a state of hypersensitivity.

In the case reported here it seems reasonable to conclude that there was a direct causal relationship between the allergic state and the migraine. There was a known allergen; there was clinical evidence of skin allergy; and there was an abrupt cessation of severe migrainous attacks on giving antihistamines before any specific therapy directed towards eradication of the filariae had been started.

The syndrome we know as migraine is probably the common end of a variety of precipitating factors, and it may be that in only a small proportion of cases is there an allergic basis. If in each instance careful search and inquiry were made, from time to time commonly occurring allergens might be found to be the factors responsible, and, by removal, relief be obtained comparable to that reported in this patient, whose allergen was more clearly defined by virtue of its rarity.

EDWIN R. BICKERSTAFF, M.D., M.R.C.P.,
Consultant Neurologist, the Midland Centre for Neurosurgery.

Reviews

SIR GORDON HOLMES

Selected Papers of Sir Gordon Holmes. Compiled and edited by F. M. R. Walshe. (Pp. 262+xii; illustrated. 20s.) London: Macmillan and Co. Ltd. 1956.

The unusual prestige of British neurology has been largely determined by the achievements of the great exponents of the last two generations. In this twentieth century no one has done more to establish British neurology than Sir Gordon Holmes. It is no exaggeration to assert that the accepted present-day techniques of clinical examination of the nervous system, which in skilful hands reveal so much, directly stem from Holmes's exemplar. Whether we realize it or not, in Medicine . . . "as in Life, the law of heredity holds good; on est toujours le fils de quelqu'un," as Oscar Wilde has truly said.

The *Guarantors of Brain*, that journal of neurology which Holmes edited so long and with such authority, wisely decided to mark the occasion of his eightieth birthday by re-issuing a number of his earlier papers. The task of selection was no easy matter, but Sir Francis Walshe did well in his eventual choice. Thus we find in the first place a series of articles dealing with the cerebellum, and therein we discern Holmes's original methods of detailed clinical analysis of the physiology of that organ in man. Holmes's researches into the visual pathways are equally well known, and the original communications fittingly find a place in this volume. His views upon the cortical representation of vision, and especially of the macula, are well worth re-reading, and they contrast with the rival opinions of Henschen and of Bouwer. Lastly, the very topical theme of visuo-psychic disturbances from gross cerebral lesions becomes illuminated in an interesting fashion when one refers to the pioneer papers written by Holmes (alone or in collaboration with Gilbert Horrax) on such notions as visual attention and spatial and visual orientation.

The reader will note the detached and careful way in which Holmes observes, records, and evaluates his facts, using the scientific and austere prose-style of a modern Tacitus. Each word is packed with meaning and stands out sincere and unembellished.

Walshe as editor has provided a valuable preface with an eloquent appraisal of Holmes and his work. All this steady accumulation of scientific research, be it noted, has been effected by dint of "private enterprise" in the medical sphere. Walshe makes the telling point that it was the voluntary achievement of a physician, without university post or title, engaged in both hospital and private practice. It might be pointed out, too, that these researches were unsupported by expense grants or financial aid of any kind, being the outcome of sheer hard work, tireless devotion to an ideal, and innate intellectual brilliance. Holmes and his accomplishments are an inspiration and at the same time almost a reproach to those of us physicians who follow him and owe him so much.

MACDONALD CRITCHLEY.

INFANT METABOLISM

Infant Metabolism. Edited by I. Herbert Scheinberg. Proceedings of the W.H.O. Seminars held at Leyden and Stockholm in October-November, 1950. Conducted by Evert Gorter, S. Z. Levine, and Arvid Wallgren. (Pp. 435+xxii; illustrated. 56s.) London and New York: The Macmillan Company. 1956.

In 1950 two seminars were organized by the World Health Organization in Leyden and in Stockholm; the proceedings of the latter have now been published under the title *Infant Metabolism*. Apparently the reporting arrangements at Leyden went wrong, but, since the Stockholm meeting to some extent repeated what had been discussed at Leyden, these verbatim proceedings probably give a good account of the total presentations. Although about 80 participants are listed for Leyden and over 60 for Stockholm, the form

of the meetings appears to have been in smaller panel discussions. The whole has been ably edited by Professor I. Herbert Scheinberg, of New York, whose name does not appear among "those present." The object of these two gatherings was to discuss advances in knowledge of metabolism in the younger age group, no doubt hoping to fill up gaps in European work created by the war. In fact the contributions from war-occupied countries were remarkably valuable. The Danes in particular seem to have carried on good scientific work despite disturbances. There are reports of ten panel discussions. Three of these are more general, concerning metabolism in premature infants and in newborn infants, and on estimating nutritive status. The remainder deal with more special topics, such as water and electrolyte metabolism, vitamins, and protein metabolism. One of the most fascinating discussions arose in the panel on calcium, phosphorus, and vitamin D. On the inevitable problem of what exactly constitutes rickets no final conclusion was arrived at, and, since this was six years ago, there is little mention of hypercalcaemia, though in some of the remarks made quite enormous doses of vitamin D are mentioned.

The book is beautifully printed and produced, but regretfully has no index. It could be a valuable reference book but for this omission. It has also to be wistfully regretted that, although nine countries were represented, the United Kingdom was left out of participation, though Dr. F. W. Clements batted well for the Commonwealth.

ALAN MONCRIEFF.

POTT'S DISEASE

Pott's Paraplegia. By D. Ll. Griffiths, H. J. Seddon, and R. Roaf. (Pp. 129+xiv; illustrated. 50s.) London, New York, Toronto: Oxford University Press. 1956.

There is much important scientific information in this small book, which is the outcome of careful observations extending over many years. The authors decided to pool their experiences of 175 patients, as they had certain views in common about the management of Pott's paraplegia and evidence of the failure of conservative treatment. Although some of this work has been published recently this book will attract attention, as the subject is difficult and the condition not very common but may be lethal. Although tuberculosis of the spine is becoming less common in the United Kingdom, it is likely to continue in some parts of the world, where this book should be particularly useful. It is acknowledged that most of this report is on patients seen before the introduction of streptomycin.

The purpose of the book is to review the clinical features and pathology of Pott's disease, the need for operative intervention, and the results of such treatment. The indications for operation are stated in categories of "absolute" and "relative." The authors find that a decompression is the most effective method of treatment for paraplegia, and in this respect their experience differs from that of Alexander. The evolution of operative treatment from laminectomy to antero-lateral decompression is described. The technique, difficulties, and dangers of antero-lateral decompression and of costo-transversectomy are stated in an authoritative manner with well-chosen and clear illustrations. There are many tables and analyses of cases, showing careful records. The illustrations are excellent, and it should be appreciated that many are from photographs and radiographs of the spine which are difficult to reproduce. The authors are to be congratulated on this record of work, to which much thought has been given.

ST. J. D. BUXTON.

Methods of Chemical Analysis as Applied to Sewage and Sewage Effluents is a small technical manual which first appeared in 1929. A second edition, revised by a committee appointed by the Ministry of Health, has now been published by H.M. Stationery Office (10s.). It describes in detail tests for measuring most of the constituents of sewage that are of significance in its disposal.

PITUITARY TISSUES

The growth and function of anterior pituitary tissue outside the domain of the sella turcica and hypothalamus have been much debated. The results of experimental work show that, though the anterior hypophysis may retain some cellular differentiation and a good blood supply after separation from the influence of the hypothalamus (by hypothalamic lesions, section of the pituitary stalk, or pituitary transplantation), gonadotrophic activity is completely lost, and adrenocorticotrophic and thyrotrophic functions are at least greatly reduced. Data are scanty on lactogenic and somatotrophic secretion. The findings of the more reliable studies show that the influence of the hypothalamus in maintaining and regulating the activity of the adeno-hypophysis is mediated through the hypophysial portal vessels of the pituitary stalk.

Metastases from primary carcinomata of the anterior pituitary are very rarely seen, if ever, though they arise only too commonly from carcinomata of other endocrine glands such as the ovary, testis, thyroid, and adrenal cortex. Sir Geoffrey Jefferson¹ has recently, in his Sherrington Lectures at the University of Liverpool, discussed the problem of the invasive adenomata of the anterior pituitary. He described fourteen cases in which an adenoma of the adeno-hypophysis showed local spread and infiltration. In many of these cases the cells were malignant in type—anaplastic and undifferentiated—though none of them showed any sign of metastases. The fact that locally malignant tumours of the anterior pituitary do not metastasize is a general finding. A. B. King,²

R. A. Willis,³ and N. W. Winkelman, C. Cassel, and B. Schlesinger,⁴ and others all agree on the rarity of the occurrence if it ever occurs. Although the usual criteria of malignancy (mitoses, anaplasia, loss of functional arrangement, and marked invasion of the surrounding tissues) are all applicable to invasive pituitary "adenomata," secondary growths do not seem to appear. Thus the question arises, Why are secondary metastases so rare from pituitary tumours when they are so common from carcinomata of other endocrine glands? Several answers suggest themselves. First, pituitary carcinomata are in themselves rare. However, Jefferson says, "Really massive extensions occur in at least 10% of pituitary adenomas." Secondly, patients with untreatable pituitary tumours may die before the tumour grows large enough to metastasize. But in Jefferson's series of invasive adenomata the majority lived four, five, or seven years. Thirdly, the pituitary gland lacks a lymphatic drainage necessary for the spread of such a tumour. It may be recalled here that gliomata of the brain very rarely spread to distant organs.⁵ However, a primary glioma of the brain is not infrequently associated with subarachnoid spinal metastases.⁶ An invasive pituitary tumour does not metastasize even in this way. Cairns and Dorothy Russell described the case of a female, aged 25 years, who died in a coma with hyperglycaemia, apparently in consequence of a large, very soft pituitary adenoma. During life this patient had cells of a peculiar type in the cerebrospinal fluid, and after death multinucleated cells identical with those forming the primary tumour were found in the subarachnoid space, though "they did not appear in any way to be grafted on to the structures in their environment." Therefore pituitary tumours and gliomata seem to differ in regard to their spread in the cerebrospinal fluid. While cells of pituitary tumours may disseminate in the cerebrospinal fluid, there is no evidence that they become implanted in distant meninges and grow as separate tumour masses.

But to account for the lack of metastases from pituitary tumours another possibility should be considered. In recent years evidence has accumulated that carcinomata in organs related to the endocrine system grow at a rate which, at least in the early stages, may be dependent on the presence of the normal stimulus to activity of the tissue from which they arise. Thus a carcinoma arising from a lactating breast has a high growth rate; the growth of a mammary carcinoma and its metastases may be arrested by hypophysectomy; and the growth of carcinoma of the prostate may be brought to a standstill

by castration or administration of stilboestrol. If, then, the growth of such primary and secondary tumours is dependent on the presence of the normal physiological stimulus to the tissue from which they arise, it might be reasoned that secondaries from tumours of the ovaries, testis, adrenal cortex, or thyroid which receive a supply of the appropriate pituitary eutrophic hormone, wherever situated in the body, may occur and grow readily, but that secondaries from pituitary carcinomata would not receive the normal stimulus to anterior pituitary activity if situated outside the vascular territory of the hypophyseal portal system of vessels and for that reason are not seen.

In a recent article J. D. Boyd⁶ emphasizes the existence of the pharyngeal hypophysis in the human foetus. He describes the presence of this structure in all but one of fifty prenatal specimens and three full-term stillborn infants, and remarks that this derivative of Rathke's pouch has structural features closely resembling those of the normal adenohypophysis. It was found to be richly supplied with blood vessels, and nerve fibres derived from the sphenopalatine ganglion were observed to penetrate it. In surveying the literature, Boyd comments that the pharyngeal hypophysis is constantly present only in man and the dog, and that its cells can differentiate to at least a slight degree, as do those of the adenohypophysis. These findings may have an important bearing on the performance of hypophysectomy for mammary carcinoma and other conditions, and it becomes of interest to know whether the pharyngeal hypophysis is a functional entity or not. Boyd suggests that the structure is active because it shows some (if slight) cellular differentiation and possesses a rich blood supply and a nerve supply. However, anterior pituitary tissue which is inactive may show some cellular differentiation and retain a good blood supply. The significance of a nerve supply is doubtful, since recent electron-microscopic studies have shown the normal pars distalis to be devoid of a nerve supply. The reasons put forward by Boyd cannot then be taken as evidence for functional activity by the pharyngeal hypophysis, and as he himself points out: "It must be stressed, however, that the association of any normal function with the pharyngeal hypophysis remains to be sought." Experimental data on the function of anterior pituitary tissue separated from the hypothalamus indicate that normal function in the pharyngeal hypophysis is hardly to be expected. What direct evidence there is argues against any activity in this embryological remnant. B. F. Kingsbury⁷ records the observations made on six adult dogs

hypophysectomized some six weeks earlier. In none of the animals was there evidence indicative of a residual hypophyseal function. Further, S. Tolins and R. A. Moore⁸ were unable to detect any endocrine activity in extracts of the pharyngeal hypophysis of the dog. However, though the dog always has a pharyngeal hypophysis, it tends to become cystic after birth. The evidence so far obtained from studies of hypophysectomy in man indicates, in spite of the claims of W. Muller,⁹ that complete removal of the pituitary gland results in a state comparable to that seen in the lower mammals. Many workers¹⁰⁻¹³ have found that typical loss of gonadotrophic, thyrotrophic, and adrenocorticotrophic function follows hypophysectomy in man. There is little reason to suspect that the pharyngeal hypophysis can compensate in any way for the loss of the pituitary gland.

CORTISONE AND ASTHMA

Despite many recent advances in treatment, bronchial asthma still remains a challenge to modern therapy. Not only do asthmatic patients continue to suffer for many years from chronic disability, but they are liable to severe and distressing exacerbations needing urgent treatment if life itself is not to be endangered.^{1,2} It is a sad reflection that most family doctors have under their care many patients who have undergone all forms of orthodox, and many forms of unorthodox, treatment and yet remain victims of constant dyspnoea and wheezing. Their suffering is only partially mitigated by continued and often surreptitious recourse to their favourite brand of antispasmodic. Since asthma is to some extent an allergic disorder it was hoped with the advent of corticosteroid therapy that cortisone and corticotrophin might bring relief and possibly offer a chance of cure to the asthmatic. Early reports soon confirmed that these drugs were efficacious, but, as so often happens, the initial enthusiasm later gave way to some scepticism and caution.^{3,4} It is not surprising that in a disorder as capricious as asthma there is some difficulty in assessing the value of treatment; indeed, it is an adage known to all clinicians that "any new treatment seems to work for a time."

In an attempt to assess more accurately the efficacy of cortisone in chronic asthma and in severe asthmatic

attacks, a subcommittee of the Medical Research Council has analysed the results of two therapeutic trials.^{5,6} In the first, the effect of cortisone was compared with that of a placebo in patients with chronic asthma—patients with respiratory infection and those given to spontaneous remissions being excluded. Neither the patients nor the physicians knew whether cortisone or the placebo tablets were being given until the results were assessed. It was concluded that the patients receiving cortisone were definitely, though not very markedly, improved during the early weeks of treatment. This early improvement, however, was not maintained beyond a period of about two months, after which there was no real difference between the treated patients and the controls. The second trial was planned to determine the value of cortisone in status asthmaticus. Cortisone was given to certain patients in addition to standard treatment, and the results of treatment compared with those achieved by using standard methods and a placebo tablet indistinguishable from cortisone. The dose of cortisone was 350 mg. on the first day, 200 mg. on the second day, and was then slowly reduced until the ninth day, after which the drug was discontinued. This trial showed beyond doubt that patients receiving cortisone responded more rapidly and more completely than the controls. Nevertheless, it is encouraging to note that routine methods for treating status asthmaticus—with antispasmodics and oxygen—were so successful that many patients recovered before cortisone treatment could be started.

Statistical evidence from blind trials of this sort does not necessarily indicate the correct treatment for individual patients, and certainly reports have shown that some asthmatics apparently do well on prolonged treatment with cortisone.⁷ But it is disturbing that a number of unexplained deaths have occurred in asthmatic patients given cortisone over a long period.⁸ The reports to the Medical Research Council confirm the impressions of most physicians that cortisone is best used in the acute and severe phases of asthma when more conventional ways of treatment have failed. Though a minority of patients might need prolonged treatment, the slight advantages of this should be carefully weighed against the serious risk of complications from continued administration and the tragic possibility, however remote, of sudden death. In the Medical Research Council's trials cortisone was used because it was more readily available and easier to administer than corticotrophin. Corticotrophin, however, has probably become the more popular drug in the treatment of status asthmaticus in hospital practice. Although corticotrophin is not yet available to general practitioners no doubt it will

become more abundant, and it would be instructive to compare results from the two drugs in controlled trials.

Nowadays when new drugs are introduced in the treatment of a disease they are usually rightly submitted to critical trial before their efficacy is accepted, whereas traditional treatment often goes unchallenged. Thus, although we are now able to appraise the role of cortisone in asthma, widely divergent opinions are held about the merits of most other forms of treatment. It would be salutary, and possibly quite surprising, to see the results of controlled trials rigidly applied to such treatment as protein desensitization, inhalation of various gases, breathing exercises, and other forms of treatment which are often used for the relief of asthma.

SOIL AND CANCER

Observations on the occurrence of multiple cases of cancer in certain houses led at one time to a "cancer house" hypothesis, and statistical studies were then made to find whether this happened more often than might be expected by chance. Such a study at Lyons in 1933¹ failed to show any difference in this respect between deaths from cancer and deaths from all causes; and in 1935 P. Stocks² found from the distribution of 3,500 fatal cases of cancer in houses in Worcester and Bristol that, though multiple deaths tended to occur in the same or adjacent houses more often than would be expected if the people were distributed uniformly, the census showed that people over 55 years of age were in fact clustered together in the same way as the cancer cases. Any effects of soil on cancer incidence would hardly be manifest in large towns, however, and should be looked for in rural areas.

Some 90 years ago W. Farr and A. Haviland³ deduced from a geological map of England and Wales that registration districts with high crude death rates for cancer in women tended to coincide with low-lying clay areas liable to seasonal flooding by rivers, whereas chalk and limestone areas tended to have low rates, and the thesis was elaborated later.^{4,5} Certification at death of many forms of cancer at that time was far from complete in rural areas, and the rates could not be standardized for age, so it was hardly surprising that the cancer maps by counties prepared by Stocks⁶⁻⁸ differed a good deal from Haviland's. In Wales crude

death rates for cancer in the early days of death registration were low, but the standardized rates in the last 30 years have been uncommonly high. Indeed, when the 60 county aggregates of rural districts in England and Wales are ranked according to their comparative mortality figures for gastric cancer, the 7 counties with highest mortality are all in Wales, and the first 17 consist of Wales and the English Lake District, where igneous rock is close to the surface, and the Fen district, with peaty soil. Of the 8 lowest-ranking counties, on the other hand, 7 have underlying chalk in their geological formation. In Holland also, J. C. Diehl and S. W. Tromp⁹ have shown by study of death rates for gastric cancer in 1946-52 in about 1,100 municipalities that peat and sea-clay soils tend to have higher rates than river-clay soils. For example, the equivalent average death rates per 10,000 males at ages between 50 and 80 were 247 on peat soils, 203 on sea clay, 194 on sandy soils, and 170 on river clay. In a more recent paper Tromp¹⁰ has produced maps of death rates for stomach cancer at different ages by provinces in 1946-52, and at ages over 50 by separate municipalities, and he concludes that mortality was in general greater in agricultural than industrial municipalities. R. I. Davies and G. Wynne Griffith¹¹ investigated the soil groups in Anglesey characterizing localities where people had died of cancer during 1943-52, the residences being pinpointed on the map of the soil survey. They classified soils into three main groups, (α) subject to late spring and summer drought owing to shallowness or excessive drainage, (β) with equable distribution of moisture owing to a fluctuating water table at all seasons, and (γ) with a prolonged wet season owing to poor drainage. There were 1,148 deaths, and the ratios of stomach to other cancer showed a statistically significant excess of stomach cancer on β soils. Later 238 of the deaths from stomach cancer were matched against non-cancer deaths, and this confirmed the tendency for stomach cancer to occur on soils of the β group, while other cancers did not show this relationship.

In his most recent progress report on the environmental survey of cancer in North Wales and the Liverpool Hospital Region P. Stocks¹² gave some first results of analysing soils from gardens of houses where a resident had died of cancer. In respect of organic carbon content and total carbonaceous matter as measured by loss of weight on igniting the dried soil, gastric cancer seems to have occurred after long residence (but not after short residence) more often where the soil contained certain proportions of these constituents than was to be expected from controls. No such peculiar relation with length of residence was found for the other forms of cancer under investigation. Moreover, the soil characteristics manifesting this statistical correlation with stomach cancer correspond in general with those of the β group defined in the independent Anglesey study. If these tentative findings are confirmed in the complete report, it will be necessary to consider in what way soil could affect the incidence of gastric cancer, whether through organic carcinogens trace elements, radiation, or other means.

FEVER AFTER MITRAL VALVOTOMY

After mitral valve operations some patients whose early course has been uneventful later develop a fever and chest pain, the cause of which is not apparent. These symptoms are usually seen about one or two months after operation, occasionally within two weeks but sometimes after longer delay, even over a year. Most reports have come from the U.S.A.,^{1,2} where the symptoms are known as the post-commissurotomy syndrome, post-valvotomy syndrome, or post-cardiotomy syndrome. The incidence of the syndrome varies from about 6% to 40% or over of the patients receiving operation. It is also seen in Britain, but not very often. Paul Wood reported a rate of 10%.³

The onset of the syndrome is usually abrupt. The most common symptom is pain, felt in the left anterior chest, usually deep-seated and constricting, sometimes sharp, and occasionally severe. It may radiate to the left shoulder or neck or sometimes to the right side. There is typically a coincident fever, with the temperature up to 102° F. (38.9° C.), rarely higher; it usually subsides after a few days but may recur after a few weeks, sometimes on several occasions. Other less common symptoms include dyspnoea, cough and haemoptysis, joint and muscle pains, pleurisy, and abdominal pain.

The fever apart, these patients seldom appear seriously ill. Rales may be heard in the lungs, especially on the left side, and pleural effusion is common. Pericardial friction or effusion is sometimes found; cardiac signs are meagre, though tachycardia is common, whether the patient has regular rhythm or atrial fibrillation. Fibrillation may begin, but its onset after operation is frequently not associated with the other features of the syndrome. Spontaneous reversion to normal rhythm may occur or be induced with quinidine. Episodes of congestive heart failure may be seen, but are usually readily controlled. Laboratory findings are not specific. A mild leucocytosis and a raised sedimentation rate are found, but no anaemia; effusions are sterile. There is no correlation between the finding of Aschoff bodies in the wall of the auricular appendage removed at operation and the occurrence of the syndrome. The chest radiograph may show pleural or pericardial effusion, and the electrocardiograph abnormal rhythm or evidence of pericarditis. The course is benign. Symptoms gradually subside during several days, and serious sequelae do not occur, though recurrence of symptoms is common.

The syndrome was first observed after mitral valvotomy, but has also occurred in cases when only exploration has been performed and no incision made in the heart. It has occasionally been seen after operations for congenital heart disease. As a rule no evidence can be found of rheumatic activity or of bacterial infection. The symptoms resemble those seen in cases of pericarditis, particularly traumatic pericarditis, and it is generally believed that this is the cause. Most surgeons

¹ Elster, S. K., Wood, H. F., and Seely, R. D., *Amer. J. Med.*, 1954, 17, 826.

after heart operations suture the pericardium very loosely, so as to allow the fluid which forms to drain into the pleura and to avoid tamponade. If the precaution is also taken of washing out or sucking away all blood clot from the pericardial cavity, the likelihood of the syndrome is reduced. As a rule no treatment is required, but aspirin relieves the symptoms and cortisone is rapidly effective. Chemotherapy has no effect and no prophylactic value. D. T. Dresdale and his colleagues² have given cortisone to all patients having operations on the mitral valve, and report a much lowered incidence of the syndrome. It is doubtful whether this practice will find universal favour.

STEREOTAXIS AS AN AID TO NEUROSURGERY

The use of a stereotaxic technique for locating structures in the brain of the living animal was first described by Victor Horsley and R. H. Clarke in 1908.¹ Clarke had designed an apparatus which allowed the physiologist accurately to place a needle electrode into most areas of the brain. During his lifetime he did not receive the recognition that was due to him for a remarkable and fruitful invention, the principle of which is simple. The head of an anaesthetized animal is firmly secured, and a movable arm holding the electrode travels along a bar parallel to the skull, so that the electrode can be inserted vertically through a burr hole to any desired depth in the brain. The instrument is calibrated in millimetres, and areas of the brain are located by the use of co-ordinates based on skull sutures and a line joining the auditory meati as reference points. Excellent atlases are available for many of the common laboratory animals, including the rhesus monkey, cat, rabbit, and rat. The instrument is particularly valuable for studying the function of subcortical areas and was first used for producing destructive lesions by electro-coagulation. Stimulation of the brain of the anaesthetized animal, analogous to the experiments carried out on peripheral nerves, soon followed. A notable advance was made by the Swiss physiologist W. R. Hess,² who, although working without the apparatus of Horsley and Clarke, showed that it was possible to implant electrodes permanently in the hypothalamus of the cat without disturbing the well-being of the animal. This has considerably extended the possibilities of the technique. Electroencephalographic recordings can now be obtained in the unanaesthetized animal, drugs can be injected through permanently implanted needle guides, and electrical stimulation can be carried out for prolonged periods. Ultrasonic waves and ionizing radiations have been used to produce necrosis of sharply defined areas of the brain.

Clarke³ hoped that his apparatus might eventually be adapted for use in human patients, and the first instrument for this purpose was described by E. A. Spiegel,

⁷ Spiegel, E. A., and Wycis, H. T., *Stereotaxic Neurosurgery*, 1952, New York.

H. T. Wycis, and their colleagues⁴ in 1947. At the present time at least a dozen instruments are available, including one designed in Britain by W. C. Lister and S. L. Sherwood.⁵ They have been used for implanting radio-isotopes into brain tumours, for injecting alcohol into the thalamus of patients with intractable pain, and for destroying subcortical tissues in patients with mental disease. Electroencephalographic recordings have also been obtained from the deeper parts of the brain. There are of course many difficulties in the design and handling of such instruments which do not arise in animal experiments. They must be light in weight, durable, able to stand up to sterilization, and easy to handle during operation. For the accurate location of different parts of the brain some form of radiographic control is necessary. Ventriculography⁶ and the position of the pineal gland, as well as bony structures of the skull, are used for reference. If the technique proves useful clinically—and the surgery of psychiatric disorders seems to be a promising field—perhaps the neuroanatomist will be able to prepare an atlas of the human brain similar to that of Spiegel and Wycis⁷ but based on the type of co-ordinates used in the experimental animal. This would greatly simplify the surgeon's task.

EMOTIONS AND EPILEPSY

Research into epilepsy has recently been extended to the study of the auras that patients experience. As is usual with studies on this disease, it is often hard to improve upon Hughlings Jackson's original, accurate, and detailed descriptions, and harder still to enlarge upon his simple but profound analysis of their pathology. Among interesting recent contributions is Denis Williams's study¹ of the structure of emotion as reflected in epileptic experiences. A hundred experiences were studied in about 2,000 epileptics. The most interesting point that emerges is that the range of emotions experienced was narrow, and confined to the "primary" emotions of fear (61), depression (21), pleasure (9), and unpleasure (9). Anger and rage were observed in some other cases, which will be the subject of a later paper. In all except one case the emotion was associated with other ictal sensations (hallucinations, déjà-vu, and somatic or visceral feelings). Cognitive activity was rarely part of the aura, and, though elaborate experiences might be described, they had the diffuse quality of dreamy states, as Hughlings Jackson so aptly called them long ago.

Williams relied mainly on electroencephalographic studies for locating the probable site of origin of the discharging lesions, though some were verified by operation. In 30 of the 61 cases showing fear he found anterior temporal foci, in 17 cases middle temporal foci, and in the other 9 none could be located. It is probable that almost all the foci were below the Sylvian fissure, mostly deep in the temporal lobe, but some were inferior frontal. This

⁵ Fenichel, O., *The Psychoanalytic Theory of Neurosis*, 1945, New York.

predominance of lesions in the region of the deep temporal lobe accords well with experimental data obtained in research on animals. Complex epileptic seizures of "psychomotor" type were found to be accompanied by movements and visceral activities that would be appropriate to the animal experiencing emotion, especially fear. Furthermore, lesions in the deeper regions of the temporal lobe (uncus, amygdaloid, hippocampus) are the commonest findings in the operative specimens obtained by temporal lobectomy.² Most of these patients had had complex auras with affective experiences.

There seems to be a neurophysiological mechanism for the expression of, and the experience of, emotional states; it comprises visceromotor and sensory, and somato-motor and sensory, and special-sense activities. An epileptic discharge activates in a typical, brief, telescoped, stereotyped fashion some or all of these various components, in the same way as an epileptic discharge in the lower level of the motor cortex produces a distortion of the smooth motor activity mediated by this region. We have not yet gained any idea why one particular epileptic attack should pick out only certain elements of what is usually a smoothly co-ordinated response. Neither the form of the spike in the temporal-lobe electroencephalogram nor the pattern of the actual seizure, if it is recorded, gives any information about the probable type of emotion experienced or what sort of visceral somatic activity might be associated with it. However, from psychological and psychiatric studies some interesting observations have been made by A. W. Epstein and F. Ervin,³ and D. Hill and W. Mitchell.⁴ Both groups of authors have pointed out that the resemblance of the dreamy state to a dream can be extended to finding in both of them similar mechanisms of distortion, condensation, secondary elaboration, and so on, such as were first described by Freud in his classical study *The Interpretation of Dreams*. Individual case histories of epileptics partially psycho-analysed have been published for many years,⁵ but most of these reports pay scant attention to the actual epileptic aura, and the type and frequency of fits are hard to discern. Epstein and Ervin have also noted that the reported content of an aura changes during psychotherapy in a psychodynamically meaningful way, as dreams do, and the number of fits increases during times of increased emotional tension. The question arises, therefore, of what elements of an aura, if any, can be ascribed directly to the epileptic discharge.

The emotions that Williams's subjects reported correspond closely to the primitive emotions described by psychologists as the only ones occurring in babies. Depression is a more elaborate state somewhat different from the rest, and it is interesting to note that the form in which this emotion appears in Williams's patients also differs from the other ictal experiences. It tends to last longer and be less clearly an aura phenomenon only, so its neurophysiological substrate is not as definite as with fear, pleasure, and displeasure. Williams speaks of a hallucinated emotion comparable to an ordinary sensory hallucination, which is a precept without apparent stimulus. He assumes a distinction between such

organic hallucinations and psychotic hallucinations, but at present this does not seem quite as clear-cut. His idea would be more useful if the mechanisms of ordinary hallucinations were understood. It seems possible that the effects of Jacksonian epileptic discharge are brief and distorted primitive emotional states, with their appropriate visceromotor and viscerosensory components. What aspects of this state may be reported by the subject and what cognitive components grafted on to it are dependent on secondary psychopathological processes comparable to the "dream work" of Freud, and related to personality structure and previous experience. The study of epileptic patients thus continues to be an important and useful method of investigating the interaction of mental and physiological events, with implications that go far beyond the phenomenology of the seizures themselves.

S.H.M.O.s IN CONSULTANT POSTS

After continued representation by the Staff Side of Whitley Committee B, the Management Side of that body has agreed to a review of the remuneration of certain senior hospital medical officers in consultant posts. According to the agreement, which is reported at p. 60 of this week's *Supplement*, three categories of S.H.M.O.s may apply for a review of their remuneration. They are those who hold posts which are established as consultant posts; those who hold posts which for the purpose of replacement would be graded as consultant posts (many in these two categories will be those who held appointments on the staffs of hospitals before July 5, 1948, but were not given consultant grading in the National Health Service, and have continued in the same appointments); and others who carry out consultant work with full and independent responsibility. The Management Side would not agree that all S.H.M.O.s in posts of a consultant nature should automatically be paid on the consultant scale. Each individual case is to be examined on its merits. It should not be difficult to define those who come into the first category. There may well be, however, a conflict of opinion on those—and the number must be considerable—whose work is of a kind that qualifies them for consideration under the second and third categories. The Management Side will no doubt look very closely at each application, but the Staff Side, by its persistence, has managed to get a foot in the door, however grudgingly it has been opened. The history of the S.H.M.O. grade makes one of the unhappiest chapters in the Health Service story. It is a record of a group—who in numbers form one-third of all specialist hospital staff and upon whom therefore the hospital service must largely depend—who have become increasingly incensed at the injustice of their lot. As Dr. C. B. V. Walker puts it in a letter at p. 61 of this week's *Supplement*, the S.H.M.O. grade has created "a class working at substandard rates . . . a sort of 'minus merit award.'" It is yet to be seen how many will benefit from this review, but if the rate for the job has any meaning in common justice a large number of S.H.M.O.s would appear to have an unanswerable case for an increase in remuneration.

THE CHILD HANDICAPPED BY CARDIAC CONDITIONS*

BY

N. B. CAPON, M.D., F.R.C.P.

Professor of Child Health, University of Liverpool

The cardiac causes of crippling in childhood fall into two main categories—congenital cardiovascular lesions and rheumatic carditis. There are, of course, other examples—often of great medical interest—but they are comparatively rare, and I need not mention them.

There is a general impression that over the past fifteen years or so congenital deformities of the heart and large vessels have become more common, while rheumatic carditis has diminished in frequency. It is difficult to obtain reliable evidence. In regard to congenital malformations, the great advances made during recent years in the surgical treatment of these deformities, and in anaesthesia for these patients, have focused the attention both of doctors and of parents upon this type of disability, and the hospital services for the detailed diagnosis and treatment of these cases are under increasing pressure. Certainly it would be interesting and helpful to know (1) whether the incidence of congenital cardiac deformity is increasing, because this might have a bearing upon possible means of prevention; and (2) the percentage of children suffering with congenital cardiac deformity that might be amenable to surgical treatment. Clearly this proportion is likely to increase, year by year, as surgical and anaesthetic techniques expand and improve.

Congenital Cardiovascular Lesions

Some light can be thrown upon the incidence of congenital cardiac deformity by studying the paediatric reports of maternity hospitals; but even the most detailed of these cannot give a certain answer, because the clinical signs of handicap may not appear until the child has left hospital; and it must be remembered that a systolic murmur can be heard in 1% to 2% of all newborn babies, and may disappear again within a few weeks. In a series of 6,053 newborn infants (live births and stillbirths) reported by Richards *et al.* (1955) it was found that 7.6 per 1,000 of the live-born had (1955) congenital cardiac deformities, and 10 of these babies (26%) died in the neonatal period. At the Liverpool Maternity Hospital the incidence of congenital abnormality of all types (not cardiovascular only) is about 20 per 1,000 live births; and an analysis of the 20,339 live births in the hospital during the eight-year period 1946–53, inclusive, shows that 56 (or 2.7 per 1,000) almost certainly had a congenital cardiovascular lesion, while an additional 43 were "possible" cases. I estimate from these figures that the incidence of congenital heart deformity in the Liverpool Maternity Hospital is probably about 3 to 4 per 1,000 live births.

It is worth noting that of the 56 definite cases 13 (23%) died during the first two months of life, and that this figure compares closely with the 26% noted in the American study as dying in the neonatal period. It would appear, therefore, that about one-quarter of all congenital cardiacs born alive have very serious, and often multiple, anomalies in the heart and large vessels, and sometimes abnormalities elsewhere; and that these cases are seldom suitable for surgical treatment, especially when there are complications such as pneumonia or atelectasis.

*Read at a Plenary Session at the Annual Meeting of the British Medical Association, Brighton, 1956.

The deaths of congenital cardiacs during the first five years of life reduce the incidence of congenital cardiac deformity to a figure that has been thought to be about 2 per 1,000 during school age, which would represent about 13,000 affected children in England and Wales. But it may be that this estimate is too small, and I am indebted to Dr. J. A. Scott, Medical Officer of Health to the London County Council, for the following information. In 1954 some 5,000 children out of a new intake of about 41,000 to the primary schools were examined to determine whether special educational treatment was necessary, and 23 cases of congenital cardiac malformations were found—an incidence of 4.6 per 1,000.

Here is a considerable problem for the medical and educational services, as well as for the affected children and their relatives. Two practical questions at once suggest themselves: (1) Is it possible to take any steps to prevent congenital cardiac deformities?; and (2) How many of the affected children can be helped, or perhaps cured, by surgical treatment? The answer to the first question, unfortunately, is no. It seems probable that many of the cases are due to genetic imperfections, though they are seldom familial. Rubella affecting the mother early in her pregnancy is a rare cause. Probably there are other maternal infections, as well as metabolic disorders and faulty implantation, that disturb the normal nutrition of the early embryo, but we do not know what they are.

Surgical Treatment

In regard to the operative treatment of congenital cardiovascular disorder, an uncomplicated persistent ductus arteriosus presents little difficulty to the experienced surgeon except in the early months of life and when the ductus is unusually wide; pulmonary stenosis (whether valvular or infundibular) is being tackled with increasing success; and operative treatment will often relieve the handicap suffered by a child with Fallot's tetralogy. Techniques are being devised and are now in use to close interatrial septal defects. Coarctation of the aorta lends itself fairly well to operative treatment, and the constricting effect of an aortic ring can often be removed.

So far we have no reliable figures giving the percentage occurrences of these various types of lesion in clinical practice, but interatrial and interventricular defects are the most frequent, followed by persistent ductus arteriosus, pulmonary stenosis, Fallot's tetralogy, and aortic coarctation in that order. Gasul and Fell (1956) have reported their findings in a series of 1,395 congenital cardiacs, 90% of whom were under 16 years of age; the patients were examined with much care, and the diagnoses were confirmed, when necessary, by angiocardiograms (850) and cardiac catheterization (450). There were also 300 necropsies. The frequency of the commoner malformations were: ventricular septal defects, 20.5%; tetralogy of Fallot, 11.1%; persistent ductus arteriosus, 10.7%; atrial septal defects, 9.6%; undiagnosed (mostly either atrial or ventricular septal defects) 8.1%; coarctation of the aorta, 5.5%; complete transposition of the great vessels, 4.3%.

Dr. J. D. Hay, who has charge of the cardiac clinic at the Royal Liverpool Children's Hospital, has kindly furnished me with the following information based upon his detailed examination of 1,324 children referred to him for his advice (in some cases his diagnosis is "provisional," but I have grouped these cases with the "definite" diagnoses):

"Functional" systolic murmur	249
Rheumatic heart	102
Persistent ductus arteriosus	222
Ventricular septal defect	207
Pulmonary stenosis	99
Tetralogy of Fallot	93
Atrial septal defect and common atria	88
Aortic and subaortic stenosis	67
Transposition of great vessels	36
Aortic coarctation	32
Miscellaneous	129
	1,324

These figures would appear to suggest—though only in very general terms—that at the present time about one-third of all children referred to a cardiac clinic may be cured or at least helped by surgical treatment.

Rheumatic Carditis

The incidence of acute rheumatism in children, as recorded in successive reports of the Ministry of Health, has been decreasing fairly steadily, though there are indications that in some areas an increase has occurred during the past year or so. The number of patients admitted to hospital annually for a particular illness cannot be taken as an accurate estimate of the prevalence of that illness in the area, but it may be a pointer. In 1943 185 children were admitted to Alder Hey Children's Hospital, Liverpool, for rheumatic infection (with and without carditis), and subsequently there was a fairly steady decline to 44 in 1950. Since then there has been a gradual increase to 63 in 1955.

Dr. J. A. Scott has informed me that in 1954 146 children were admitted to Queen Mary's Hospital, Carshalton, under the London County Council's rheumatism scheme, representing an incidence of 0.33 per 1,000 of the total school population. But it should be noted that only 30 (20%) of these 146 patients were diagnosed as suffering from rheumatic carditis. Dr. Peter Henderson, Principal Medical Officer to the Ministry of Education, has kindly given me the results of an analysis, made during 1955, of the school medical records of the 14,000 children in Oxford City schools. Only 37 (or 2.6 per 1,000) were found to have organic heart disease (including deformities) or a history of acute rheumatism. Twenty of the 37 had congenital heart lesions, and the remaining 17 had had one or more attacks of acute rheumatism; but only 6 of the 17 had permanently damaged hearts. There is little doubt, however, that in the northern industrial districts the incidence of rheumatic infection is higher than this; and it must be remembered that the report of the Registrar-General for 1954 shows that the total deaths in England and Wales, at all ages, certified as due to acute rheumatism and rheumatic heart disease, numbered 8,895.

Sir John Parkinson (1945) estimated that there were at that time at least 200,000 persons between the ages of 18 and 41 years in Great Britain suffering from acquired heart disease—mostly rheumatic, and usually contracted during childhood. This estimate is supported by Kerley's (1949) observation that in the mass radiography of 3,000,000 adults during the period 1945 to 1948, 4 per 1,000 were found to have undoubted radiological evidence of rheumatic carditis, and he thought that the correct figure would probably be nearer to 6 or 7 per 1,000. At the same time, Kerley noted that 20% of the cases detected were unaware of any disability and gave no history of rheumatic infection. Even if the incidence of acute rheumatism in childhood is only 0.3 per 1,000 children of school age (as indicated by the statistics from areas where acute rheumatism is notifiable and shown in the Ministry of Health Report, Part II, for 1954), the total number of new cases in each year must be about 2,000. We do not know what proportion of these patients will develop permanent carditis, but we can be sure that even the present incidence of rheumatic infection provides a terrible load of mischief for a nation to carry.

Prevention and Treatment

Is it possible to prevent not only the first attack of rheumatic infection, but also the recurrences which are so liable to occur when the individual's defences have been breached, especially during the early years following the initial infection? On this subject a committee of the American Heart Association (1955) has prepared a statement stressing the paramount importance of controlling group A haemolytic streptococcal infections and claiming that adequate and early penicillin treatment over a period of 10 days will eliminate streptococci from the throat and will usually prevent an attack of rheumatic fever. The dose recommended is one

intramuscular injection (600,000 units) of benzathine penicillin G; or one intramuscular injection of procaine penicillin (300,000 to 600,000 units) in oil with 2% aluminium monostearate, given every second or third day for three doses. Oral penicillin is also recommended in a dose of 250,000 units three times daily for 10 days. For the prevention of rheumatic recurrences in subjects who have had the initial attack (whether rheumatic fever or chorea or heart damage) it is suggested that a daily dose of 0.5 to 1 g. of sulphadiazine be taken each morning, throughout the year, and continued for years. Alternatively penicillin may be used, either by mouth in a dose of 200,000 to 250,000 units once daily, before breakfast; or as a monthly injection of 1,200,000 units of benzathine penicillin G.

Markowitz and Hemphill (1955) found that a daily dose (oral) of benzathine penicillin G, 200,000 units, was more effective than a sulphonamide in preventing rheumatic recurrences and caused fewer toxic reactions. When rheumatic patients are in hospital wards, and therefore in possible contact with streptococcal carriers or patients with active streptococcal infection, particular attention must be paid to the accepted techniques for avoiding cross-infections.

Those who may feel opposed to ordering a prolonged course of either sulphonamide or antibiotic treatment—and I confess that I am somewhere on the fringe of this group—should remember the sinister character of rheumatic recurrences, which are often initiated by quite mild recurrences of streptococcal infection; yet they invade the heart with ever-increasing damage, as a river in mounting flood erodes its banks. In practice one frequently finds that a prolonged course of prophylaxis breaks down because the parents forget to give the drug regularly. A less common difficulty is that the patient shows toxic reactions. Fortunately, there is at present little evidence that beta-haemolytic streptococci become resistant to penicillin.

Another important aspect of the prevention of rheumatic infection must be mentioned under the comprehensive heading of "home circumstances"; for there is little doubt that social status, poverty, housing conditions, overcrowding, and the prevalence of respiratory infections play a part in determining the incidence of rheumatic infection.

Care of Cardiac Cripples

To make adequate provision for the care of cardiac cripples—whether due to congenital cardiovascular deformity or to rheumatic infection—we must consider the needs of each individual patient from a number of angles. This is, of course, true for all types of handicap. A civilized community takes care of its weaker members; it considers their happiness, their medical attention, their education, their training for a suitable occupation, their future economic position, and their spiritual needs. It gives thought to the human and financial strains that may develop in a household that includes a handicapped child, and to the wider social and economic implications of crippling. It makes plans to prevent, in every way possible, the cause or causes of the disability. It should, moreover, keep very much in mind the duty of each individual, whether healthy or handicapped, to make some contribution to the welfare of society. Perhaps the most important, and certainly the most difficult, task of a community in accepting these obligations is to administer its benefits and services in such a way that they do not undermine the sense of responsibility of each family group to face its particular problems bravely and intelligently.

It needs little imagination to realize that a child crippled by cardiac disease or deformity is an individual to whom the handicap is little short of a tragedy, for it interferes with the activity of a full normal life. Depressing psychological reactions are almost inevitable, but they may be modified by understanding and appropriate management. This point was well brought out by Dr. Morris Fishbein (1955) in the following words:

"The poet John Donne wrote that no man is an island. Never was this more apt than when applied to the person who is suffering with a crippling disease. For him isolation is disastrous. If intelligent and left too much alone, he becomes embittered, sullen and perhaps an enemy of society. If unintelligent, he deteriorates slowly and steadily into a parasitic, vegetable-like existence, which may eventually sap the lives of all about him. The modern approach to the problem emphasizes adjustment of the handicapped person to the family, the community, and even the nation. All these forces are brought to bear from the social, economic and psychological points of view, so that such a person is able to live an existence as nearly normal as possible. He contributes to rather than lives upon the society that encompasses him."

The adjustment to which Dr. Fishbein refers should be, in fact, mutual, at all events in respect of the handicapped child and his family, and the doctor should seek every opportunity of explaining to the child's parents the nature and extent of the patient's crippling, so that they may be the better able to accommodate themselves to the situation. This medical opinion should be based mainly upon the child's functional incapacity; we have all known patients who have been condemned to live a life of invalidism when, in fact, they were well capable of enjoying a more active life. Complete rest is essential during recurrences of rheumatic carditis; but subsequently it should be remembered that in childhood the heart, like most other organs, possesses a remarkable capacity for recovery, and that with graduated exercises and physiotherapy there are many cardiac patients who can be gradually promoted towards a more normal life. In short, the doctor should maintain an optimistic outlook, using as yardsticks of the patient's condition such tests as heart rate, liability to dyspnoea and fatigue, diminution of oedema and venous congestion, and the child's appetite and feeling of well-being.

Institutional or Home Care

The pros and cons of institutional as against home care need careful thought in each case separately. Institutions for cardiac cripples have proved their usefulness, particularly for children whose home conditions are unfavourable. In addition to the medical and nursing care that the children receive in them, education can be provided without difficulty, physiotherapy and occupational therapy can be made available to them, and group interests, like games, concerts, television, etc., can be satisfied more easily than when the patient is in bed at home. A library service is another much-appreciated recreation.

On the other hand, institutional life has its disadvantages, especially for those children who seem predisposed to develop the invalid outlook; and is it not true that for most children "there's no place like home"? The family doctor who is well acquainted with the home situation is in the best possible position for giving advice to the parents, and he is able to call upon the ancillary services provided by the local authority, such as home nursing, home helps, health visitors, and so forth. In particular, he knows the child and the parents as individuals, and he can ensure that the various services available to the child are suitably balanced. The need for overall and continuing supervision of the handicapped child by one doctor—the captain of the team—is properly receiving emphasis in these days when so many different services, often specialized, are available. It is a need which certainly holds good for the cardiac cripple.

SADISM AND POWER

A PHYSICIAN ON DE SADE

"Unlimited power is apt to corrupt the minds of those who possess it," the first Earl of Chatham told the House of Lords in 1770. The same moral was drawn by Dr. A. H. Douthwaite, senior physician to Guy's Hospital, when he spoke on sadism at a meeting of the London Jewish Hospital Medical Society on January 31. Dr. Douthwaite used to illustrate his theme the lives of the Marquis de Sade, the eponym of our words sadism and sadistic, and of Gilles de Rais, de Sade's evil inspiration. Both men, he said, had possessed great power, largely by virtue of their wealth.

Basis of de Sade's Reputation

Sadism and sadistic were words used freely by both the profession and laity, said Dr. Douthwaite, yet many of those who did so knew little of the man from whom they were derived. The Marquis de Sade (1740–1814), the son of aristocratic parents, had shown himself a brave soldier as a young man, attaining the rank of lieutenant-general at the close of the Seven Years War; and his sexual appetites at first had been normal. But at the age of 23, threatened with imprisonment if he disobeyed, he was forced by his father into a distasteful marriage with the elder daughter of the de Montreuil family. The tragedy was sharpened by the fact that the woman de Sade wanted to marry was his wife's beautiful sister, Louise, whom later he was to seduce, carry off to Italy, and debauch there. It was his wife's large dowry that made possible the excesses of his subsequent life. These landed him often in prison, and although on occasions de Sade indulged in abnormal sexual practices the latter were not so gross or frequent as to justify the universal execration in which his name was now held. It was his books.

Living in the Bastille in great comfort, thanks to the lavish table provided for him by his mother-in-law, de Sade in 1784 wrote his most notorious work, *Cent-vingt Journées de Sodom*, whose three volumes he completed in 37 days. It was kept in the hands of his family until its publication in 1904. The book told of a group of aristocrats who used their extreme power and wealth to abduct men, women, girls, and boys to a castle where was practised every conceivable sexual abnormality amid bouts of extreme cruelty. It was a most boring and repetitious exercise in pornography. Other books followed, of which *Justine* was the best known. It was on his pen, much more than on his deeds, that de Sade's posthumous reputation rested. Of his 74 years of life, the first 28 had been unexceptionable for a rich young man of his times. The last 36 years were spent largely in prison, and of the ten years when he was free to practise the cruelties attributed to him—many of them exaggerated—de Sade was in exile for at least four.

Influence of Gilles de Rais

What influence, then, had led de Sade to imagine atrocities he could never have practised? The answer, said Dr. Douthwaite, lay in his reading. De Sade had enjoyed Suetonius's lives of the Roman emperors and revelled in the cruelties of those days. But above all he had been fascinated by the shocking cruelty and unbridled sexual abnormalities of Gilles de Rais.

Gilles de Rais, Marshal of France, born more than three centuries earlier than de Sade in 1404, was like him in his wealth, his aristocratic origin, and his personal bravery. Like de Sade also he had studied the lives of the Roman emperors. But de Rais was a sadist in the fullest sense of that term.

As a young man Gilles de Rais had earned a good name for his behaviour at court, and when in 1429 Joan of Arc had appeared there he supported her cause. He went further still. He was her squire at Orleans, where, although wounded,

he saved Joan from capture. For this, at 25, he was accorded the unparalleled military honour for his age of being made Marshal of France. When later, in consequence of the king's half-hearted support, Joan of Arc was finally taken, Gilles de Rais set forth again and laid siege to Rouen. Indeed, Joan's martyrdom was probably the turning-point of his life. Leaving the army and court in disgust, Gilles de Rais and a boon companion embarked on a career of seduction and cruel murder of boys. The children were taken to his castle in Normandy, where they were killed slowly by slitting their abdomens or by strangulation during sexual orgies; others were sacrificed for the purposes of black magic. More than 200 such murders were committed before Gilles de Rais was arrested and hanged in 1440. Gilles de Rais, it was said, was the original of the Normandy legend of Bluebeard.

Sadism To-day

If it were thought, said Dr. Douthwaite in conclusion, that such horrors could not occur in our time, it might be well to ponder what had already taken place in this century. States or dictators had emulated and surpassed Gilles de Rais—and certainly de Sade—in mass murders and torture. One could only pray that our country would never fall into the control of the human fiends who clearly lurked in all societies in every century.

Correspondence

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

The Black Sheep

SIR,—Your leading article on this subject (*Journal*, January 26, p. 217) is timely, on the eve of the month when we expect the peak incidence of Sonne dysentery. During the past three weeks 60 specimens of faeces have been delivered by my patients to our public health laboratory: 11 specimens have been reported positive for *Shigella sonnei*, 37 specimens were negative from convalescents or contacts of Sonne dysentery, and another 12 negative specimens were from single cases of diarrhoea of a more dramatic type than that associated with Sonne infection. In no case was a patient seriously ill or even confined to bed. Out of seven families (one or more of whose members submitted infected faeces for examination during the past three weeks), four families have good standards of hygiene. One family has no conception of the need for hygiene, and lives in filth. One family is numerous, poorly disciplined, but usually washed. The other family has been dealing with relapses since November (in my opinion through special difficulties beyond their control), but is now finally clear. It is noticeable that quite moderate standards of hygiene suffice to prevent cross-infection, under mother's supervision, but school teachers cannot be expected to enforce successfully proper standards in a crowd if children with diarrhoea are allowed to mix with healthy children in school premises.

Comment on three weeks' results from a single practice can be at best one scene from a moving battle, but it raises the question of whether Sonne dysentery deserves to be dignified by the ritual of notification. It is usually one of the mildest of diarrhoeas, and its very mildness produces the frequent comment from my patients that they know scores of people who continue to send their children to school with diarrhoea. Diarrhoea of any sort should (in a civilized community) be regarded as the result of a breakdown of hygiene and the evacuation of the poison which has been ingested. The sufferer should be isolated, and hand-washing ritual (including soap) be rigorously enforced. I maintain that persistent repetition of this simple theme, through every possible

medium of publicity, will do far more to eliminate Sonne dysentery in 1957 than all the painstaking (and heart-breaking) work of laboratories and inspectors in 1956. May I suggest that Sonne has its peak incidence in February just because hand-washing is least welcome in cold weather?—I am, etc.,

Nottingham.

MAURICE HARGREAVES.

Mitral Valve Mobility

SIR,—I was delighted to see that the view expressed by Professor D. M. Douglas (*Journal*, January 26, p. 191) on the signs of mobility of the mitral valve coincided so closely with mine.¹ The "closing" and "opening" snaps are signs of mobility of a diaphragmatic valve, not of stenosis; it so happens that the pathological processes which cause loss of mobility—i.e., heavy scarring or calcification—also lead to regurgitation, as there is no redundant tissue to overlap the rigid valvular orifice during ventricular systole. It is for this reason only that the loud first sound and the "opening snap" have been regarded as signs of pure stenosis. Valve mobility and dominant incompetence may in fact occur together.

I agree with his statement that mitral incompetence may be due to disproportionate shortening of the chordae tendineae in some cases, such as his first and third patients. These clearly had an element of stenosis and were examples of dominant mitral incompetence with diaphragmatic valves: the valve orifice in both was 2 cm. across only. The second case he described was a straightforward example of dominant stenosis with unimportant incompetence also in a diaphragmatic valve. None of the three cases correspond to the group of "hypermobile" valves described. These patients have no stenosis whatsoever; the orifice is at least 4 cm. long. They constitute a different pathological entity, due, I still think, to a rupture of a chorda. I referred to nine cases similar to Professor Douglas's cases 1 and 3. In these I advocated completion of the separation of the cusps despite the presence of dominant mitral incompetence. It is not clear whether or not this was done in his patients. I also referred to 17 valves similar to the one he met in case 2. As in his case, the results proved fairly good because the stenosis was the main cause of the disability.—I am, etc.,

London, E.2.

Carbon Monoxide Poisoning

SIR,—The Registrar-General's *Statistical Review of England and Wales for the Year 1955*, just published, shows that in the three years 1953–5 9,143 persons died of carbon monoxide poisoning—2,168 accidents and 6,975 suicides. This total is 2,000 more than might have been expected from the figures prevailing in the previous five years. A year ago (*Journal*, February 11, 1956, p. 347) I suggested that increased deaths might possibly have been due to withdrawal from ambulance and other first-aid services of 7% CO₂ and 93% oxygen on the advice of a committee of the Medical Research Council. The chance of survival of badly poisoned patients depends mainly on the effectiveness of first-aid treatment.

The Medical Research Council asked its statistical research director, Professor A. Bradford Hill, to make an inquiry. His report (*Journal*, November 24, 1956 p. 1220) concludes that change in resuscitation procedures was not the cause of the large rise in deaths and that this was associated with a concurrent rise in the number of cases occurring as measured by ambulance emergency calls. This conclusion is of great importance because on it may depend official policy in regard to the emergency treatment of a condition which causes nine deaths a day. If it happens to be mistaken then needless loss of life may continue. I submit, with respect, that the evidence upon which it is based is inadequate, and therefore the conclusion may be incorrect.

The evidence for increase in total cases is presented in three tables. Table II shows London ambulance calls for coal-gas suicidal cases, and the main inference from it reads that "the number of cases carried has, in fact, increased very substantially—from, roughly, a little over 100 in 1951 to 202 in 1952, to well over 200 in 1953 to 1955." This inference means that from 1953 onwards coal-gas suicidal attempts in London suddenly doubled. Can this really have happened? The answer lies in a fallacy, mentioned in the report, concerning change of labelling of cases as "accident" or "suicide." Up till 1952 in London a call was entered as "accident" unless definitely known to be suicide; after 1952 this charitable convention was discontinued and a case was entered as "suicide" unless it was definitely known to be an accident. Because of this source of error a special search of ambulance records was made for the years 1951 and 1953 and all coal-gas cases extracted irrespective of labels. This showed a rise in total coal-gas emergency calls of 36% as between these two years. This figure is more credible, but it is a statistical comparison limited only to two selected years. In spite of the admitted labelling flaw, with its probable very large error, table II was still put forward as evidence and the above-quoted inference made that cases increased by 100%.

Tables III and IV show figures from eight provincial towns in which cases increased by 30%. The combined total populations of the eight towns is slightly less than total populations of the eight towns in England and Wales. What 4% of the population of England and Wales. What guarantee is there that other towns, from the remaining 96%, might not show different figures? Yet these scanty data, plus fallacious table II, are made the basis for a dogmatic conclusion that cases throughout the country suddenly greatly increased from 1953 onwards.

Whatever else emerges, it is clear that change of first-aid treatment was not followed by any fall in deaths as might have been expected if the theoretical argument in the committee's report had been correct. If there has been no decrease in mortality and, instead, a very big rise in deaths, then why persist with reversion to treatment discarded over a quarter of a century ago? Why not at least try CO₂/O₂ once more (for carbon monoxide poisoning only) and see if deaths fall? Over a year ago (*Journal*, October 15, 1955, p. 966) the chairman of the committee said experimental work was planned. It would seem time that the mental work should be apparent. If it is not unequivocally in favour of pure oxygen then it is surely indefensible to continue to deny CO₂/O₂ to first-aid services.

It now becomes evident that the advice of the committee was circulated to local authorities about four years before publication in the medical press. This may have been done in response to requests for guidance, but such practice may be dangerous—particularly when unproved advice, contrary to accepted opinion, is put out under the prestige label of the Medical Research Council. Administrative officials, medical or lay, can hardly fail to act on it. Publication in medical journals is less mandatory because officials do not receive it in the guise of circulated instruction from higher authority. And publication has the vital safeguard of public criticism which can be made in time if there is chance of error. It is disquieting that a small committee can scrap a standard method of treatment, for a common and urgent condition, without the medical profession as a whole being informed till years afterwards.

The most serious consequence of private direction, long prior to publication, is that the Medical Research Council may be put in an awkward position if there is subsequent question that the advice given may have been wrong, and caused loss of life. The council is then on the defensive, and in consequence its ability to weigh the matter dispassionately becomes open to doubt. Because that is the present situation, I submit, Sir, that there are grounds for Ministerial or Parliamentary inquiry concerning the desirability of transfer of official advisory responsibility regarding carbon monoxide poisoning to some other body.—I am, etc.,

H. L. MARRIOTT.

London, W.1.

Vaccination Against Whooping-cough

SIR,—In a reprint of the report to the Medical Research Council on vaccination against whooping-cough (*Journal*, August 25, 1956, p. 454) I read the following opinion: "Thus the use of chloramphenicol for the siblings of vaccinated children did not reduce the risks of the vaccinated children developing the disease." At the Clinic for Infectious Diseases in Childhood, Warsaw, we think this conclusion is in some respects not quite correct, as it does not take into consideration the time at which chloramphenicol is given. It is possible that if given too late it will not be effective in preventing the disease.

I would like to report our results with chloramphenicol administered for a longer period to protect children exposed to the risk of developing whooping-cough. We started our trials on the supposition that, although vaccination is the main prophylactic measure against pertussis, it has its deficiencies. First, the degree of immunity acquired from vaccination is uncertain, and, secondly, vaccination of newborn infants, so far as I can gather from the literature accessible to me, has not as yet given any clear results. Yet up to the age of 6 months the mortality from pertussis is high.

With this in mind we carried out trials in the home, where there were infants in contact with older children who had contracted the disease, and in nursery schools for babies up to 3 years. There were 271 children in four schools. At the time of the trial there were 37 cases of pertussis (tested bacteriologically, clinically, and by blood examination). As soon as they were diagnosed the sick children were sent home or to hospital, but in spite of this further cases developed. We therefore started the administration of chloramphenicol prophylactically. Some of the children had been vaccinated, and we had also had cases of pertussis among vaccinated children earlier on.

Chloramphenicol was given in doses of 50 mg./kg. body weight every 24 hours for 7 to 10 days under blood examination control and urinalyses. Chloramphenicol was given four times a day—three times in the nursery school and once at home. Bacteriological examinations were carried out after the treatment was finished. The pertussis bacillus was not once found in those children. After this prophylactic treatment was started not one child developed whooping-cough, and after three weeks new children were admitted to the schools without any further cases developing. In 20 home exposure cases chloramphenicol failed to prevent the onset of the disease only in one case. Therefore it seems that the administration of chloramphenicol for 7 to 10 days has a strong sterilizing action on the whooping-cough bacilli, and that it is worth while trying this method against the infection, especially in infancy. We have no experience in prophylaxis with hyperimmune serum or gamma-globulin. This method is very troublesome, and there are difficulties in obtaining these substances in quantities sufficient for large-scale trials.—I am, etc.,

Warsaw.

J. BOGDANOWICZ.

Rh-Hr Nomenclature

SIR,—The purpose of this letter is to call the attention of your readers to the tentative supplementary report of the committee on Medico-Legal Problems of the American Medical Association on the Medico-Legal Application of Blood Grouping Tests.¹ The most important item in this report is the recommendation of a single uniform system of Rh-Hr nomenclature for medico-legal reports. "It is recommended that unless and until some other convention can be agreed upon the original Rh-Hr notations must be retained as the standard and sole nomenclature for the preparation of approved medico-legal reports on Rh types." In response to an editorial request for criticisms and suggestions, close on 50 letters were received from workers in the field. Approximately half the correspondents heartily approved the recommendation, whereas the remainder vigorously attacked it. The adverse criticisms have been

abstracted and will be published in the form of a supplement to the report, together with footnotes explaining to the readers the fallacies and paradoxes of the arguments of the C-D-E protagonists. The body of the report has also been revised, but no valid argument has been received why the recommendation regarding nomenclature should be changed. Therefore it is anticipated that the revised report will be approved for publication at the committee meeting to be held at the end of February, so that the final report should appear in April or May. Study of the correspondence received has merely served to fortify the committee in its conclusion that the C-D-E notations must be discarded.

The dilemma of workers who still use the C-D-E notations could have been avoided through familiarity with the history of the blood groups, since the same problems arose in connexion with the A-B-O groups. As can be seen in my book on *Blood Groups and Transfusion*,² in addition to the theory of multiple alleles the possibility of heredity by independent pairs of genes or by linked genes was considered. In the absence of crossing over, the hypothesis of completely linked genes was also considered, although 30 years ago the impressive term pseudoallelism had not yet been introduced. Now the theories concerning Rh-Hr heredity have gone through the same process of evolution—namely, multiple alleles, linkage with crossing over, and then completely linked genes. Since a set of completely linked genes is really a unit, this represents a complete circle with a return back to the theory of multiple alleles. Also, the controversy regarding nomenclature is reminiscent of the Moss-Jansky terminologies for the A-B-O groups, except that the latter preferred numbers instead of letters for their notations. The use of the so-called shorthand notations again represents a complete circle, since these notations are nothing but a slightly altered version of the original Rh-Hr nomenclature.

In conclusion, one cannot help but note the parallelism between the following two quotations: "What genotypes correspond to the phenotype large C plus, large D minus, large E plus, small c minus, and small e plus?" asked the professor. (This professor must have just run out of little d antiserum.) "I don't know," said the student; "I lost track. Could you give me the phenotype name in shorthand symbols?" "You fail. You don't know your rhesus blood types," said the professor.—*Somewhere in England*. "What is one and one and one and one and one and one and one and one and one and one?" "I don't know," said Alice, "I lost count." "She can't do addition," said the Red Queen.—*Lewis Carroll*.—I am, etc.,

New York.

Reactions to Acetarsol Vaginal Pessaries

SIR.—Considering the vast number of patients who have been treated with acetarsol vaginal pessaries during the last twenty years, reported systemic reactions have been few, and Dr. A. White's memorandum (*Journal*, December 29, 1956, p. 1528) prompts this further report of a case.

A healthy primipara, aged 27, developed a trichomonas vaginitis at the 12th week of her second pregnancy. One acetarsol 4 gr. (220 mg.) vaginal pessary was inserted nightly for twelve nights with improvement at first, followed by an increase in the discharge, swelling of the labia, and erythema and folliculitis in the skin of the medial surface of the upper thighs. Misdiagnosis at this stage resulted in the application of ten acetarsol 4 gr. (220 mg.) pessaries in the vaginal fornices.

The patient spent a restless night and was ill the next day, with malaise, photophobia, and generalized pruritus; her temperature was 103° F. (39.4° C.), pulse rate 120 beats to the minute, and there was a generalized maculo-papular rash, confluent in places, with bullae on the skin of the upper medial aspects of the thighs, and vesicles on the swollen, cyanosed lips and buccal skin. The vagina was emptied and cleaned, pulmonary tuberculosis was excluded, and the

fasting blood sugar found to be 116 mg. per 100 ml. One 5 mg. prednisolone tablet was given 4-hourly for five days, 6-hourly for three days, 12-hourly for three days, and she made an uneventful recovery. There was no history of previous treatment with arsenical compounds and no history of allergy either in the patient or her family.—I am, etc.,

Great Baddow, Essex.

ANTHONY PEARSON.

Lesions of the Feet in Diabetes

SIR.—May I refer those who are interested in the aetiology of lesions of the feet in diabetes to the recent work of Dr. A. L. Woolf? In a paper read to the Pathological Society of Great Britain in January, 1956, Dr. Woolf has described changes in the intramuscular nerve endings in diabetic neuropathy, and his technique based on a biopsy study should enable a definite decision to be made on the presence of diabetic neuropathy. Dr. Wilfrid Oakley and his colleagues (*Journal*, October 27, 1956, p. 953) might be able to settle the point in question by making use of Dr. Woolf's method.—I am, etc.,

Southampton.

R. A. GOODBODY.

Glycyrrhetic Acid

SIR.—Dr. E. Colin-Jones mentions our work¹ in his letter (*Journal*, January 19, p. 161) in support of his contention that glycyrrhetic acid has therapeutic value in skin diseases. The National Research Development Corporation, acting on behalf of our employers—the Medical Research Council—took out a patent on a preparation of ours which contained a highly active substance which depressed sensitivity to tuberculin in B.C.G.-infected guinea-pigs. This substance was not glycyrrhetic acid, which we found to have no measurable desensitizing effect.—I am, etc.,

London, N.W.7.

REFERENCE

- 1 British Patent 713, August 18, 1954, 651.

SIR.—I have hesitated for some months from adding to the dreary correspondence on the efficacy of glycyrrhetic acid. Some say it cures eczema, some say it does not. Drug firms send sheets of "literature" and stacks of samples. To me it has always had a pseudo-scientific ring about it. To be sure, it is fairly cheap in comparison with hydrocortisone, but, as ointments containing it do not, in my experience, do the least good, it really seems a waste of money. I am sure Dr. E. Colin-Jones (*Journal*, January 19, p. 161) is absolutely right about glycyrrhetic acid being frightfully complex chemically, but that doesn't make it any more useful clinically—and how does one tell an "active" isomer from an inactive one, anyway? I presume because of the "biosone G.A." side chain.

It is a great misfortune that dermatologists to-day have to rely more and more on ready-made proprietary preparations when taking advantage of the tremendous advances in therapeutics which have occurred during the last few years. Under such conditions it behoves us to be particularly cautious in extolling the virtues, or even mentioning the trade name, of any particular product, let alone repeating its commercial claims, while many of one's experienced colleagues are patently unconvinced.—I am, etc.,

Plymouth.

R. D. SWEET.

Translumbar Aortography

SIR.—Dr. David Sutton (*Journal*, January 26, p. 225) has expressed his opinion that Mr. H. Gaylis and Dr. J. W. Laws (*Journal*, November 17, 1956, p. 1141) advocate the use of a quantity of contrast medium (30–40 ml. of 70% diodone) for translumbar aortography which he would now regard as excessive. Dr. Sutton states that he never uses more than 25 ml. of 70% sodium acetizolate or 70% diodone. He then states: "Mr. Gaylis and Dr. Laws suggest that other previously reported complications of aortography have been

due to dissection. . . This suggestion cannot be refuted, but I think toxicity of the medium when given in excessive doses is the major factor in such accidents." With this we are in agreement. For that very reason, in the Bristol Royal Infirmary we have reduced the concentration of diodone from 70% to 50% (25–30 ml.) for the last 18 months. Though we do not get radiographs of such high contrast as we did with 70% diodone, they are of quite adequate contrast for diagnostic purposes. Assuming the same rate of injection, we are personally of the opinion that a contrast medium of high concentration should never be injected into the vascular system anywhere, if one of lower concentration will give diagnostic radiographs. This is quite definitely the case with translumbar aortography, especially in patients with obliterative arterial disease. When one or both femoral pulses are absent, it is imperative that diodone of not more than 50% concentration be used, because thrombosis of a narrowed iliac artery may take place when the opposite artery is already blocked. In addition, when the iliac arteries cannot drain off the contrast medium a massive dose may perfuse the kidneys or large intestine. In short, we would enter a plea that 50% diodone in similar quantities is quite adequate for translumbar aortography and that it is unnecessary to use 70% diodone to obtain radiographs of diagnostic quality in most cases. We are sure that the use of the lesser concentration would materially reduce the risk of complications.

Having regard to the potential dangers, it is doubtful if aortography should be employed except in disease of the aorta or great intra-abdominal arteries of such a nature that direct surgery is contemplated and will be made easier by the addition of radiographic delineation of the disease.—We are, etc.,

R. E. HORTON.

Bristol.

Tonsils and Adenoids

SIR.—Dr. John Fry's excellent article (*Journal*, January 19, p. 124) led me to look into my bottom drawer and to extract the following notes.

In 1949 I joined a conference on tonsils and adenoids as the sole paediatrician. My otorhinolaryngological colleagues were all top-level consultants surveying the problem from within their own beautifully run departments. The great mass of these operations is in fact performed away from university centres. I collected information about the reasons for which 1,034 sets of tonsils and adenoids had been removed in a small London children's hospital and a paediatric unit in the Home Counties between September, 1946, and September, 1949. The peak ages for operation were 4, 5, and 6 years (664 cases). The indications taken from the case records were grouped under six headings. There were none on account of size and appearance only.

	Cases	Per cent.
(1) (Fry 2 and 5) Recurrent tonsillitis and for cervical adenitis, sore throats, and colds	592	57.3
(2) (Fry 3) Nasal symptoms including sinus disease	123	11.8
(3) (Fry 4) Aural disease	79	7.6
(4) (Fry 6) General medical diseases—e.g., rheumatic fever, asthma, acute nephritis	45	4.3
(5) (Fry 3) Ill-defined reasons—e.g., underweight, general ill-health	52	5.0
(6) No reason ascertainable from the records	143	13.8
	99.8	

Group (1) accounts for the largest number, but the size of the unknowns in group (6) is disconcerting. The aural cases (3) provide a surprisingly small number. In the smaller hospital only 9% of cases had been followed up, and of these there was definite improvement in only 68%. Whatever may have happened, the only information available to the surgeon was that six out of every hundred had improved and three had not. About the remaining 91 there was no comment. This group included two sisters, one was operated upon for no clear reason, and her sister "be-

cause it would be nice to get them done together." In the children's hospital all cases were seen one month after operation, but very few subsequently.

In the hope of comparing the list of reasons for operation with that in the hospital group, we scrutinized a school waiting-list in a borough near London. Such lists contain many cases which never get treated, and therefore we expected, and found, a larger proportion of indefinite cases. The proportion was so high as to make worthless any comparison with the hospital operation series.

The records of 15,000 school and infant welfare clinic children out of a total of 16,000 covered by the service were examined. No account was taken of cases referred directly from the family doctor to a hospital outside the area. The waiting-list contained 795 names, including 84 cases for adenoidectomy only. There were still (1949) 110 cases put on the list in 1947, 327 put on in 1948, and 328 in 1949. The largest number was put on at 5 years, probably as the result of the first school examination (259 or 33.8%). In over 14% the reason stated was large tonsils, deep-set tonsils, unhealthy-looking tonsils, or blocked crypts, and these appearances were not correlated with a clinical history. Little care was taken to get such a history. The cases were all referred by the school doctor to an otorhinolaryngologist; he seldom turned down a case. For what they are worth the reasons for placing on the "T and A" list are set out:

	Cases	Per cent.
(1) Recurrent tonsillitis and/or cervical adenitis, sore throats, and colds	105	13.7
(2) Nasal disease including sinus disease	67	8.7
(3) Aural disease	17	2.2
(4) General medical disease	2	0.2
(5) Ill-defined reasons	23	3.0
(6) No reason given or no indication on case sheet	442	57.8
(7) Enlarged tonsils without symptoms	109	14.2

There seemed to be a real indication properly recorded in only 25% of cases.

There was a further "observation list" for children who were re-examined every six months and then transferred to the operation list or to "normal." This list numbered 446. Half of these were put on the list at the age of 5 years, and 206 for "enlarged tonsils without symptoms."

Dr. Fry comments, as we did in 1949, that too much regard is still paid to the appearance of the tonsil and too little to the history. The throat specialist did not always take a critical enough view of the case presented, possibly because in clinics he saw too many cases at a sitting. The parents were not always consulted about the history. There was scanty follow-up information to record the effect of the operation, a gap that Dr. Fry still finds. No treatment was carried out while the child's name remained on the waiting-list to try to improve conditions or prevent operation. We noted, like Dr. Fry, that no reassessment of the waiting-list case was attempted even after two or three years. We felt that too many parents and doctors look on tonsillectomy as an inevitable step in the child's life and take too light a view of the whole business. Dr. Fry points to extraordinary differences in the frequency of operation in different areas. It still seems necessary to stress that each child and not only the "T's and A's" should be most fully and carefully studied before operation is advised (or, indeed, refused) and reassessed during the waiting period. This is another way of saying that knowledge of the best laryngological practice still needs to be disseminated through the whole profession. I am greatly indebted to my friend and colleague Dr. Jill White (formerly Clarke), who carried out the real work of the inquiry.—I am, etc.,

London, W.1.

ALFRED WHITE FRANKLIN.

SIR.—Dr. John Fry, in his courageous and unsparing article on the removal of tonsils and adenoids (*Journal*, January 19, p. 124), makes no mention of the microscopic investigation of these structures. My experience in the last five years, which perhaps is shared by other pathologists, is

that, unless some condition such as tubercle or neoplasm is suspected, no histological report is demanded. During a spell of twelve years abroad, in Army practice and with a large commercial concern operating in the Middle East, it seemed to be the rule to send tonsils and adenoids to the laboratory. Records of these are no longer accessible, but my recollection is that one or two cases of caseous tubercle and one of a malignant neoplasm occurred in several hundred examinations. The rest showed either no sepsis or a thin film of pus in the tonsillar clefts. Certainly in the great bulk of cases little could be found to justify operation. It may be that there are hospitals here with a large "T and A" trade where histological investigations are routine practice. If so, perhaps the pathologists will come forward boldly to Dr. Fry's support, though their relations with their surgical colleagues may suffer as a result.—I am, etc.,

Keighley.

IAN STEWART.

Drug Sensitivity Presenting as Penile Herpes

SIR,—The case of drug sensitivity presenting as penile herpes reported by Dr. John E. Underwood (*Journal*, January 19, p. 162) is most interesting. However, I should doubt if the case is really one of true herpes simplex virus infection induced by the drug. It is most likely to be a "fixed" drug erythema due to phenolphthalein sensitivity. A case of this type on the penis (with mucosal involvement suggesting urethritis) was reported by Haber.¹ Since that time Dr. Haber's experience has enabled me to diagnose fixed drug eruptions on the penis on several occasions. While phenolphthalein is the commonest drug which induces it, the reaction may also result from sensitivity to suphonamides, barbiturates, and other drugs, and can be proved by a test dose.—I am, etc.,

London, W.C.2.

REFERENCE

¹ Haber, H., *Brit. J. Derm.*, 1950, 62, 22.

SIR,—With reference to the letter by Dr. J. E. Underwood (*Journal*, January 19, p. 162), entitled "Drug Sensitivity Presenting as Penile Herpes," may I suggest that this is an extremely mild case of erythema multiforme exudativum (Stevens-Johnson syndrome)? I am at present preparing a case record of this condition for publication, and would point out that penile vesicles are common and that phenolphthalein has been incriminated as one of many possible causative allergens.—I am, etc.,

Paisley.

J. H. MITCHELL.

Preservation of Parasite Ova

SIR,—In response to Dr. Shafi Muhammad Shaikh's letter (*Journal*, December 29, 1956, p. 1545), we keep ova at the Royal Army Medical College in 10% formol saline for teaching purposes. Some have been here up to thirty years and still show structures clearly enough to demonstrate.—I am, etc.,

London, S.W.1.

LENOX MACFARLANE.

Treatment of Acute Appendicitis

SIR,—Interesting though Mr. E. Coldrey's article may be (*Journal*, December 22, 1956 p. 1458), I think it contains some dangerous advice, and I am surprised that no one has raised yet any of the following points. In the first place, in view of the possibility of blood dyscrasia resulting from the administration of chloramphenicol, the use of this drug for the treatment of acute appendicitis when so many others are available would seem to be quite inexcusable. Secondly, the prescribing of a broad-spectrum bacteriostatic agent with a bactericidal antibiotic is surely a policy that few pharmacologists would recommend.

Although conservative treatment in early cases may be preferable in special circumstances, I can see no advantage in carrying this out in surgical units when early operation means a quick discharge from hospital, benefiting both the

patient and the National Health Service, and a relief from tension and anxiety for the patient, surgeon, and nursing staff. Conservatism usually means hospitalization twice or three times that of the operated case, with still the prospect of a future admission. Few surgeons would disagree with the expectant treatment of the late case, but even here the position may be fraught with danger, as the correct diagnosis can elude the most perceptive and intuitive person. I have seen several cases of carcinoma of the caecum presenting as typical late cases of acute appendicitis with mass formation. On conservative treatment the pyrexia, tachycardia, and leucocytosis returned to normal, with corresponding clinical improvement apart from the fact that the mass, although decreasing in size, did not completely subside. Laparotomy revealed the true nature of the disease. Earlier surgery might have been more beneficial to the patient. Also, recently, at an interval appendicectomy I found a chronic pelvic abscess. This had been symptomless and was not palpable abdominally or per rectum (admittedly the patient was obese), although originally a mass had been clearly felt and appeared to resolve completely under the influence of antibiotics. Finally, it is a brave man who will treat all cases of peritonitis, especially in children, without operation. I know that if I were suffering from such a condition I would demand immediate laparotomy.—I am, etc.,

London, S.E.10.

R. F. BOLAM.

Congenital Absence of Spleen

SIR,—The case reported by Dr. D. E. M. Plowman (*Journal*, January 19, p. 147) prompts me to record a further case upon which I performed the necropsy examination.

A full-term male was born to the British wife of a serving soldier in Germany. The pregnancy and delivery were normal apart from a rapid second stage of labour. The birth weight was 6 lb. 14 oz. (3 kg.). The child was soon found to be cyanosed and respiring poorly. A clinical diagnosis of intracranial haemorrhage was made, and, following a steady downhill course, the child died on the ninth day. Unfortunately no examination of the blood was performed. At necropsy, apart from being deeply cyanosed, the child appeared externally normal. Internally both the chest and abdomen showed gross congenital abnormalities. Both lungs were divided into three lobes. The heart consisted of two atria joined by a patent foramen ovale. These chambers drained into a single ventricle from which only one efferent trunk arose. This vessel ascended to arch over the right main bronchus and then descended as the thoracic aorta. From the ascending portion of the aorta two large trunks arose which supplied the lungs. The inferior vena cava and the right innominate vein entered the right atrium. The left innominate vein fused with the venous drainage of the lungs to enter the left atrium as a single vessel. In the abdomen no trace of the spleen could be found. The gut showed partial failure of rotation. The duodenum extended only as far as the right kidney. The rest of the mesentery then ran upwards to the upper pole of the left kidney where the caecum was found. From here large gut descended in the usual way. No other abnormality was found.

This was the second child, the first being healthy. Subsequently the mother has miscarried at three months.—I am, etc.,

Hano-ver.

N. A. G. LEADBEATER.

SIR,—In the valuable annotation (*Journal*, January 19, p. 153) on congenital absence of the spleen the following statement appears: "The origin of splenic agenesis and of all the commonly associated anomalies can be dated between the fifth and seventh week of foetal life." This indeed has been the commonly accepted view, repeatedly expressed in the rather large number of papers published in recent years on this condition.

Some months before his untimely death in July, 1956, the late Dr. Hugh Middleton and I wrote a paper entitled "Congenital Absence of the Spleen Associated with Malforma-

tions of the Heart and Transposition of the Viscera," which was subsequently published.¹ From study of the heart malformations in two cases we were able to date the onset of faulty morphogenesis at not later than the 24th–27th day of embryonic life (ovulation-age), an age corresponding to the 11th or 12th "developmental horizon of the embryo."² Such precise dating was possible from recognition of the fact that there had been failure of development of the septum which normally grows at this time between the left horn of the sinus venosus and the primitive atrium, and which leads eventually to the formation of the coronary sinus of the heart. Published accounts of the anatomy of the heart from similar cases mostly fail to comment on the presence or absence of a coronary sinus, but it seems not unlikely that many specimens of cor biloculare and cor triloculare would show absence of this structure.³

In the future study of the condition of spleen agenesis and associated anomalies, whether or not the aetiology will prove to be endogenous (genetic) or exogenous (resulting from a temporary disturbance in the environmental conditions in which the embryo is developing), we have suggested that particular attention be paid to the time of, or shortly after, the mother's "first missed menstrual period."—I am, etc.,

Supply of Bodies for Dissection

SIR,—Dr. G. C. Milner writes (*Journal*, January 12, p. 108) that you stated (*Journal*, December 8, 1956, p. 1357): "There is thus an urgent need for more people to leave their bodies." I understand that nobody can legally dispose of his body, and that only the executor can do this, or the next-of-kin. A will is usually opened after the burial of the testator, and it would seem that all one can do is to make known before death one's wishes to the next-of-kin. Dr. Milner also suggests that all general practitioners should hang in their waiting-rooms "forms, particulars, and suitable notices" (requesting his patients to leave their corpses to be dissected). Has any more fantastic suggestion ever been made? Imagine the reaction of any patient, presumably anxious about his health, who on entering his doctor's waiting-room finds that his doctor is already regarding him as a corpse. I feel sure that any doctor foolish enough to carry out this suggestion would very quickly find that he had no longer any patients.—I am, etc.,

Hampstead.

E. N. RUSSELL.

Natural Childbirth

SIR,—As a humble follower and practitioner of Dr. Grantly Dick Read's teaching on natural childbirth, I feel that Dr. Sita Sen's letter (*Journal*, December 29, 1956, p. 1545) cannot be left unchallenged. A little study of Dr. Read's writing would have avoided some misconception. First, Dr. Dick Read neither demands nor promises a labour completely devoid of pain; he does say that "over 90% of women can have their baby safely and without unbearable discomfort" (my italics) by the practice of natural childbirth.¹ Secondly, it is incorrect to call his of natural childbirth.¹ Secondly, it is incorrect to call his training programme elaborate. Certain routines, mis-called "natural childbirth," are indeed elaborate, but these often result from over-enthusiastic physiotherapy which is quite unnecessary and indeed may be harmful. Dr. Read's unnecessary and indeed may be harmful. Dr. Read's training programme consists of (1) education, (2) correct breathing, (3) relaxation, and finally (4) a few simple exercises—in this order of importance. Some six to ten 1–1½ hourly sessions during pregnancy cover the whole routine. Thirdly, the "unsophisticated girl" is frequently highly educated in the process of childbirth (by native midwives, etc.), whereas her sophisticated sister is quite uneducated and needs all the training that can be offered to her. Fourthly, to say that confidence in the

accoucheur is neglected is quite untrue. In general practice at least, the patient is under the care of the same personnel right through her pregnancy, labour, and puerperium. If such trained patients do have long arguments with the medical attendant, all I can say is that I have not found it so. At the classes they are encouraged to ask all the questions they wish, and incidentally none has yet asked which suture material is used for an episiotomy. Episiotomy is not part of natural childbirth and routine instruction about it is not given. Finally, it is certainly not possible at routine antenatal clinics to give satisfactory explanations. In my experience classes in natural childbirth are of incalculable value for expectant mothers, and I suggest that Dr. Sen both studies Dr. Read's writings and watches his programme put into practice before launching out into print against it.—I am, etc.,

Southampton.

Domiciliary Treatment of Pneumonia

SIR,—I was interested to read Dr. H. J. Cronhelm's letter (*Journal*, January 19, p. 157), and would agree that massive injections of crystalline penicillin would rapidly cure most cases. This therapy, however, is difficult to carry out in a large practice, and moreover certain organisms—that is, many staphylococci, *H. influenzae*, and viruses, the two former of which are likely to be found in cases of pneumonia complicating chronic pulmonary disease—are insensitive to penicillin, and valuable time may be wasted in employing this drug, possibly with fatal results. I should like to put in a plea for immediate and adequate tetracycline therapy for severe pneumonia, particularly if complicating chest disease—that is, chronic bronchitis—or evidence of myocardial failure is present. I prefer oxytetracycline fortified by vitamin B complex, and give 500 mg. every six hours until the temperature has been normal for 24 hours, when I give half the dosage for a further three to four days. If the case is uncomplicated or less severe I employ daily injections of benzylpenicillin diethylaminoethyl ester hydroiodide (0.5 to 1 mega unit) with oral sulphadimidine. In many cases, however, I have found oral penicillin plus oral sulphonamide very satisfactory.—I am, etc.,

Birmingham.

H. JOSEPHS.

Smoking and Lung Cancer

SIR,—The carcinogenic bodies present in tobacco smoke are, it is understood, liquids of high boiling point present in the droplets of the tar-fog. Tar-fogs consist of a suspension of droplets of widely differing size from extremely small, which will pass through most filters, to comparatively large droplets which tend to deposit on any solid surface with which they come into actual contact. To render the smoke relatively harmless it would appear to be necessary to remove only that portion of the tar-fog which will deposit tar on the lungs or throat.

It is likely that the passage of the smoke through a filter-tip consisting, for example, of a plug of tightly packed cotton-wool would remove the heavier droplets, and I suggest that the tar-fog which passes through such a filter would be unlikely to deposit much of its tar on the throat or lungs, which would probably present fewer contacts for the tar droplets than the cotton-wool filter. It is therefore probable that the passage of the smoke through a good filter-tip will remove the harmful constituents to a very much greater degree than is represented by the actual percentage of the tar-fog removed.

I should state that my qualifications for writing this letter are based on research experience in the removal of tar-fog from coal gas—a somewhat similar problem—and not on medical research work.—I am, etc.,

Stockport.

H. FRANKLAND TAYLOR.

Delayed Reaction to Primidone in Pregnancy

SIR.—Primidone ("mysoline") is an anti-convulsant drug which has been gaining wide popularity during recent years. Many workers have rightly emphasized its low toxicity compared with other available substances. The following case is described in order to indicate the possibility of delayed or chronic toxicity in certain circumstances.

A 29-year-old married woman was put on primidone in March, 1956, having previously had many years of phenobarbitone medication. The commencing dosage was 0.75 g. daily, gradually increasing over the next few months to a maximum of 1.25 g. daily. The patient had become pregnant at about the time treatment began. During the first six months there were no side-effects whatever. However, in the last three months of pregnancy the patient complained of increasing drowsiness, depression, slight oedema of hands, arms, and face, and pitting oedema of the legs. She appeared to be quite toxic, although there was never the slightest evidence of cardiac or renal insufficiency. There was occasional bleeding from the nose and marked hypertrophy of the gums during the last weeks of pregnancy. Following the birth of the child the symptoms described above did not abate. The patient felt increasingly lacking in any desire to undertake both mental and physical tasks. A generalized itchiness of the skin began three weeks after delivery, followed two days later by an intensely pruritic morbilliform rash. There were night sweats and transient sore throats. Antihistamine drugs had no effect. Within a few days persistent vomiting began, accompanied mentally by a frank toxic confusional state. At this time the blood picture was normal with the exception of a 10% eosinophilia. The white cell count was 5,700/c.mm. Primidone was totally withdrawn and phenobarbitone was substituted. Recovery was almost immediate, the pruritus, oedema, and rash disappearing within 48 hours. At the same time the mental state returned to normal, the patient regaining her usual energy and cheerfulness.

The above symptoms have all been described by Handley and Stewart,¹ Whitty,² Greenstein and Sapirstein,³ Goodman,⁴ and many others; but it seems that such symptoms have always been reported as appearing during the early weeks of treatment. This case suggests that a chronic reaction can also occur; and it may be of value to speculate whether pregnancy was either a direct cause, or by influencing excretion may have given rise to retention of primidone in sufficient quantity to produce a delayed type of toxicity. It is perhaps worth noting that Timberlake⁵ indicated the possibility of a cumulative reaction to primidone similar in nature to an initial side-effect reaction and "not a different type of reaction as implied by the term idiosyncrasy." He does not describe any cases, and seems to have reached this conclusion from theoretical considerations.

I would like to thank Dr. Alastair Cruickshank for his permission to publish this case, and to acknowledge the helpful information supplied by Imperial Chemicals (Pharmaceutical Division), Grangemouth.—I am, etc.,

Edinburgh.

Treatment of Barbiturate Poisoning

SIR.—Dr. H. G. Penman raises an interesting point in his letter (*Journal*, December 8, 1956, p. 1365). Can the treatment of acute barbiturate poisoning with bemegride and amiphenazole ("daptazole") be simplified by the omission of amiphenazole? The answer is, in most cases, yes. I pointed this out in an early article.¹ Amiphenazole was included in the early treatments because it was believed, on the evidence of certain animal experiments, that this drug lowered the toxicity of bemegride. More recent experiments throw doubt on the general applicability of this find-

ing. Further, we know from the work of Delay,² which we have confirmed, that bemegride is not a very toxic drug in man.

Amiphenazole is a mild respiratory stimulant in man. From reports received, one would expect benefit in about 50% of cases of non-specific respiratory depression. If, in the treatment of a case of barbiturate poisoning with respiratory depression, one did not obtain an improvement in respiratory function with bemegride alone, then one might employ amiphenazole. However, I have not had a report of such a case which did not respond to bemegride alone.—I am, etc.,

Tibial Traction

SIR.—I should like to put in a plea against the use of tibial traction in the treatment of fractures of the femur. I see quite a lot of these cases after their hospital treatment is finished, and am impressed by (1) the excellence of the result so far as the femur is concerned: the alignment is good and shortening is rare; (2) the deplorable result as regards the knee-joint, which, too often is left permanently stiff and painful. When traction is applied to the femur by way of the tibia the considerable force used is exerted through the knee-joint, pulling the articular surfaces apart and straining the ligaments. It is not surprising that the joint responds to these insults by synovial effusion, instability, and traumatic arthritis.

Surely there must be a better method. I wonder why orthopaedic surgeons (if they must use skeletal traction) do not put their Steinmann pins through the lower end of the femur and so spare the knee-joint this appalling trauma and its consequences.—I am, etc.,

Derby.

W. L. TURNER.

Suicide in Obsessional States

SIR.—On reading Dr. John Pollitt's article, "Natural History of Obsessional States" (*Journal*, January 26, p. 194), one may get the impression that suicide is unlikely in obsessional illnesses. Such an assumption could be dangerous. I have known several patients with obsessional illnesses who have committed suicide. The last was a man of 35 years, severely incapacitated by ruminations, rituals, and indecision, who said he was "so undecided he didn't know what to be undecided about." He had been a voluntary patient in a well-known hospital and diagnosed as having a hysterical illness.

Obsessional disorders are notorious for being missed, and tend to masquerade in old case histories (including some of my own) as depressions or anxiety states with hysterical features. Often such patients are too carefully dressed or groomed to "ring true" and pass muster as a depressive illness. There is, indeed, a strong case for calling obsessional features signs as opposed to symptoms, since they are more often elicited by the physician than volunteered by the patient. I think it is likely that some suicides occur in patients with obsessional disorders who are diagnosed as something else. *En passant*, violence seems a characteristic quality in patients with obsessional disorders. I can recall three suicides of a violent type, two who jumped under tube trains and one who cut his throat with a razor blade.

Out of Dr. Pollitt's series of 150 cases, 101 were followed up, and it was found that one committed suicide and two attempted it. I would predict that several of the remaining 49 who did not reply to the questionnaire have committed suicide. Obsessionals are secretive about their symptoms when alive, and dead men tell no tales. Quite often, I have found, nor will their relations.—I am, etc.,

St. Albans.

RUSSELL BARTON.

Obituary

Sir JAMSHEDJI DUGGAN, K.B.E., C.I.E.
F.C.P.S., D.O.

Sir Jamshedji Duggan, formerly professor of ophthalmic medicine and surgery in the Grant Medical College, Bombay, died on January 15 at the age of 72.

Jamshedji Nusserwanji Duggan was born in Bombay on April 8, 1884, and received his professional training at the Grant Medical College, Bombay, where he obtained the diploma of L.M.S. in 1905. He took the Oxford D.O. in 1912, and was elected a Fellow of the College of Physicians and Surgeons of Bombay in 1918. Sir Jamshedji Duggan concentrated on ophthalmic work throughout most of his career, but for some time he was superintendent of the Tata Memorial Hospital for Cancer. From 1922 to 1939 he was professor of ophthalmic medicine and surgery in the Grant Medical College, and superintendent of the Sir Cowasji Jehangir Ophthalmic Hospital. In 1934 he was president of the All-India Ophthalmological Congress. A frequent contributor to ophthalmological journals, he was the author of the chapter on presbyopia in the 1938 edition of the *British Encyclopaedia of Medical Practice*, and was the Bombay representative on the editorial committee of the *British Journal of Ophthalmology*.

Throughout the first world war Sir Jamshedji Duggan served as a major in the Indian Medical Service, and in the second world war he was chairman of the Bombay Provincial Joint War Committee of the Indian Red Cross Society and St. John Ambulance Association. A justice of the peace for Bombay since 1918 and sheriff of Bombay since 1942, he was appointed O.B.E. in 1929 and C.I.E. in 1933. He was created a knight in 1935 and promoted to K.B.E. in 1945. He married in 1914 and for over forty years had devoted support from his wife in all his activities. He is survived by Lady Duggan, by whom he had two sons, and the sympathy of all his friends, both in India and London, is extended to her and to the other members of his family in their great loss.

J. M. STALKER, M.D.

Dr. J. M. Stalker, regional medical officer at Dundee under the Department of Health for Scotland, died on January 21 in Dundee Royal Infirmary, where for a number of years he had been on the staff as a physician. His illness had lasted about three months.

James Miller Stalker was born at Dundee in 1892, the son of the late Professor A. M. Stalker, physician at Dundee Royal Infirmary and professor of medicine in St. Andrews University. He was educated at Dundee High School and at the universities of Edinburgh and St. Andrews, graduating M.B., Ch.B., St. Andrews, in 1916, and proceeding to the M.D. in 1936. In the first world war he served in France as a student dresser with the British Red Cross, returning to qualify in 1916. Thereafter he served with the R.A.M.C. and was wounded in 1917. After the war he took up general practice in Dundee. Later, in 1923, he was appointed an assistant physician to Dundee Royal Infirmary. In 1936 he was promoted consulting physician to the infirmary and lecturer in clinical medicine in St. Andrews University. He was a medical referee under the Workmen's Compensation Act for some twenty years. After

the outbreak of the second world war he was appointed consulting physician to the Emergency Medical Service hospital at Bridge of Earn, in Perthshire. He returned to Dundee on the cessation of hostilities and resumed practice until appointed regional medical officer for the area, under the Department of Health for Scotland, in 1952. He was a past president of the Forfarshire Medical Association and of the Dundee Medical Club, to which he contributed papers on several occasions. He had been local chairman of the College of General Practitioners since its inception, and three years ago he contributed an article to this *Journal* on "General Practice: Need for Hospital Technique in the Home." Of a philosophical mind and considerable literary talent, he will be remembered for his cultured and often witty speeches. He was an elder of the St. George's Parish Church, and at his funeral a large attendance of colleagues and friends paid tribute to the esteem in which he was held. He is survived by his widow, Dr. Jeannette Stalker, and his son, Dr. Alexander M. Stalker, both of whom practise in Dundee, and by a younger son, who is a chartered accountant in Malaya.

C.-E. A. WINSLOW, M.S., Dr.P.H.

Professor C.-E. A. Winslow, professor emeritus of public health at Yale University, died at New Haven on January 8, aged 79. He had edited the *Journal of Bacteriology* and the *American Journal of Public Health* for many years.

Charles-Edward Amory Winslow was born at Boston on February 4, 1877, and graduated in science at the Massachusetts Institute of Technology, where he worked first as an assistant in the department of biology and later as assistant professor of sanitary biology. For some years also he held the post of assistant health officer at Montclair, New Jersey. In 1910 he moved to New York as associate professor of biology at the New York City College, holding at the same time the curatorship of public health at the American Museum of Natural History. In 1915 he went to Yale as Lauder professor of public health in the school of medicine, and for the next thirty years he was one of the most active and influential of public-health workers in the United States. His range of interests was enormous, and, besides being a bacteriologist and teacher of renown, he was an expert on health education, on sanitary engineering, and on international aspects of public-health work. Meanwhile he accepted added responsibilities as editor of the *Journal of Bacteriology* and the *American Journal of Public Health*, and he wrote several books.

Among the first of those who helped to organize the health work of the League of Nations, Professor Winslow was one of the "expert assessors" of its health committee from 1927 to 1932, and he was also for a short time scientific director of the International Health Division of the Rockefeller Foundation. His work for the World Health Organization culminated in the publication of his monograph *The Cost of Sickness and the Price of Health* in 1951. He was made president of the Society of Bacteriologists in 1913, of the American Public Health Association in 1926, and of the American Society of Heating and Ventilating Engineers. He gave the *Cutter Lecture at Harvard* in 1928, and among the awards he received for his services to the cause of preventive medicine were the Sedgwick Medal of the American Public Health Association, the Shattuck award, the Léon Bernard Medal (W.H.O.), and the Lasker Award.

Sir CHAD WOODWARD, M.B., F.R.C.S.

Sir Chad Woodward, who practised in London as a surgeon for a few years before the first world war and was at one time chairman of the Worcestershire County Council, died on February 2 at Queen Elizabeth Hospital, Birmingham, aged 76.

Alfred Chad Turner Woodward was born on March 2, 1880, the son of Robert Woodward, D.C., J.P. From Radley School he went on to study medicine at Edinburgh, graduating M.B., Ch.B. in 1904 and taking the F.R.C.S. of Edinburgh in 1908 and of England in 1911. After graduation he held the posts of house-surgeon at the Edinburgh Royal Infirmary and of resident surgical officer at the Birmingham General Hospital. When he returned from a period of postgraduate study on the Continent he was elected to the staff of the Royal Orthopaedic Hospital, Birmingham. Later, he moved to London, and was surgeon to out-patients at the Hampstead General Hospital and at the Temperance Hospital and assistant surgeon at the Belgrave Hospital for Children. At this time he wrote a number of papers, mainly on orthopaedic subjects, and he was the author of the chapter on burns and scalds in *Choyce's System of Surgery* (1912). During the first world war, in which he served as a major in the R.A.M.C., his elder brother was killed and he became heir to the family estate at Arley, near Kidderminster. Thereafter he took a prominent part in public life in Worcestershire, as his father had before him. He became not only chairman of the Worcestershire County Council but of the Severn Catchment Board and of the Board of Conservators of the Severn Fishing District. He put his medical training to good use as a member of the Radium Commission and as a governor of the London School of Hygiene and Tropical Medicine. He was also a governor of Birmingham University. For his many public services he was knighted in 1944.

He married in 1934, and is survived by his wife and three daughters.

The sudden death of Dr. P. T. HULL on December 22, 1956, at the early age of 37 came as a great shock to his very many friends. Patrick Terence Hull was born on June 10, 1919, and began his medical education at King's College, London, in 1938, but joined the Army not long afterwards. In 1947 he became a medical student again at King's College, going on to the Westminster Hospital, and qualifying M.R.C.S., L.R.C.P. in 1951.

Dr. G. D. REES writes: I first met "Pete" Hull in October, 1938, when we started the first M.B. course at King's College, London. He quickly became a popular member of the medical faculty, and this popularity increased when the faculty moved to Glasgow and subsequently to Birmingham after the outbreak of war. While at Birmingham he gave up his studies and joined the Army. After training in this country he served in India and subsequently in Japan with the British Commonwealth Occupation Forces. He returned to this country and resumed his studies in January, 1947. After leaving King's College he went on to Westminster Hospital, where he soon became well known and well liked. He was keenly interested in all forms of sport, particularly Rugby football, and in spite of a somewhat rotund build was a proficient centre three-quarter. Immediately after qualification he joined his father and brother in practice at Rogerstone, Newport, Monmouthshire, and became a popular and respected member of the community. He married in the spring of 1956. The medical profession has lost a most colourful personality and many of us have lost an invaluable friend. To his wife and family we extend our sincere sympathy.

Dr. CATHERINE EVANS, a general practitioner in Herne Bay and specialist anaesthetist to the Canterbury and Isle of Thanet Groups of Hospitals, died on December 28, 1956. She was 56 years of age. Grace Catherine Evans was born on April 29, 1900, within a stone's throw of the Royal Free Hospital, where her father was on the teaching staff, and equally near to the London School of Medicine for Women, of which her maternal great-grandfather, John Turle, was a founder and at which she later studied medicine. The family moved to Herne Bay in 1908, when her father set up in general practice, and it was there that she received her early schooling before following the family tradition, the fifth generation to do so, by qualifying to practise medicine. When her studies were interrupted by a year in hospital as a patient she was told from all sides that she could never complete the course. But Catherine Evans was never one to give up, and her courageous determination carried her through in the shortest possible time. She qualified by taking the London Conjoint diploma in 1927. This early demonstration of a refusal to allow difficulties or illness to quell her spirit was echoed in a lifelong disregard of a constitution that was not at all robust. Her devotion to her vocation was shown in her conscientiousness in working for her patients' best interests, both within and outside the medical sphere. After a few years as assistant to her father she set up in general practice by herself. For twenty years she covered the duties at the infant-welfare and antenatal clinics in the locality, and was beloved by mothers and children. She showed a marked dexterity and speed in all her skills, and made herself an excellent anaesthetist, joining the hospitals staff in an honorary capacity as an anaesthetist before the inception of the National Health Service in 1948 and subsequently as an established part-time specialist. At the early age of 36 she was appointed to the bench of magistrates and took a lively interest in local public affairs. She served for many years on the executive committee of the East Kent Division of the British Medical Association, and was representative at the Annual Representative Meeting from 1946 to 1953. Representatives will remember her forthright and fearless expression of opinions, voiced because they were her sincere belief and never withheld if they were unpopular. It was always a joy to be pinned to the wall by her criticism or energetic disagreement, for she was the soul of candour and courage. How she continued to do her work crippled with illnesses any one of which would have reduced an ordinary mortal to helplessness will ever remain a marvel and an inspiration to those who knew her. A great fighter for life, she was overwhelmed by illness, but she never surrendered. There hung in her surgery the framed text, "The Peace of God Passeth Understanding," and underneath was added, "Peace of Conscience, Peace of Character, Peace of Conviction, Peace of Confidence." The strength that Catherine Evans drew from that inner peace throughout her years of conflict swelled out as a triumph in the organ notes of Mendelssohn's "Be Not Afraid" at the crowded funeral service to mourn the passing of this courageous lady. She leaves a sister and three brothers, of whom two are in medicine, while the son of the third is the sixth generation of doctors.—M. S. H.

Dr. R. S. RYCE, who was in practice at Pentrebach, Merthyr Tydfil, Glamorganshire, for forty-five years, died at his home there on January 8 at the age of 86. Richard Samuel Ryce was born at Cork on December 6, 1870, and was educated at the former Queen's College, Cork, graduating M.B., B.Ch. at the old Royal University of Ireland in 1897. He proceeded to the M.D. in 1901 and to the M.Ch. in 1902, when he was also elected a Fellow of the Royal College of Surgeons in Ireland. Soon after graduation he became an assistant in a general practice at Aberdare, but in 1906 he set up on his own account at Pentrebach and Abercanaid, then two very small villages near Merthyr Tydfil, where he was surgeon and radiologist at the local hospital. His practice was mainly among miners and their families, and by the time he retired the population of Pentrebach and Abercanaid had risen to over 5,000. A

member of the British Medical Association for forty years, he was chairman of the North Glamorgan and Brecknock Division in 1929-30, and for many years he was a representative at the Annual Panel Conference. He took a prominent part in the life of the district, and was a past president of both the Merthyr Rotary Club and the Abercanaid Recreation Association. Archaeology was a subject in which he was always specially interested. A widower, Mrs. Ryce having died in 1914, he is survived by his son, Dr. J. L. Ryce, who succeeded him in the practice.

Dr. JOHN LOW died at the Princess Elizabeth Hospital, Guernsey, Channel Islands, on January 1 at the age of 80. For many years he was a well-known general practitioner at Oldham, Lancashire. John Low was born at Aberdeen, and received his medical education at the university there, graduating M.B., Ch.B. in 1899. After holding house appointments at hospitals in Sheffield, Wigan, Derby, and Rochdale he went into general practice at Oldham in 1904, where he remained for thirty-five years. He was also factory surgeon for the Oldham East district. For many years a member of the Oldham Borough Council, he served as chairman of the watch committee and the police committee at various times. He was awarded the Military Cross in 1917 for conspicuous gallantry and devotion to duty in Mesopotamia while serving in the R.A.M.C. in the first world war. In 1950 Dr. Low moved to Guernsey, where he lived in retirement until his death.—F. R. L.

The death occurred at St. Andrews, Fifeshire, on January 9 of Dr. ELIZABETH M. RAMSAY, at the age of 91. She was the widow of Dr. Andrew Maitland Ramsay, the eminent Scottish ophthalmic surgeon, who died in 1946. Elizabeth Margaret Pace, one of the pioneers among medical women—she was a member of the B.M.A. for 64 years—graduated M.B. at London University in 1891 and proceeded to the M.D. four years later. She settled in practice in Glasgow, and became gynaecologist to the Victoria Infirmary Dispensary. Later she went into partnership with the late Dr. Alice McLaren, who died in 1945. A notable achievement of the partnership was its founding in 1903 of the Glasgow Women's Private Hospital, now known as the Redlands Hospital for Women, which was staffed by women doctors for the treatment of women and which became eventually a complete general and maternity hospital staffed by women specialists in all departments. Dr. McLaren was the first woman gynaecologist in Glasgow and the first medical superintendent of the hospital. Dr. Pace married Dr. A. Maitland Ramsay in 1907, and both continued to practise in Glasgow until about 1924, when they retired to live at St. Andrews.

A friend writes: The Ramsays had an ideally happy marriage, as the large number of those in St. Andrews who enjoyed their hospitality were aware. The Castle House, which was their home, became a place of pilgrimage for many of their old patients, and there they so warmly received a multitude of new friends. Their concern for education prompted them to take that vigorous interest in the university and in St. Leonard's School which animated them until the end of their lives. On the council of the latter, Mrs. Ramsay was a deeply respected member for many years. Eventually, after her husband's death, she found herself compelled to leave her house, and in recent years had lived in the Graigmount Nursing Home, where, with all her old alertness of mind and with the large-heartedness which was hers to the end, she received her friends. Generous, keen-witted, kind, and affectionate, she found her happiness latterly in identifying herself with the concerns of others. All her friends will sadly miss her; they will ever remember her with affection and gratitude.

Dr. C. E. E. HERINGTON, who was medical officer of health for Dagenham for twenty years, died on January 15 at his home in Selsey, Sussex, where he had been living in retirement. He was 63 years of age. Cecil Edward Eede Hering-

ton was born in Sussex on May 10, 1893, and received his medical education at St. Bartholomew's Hospital, qualifying by taking the London Conjoint diploma in 1918. During the first world war he served first in the Army and then in the Royal Navy. After demobilization he took the London degrees of M.B., B.S. in 1920—proceeding to the M.D. in 1943—and was in general practice at Longton, Staffordshire, and Twickenham and Teddington, in Middlesex. Having decided upon a career in public health, he took the D.P.H. of the English Royal Colleges in 1923, and was appointed deputy medical officer of health for Doncaster in 1925, after having gained experience as assistant medical officer of health under the Surrey County Council. He left Doncaster in 1926 to become medical officer of health for Ilkeston, where he stayed until 1928, when he was appointed medical officer of health for the Erith Urban District. In 1934 he obtained the appointment of medical officer of health for Dagenham, where he remained until he retired in 1954. While at Erith he was president of the local Rotary Club, of which he was a founder member, and president of the Erith branch of the National Association of Local Government Officers. He was also honorary secretary of the Kent branch of the Society of Medical Officers of Health, and in 1953 he became honorary treasurer of the society itself, an office he held until his death. A member of the British Medical Association for some thirty years, he was chairman of the South Essex Division in 1950-1. He also served on a number of committees at B.M.A. Headquarters, including the Central Medical Recruitment Committee, the Services Subcommittee, and the County District Medical Officers of Health Subcommittee. During the second world war he was in charge of the Dagenham casualty services, and his work at that trying time will always be remembered there. He is survived by his widow and two sons, one of whom is a doctor.

A friend writes: It is not so much as a medical officer of health that Dr. C. E. E. Herington will be remembered but as a man. He was a really delightful person, and those of us who were privileged to be his personal friends will never forget his quiet, kindly manner. He was one to whom one could go easily for advice and help. He was a keen follower of county cricket, and took every opportunity to watch his adopted county, Essex. An enthusiastic gardener, he was an authority on chrysanthemum growing, and to spend a summer afternoon with him was something to be remembered.

Dr. O. L. SCARBOROUGH died in the Selby War Memorial Hospital on January 16 at the age of 80, after being in practice almost forty years. Born in Halifax on June 28, 1876, Oswald Lowndes Scarborough was educated at Bradford Grammar School and St. John's College, Cambridge, going on to the Leeds General Infirmary for his clinical training. He qualified M.R.C.S., L.R.C.P. in 1905, and many years later, in 1941, he graduated M.B., B.Ch. at Cambridge. After qualification he held a number of resident appointments and then went into general practice in Chapel-town, Leeds. He volunteered for the R.A.M.C. at the outbreak of the first world war, and served until 1919, when he finally became a general practitioner in Selby. For many years he was a member of the medical staff of the Selby Hospital and also divisional surgeon to the St. John Ambulance Brigade. In 1935 he had two attacks of coronary thrombosis, which kept him away from his work for almost a year. Ten years later the youngest of his three sons died while still a medical student, and in 1946 his wife died.

C. R. H. writes: Dr. Scarborough symbolized the old family doctor at his best. With his old-world courtesy and charm of manner, his rare physique, and conscientiousness in his work, he built up a very extensive practice. A founder-member of the Selby Rotary Club, he always gave of its first principle, "Service before self." His serious demeanour, his keen, penetrating expression, his monocle and cravat were always apt at first to make his patients a little apprehensive, but his rare gift for hard work coupled

with his obvious medical skill inspired infinite trust, which was always acknowledged by colleagues and patients alike. The high esteem in which he was held was fittingly demonstrated at his funeral service. Many people, some from miles away in the country, came to pay their last tribute and revere his memory in the quiet beauty and dignity of the lovely Abbey Church at Selby, for which he had been a devoted worker. Our sympathy is extended to his sister, who looked after him so well in his later years, and to his two sons, both members of the medical profession.

Dr. J. H. SIMMONS, consulting physician to the Lewisham group of hospitals, died in Lewisham Hospital on January 17, aged 54, after a brief illness. John Howard Simmons received his medical education at King's College Hospital, qualifying with the London Conjoint diploma in 1925, and later graduating M.B., B.S. in 1926. He took the M.R.C.P. in 1930 and proceeded M.D. in the following year. After house appointments at King's College Hospital he spent some time in general practice, but early in the 1930's he joined the hospital service of the London County Council. His outstanding medical ability led to steady promotion, and he served in no fewer than six of these hospitals, his final appointment being that of physician specialist to Lewisham Hospital in 1944. With the advent of the National Health Service he became consultant physician, and he served the hospital as senior physician up to the time of his death. He also served on the staff of St. John's Hospital in a similar capacity. His opinion was respected and widely sought, and his kindly nature and good advice brought him many friends. He was always interested in hospital administration and had served as deputy medical superintendent at Mile End and St. Charles's Hospitals. He was chairman of the Lewisham hospital staff committee for a period, and later for three years he served as chairman of the group medical advisory committee. In this capacity his tactful handling of many difficult problems proved a very valuable asset in the early stages in the development of the Lewisham hospitals as a group. After the retirement of the late medical superintendent in 1951 Dr. Simmons undertook the medical administrative duties of the hospital—under the title of executive medical officer—but he still gave the greater part of his time to his clinical work and to the welfare and medical care of the nurses, who held him in great affection. Many of his leisure hours he devoted to his garden, of which he was very fond. He had a happy family life, which he shared freely with a large circle of friends, and at Christmas he and his wife used regularly to entertain students from the Commonwealth. A large congregation of colleagues and friends paid their last respects at a memorial service at St. Mary's Parish Church, Lewisham, on January 26. His sudden and tragic death—in the prime of his life—has been a very severe loss to his colleagues and friends, who will wish to extend their sympathy to his widow and daughter.—J. J.

By the death of Mr. ARTHUR H. CROOK on January 19 Eastbourne has lost a revered and well-known member of the medical profession. He was 72 years of age. Arthur Henry Crook was born at Southampton on August 19, 1884. From Christ's College, Cambridge, he went on to Guy's Hospital with a scholarship in 1906. Qualifying by taking the London Conjoint diploma in 1908, he took the F.R.C.S. in 1911, the Cambridge M.B. in 1912, and the M.Chir. in 1913. After qualification he held the appointments of out-patients officer, house-surgeon to Sir Charters Symonds, and resident obstetrician at Guy's Hospital, and then settled in practice with Dr. Astley Roberts at Eastbourne, where he was appointed assistant medical officer to the Princess Alice Memorial Hospital. A member of the R.N.V.R., he was called up immediately the first world war broke out and served at Antwerp and Gallipoli, being mentioned in dispatches. On return to civilian life he again took up his work at the Princess Alice Memorial Hospital. In 1936 he was due to retire from the honorary staff of the hospital after fifteen years as a senior, but his services were con-

sidered of such value that the post of fracture surgeon was created and he was appointed to fill it. To fit himself for this work he undertook postgraduate study abroad and in England. He served on the staff of the hospital for 38 years, from 1914 to 1951, but up to as late as last year he returned to duty as locum during holiday periods. When the British Medical Association held its Annual Meeting at Eastbourne in 1931 he served as vice-president of the Section of Obstetrics and Gynaecology. Arthur Crook was a keen sportsman. While at Cambridge he was captain of an Association football team, and from 1906 to 1910 he played for the Guy's Hospital Rugby fifteen. In 1933 he helped Dr. M. Ross Taylor to found the Eastbourne Sailing Club, of which he was at first vice-commodore, then commodore, and ultimately vice-president for life. He was an enthusiastic Sussex Townsman and District Officer for a number of years. He had travelled widely on the Continent, and was interested in people and their welfare more than in the arts or in antiquities. His family life was one of great happiness, and our sincere sympathy goes out to his widow, formerly Miss Margaret Witherbee, whom he married in 1913, and his three sons and daughter. He saw his last patient on January 16 and died three days later, truly in harness to the end, as he would have wished.—E. W. H.

Dr. JANET MCGILL died in the South London Hospital for Women on January 25 after a short illness. Janet McAllister McGill was born at Falmouth on April 26, 1894. She received her medical training at the London School of Medicine for Women and St. Mary's Hospital, graduating M.B., B.S. from London University in 1918, proceeding to the M.D., gaining the University gold medal, in 1921. After graduation she held resident posts at St. Mary's Hospital, the Elizabeth Garrett Anderson Hospital, and Paddington Green Children's Hospital. In 1922 she settled in general practice in Streatham, and became known to a large circle of patients, who valued her thoroughness and judgment and her quick insight and sympathy, and who came to know her as their friend. She loved children, and with her understanding and sense of fun she readily won their confidence. She held a variety of appointments and gave herself to each with the zest and interest which were characteristic of her. For many years she was medical officer to the Balham Infant Welfare Centre and was medical officer to the Streatham Babies' Hospital until its closure in 1939 at the outbreak of war, during which she took an active part in the training of A.R.P. personnel and was medical officer to a first-aid post. She became medical officer to the Magdalen Hospital School in 1928, and was also for some years medical officer to a home of the Fellowship of St. Michael and All Angels, caring for unmarried mothers and their children, and in both she was a friend both wise and gay to the girls and to the staff. Her cheerful energy and capacity for hard work enabled her to overcome serious handicaps of ill-health. Towards the end of 1952, however, her health became worse, and she was obliged to retire from much of her work, keeping only some private practice, and her post at the Magdalen Hospital School. She was happy to have more time for reading and her garden and for her friends. She had a wonderful memory and wide interests, and her sense of enjoyment was infectious. In difficulty or trouble she seemed to have, for her friends as for her patients, a boundless store of encouragement and good counsel, and this sprang essentially from the faith which was the mainspring of her life. All who knew her are indeed grateful for her example and companionship.—E. M. S.

Dr. A. I. ROSS, who died suddenly at his home at Sutton, Surrey, aged 45, on January 25, was a well-known figure in the Croydon area, where he held the office of group pathologist at Croydon General Hospital. The son of a general practitioner in Stockton-on-Tees, Alastair Ian Ross was educated at Fettes and Aberdeen University, where he followed the family calling of medicine. After graduating M.B. in 1935 he worked as house-physician and house-

surgeon at Sheffield Royal Hospital, and then spent a period studying abroad at the institute of pathology, Freiburg University. He returned to Britain to take the D.P.H. in London in 1938. He then held, in succession, the appointments of assistant in the Nuffield Department of Pathology and Bacteriology at the Radcliffe Infirmary, Oxford, and assistant lecturer at the Postgraduate Medical School, Hammersmith. In 1942 he joined the R.A.M.C. and served as a graded specialist in pathology, with the rank of major, in North Africa and Italy. On demobilization in 1946 Ross returned to Hammersmith. Then he went to the Kent County Hospital, Farnborough, and in 1948 to his final appointment in Croydon as a consultant. In Croydon Ross found himself faced with the need for unification and modernization of the laboratory services in a diverse group of hospitals. In spite of many difficulties, and with very little assistance, he achieved in a short time a remarkable measure of reorganization. As a man Ross combined a large, strong frame with a reserved, even shy, demeanour. He was essentially sincere and straightforward, though in personal dealings these qualities could make him seem, on occasions, somewhat brusque. To those who knew him he had an innate and sometimes disarming candour and modesty. He was methodical, instinctively cautious, and always knowledgeable in his work. His opinion in matters of surgical pathology was very sound indeed. In the last year or two his career and activities generally were clouded by a tragic illness, which he bore courageously. His organizing ability in Croydon, his respect for the needs of general practitioners, and his touches of kindness will be remembered. Dr. Ross leaves a widow—herself a doctor—and three children.—G. T. S.

Medico-Legal

INSULIN AND DRIVING

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

By Section 15 (1) of the Road Traffic Act, 1930, anyone who, when driving or attempting to drive or when in charge of a motor vehicle on a road or other public place, is under the influence of drink or drugs to such an extent as to be incapable of having proper control of the vehicle is liable to serious penalties. He is liable to disqualification from driving for at least a year. On indictment he is liable to six months' imprisonment or an unlimited fine or both. On summary conviction before justices he is liable for a first offence to a fine of £50 or four months' imprisonment, and for a subsequent offence to a fine of £100 or four months' or both. Section 9 (1) of the Road Traffic Act, 1956, provides that, if he is not driving, a person shall be deemed not to have been in charge of the motor vehicle if he proves that there was no likelihood of his driving the vehicle so long as he remained unfit to drive and that after becoming unfit to drive he had not in fact driven the vehicle on a road or other public place. The penalties, then, are heavy, though not in comparison with the disastrous consequences to others which can and often do follow the offence.

On January 30, 1957, an appeal¹ was heard before the Queen's Bench Divisional Court against the dismissal by the Prestbury (Cheshire) Justices of an information charging Mr. J. W. Clark with unlawfully driving a motor-car on the road when under the influence of a drug to such an extent as to be incapable of having proper control of the vehicle. The facts were that Mr. Clark, a chemist, had suffered from diabetes for 12 years. On August 13, 1956, after taking by injection his usual and prescribed dose of insulin, followed by a regulated meal, he had driven himself two miles to the cinema. Some hours later he was found sitting semi-comatose at the wheel of his car in a hypoglycaemic coma. The justices dismissed the information on the basis that insulin was not a "drug."

¹ *Armstrong v. Clark*, *The Times*, January 31, 1957.

The Lord Chief Justice, in the course of his judgment allowing the appeal against the justices' decision and remitting the case to the justices with a direction to convict, said that of course insulin was a "drug" for the purpose of the Road Traffic Act. The justices must remember that the section of the Act was designed for the protection of the public, and if people were in a condition of health which rendered them subject to comas, or the remedies for which might send them into comas, they ought not to drive because of the danger which resulted. Mr. Justice Cassels, in a concurring judgment, said that it would be small consolation for anyone injured by a motorist to be told that the motorist was under the influence of a drug and it was not his fault.

Proper Control

This decision is reported to have caused concern to the British Diabetic Association, with its 20,000 members. This concern should be dispelled so long as the precise constituents of the offence are remembered. It is not an offence to drive a motor vehicle while under the influence of a drug. It is an offence, and for the protection of the public it obviously must be an offence, to drive when under the influence of a drug to such an extent as to be incapable of having proper control of the vehicle.

If the accurate regulation of insulin intake and diet makes the risk of hypoglycaemia negligible, and a doctor is satisfied that his patient understands the situation and can be trusted to regulate his intake accurately, there is no reason why he should advise him not to drive. But if the patient for any reason does develop hypoglycaemia he will be as grave a danger to people on the road as if his control of his car was impaired by drink, and he will be liable to the same penalties. The fact that he deserves more sympathy than the alcoholic will be no consolation to his victim if he hits someone. Once his condition is such that he is incapable of having proper control, it is chance which decides whether he will hit anybody or not.

THEFT OF HOUSE-PHYSICIAN'S CLOTHES

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

One of the terms on which Dr. V. A. Edwards was engaged as resident house-physician at the Watford and District Peace Memorial Hospital was that he should live in a hostel near the hospital and provided by the West Hertfordshire Group Hospital Management Committee. A deduction of £125 was to be made from his salary of £425 per year in respect of the board, lodging, and other services which the committee provided there. The terms of his engagement were as negotiated between the Whitley Council for the Health Services and the B.M.A.

On December 17, 1955, Dr. Edwards got home to his room in the hostel at 2 a.m. to find that £70 worth of his clothes and personal belongings had been stolen. He brought an action against the management committee on the ground that they owed him a duty to take reasonable care of his bedroom and his personal clothes and effects, and of the keys to the door, and that it was an implied term of his contract of employment that they would perform that duty. The Watford County Court Judge decided in favour of the committee, and on January 31, 1957, Dr. Edwards's appeal against this decision was dismissed by the Court of Appeal.¹

In his judgment Lord Justice Hodson said that, on the authorities, a boarding-house keeper was under a duty to take some care of the goods of his guests, but that the duties which arose in the case of a boarding-house could not arise in the present case. The committee was not conducting the hostel as a boarding-house any more than if the staff was resident in the hospital building itself and getting food and lodging free. This was simply a case of master and servant when the master was paying his servant partly in cash and partly by giving him food and lodging, and

¹ *The Times*, February 1, 1957.

² *Deyong v. Shenburn*, [1946] K.B. 227.

it made no difference that the food and lodging were valued at £125. It had been said by Lord Justice du Parc² that there had never been a decision that, merely by reason of the relation of master and servant, the master must take reasonable care of his servant's belongings in the sense that he must take steps to ensure, so far as he could, that no wicked person should have the opportunity of stealing his servant's goods. This was not confined to domestic servants, and there was no implied term in the contract which laid such a duty on the committee.

Lord Justice Morris and Lord Justice Sellers agreed, and the court refused leave to Dr. Edwards to appeal to the House of Lords.

The Medical Defence Union instructed Messrs. Hempsons, solicitors, to act for Dr. Edwards.

Medical Notes in Parliament

Industrial Health Service

The MINISTER OF LABOUR said in reply to Mr. F. WILLEY (Sunderland, North, Lab.) on January 29 that he could not tell when he would be able to make a statement on industrial health services and organization as envisaged in paragraph 143 of the Report on the Staffing and Organization of the Factory Inspectorate. Mr. WILLEY observed that it was heartening to read in the report that much thinking was taking place; but was it unrealistic to expect effective action as a result in the near future? Mr. IAIN MACLEOD said the main thinking referred to in paragraph 143 was being done by the Industrial Health Advisory Committee. He would not like to hurry that. It was more important to get the right answer than to come to a conclusion quickly. In particular, they would want the report of the survey going on in Stoke-on-Trent into the pottery industry, which would not be available till the end of the year.

Mr. A. SKEFFINGTON (Hayes and Harlington, Lab.) asked when it was proposed to announce a successor to the senior medical inspector of factories. Mr. MACLEOD said he hoped to do so well before August, when the senior medical inspector would retire. Mr. SKEFFINGTON urged that in building up an effective department the name of the person to be in charge should be known soon. Mr. MACLEOD said he recognized that, and attached the greatest importance to the medical inspectorate.

Sir LESLIE PLUMMER (Deptford, Lab.) asked the Minister of Labour on January 31 if he would improve the grading of the post of senior medical inspector. Mr. MACLEOD replied "No." The present grading of the post was based on the recommendations of the Howitt Committee, which reported in 1951. The salary had been adjusted in accordance with the recommendations of the Royal Commission on the Civil Service.

Mental Hospital Patients

Mr. C. DOUGHTY (Surrey, East, Con.) asked the Minister of Health on January 29 which officials of mental hospitals were responsible for the discharge of patients; on what basis they were remunerated; and whether their remuneration was related in any way to the number of patients in the hospital. Mr. D. VOSPER replied that no official was authorized to discharge a patient in a mental hospital, but any two members of the hospital management committee when ordering the discharge of a temporary or certified patient must do so with the advice in writing of the medical superintendent. The salary of medical superintendents was generally based on length of service in their clinical grade and not on the number of patients.

Moulded Rubber Footwear

Mr. N. DODDS (Erith and Crayford, Lab.) asked the Minister of Health on January 31 from what sources he inquired about the effect of moulded rubber footwear in respect of foot ailments; and what advice he received in

connexion with the use of synthetic materials. Mr. VOSPER told him that advice was sought from consultants in dermatology and orthopaedic surgery. No distinction was made in this advice between synthetic materials and natural rubber, or a mixture of the two.

Industrial and Medical Gases

The PRESIDENT OF THE BOARD OF TRADE, who was asked on January 31 what action he proposed to give effect to the recommendations of the Monopolies Commission on the supply of certain industrial and medical gases (*Journal*, January 12, p. 101), said he must consider the report further before deciding what action to take. Mr. D. WADE (Huddersfield, West, Con.) said the Commission's comment that existing legislation did not seem to provide any effective means of dealing with the situation appeared to endorse the view that there were loopholes not covered by the Restrictive Trade Practices Act. Sir DAVID ECCLES replied that that was one of the parts of the report he had in mind.

Cancer and Diesel Fumes

Mr. READER HARRIS (Heston and Isleworth, Con.) asked the Minister of Health on February 4 what information his department now had on the connexion between diesel engine fumes and the increase in cancer. Mr. VOSPER stated that the investigations being made under the auspices of the Medical Research Council into the nature and effects of the exhaust products of diesel engines had provided no evidence to support the suggestion that these fumes were a cause of cancer. Mr. HARRIS said there was still some concern about a possible connexion, and asked if further investigations were being made. Mr. VOSPER replied that investigations would continue, but he could assure Mr. Harris that there was no connexion whatever. In a similar inquiry among London Transport employees it was found that the cancer incidence among those working with diesel engines was no greater than among those working with other vehicles.

Research Expenditure

Mr. M. LIPTON (Brixton, Lab.) asked how much was being spent from public funds on research into the connexion between smoking and lung cancer. Mr. VOSPER informed him that in the current financial year the Medical Research Council were spending about £29,000 on research on this subject. Most of this sum came from the lung cancer research fund put at the disposal of the Council by a group of British tobacco manufacturers. Mr. LIPTON said it was deplorable that the Government were making no contribution. Was this explained by the Treasury's policy that they did not want too many people to stop smoking? Mr. VOSPER retorted that the Government were making a contribution to this research. The Medical Research Council were spending £327,000 from public funds this year on cancer research, but the mere expenditure of money would not necessarily find the answer.

Proprietary Drug

Mr. M. EDELMAN (Coventry, North, Lab.) asked the Minister whether he had studied the claims contained in the advertisement of a proprietary drug; what was its composition; whether it was to be included in *Prescribers' Notes*; what equivalent preparation of a non-proprietary nature was already included in *Prescribers' Notes*; and at what cost. Mr. VOSPER stated that he had studied the claims. Its composition was 50 mg. of caffeine per tablet. The preparation had been noted for inclusion in the list of preparations advertised to the public which doctors had been asked not to prescribe. A standard drug of similar therapeutic effect was included in the *British Pharmaceutical Codex*, retail price 11½d. for 25 tablets, and he was advised that its clinical use was small and diminishing. He added that the drug was not harmful; the effect of one tablet was about the equivalent of a cup of tea or coffee. On social grounds it was undesirable.

Prescription Charge

Mr. ARTHUR LEWIS (West Ham, North, Lab.) asked the Minister in what numbers he had received letters of support and opposition, respectively, to the Government's increased 1s. per item prescription charge. Mr. VOSPER told him that approximately 600 letters had been received criticizing the revised charge. Some letters had been received expressing approval of it. Dr. EDITH SUMMERSKILL (Warrington, Lab.) asked how many executive councils had written. Mr. VOSPER replied, "A very large number," and added that their replies all expressed the view that the scheme was working well except in three or four instances.

Group Practices

Dr. BARNET STROSS (Stoke-on-Trent, Central, Lab.) asked the Minister how many group practices existed; whether he was satisfied that sufficient loan capital was still available for them; and what amount of increase over the annual sum of £100,000 was contemplated. Mr. VOSPER stated that the total number was not known, but loans to about 100 such practices had been approved in England and Wales and the money involved was about £450,000. The fund was now increasing by over £100,000 a year, and he thought this should be sufficient.

Food-poisoning

Mr. SOMERVILLE HASTINGS (Barking, Lab.) called attention to the increase by 49% of food-poisoning incidents in 1955; and asked whether the Minister would arrange for an inquiry into the causation and prevention of such incidents. Mr. J. K. VAUGHAN-MORGAN, the Parliamentary Secretary, said the cause and means of prevention were being continuously investigated by medical officers of health, supported by the Public Health Laboratory Service and the Ministry's medical staff, and he did not think that a special inquiry was required.

Universities and Colleges

UNIVERSITY OF DURHAM

In Congregation on December 15, 1956, the following degrees were conferred:

M.B., B.S.—Elizabeth Arnott (*in absentia*), J. B. G. Arthur, S. A. Banful, B. A. Black, B. Ehrlich (*in absentia*), Alwynne Gray, N. Manson, Emily S. S. Mochrie, N. L. K. Robson, J. A. Smith, J. K. Todd, H. N. Williams.

UNIVERSITY OF MANCHESTER

The following candidates have been approved at the examinations indicated:

FINAL M.B., Ch.B.—K. S. Ansell, P. J. Barber, K. Bass, A. Booth, A. T. Cartmell, B. W. Chant, J. D. Corcoran, Joan M. Curtis, E. W. Dade, Moira P. Dillon, Cynthia M. Dixon, A. M. Easty, W. O. Goldthorp, B. Graham, E. A. G. Hamilton, G. A. Harris, D. D. Hilton, Irene Holbrook, K. Horsfield, H. C. Jennings, T. A. Lambros, Elizabeth J. Larrad, J. R. Ledwich, Brenda J. Lovejoy, K. A. Mackenzie, P. McKelvie, Elizabeth M. B. McKenzie, Edith M. Meyer, P. Morris, H. Nickson, J. P. O'Loughlin, M. A. Pacovsky, H. W. Proctor, A. R. Robertson, D. T. Robinson, J. H. Scotson, Barbara S. Seymour, D. B. Shaw, N. M. Shaw, S. A. Silver, J. J. Slater, Eleanor M. Stocks (awarded distinction in medicine), A. G. Tetlow, M. H. Vause, D. Walker, W. B. Waring, R. D. Wood, A. B. Wooltiff.

DIPLOMA IN PUBLIC HEALTH.—Cecilia F. G. Wild.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS

At a meeting of the Faculty held on December 3, 1956, with the President, Professor Stanley Alstead, in the chair, the following were admitted Fellows of Faculty: J. S. Beck, A. Smith, J. M. J. Supramaniam.

CONJOINT BOARD IN IRELAND

The following successful candidates in the recent final examinations under the Conjoint Board were admitted by the President of the Royal College of Physicians of Ireland to the Licence in Medicine and Midwifery on December 7, 1956:

Alice N. Abdelnour, N. A. Barry, D. P. Beirne, R. G. E. Benson, Erda P. Bodden, J. C. Briggs, W. O. Brinckenhoff, H. I. C. P. Browne, B. G. Curtin, J. E. L. Daly, Mary Duffy, J. R. Duksta, W. A. K. Dwyer, S. O. Ejlwunni, D. G. Elletberry, J. I. Horowitz, M. Kelly, A. Kenny, A. Kleskiewicz, Wanda Lawendel, M. N. Lynch, M. P. Moran, B. N. Murray, F. U. K. Ozeah, B. Redfern, N. S. Ryan, R. I. R. Shannon, J. H. Smyth, Zofia W. Swistak, P. D. Tanham, W. R. Watkins, Virginia M. L. Wong, J. Wyganowski.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending January 19 (No. 3) and corresponding week 1956.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES in Countries and London	1957					1956

Vital Statistics

Poliomyelitis Vaccine

The Ministry of Health has informed medical officers of health that it is hoped distribution of poliomyelitis vaccine will begin again about the middle of this month. One large batch due last month was rejected because it was found to be contaminated, though it contained no live virus. Another batch was expected to be ready within a matter of days, but under the Therapeutic Substances Act one test has to be done again, and it will take about fourteen days to complete. Each of the next few issues of vaccine should be approximately equal to the total amount available last May—enough to give two injections to about 200,000 registered children aged 2 to 9.

Week Ending January 26

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 829, whooping-cough 3,233, diphtheria 1, measles 9,527, acute pneumonia 572, acute poliomyelitis 27, dysentery 635, paratyphoid fever 2, and typhoid fever 1.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases (deaths for influenza) of certain diseases notified weekly in England and Wales (great towns for influenza). Highest and lowest figures reported in each week during the years 1947-55 (influenza, 1952-5) are shown thus ----, the figures for 1956-7 thus ———. Except for the curves showing notifications in 1956-7, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

The largest fluctuations in the numbers of infectious diseases in England and Wales during the week ending January 19 were decreases of 1,106 for measles, from 9,281 to 8,175, 132 for acute pneumonia, from 648 to 516, and 53 for dysentery, from 530 to 477, and increases of 178 for whooping-cough, from 2,486 to 2,664, and 165 for scarlet fever, from 528 to 693.

The largest declines in the incidence of measles were 208 in Lancashire, from 2,139 to 1,931, 170 in Surrey, from 498 to 328, 147 in Yorkshire North Riding, from 443 to 296, 146 in Warwickshire, from 271 to 125, and 140 in Essex, from 813 to 673; the only large exception to a decreasing incidence was a rise of 105 in Durham, from 561 to 666. A small rise in the incidence of scarlet fever was recorded in most regions, but there were no large fluctuations in the local trends. The largest increase in the number of notifications of whooping-cough was 44 in Lincolnshire, from 31 to 75. 4 cases of diphtheria were notified, being 5 fewer than in the preceding week; 2 of the cases were notified in Birmingham C.B.

41 cases of acute poliomyelitis were notified, and these were 17 fewer for paralytic and 14 fewer for non-paralytic cases than in the preceding week. The largest returns were London 7 (Camberwell 2), Essex 6, and Lancashire 4.

The largest centres of dysentery were Yorkshire West Riding 80 (Leeds C.B. 24, Sheffield C.B. 19, Bradford C.B. 10, Keighley M.B. 10), Lancashire 73 (Stretford M.B. 24), Warwickshire 63 (Coventry C.B. 46, Birmingham C.B. 13), London 49 (Lambeth 16), Nottinghamshire 27 (Arnold U.D. 16, Nottingham C.B. 11), and Staffordshire 25 (Kingsgrove U.D. 21).

Industrial Accidents and Diseases

The number of workpeople (other than seamen) in the United Kingdom whose deaths from accidents in the course of their employment were reported in December was 116, compared with 120 in the previous month and 121 in December, 1955.

The numbers of cases of industrial diseases in the United Kingdom reported during December, 1956, were as follows: lead poisoning 3, phosphorus poisoning 2, aniline poisoning

8, chronic benzene poisoning 1, anthrax 2, epitheliomatous ulceration 34, chrome ulceration 27; total 77. There was one death due to anthrax.—*Ministry of Labour Gazette*, January, 1957.

Venereal Diseases

In England and Wales during the quarter ending September 30, 1956, 1,199 new cases of syphilis were reported as attending the clinics. Of these, 208 were classified as primary, secondary, or latent in the first year of infection. 9 cases of congenital syphilis in children aged under 1 year were reported, and 127 in persons over that age. New cases of gonorrhoea numbered 5,790, of chancroid 65, and of non-gonococcal urethritis (males only) 4,066.—*Monthly Bulletin of the Ministry of Health*, January, 1957.

Medical News

Tribute to Sir Gordon Holmes.—On the twenty-second of this month Sir GORDON HOLMES, F.R.S., consulting physician

to the National Hospital for Nervous Diseases, Queen Square, will be 80. This event was celebrated at "The National" on Thursday when Sir FRANCIS WALSHE, F.R.S., unveiled the portrait of Sir Gordon Holmes which is reproduced opposite and formally presented it to the Institute of Neurology, where it will hang in the lecture theatre. The portrait is the work of Mr. HAROLD KNIGHT, R.A.

Already British neurologists have shown their eagerness to honour Sir Gordon Holmes: the guarantors of *Brain* recently sponsored a monograph comprising a selection of his published papers, which is reviewed elsewhere in this issue (p. 328). For the benefit of future neurologists it was decided to commission the portrait of Sir Gordon Holmes to serve as a permanent reminder of his genius and achievements, and the co-operation of a very large number of Sir Gordon's former residents, clerks, and students at the National Hospital was enlisted. Many of them, especially those now living elsewhere in the Commonwealth or in the United States, sent personal messages of gratitude to Sir Gordon. Sir FRANCIS WALSHE, in unveiling the portrait, paid tribute to Sir Gordon Holmes's inspiration to his pupils. "I should not be doing justice to the occasion," he said, "if I did not stress the greatness of the debt we all owe to you and now gladly acknowledge. The lessons you so incomparably taught us are as essential to the neurologist to-day as ever before: the lesson of exhaustive and accurate observation, of faithful and methodical recording, and of a mind ever alert to seek the significance of the patterns and sequences of what we observed. These are the very foundations of training in clinical medicine." The portrait was then accepted on behalf of the Institute by Sir ERNEST GOWERS, chairman of the School's committee of management.

Atlantic Crossing in Canoe.—A Hamburg doctor, Dr HANNES LINDEMANN, who arrived in New York on January 29, has sailed from Las Palmas in the Canary Islands to St. Martin in the Dutch West Indies—a direct distance of about 3,000 miles—in a 17-ft. rubber kayak, according

to a report in the *New York Times* (January 30). He started this remarkable passage on October 20 and reached the West Indies on December 30, after twice having capsized in storms. He had originally sailed from Spain. According to the *New York Times* Dr. Lindemann took no water, but his 175 lb. of concentrated food included about 130 lb. of evaporated milk and canned beer. Before the trip he deliberately fattened up to 14 st. 13 lb., and during the voyage he lost 3 st. 1 lb. He is now back to his ordinary weight of 12 st. 7 lb. The canoe was rigged with two small square-sails, fore and aft, in addition to a main-sail. Dr. Lindemann, whose age is stated to be 34, said on his arrival in New York that he wanted to carry out further research on survival at sea while in the United States.

W.H.O. Executive Board.—On January 30 the Executive Board of the World Health Organization concluded its 16-day meeting in preparation for the Tenth World Health Assembly, which opens in Geneva on May 7. The Board met under the chairmanship of Professor G. A. CANAPERIA, of Italy. The Board's most important task was the scrutiny of the director-general's proposals for W.H.O.'s programme and budget for 1958. The Board recommended a basic budget of \$11.76m., \$1m. less than the director-general asked for, but made provision for a supplementary budget up to \$1.87m., depending on the extent to which inactive member States might resume participation. Besides Albania, Bulgaria, and Poland, who recently notified their intention of resuming active membership, it was known that Czechoslovakia, Russia, and Hungary were also considering this step. The Suez crisis had led to the evacuation of the staff of the Eastern Mediterranean Regional Office to Geneva, but their return was planned for the near future. Dr. ABDOL H. TABA would succeed Dr. A. T. SHOUSA as director of this office on September 1. The International Diabetes Federation, the International Confederation of Midwives, and the World Federation of Societies of Anaesthesiologists were added to the 40 non-governmental organizations with which W.H.O. has official relations. The United Kingdom delegate on the Board was Sir JOHN CHARLES, Chief Medical Officer of the Ministry of Health.

Clinical Teachers at Oxford.—On January 29 Congregation approved new titles for clinical teachers in the medical school at Oxford. Since the school was opened many members of the staff of the United Oxford Hospitals have taken a full share in the teaching of the students, and in 1949 the University recognized their services by conferring the title of clinical lecturer on a number of them. In the past eight years, however, the number of hospital staff engaged in teaching has increased considerably, so that the Board of Faculty of Medicine put forward proposals for a revision and extension of the list of recognized clinical teachers. It is these new proposals which are now approved. Those who previously had the title "clinical lecturer" are now to be known as university lecturers; in addition, one other teacher not previously a "clinical lecturer," Dr. E. M. BUZZARD, is also made a university lecturer (in medicine). This is regarded as the senior grade. Others who take a substantial part in the teaching of the students, but hitherto have had no official recognition, are to receive the title "clinical lecturer." Eighteen names are included under the latter title. As in the case of the original clinical lectureships, no stipend from the University will be paid to the holders of these titles.

Drugs Exported.—British exports of drugs and medicines reached a new record in 1956 of nearly £36m., states the Association of British Pharmaceutical Industry. Of this total, antibiotics accounted for nearly £7m. and vitamins for nearly £3m. Sulphonamide preparations (£11m.), aspirin and synthetic antimalarial drugs (£1m. each), and barbiturates, insulin, and antihistamine drugs (around £11m. each) also contributed significantly to the total. Proprietary medicines not covered by specific headings in the Board of Trade returns amounted to over £10m. Australia and India were the leading export markets for British drugs, with purchases around £3m. Next came Nigeria, Pakistan, South Africa,

New Zealand, the Republic of Ireland, and Burma, in that order, all taking between £1m. and £2m. Sales to Egypt at £742,000 were nearly £400,000 down on the previous year, but there was a great improvement in sales to the United States of America, which at nearly £1m. easily surpassed last year's record of £660,000.

R.C.O.G.—The Royal College of Gynaecologists and Obstetricians announces the election of Sir RUSSELL BRAIN, P.R.C.P., and Dr. I. C. RUBIN, of New York, to honorary fellowships of the College in recognition of their outstanding services to medicine. Dr. Rubin became clinical professor of obstetrics and gynaecology at New York University medical college in 1948.

Statistical Prize.—A competition for the 1957 Frances Ward memorial prize of 50 guineas is announced by the council of the Royal Statistical Society. The prize is open to investigators under the age of 35 on October 1, 1957, whether fellows of the Society or not. The prize is for the best investigation, on statistical lines, of any problem bearing directly or indirectly upon economic or social conditions. Members of the Society's medical section are mentioned among those who may wish to enter for the prize. Essays should be limited to between 5,000 and 10,000 words, and the closing date is September 30. Further details may be obtained from the Royal Statistical Society, 21, Bentinck Street, London, W.1.

D.G.M.S., Air Ministry.—Air Marshal P. B. LEE POTTER, Q.H.S., has been appointed Director-General of Medical Services, Air Ministry, from February 1. He succeeds Sir JAMES KILPATRICK, who is retiring from the Royal Air Force.

Diagnostic Radiology and Radiotherapy.—The Faculty of Radiologists is now arranging courses, starting in October, for candidates for the D.M.R.D. and D.M.R.T. Further information will be found at p. 54 of our advertisement pages.

Cambridge University.—Dr. J. D. LEVER, university lecturer in anatomy, has been elected to a staff fellowship at Trinity College on his appointment as college lecturer.

Professor W. M. Mitchell is to retire from the chair of veterinary surgery at the Royal (Dick) Veterinary College, Edinburgh University. He became principal of the College in 1946, and five years later was made director of veterinary education in the University of Edinburgh. He joined the staff of the College in 1910. Professor Mitchell graduated in medicine after his veterinary training.

COMING EVENTS

Royal Eye Hospital Centenary Year.—Medical staff dinner at the Royal College of Surgeons, February 21, 7.30 for 8 p.m. Tickets (30s.) from the medical secretary, Royal Eye Hospital, St. George's Circus, London, S.E.1.

Institute of Dermatology.—Semi-permanent exhibition on "Cosmetic Dermatitis," March 4-25.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Saturday, February 9

ASSOCIATION OF CLINICAL BIOCHEMISTS: SOUTHERN REGION.—At West Middlesex Hospital, Twickenham Road, Isleworth, 2 p.m., scientific papers.

Monday, February 11

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—3 p.m., Dr. J. McClintock (New York): Thyroid Cancer (Lecture and coloured talking film); 4 p.m., Dr. Sheila Sherlock: Portal Hypertension.

Tuesday, February 12

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Mr. H. J. Seddon: Recent Work on Paralytic Poliomyelitis.

CHELSEA CLINICAL SOCIETY.—At Rembrandt Hotel, S.W., 8.30 p.m., discussion to be opened by Dr. J. A. Dudgeon and Dr. F. O. MacCallum: Prevention and Laboratory Diagnosis of Virus Diseases.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. O. L. S. Scott: Genodermatoses.

ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Lord Cohen of Birkenhead: Concept of Collagen Disease.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Institute Theatre, 5 p.m., Mr. W. G. Mills: Dysmenorrhoea and Pelvic Pain.

Wednesday, February 13

EUGENICS SOCIETY.—At 26, Portland Place, W., 5 p.m., Galton Lecture by Professor Tage Kemp: Genetic-Hygienic Experiences in Denmark in Recent Years.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. H. Haber: Clefts, Vesicles, and Bullae.

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Mr. D. M. E. Thomas: Surgery of Primary Tuberculosis.

INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Mr. H. K. Vernon: Indications for Treatment in Enlarged Prostate.

LONDON UNIVERSITY.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., special university lecture in pathology by Professor J. B. Duguid: Mechanical Factors in Atherosclerosis.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Professor C. L. Oakley: Food Poisoning Due to *Clostridium welchii*.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH.—3.30 p.m., Sir Harold Stiles: Lecture by Mr. G. E. Mavor: Administration of Potassium to the Hypothermic Heart.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—5 p.m., Walker Lecture by Dr. E. N. Chamberlain: British Contributions to Cardiology.

THURSDAY, FEBRUARY 14

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. W. J. Whelan, Ph.D.: D.Sc.: Synthesis and Degradation of Polysaccharides.

GLASGOW UNIVERSITY MEDICO-CHIRURGICAL SOCIETY.—7.30 p.m., Mr. S. A. Barnett: Freud and Instinct.

HUNTERIAN SOCIETY.—At Savoy Hotel, 7 for 7.30 p.m., annual dinner.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. S. C. Gold: Bullous Eruptions.

LIVERPOOL MEDICAL INSTITUTION.—At Liverpool Royal Southern Hospital, 2.30 p.m., afternoon clinical demonstration.

LIVERPOOL UNIVERSITY MEDICAL SOCIETY.—5.15 p.m., B.M.A. Lecture by Sir Daniel T. Davies: To-morrow's Doctor.

LONDON UNIVERSITY.—At Meyerstein Lecture Theatre, Westminster Medical School, 5.30 p.m., special university lecture in pharmacy by Dr. E. Weston Hurst: Approaches to the Chemotherapy of Virus Diseases.

NUFFIELD ORTHOPAEDIC CENTRE.—At Wingfield-Morris Orthopaedic Hospital, 8.30 p.m., Mr. J. M. Zarek: Biochemical Problems in the Reconstruction of the Femur.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—4 p.m., Hunterian Oration by Sir Ernest Finch: Influence of the Hunters on Medical Education.

ROYAL MEDICO-PSYCHOLOGICAL ASSOCIATION: CHILD PSYCHIATRY SECTION.—At 11, Chandos Street, W., 5.30 p.m., discussion: Psychological Factors in the Production of Epilepsy.

ROYAL MEDICO-PSYCHOLOGICAL ASSOCIATION: PSYCHOTHERAPY AND SOCIAL PSYCHIATRY SECTION.—At Royal Society of Medicine, 8.15 p.m., Dr. G. M. Carstairs: Preventive Psychiatry: Is there such a Thing? (Open to members and guests.)

ROYAL SOCIETY.—4.30 p.m., Dr. Honor B. Fell, D.Sc., F.R.S.: Effect of Excess Vitamin A on Cultures of Embryonic Chicken Skin Explanted at Different Stages of Differentiation.

ROYAL SOCIETY.—4.30 p.m., Dr. Margaret L. R. Harkness, Dr. R. D. Harkness, and Dr. D. A. McDonald: Collagen and Elastin Content of the Arterial Wall in the Dog.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Dr. M. A. Partridge: psychiatry demonstration.

FRIDAY, FEBRUARY 15

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. P. F. Borrie: clinical demonstration.

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. A. P. Norman: Cystic Fibrosis of the Pancreas.

INSTITUTE OF LARYNGOLOGY AND OTOLARYNGOLOGY.—3.30 p.m., Mr. K. G. Rotter: Common Diseases of the External Ear.

KENT AND CANTERBURY HOSPITAL.—8 p.m., clinical meeting.

LONDON UNIVERSITY.—At Meyerstein Lecture Theatre, Westminster Medical School, 5.30 p.m., special university lecture in pharmacy by Dr. E. Weston Hurst: Approaches to the Chemotherapy of Virus Diseases.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—10 a.m., Professor J. B. Kinmonth: Lymphoedema; 4 p.m., Dr. E. N. Rowlands: Symptomatic Injury of Peptic Ulcer.

ROYAL MEDICAL SOCIETY, EDINBURGH.—8 p.m., dissertation by Mr. I. B. MacLeod: Intestinal Obstruction.

ROYAL MEDICO-CHIRURGICAL SOCIETY OF GLASGOW.—At Royal Faculty of Physicians and Surgeons of Glasgow, 8.30 p.m., Dr. J. H. Cyriak: Backache.

SOCIETY OF MEDICAL OFFICERS OF HEALTH: WELSH BRANCH.—At B.M.A. House, 195, Newport Road, Cardiff, 6.30 p.m., Dr. Alice M. Stewart: Survey of Malignant Disease in Childhood.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Love.—On January 18, 1957, to Joan (formerly D'Arcy), M.D., D.C.H., and Lester Love, of Banstead, Surrey, a second daughter—Jane Anne.

DEATHS

Benson.—On January 12, 1957, in hospital, London, John James Benson, L.R.C.P.&S.I. and L.M., Surgeon Commander, R.N., aged 50.

Bowen.—On January 14, 1957, Owen Henry Bowen, M.R.C.S., L.R.C.P., of 146, Stag Lane, Kingsbury, London, N.W.

Crook.—On January 19, 1957, at his home, 2, Chiswick Place, Eastbourne, Sussex, Arthur Henry Crook, M.Ch., F.R.C.S.

Dal.—On January 16, 1957, at Lochhead, Dalhousie Place, Arbroath, Arthur David Ducat, D.S.O., T.D., M.B., late of Chiswick, London, W., aged 86.

Forrest.—On January 13, 1957, Alfred Wightman Forrest, M.B.E., M.B., C.M., of Myrtle Cottage, Mare Hill, Pulborough, Sussex.

Haslam.—On January 11, 1957, in London, Ivy Evelyn Haslam, M.D., M.R.C.P., aged 79.

Herrington.—On January 15, 1957, at Selsey, Sussex, Cecil Edward Eede Herrington, M.D., D.P.H., of 27, Bonnar Road, Selsey.

Honourfield.—On January 15, 1957, Sydney Comland Honourfield, M.R.C.S., L.R.C.P., of Fairway, Felixstowe Ferry, Suffolk, aged 84.

Lynch.—On December 31, 1956, at Vancouver, British Columbia, Canada, Arthur Lynch, M.D., F.R.C.S. Ed., aged 75.

Taffs.—On January 6, 1957, at Salisbury, Southern Rhodesia, Cullis Charles Taffs, M.R.C.S., L.R.C.P., D.T.M.&H., formerly of Watton-at-Stone, Herts. and Desford, Leics.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Aetiology of Microcephaly

Q.—Have there been any recent advances in our knowledge of the aetiology of microcephaly?

A.—There has been little advance in our knowledge of the aetiology of microcephaly recently. A number of authorities consider that there is a distinct type of microcephaly known as the "true" variety. Brushfield and Wyatt¹ found that approximately half of 147 cases were "true" microcephalics. Penrose² considers that the true variety, which he distinguishes as having a relatively long and narrow head, is due to a recessive gene, and Hanhart³ found 10 microcephalics who were related to each other. However, the clinical distinction into "true" and "other" cases is very difficult in practice. It is now well established that some cases are due to irradiation during pregnancy,⁴ and it has also been shown⁵ that a number of cases followed the atomic bomb explosions in Japan. It seems very likely that many other cases of microcephaly are due to environmental factors operating early in pregnancy.

Precooked Meat

Q.—It is usual in some hospitals and institutions to pre-cook meat, particularly roasts, on the day before it is required and then to reheat before serving. This is done for administrative convenience. I understand that certain education authorities have forbidden this practice in the case of meals for schoolchildren. Are there any dangers in it?

A.—If cooling is slow and there is a period of warm storage, precooking meat or poultry carries a risk of *Clostridium welchii* food-poisoning. This is true not only when the precooking is done on the previous day but even when it is done only a few hours before the meat is eaten.

The spores of certain food-poisoning types of *Cl. welchii* can withstand boiling or steaming for 4 or 5 hours, and furthermore these organisms multiply rapidly at fairly high temperatures—e.g., 40–50° C. Food-poisoning strains of *Cl. welchii* may be found in a proportion of animal carriers and also on and within meatstuffs and poultry as they reach the canteen.

To overcome this danger meats should be either cooked so that contaminating spores are killed (e.g., by steam under pressure, possibly by radiation, or by the efficient roasting of small joints); or cooked in the ordinary way and eaten the same day with as short a gap as possible between cooking and eating; or cooked, cooled rapidly (within 1½ hours), and refrigerated until required. If there is no possible alternative but the last procedure, then the size of joints should be limited to not more than 6 lb. (2.7 kg.) in joints should be limited to the penetration and loss of heat; order to facilitate both the penetration and loss of heat; while bulks of steaks or soups should be distributed into shallow containers to accelerate the speed of cooling before refrigeration. The criticism that meats can be carved economically only if cold is now invalid, as new makes of machine are able to slice as thinly from hot joints as from cold.

The reheating of meat at temperatures sublethal to bacteria may serve to increase the numbers of organisms

present. It may even convert a non-infective or non-toxic dose of bacteria or toxin to one which will cause symptoms. These principles apply also to gravies and stocks.

As well as the particular hazard of *Cl. welchii* food-poisoning, there is a danger that other types of food-poisoning organisms such as staphylococci or salmonellae may develop on precooked meats if they are carelessly handled after cooking and stored at temperatures conducive to bacterial multiplication.

Standards of Growth in Adolescence

Q.—How can one decide whether an adolescent's shortness in stature represents simply a normal variation from the mean for his age, weight, and build, or a condition demanding further study? If the latter, what investigations are indicated?

A.—Unfortunately, there are at present no adequate standards for heights and weights applicable to adolescents in Britain. In any case the assessment of normality of size in adolescence must be made in relation to whether or not the adolescent spurt in growth has occurred, and not in relation to chronological age, which at adolescence means very little.¹ The best way to go about this problem would seem to be as follows: Take a radiograph of the left hand and wrist of the adolescent in question and determine his skeletal age.² Then, from the Bayley and Pinneau tables,³ see what adult height is predicted from the present height and skeletal age. The decision whether or not the predicted adult height is normal can then be made in the light of general experience.

If the predicted adult height is grossly below normal the only investigations that are likely to help would be measurements of the father and the mother to assess the factor of heredity, and a general medical investigation to make sure that the child was not suffering from any chronic disorder. Investigations in such cases, however, usually yield negative results, and at present treatment is quite unsatisfactory. It may well be that such patients have suffered from a lack of growth hormone during the growing period, but we have at present no means of determining whether or not this is the case; and growth hormone preparations are not as yet effective therapeutically.

Underclothes for All Seasons

Q.—What is the best all-the-year underclothing for a person who works in the hot atmosphere of operating theatres during the week and at week-ends attends to his smallholding in all weathers? Is the string vest the answer?

A.—Underclothing is a matter of personal preference and prejudice. Any advice given is inevitably coloured by personal experience, and any advice received contrary to "experience" is likely to be ignored; but I would say that, unless the questioner is prepared to vary his outer garments according to weather, activity, and environment, he will never be comfortable wearing the same weight and type of underclothes all the year round. This assumes that underclothes are being worn for warmth and not simply for hygienic reasons.

The thermal insulation provided by any garment is a function not of the fabric *per se* but of the air trapped in and under it; the string vest by itself traps very little air, but it allows more air than otherwise to be trapped by garments worn over it, thus improving their insulation. The "warmth" of the string vest therefore depends upon its being covered up; worn under the surgeon's apron and gown it would be almost totally enclosed (unless the surgeon leaves the back of his gown undone) and would be somewhat hot to wear in the operating theatre. But for hard work in the open, especially in a cool climate, a string

vest is the ideal garment. The outer garment must be so designed that it can be opened up widely, exposing the vest and allowing the trapped air to escape, so that when the wearer has warmed up insulation can be reduced; when he stops working and begins to cool off the outer garment can again be closed over the vest to conserve body heat. Properly used in this way, the string vest is effective and comfortable.

Hiccups in Elderly Hypertensive

Q.—What treatment is advised for repeated attacks of severe hiccups in an elderly hypertensive who has had a coronary thrombosis and a hemiplegia in the past and who now from time to time suffers from attacks of congestive failure? The hiccups come on every two or three weeks, and last a few days without intermission. Chlorpromazine and barbiturates have proved ineffective.

A.—The problem is to break the rhythmic reflex. Simple measures like sucking ice may occasionally do the trick. Sedation in this case has apparently failed. Local analgesics such as very dilute procaine solution, if swallowed, may break a reflex from the pharynx or oesophagus. Re-breathing (from a paper bag) to get a strong carbon-dioxide stimulus to respiration may help. Operations on the phrenic nerve have actually been done for this condition, but are not recommended.

Carpal Tunnel Cuff Test

Q.—What is the "carpal tunnel cuff test"? How useful is it in the diagnosis of the carpal tunnel syndrome?

A.—The "carpal tunnel cuff test," correctly styled the pneumatic tourniquet test for the carpal tunnel syndrome, was described by R. W. Gilliatt and T. G. Wilson.¹ It depends upon the theory that paraesthesiae, the outstanding complaint of patients with the carpal tunnel syndrome, are caused by ischaemia of nerve trunks. In normal persons the inflation of a sphygmomanometer cuff around the upper arm produces "pins and needles" felt mainly in the palm and in the ulnar half of the hand, never predominantly in the thumb, index, and middle fingers. In patients whose median nerves have already been rendered somewhat ischaemic by compression in the carpal tunnel the inflation of such a cuff produces "pins and needles" predominantly in the median area of the hand. In some such cases actual sensory loss develops in the median area a minute or so after the cuff is inflated.

The test is simple and useful. But, like so many other clinical tests, its usefulness is rather limited by the fact that, though it is positive in the obvious case of median compression, it is often equivocal and unhelpful in the doubtful case. A negative tourniquet test does not mean that the patient will not be cured by decompression of the median nerve.

Causes of Leucopenia in Some Infections

Q.—Some infections promote a leucocytosis whereas others are associated with a leucopenia. Why should this be so, and in particular why should typhoid fever be associated with a leucopenia?

A.—On the whole, infections that cause the formation of pus stimulate a polymorphonuclear leucocytosis, while those not producing pus do not. In these cases the leucopenia—really a neutropenia, as the lymphocytes are hardly affected—may be due to three causes: diminished production of polymorphs in the bone marrow, the result of toxins or nutritional factors; increased destruction, as in some cases of agranulocytosis; or alteration in distribution. This last appears to be the most important cause, and has been shown by Menkin¹ to be due to a leucopenia-producing material which can be isolated from inflammatory exudates. Injections of this substance lead to trapping of polymorphs in the lungs,

liver, spleen, and bone marrow with a resultant neutropenia. Robertson and Yu² found that injections of filtrates of *Salmonella typhi* caused accumulation of leucocytes in the liver and spleen, and concluded that the leucopenia in this disease was due to redistribution.

NOTES AND COMMENTS

Congenital Cataract and Mental Defect.—Dr. GORDON DUTTON (Ottershaw, Surrey) writes: The answer to the question on congenital cataract and mental deficiency ("Any Questions?" January 19, p. 181) seems to leave out one very important point—the question of galactosaemia. As this may well be a preventable disease in that removal of lactose from the diet may lead to considerable amelioration of the signs of oligophrenia as well as regression of cataracts, and as the condition also appears to be a genetically determined syndrome, it is important to exclude it by testing for reducing substances in the urine.

OUR EXPERT replies: It is a wise precaution, as Dr. Dutton suggests, to consider the diagnosis of galactosaemia in any child with cataract and mental defect. There are a number of reasons why this diagnosis is improbable in the children in question. The cataracts are specified as congenital; in galactosaemia they develop in the first few months of life. No history is given of such prominent features of galactosaemia as failure to thrive, albuminuria, and hepatic enlargement. The medical practitioner who sent in the question had presumably performed routine tests for reducing substances in the urine on several occasions and found none. But, since the presence of galactose may be missed in routine testing for sugar in urine, Dr. Dutton's suggestion is a practical one.

Doctors with Cancer.—Dr. M. DONALDSON (Oxford) writes: The last part of the answer to the first question refers to a comparison between doctors and lay people in the delay in seeking advice when suffering from cancer ("Any Questions?" January 5, p. 57) and quotes a paper by Robbins and others.¹ Surely it is statistically unsound to accept a comparison between such different figures as 229 cases among doctors and 2,000 lay patients. Moreover, there is insufficient detail about the types of cancer grouped under "Superficial," "Thorough," and "Special" to justify any such comparison. The figures in the first half of the answer seem to contradict the conclusions. The death rate for cancer among the profession at each of the important sites is lower than among white males in general. It is improbable that this could be true without earlier diagnosis.

REFERENCE

- ¹ Robbins, G. F., Macdonald, M. C., and Pack, G. T., *Cancer*, 1953, 4, 624.

OUR EXPERT replies: The comparison between 229 patients on the one hand and 2,000 on the other is admittedly open to criticism. Unfortunately I do not know of any other or better investigation which can be quoted. Dr. Donaldson's contention that a lower death rate among doctors than among laymen could hardly be true "without earlier diagnosis" is equally open to criticism. It could easily be true if, for instance, they had better treatment, as well they might have done.

Books of "Any Questions?" and Refresher Course Articles.—The following books are available through booksellers or from the Publishing Manager, B.M.A. House, Prices include postage. *Any Questions?*, Volumes 2 and 3 (8s. each); *Refresher Course for General Practitioners*, Volumes 2 and 3 (26s. 6d. each inland, 26s. overseas); *Clinical Pathology in General Practice* (22s. 3d. inland, 21s. 9d. overseas).

MEDICAL ASPECTS OF BOXING, PARTICULARLY FROM A NEUROLOGICAL STANDPOINT*

BY

MACDONALD CRITCHLEY, M.D., F.R.C.P., F.A.C.P.

Neurologist, King's College Hospital; Physician, National Hospital, Queen Square, London

Traumata arising in the course of boxing contests or during a pugilistic career are diverse in character. Whether they are to be regarded as commendably rare or as alarmingly common is a matter of opinion. It is sometimes claimed that boxing *per se* causes no more injuries or fatalities than some other sporting events. Thus Johansen (1955), of Oslo, has analysed a series of 6,057 sport injuries occurring during the period 1946-8: of these, boxing, which came tenth out of a list of 14 athletic pursuits, was held responsible for only 100 accidents (1.65%). This contrasts with the numbers attributed to skiing (1,784, or 29.4%) and to football (1,320, or 21.8%).

One important distinction, however, distinguishes boxing from most other forms of athleticism. Injuries are coincidental in other sports, but in boxing the aim and object—explicit or implied—is to render the opponent *hors de combat*. Traumata are therefore not so much regretted as regrettable.

This paper makes no plea either for or against pugilism. Amateur boxing can certainly fulfil many useful purposes, sociological as well as personal. Whether the benefits of amateur boxing outweigh the drawbacks is a question for others to decide; while some may well consider that professional pugilism forms a problem all of its own. The purpose of this communication is merely to enumerate some of the principal ill effects which have been ascribed to boxing, with particular reference to the neuro-psychiatric deterioration which may develop late in the career of a prize-fighter.

The "Knock-out"

The "knock-out"—so dramatic a spectacle in professional contests—entails the deliberate and violent production of a state of motor hypotonus and helplessness coupled with a severe—if short-lived—disturbance of consciousness. As a rule this knock-out phenomenon is the result of a violent blow to the point or side of the chin. The victim collapses heavily and remains immobile or inert for a matter of seconds or minutes. The unconsciousness produced by the knock-out blow is clinically rather unusual, being as a rule very abrupt in onset, quite short in duration, and comparatively complete in recovery. In falling, the head may forcibly strike the ground, thereby producing a second and direct injury to the head which of itself may complicate the clinical picture. If the boxer is rendered so helpless as to be unable to regain the erect stance within 10 seconds, he is "counted out." After a knock-out blow most boxers

*Being the opening paper at a discussion upon this topic held at the Chelsea Clinical Society on November 13, 1956.

are able to leave the ring within a minute or two, though ordinarily with the help of their seconds. Longer periods of powerlessness, or of unconsciousness, are by no means unknown, however.

According to the sporting fraternity there are causes of a knock-out other than a blow to the chin. Thus there is the "solar plexus knock-out," which is not ordinarily attended by unconsciousness. Jokl (1941) believed that this type of injury is identical with the experimental *Klopfversuch* studied so thoroughly by Goltz (1863). There is also a "heart knock-out" (or *commotio cordis*), which on occasion has proved fatal. Blows to the side of the neck may provoke what physicians may regard as a "carotid sinus knock-out." The physiological mechanism of this lesion has been particularly associated with the work of Hering (1927). According to Boigey (1938), the right side of the neck is more sensitive to blows than the left, so far as the carotid sinus is concerned. There are, in addition, certain types of foul punch which are apt to produce a knock-out. These include a downward chop to the nape of the neck (rabbit punch); blows "below the belt" (a euphemistic term for direct injury to the testicles, which is apt to produce much pain, shock, and occasionally unconsciousness); and "kidney punches," which have been known to provoke haematuria and even renal lacerations.

The ordinary classical knock-out blow is, however, an indirect head injury, where the point of impact of the fist is to the "button"—that is, the point of the chin. The violence is transmitted up and back to the base of the skull. The exact mechanism of the loss of consciousness and tonus has been a source of controversy. Sherrington's (1906) description deserves quotation: "The 'knock-out blow,' where the lower jaw conveys concussion to the otocyst, reduces in a moment a vigorous athlete to an unstrung bulk of flesh whose weight alone determines its attitude, if indeed a reactionless mass can be described as possessing attitude at all." It is interesting to note that Sherrington did not mention disordered consciousness. In other words, concussion of the otocyst is—in his opinion—the essential factor of the knock-out, leading to an abrupt hypotonus of vestibular origin. Somen (1913-14) also implicated the inner ear; and, according to Somen, Babinski concurred. La Cava (1952) believed that a violent blow to the mandible involves nerve structures immediately behind the angle of the jaw, and leads to an abrupt drop in blood pressure. Denny-Brown and Russell (1941) visualized a sudden stimulation of vasomotor centres leading to a temporary depression in cardiac, vasomotor, and

respiratory function. Jokl (1941), like Winterstein (1938), also imagined a condition of mechanical medullary dysfunction which may be complicated by concussion due to the direct effect of the fall.

More precisely Jokl and Winterstein (and also Gonzales, Vance, and Helpen, 1937) believed that a blow to the chin produces a two-phasic jerk which involves the medullary centres. In the first place, the clivus and the anterior edge of the foramen magnum impinge violently against the pons and upper medulla; while during the second phase, by virtue of a *contre-coup*, the medulla bounces back against the occipital bone and the posterior edge of the foramen magnum. Gonzales *et al.* described this double impact as "oscillation" of the brain.

The investigations made by Larsson *et al.* (1954), though not conclusive, are rather against any theory that a drop in blood pressure is the *modus operandi* of the knock-out, suggesting that the factors responsible are essentially concussive in type.

Other hypotheses about the cause of the knock-out include that of Flint (1920), who imagined that a distortion of the jaw mechanically impinges upon the carotid artery and so produces a temporary cerebral anaemia. Pfeiffer (1922) implicated a mechanical and short-lived obstruction of the jugular vein.

Amnesias due to Boxing

Just as different types of knock-out can be isolated, so too one can identify a number of different types of amnesia or loss of memory in association with boxing. Thus there may be a period of retrograde amnesia immediately preceding the spell of unconsciousness due to a knock-out. Sometimes there is a more lengthy period of retrograde amnesia, so that the boxer afterwards has no recollection whatsoever of any events of that particular contest. Indeed, he may not be able to remember that the fight even began. This amnesia is of course permanent. Then there are the anterograde amnesias where the pugilist goes on fighting after a knock-out, but without subsequent recollection thereof. This is the groggy-state automatism. Quite independent, of course, is the gross day-to-day memory-defect of the dementing punch-drunk victim. These phenomena are described below.

Other Injuries from Boxing

It does not come within my province to describe in detail the various surgical injuries which have been reported as consequent upon amateur or professional boxing. Some of them are admittedly quite rare, such as ruptured muscles, fractured arm, arteriovenous aneurysm, direct damage to a single nerve—for example, the facial nerve or the long thoracic nerve of Bell (the "commotio nervi" of Jokl). Quite unspecific is the occurrence of bouts of vomiting ("athlete's sickness") which may follow any violent physical exertion. Other injuries are so commonplace as to constitute the ordinary occupational marks of an experienced pugilist. Here belong such physical signs as the cauliflower ear, the flattened nose, hypertrophied superciliary ridges, and arthritis of the first metacarpo-phalangeal joint.

Injuries to the eyes are much more serious and more variegated in character. They have been well described by Doggart (1951, 1955) in this country and by Favory and Sédan (1951) in France. Just how common they are in the course of a boxing career has not been made clear. Among the injuries listed by Doggart are, first, damage to the outer eye. Here belong trauma to the conjunctiva and to the cornea, folding or rupture of Descemet's membrane, and scleral rupture. Secondly, a great diversity of lesions of the inner eye may occur. These include tears of the iris, perhaps involving the sphincter muscle of the pupil. Persistent hypotony may result from lesions of the ciliary body. Chronic iridocyclitis may develop, and go on to a phthisis bulbi. Accommodation may be paralysed. The lens of the eye

may be subluxated or dislocated. Cataract is not uncommon. Haemorrhage into the vitreous may take place, and, though it often resolves satisfactorily, it may lead to a retinitis proliferans. Retinal detachment, which may be bilateral, is a disastrous complication, for it is only rarely amenable to surgery. Cystic and pigmentary changes at the macula and retinal or choroidal haemorrhages may also occur.

Doggart draws special attention to irregular patchy choroidal degeneration in boxers, a feature which he speaks of as "cauliflower choroids." Optic atrophy, avulsion of the optic nerve, haemorrhage into the nerve sheath, and recurrent congestive glaucoma are among some of the other disastrous sequelae that have been described as due to boxing injuries. Doggart finally enumerates injury to the neighbouring structures: fractures of the orbit, periosteal thickening, orbital emphysema, damage to the lacrimal gland or duct. Implication of any of the ocular muscles may occur, especially the superior and inferior obliques.

Boxing Fatalities

Injuries sustained in the ring have ended fatally. Just how the recorded figures strike one depends mainly upon the prejudices and emotions of the reader. Thus, Blonstein and Clarke (1954) have spoken of six deaths over the course of seven years' experience—all in the course of amateur boxing. Kaplan and Browder (1954) have had 26 years' medical experience of the professional ring and have assisted at the necropsy study of five cases. Jokl (1941) went into the published statistics in some detail. He said that Flint (1920) had stated that 124 fatal cases had been recorded up to that time. Since then Jokl had been able to collect another 41 cases between 1920 and 1938. According to Steinhaus (1950b), in the four years prior to 1950 42 professional boxers and 22 amateurs had died from occupational injuries. While the total to the end of 1956 is uncertain, we can say that, up to 1950, at least 207 fatalities had been recorded.

Most of the deaths were due to subdural haemorrhage; some to intracerebral bleeding. At times a heavy fall on the back of the head in the ring was held responsible, rather than blows to the face by a gloved fist. In some cases necropsy demonstrated an innate and unsuspected thinness of the cranial bones. The youthful age of some of the victims is striking—for example, 16 years (case of John Shoddy, 1951); 15 years (Weimann, 1931; Berg, 1933; Kappi, 1938), and 13 years (case of David Zimmerman, 1951). Quite a number of these fatalities had occurred in amateurs and not professionals. In some of them, death had occurred from a blow struck in the first round of a contest.

Besides these deaths from haemorrhage, there are the rarer cases of "reflex death" and "fatal commotio" which may or may not be associated with status thymolymphaticus.

The Punch-drunk State

To a neurologist the chief interest centres in those experienced boxers, whether amateurs or professionals, who have undergone gradual physical and mental deterioration as a direct accumulated result of their careers. This is the condition popularly termed punch-drunkness. We do not know who it was first coined the term "punch-drunk." Probably it was a layman. Its introduction into the medical literature dates from the paper by Martland in 1928. Since that time it has established itself in medical terminology, and a not inconsiderable literature has developed. The term has also become well known to the laity, and in sporting circles certain pejorative—almost derisory—connotations have become attached both to this particular word and to its synonyms "punchie," "goofy," "slug-nutty," "paper dolls," "stumble-bum," and "slap-happy." For such reasons attempts have been made to introduce a more esoteric and less offensive expression. Thus we have "traumatic encephalopathy" (Parker); "traumatic encephalitis" (Ravina); "dementia pugilistica" (Millsbaugh); "chronic brain injury after boxing" (Bøje). If we really require a suitable scientific alternative to "punch-drunkness" we may perhaps adopt the

term "chronic progressive traumatic encephalopathy of boxers."

Up to date, my own neurological experience has comprised a series of 69 cases of chronic neurological disease in boxers. Many of these—perhaps the great majority—should be looked upon as examples of punch-drunkness, either early or well established. In only a comparatively few cases does legitimate doubt occur about the possibility of there being some coincidental and non-related nervous or mental disease—for example, epilepsy; psychopathy; presenile dementia; cerebral arteriopathy.

The details of the boxing careers in punch-drunk patients are significant. Punch-drunkness is much commoner among professionals than among amateurs. It is commoner in second-rate or third-rate performers than in the intelligent scientific exponent with a championship title. It is very rare in coloured boxers. As fighters, the punch-drunk ex-pugilists have been slow on their feet rather than nimble, and notorious as being able to "take it." They can perhaps be looked upon as "sluggers" rather than scientific boxers. Punch-drunk states have been found in fighters of all weights, but most characteristically in small men who had not been particular about the size of their opponents, having often taken on contestants heavier than themselves. There is a correlation between the degree of cranio-facial marking and the intensity of the punch-drunk syndrome. The sum total of contests is important, as well as the number of occasions upon which the boxers have been rendered unconscious. Being "knocked out on the feet" is perhaps just as significant as being floored.

Of special aetiological importance is that humbler side of boxing where the contestant travels in fairs in the boxing-booth (or "blood-tub"), taking on all-comers at any weight. Almost as characteristic is the story of the boxer who eventually gives up the ring, having failed to make the grade, later to become what they call a "punch-bag"—that is, one of a team of sparring partners to a first-class heavyweight. A typical story is that the boxer, after a promising early career in the ring, begins to slow up; to be knocked out more often; to win fewer contests; and to be seedy for increasingly longer periods after each affray. Most characteristic of all is the admission on the part of the boxer that he finally abandoned the ring because of his wife's increasing disapproval of his career.

The symptoms and signs of a punch-drunk state are variegated, but there are certain clinical features which underlie all the diverse patterns of the disease. As a rule, gradual evolution of mental and physical anomalies marks the insidious onset of the encephalopathy. Among mental symptoms there is the slow appearance of a fatuous or euphoric dementia with emotional lability. The victim displays but little insight into his deterioration. Speech and thought become progressively slower. Memory deteriorates considerably. In Service experience there is a falling-off both in efficiency and in conduct. There may be mood-swings, intense irritability, and sometimes truculence leading to uninhibited violent behaviour. Simple fatuous cheerfulness is, however, the commonest prevailing mood, though sometimes there is depression with a paranoid colouring.

From the clinical standpoint, the neurologist may encounter almost any combination of pyramidal, extra-pyramidal, and cerebellar signs. Tremor and dysarthria are two of the commonest findings. In an earlier paper upon this topic (Critchmore, 1949) three or four commonly recurring syndromes lay within the punch-drunk state were enumerated. Thus one could isolate a syndrome reminiscent of general paralysis; and another which closely resembled disseminated sclerosis; and a third where differentiation was necessary from a frontal lobe tumour. This paper was mainly based upon wartime experience. Since the war one has been impressed with the frequency, in civilian practice, of types of punch-drunkness in which pallid and striatal defects are conspicuous. Here the clinical combination of a mask-like face, slurred monotonous speech, extrapyramidal rigidity, and tremors of the

arms and head constitutes a syndrome which superficially resembles a post-encephalitic Parkinsonian state.

The foregoing constitute the clinical findings in cases of punch-drunkness. The victim, as a matter of fact, may spontaneously admit to but few disabilities, if any at all. Here, then, is evidence both of the insidious development of the encephalopathy and of the lack of awareness so characteristic of the dementing patient. He may, however, complain of such symptoms as persistent dull headache, postural dizziness, deafness, poor vision, intolerance towards alcohol, unsteady gait, and shakiness. Very occasionally periodic convulsive seizures bring the victim to the doctor. In Service medicine the punch-drunk victim is often identified quite early for other reasons—namely, in his role as a persistent offender. Delinquency therefore may be the evidence of a rapidly changing personality, associated with progressive brain damage.

Illustrative Cases of the Punch-drunk State

The following clinical notes illustrate some of the characteristics of traumatic progressive encephalopathy in boxers.

Case 1: A Punch-drunk Syndrome reminiscent of a Frontal-lobe Tumour.—A professional heavyweight who had been sparring partner to Walter Neusel, Tommy Farr, Eddie Phillips, Max Baer, Jack Hyams, and others gave his story with extreme slowness, and some dysarthria. His actual words were, "I can't think properly and I can't remember things; my speech has been getting bad for 18 months, and for the past two weeks it has been playing hell with me. I can't talk any quicker than I am now. My head goes blank at times. I get pain over my left eye nearly every morning when I wake, but if I rest it goes away, but I feel thick-headed all day long. I get dizzy but I've never lost my senses. The left ear is a bit deaf, and the sight isn't good in the left eye. I can't give my mind to reading; it makes my head worse, I just look at the illustrations."

Case 2: Incipient Punch-drunk Disability in a First-class Heavyweight.—This boxer, who was always liable to headaches after each contest, had found them more persistent in the last few months. It was noticed by others that he was becoming a little slower, and the speech somewhat thick. On the occasion of his last contest he was knocked out, and headaches thereafter became troublesome. Although the patient maintained that he felt well, he was noticeably dysarthric and slow in cerebration. There was a strong suspicion here of an early punch-drunkness and he was advised to rest. In this view the British Boxing Board of Control concurred, but the U.S. authorities dissented. They insisted on his fulfilling his American contracts, but thereafter he rapidly deteriorated both medically and professionally, and the diagnosis of punch-drunkness was ultimately agreed upon.

Case 3: Mild Case of Punch-drunkness with Dementia, Euphoria, and Dysarthria.—This man, aged 61, had fought as a professional lightweight between 1910 and 1926. He became flyweight champion of Essex. Later he went to seed and took on various female boxers, including Madame Carpentier, the world's champion lady boxer. When examined he was complaining of poor powers of concentration and forgetfulness. He would lose the thread in his conversation and had to rely on written memoranda. His mood was extremely euphoric and his speech grossly dysarthric. There was a traumatic arthritis of his thumb-joint with evidence of an old fracture. The E.E.G. was flat. The patient asserted that he would never allow his children to box, and said that "it ought to be stopped."

Case 4: Isolated Convulsive Seizure in a Professional Boxer.—? Epilepsy. ? Early Punch-drunkness.—A man aged 23, who had been a professional lightweight for about four years, had been knocked out only once. Recently, while flying from South Africa, he began to vomit in the aircraft and then lost consciousness and became convulsed. Clinical examination was negative, but the E.E.G. was abnormal, with bilateral synchronous rhythmic slow-wave

discharges suggestive of idiopathic epilepsy. He was advised not to fulfil his engagement to fight the following week; but this warning was not heeded.

Case 5: Delinquency associated with Early Punch-drunkness.—A naval rating aged 29 was sent to the medical officer with the following report from the regulating petty officer: "He has been adrift for two and a half hours . . . he has lost his respirator in a pub. When spoken to, he belched offensively and without regard. He is a general nuisance, not intelligent, a bad influence. In short, he is evil." When asked what symptoms he complained of, he hooted with laughter and said in a grossly dysarthric fashion, "I've been adrift." Inquiry revealed that he had taken up boxing at 13 and that he had turned professional. He believed he had won about three-quarters of his 300-odd fights. Latterly, after some of his longer fights, he would be groggy and complain of misty vision.

Case 6: Gross Delinquency in a possible mild case of Punch-drunkness.—A featherweight professional boxer aged 27, at one time sparring partner to Seaman Watson, was seen in 1942. In 1937 he had been charged with inflicting grievous bodily harm, but was acquitted. He entered the Service in 1940, and promptly went adrift for 24 hours and then deserted for 14 days. After serving 90 days' detention he almost at once deserted for 21 days. Later he deserted a third time, and was convicted of theft, going to gaol for three months. Thereafter he deserted for seven weeks and married a woman he had met the day previously. He left her immediately after the ceremony and never saw her again. Since then he was charged with a fourth term of desertion. His medical state comprised: headache, poor memory, a tendency towards losing himself in familiar environments, depression, and intolerance towards alcohol.

Case 7: Recurrent Attacks of Hysterical Blindness associated with a Punch-drunk State.—A former bantam-weight champion of Wales and of the West of England aged 27 had been knocked out some 60 times in all. He gave up the ring in 1938 after a fight on account of failing eyesight and hearing. The first attacks of blindness followed a vitriol-throwing incident when he tried to rescue a prostitute from some low joint. He had met her a few days before and had, he thought, persuaded her to go straight, and had given her her fare home. Another attack of blindness took place when he narrowly escaped being run down by a lorry. He suddenly lost his eyesight once again in the naval barracks, and he was examined two weeks later in the R.N. Hospital, Chatham, showing all the dramatic characteristics of a case of hysterical blindness. His vision suddenly returned, but it disappeared once again when he received an anonymous letter impugning the fidelity of his wife.

Case 8: Striatal Type of Punch-drunk Syndrome.—This man, aged 27, began to box at the age of 16 and turned professional. He fought about 200 contests as a bantam-weight, sometimes two or three times a week. Later he appeared in boxing booths, for it was becoming increasingly obvious to him that he was deteriorating. About this time—that is, when aged 27 years—he was rejected at the recruiting office, and he realized then that his sight was poor and that his gait was unsteady. Three months later his hands became tremulous. His symptoms increased up to a point and then remained stationary. On examination he was found to be slightly forgetful. He had a nasal type of dysarthria, his face was expressionless, and he tended to dribble. He had a tremor of the outstretched hands, some increase in muscle tonus, and slight but definite ataxia. Tendon-jerks were increased and there was a right extensor response. The gait was titubant, short-stepped, and stiff.

Case 9: Cerebellar Type of Punch-drunkness, reminiscent of Disseminated Sclerosis.—This man, aged 37, was a professional boxer between the ages of 21 and 31. Successful at first as a lightweight, he deteriorated and took on opponents out of his weight class. He did not think he came to much harm until a particular fight in the Albert Hall when—being distracted by a spectator calling out his name—he was knocked down. He got up after a short count and was floored a second time. This state of affairs

went on again and again, and though he finished the fight he subsequently remembered very little of what happened. His symptoms consisted of progressively increasing tremor and clumsiness of the right upper limb. Examination revealed a slight dysarthria, bilateral intention tremor, increased tendon-jerks, but flexor plantar responses. Appropriate tests brought to light a mild degree of intellectual deterioration.

Case 10: Striato-cerebellar Type of Punch-drunkness.—A professional welterweight, aged 27, whose record had gradually deteriorated, had been knocked out three times. In 1948 (aged 24) after losing his temper with his fiancée, he started to tremble all over. This subsided except in the left hand, where the tremor persisted with increasing amplitude. After six months it involved the head, and his leg began to drag. His articulation altered. Examination revealed a fine tremor of the head, which was held in a curious retracted posture. The speech was dysarthric and staccato. On the left side there was an unusual type of intention tremor, associated with dysidiadochokinesis. The gait showed a steppage abnormality of the left leg. Both plantar responses were extensor in type.

Case 11: Cerebellar Type of Punch-drunkness in an Amateur Boxer.—A man aged 39, who had been four times schoolboy champion of Great Britain, began to develop tremor of the arm during the war, on which account he was invalided from the Army. His symptoms increased slightly and he showed an impassive, rather mask-like face; marked dysarthria; titubation of the head, with some hypertrophy of the muscles of the neck; incoordination of the arms and legs, more so on the left; with intention tremor and dysidiadochokinesis. Originally of superior intelligence, he later showed both an intellectual falling-off and a curious alteration in personality.

Traumatic Encephalopathy

The interval between the onset of a boxing career and the onset of punch-drunk manifestation is often difficult to gauge precisely, but it is usually a matter of years. In an earlier paper (Critchley, 1949) it was stated that in the case of 21 punch-drunk naval patients the interval between the taking-up of a boxing career and the development of neurological symptoms or signs averaged 16 years, with extremes of 6 and 40 years. Of great interest, pathological as well as practical, is the fact that this traumatic encephalopathy is a progressive condition. Once established it not only does not permit of reversibility, but it ordinarily advances steadily. This is the case even though the boxer has retired from the ring and repeated cranial traumata are at an end.

Neurologists have visualized this state of chronic traumatic encephalopathy as being based upon multiple minor cerebral contusions, possibly with initial pinpoint haemorrhages later replaced by a gliosis, cortical atrophy, and internal hydrocephalus. It is a matter of surprise that actual pathological verification should have been so dilatory in its appearance. At the time of the publication of my earlier paper on the punch-drunk syndromes—namely, in 1949—no necropsy material was available. Since that date there has been a report of a single case of punch-drunkness with thorough pathological study (Brandenburg and Hallervorden, 1954). The outstanding findings consisted in a rich profusion of "senile" plaques scattered throughout the shrunken cortex, especially in the frontal lobes. Although the patient was only 51 years of age at the time of death, the histological picture was that of senile dementia, or, alternatively, of an Alzheimer psychosis.

Special *in vivo* investigations of cases of punch-drunkness may indicate the existence of a cerebral atrophy. Air-studies are of particular merit here in that they may demonstrate an atrophic process, especially of the frontal lobes, with corresponding shrinkage of the white matter. Electroencephalography has been widely practised of late in cases of punch-drunkness. The findings have mainly revealed a non-specific type of disordered cortical rhythm, indicative merely of an atrophic process.

This particular method of investigation is of importance in that it might conceivably prove to be a more delicate index of cerebral dysfunction than clinical study. It might lend itself to a screening procedure. By submitting boxers to this test, before a contest and after a contest with or without a knock-out episode, information of value might perhaps be forthcoming. The test could furthermore be applied to experienced pugilists of all types—that is to say, those who proclaim themselves entirely fit and who display no mental or physical deterioration, as well as those who show symptoms or signs of incipient or advanced encephalopathy. A certain amount of electroencephalographic evidence is already to hand.

Although E.E.G.s were carried out on a number of my Royal Naval cases of punch-drunkness during the war, the literature on this particular topic starts with the paper by Guillain, Sévileano, and Fandré (1948), who observed pathological E.E.G. records in two cases. Thereafter the literature contains many references to electroencephalographic data in boxers. Though of interest, and not without promise of ultimately affording diagnostic assistance, much of the available material is contradictory (Titeca, 1952; Busse and Silverman, 1952; Temmes and Huhmar, 1952; Taylor, 1953; Marquardsen, 1954; Larsson *et al.*, 1954; Kaplan and Browder, 1954; Blonstein and Clarke, 1954; Kampus and Grote, 1956).

From one's personal experience, taken in conjunction with the published evidence, the electroencephalographic aspects of the boxing problem can perhaps be summed up by saying that: (1) minor non-specific anomalies are common in the records of experienced boxers; (2) such findings are commoner and often more intense in cases of punch-drunkness; but, (3) the E.E.G. record is at the present time a less sensitive index of punch-drunkness than is the clinical evidence, for symptoms and signs may be present at a time when the E.E.G. records are within the limits of normality; and (4) a return to a normal state in a series of E.E.G. records taken in a particular patient cannot be regarded as a *restitutio ad integrum*, whether physiological, anatomical, or clinical.

"Groggy States"

Intermediate between the knock-out (the most acute manifestation of cerebral dysfunction among boxing injuries) and the punch-drunk state (the most chronic among the disorders) is a condition which is referred to in lay terms as the "groggy state." Here, as the result of severe battering sustained during a particular contest, the victim develops a mental confusion with subsequent amnesia, together with an impairment in the speed and accuracy of the motor skill represented by the act of boxing. The affected pugilist may continue to fight, but in an "automatic fashion," to use a lay expression again. The constellation of movements needed for defence and attack takes place at a more inferior level of consciousness, without there being a vigilant awareness of each muscular movement. Unlike many motor skills—for example, driving a car, typing, playing a musical instrument—the motor pattern of a pugilist in the ring depends upon imponderable circumstances—that is, the actions of the opponent. Consequently the movements cannot be carried out with full efficiency unless awareness is intact. Each movement is much more a willed deliberate volitional act than, say, in the case of a skilled typist or pianist, who can go through a set repertoire of actions while thinking and talking of something quite different.

In the groggy state this process of active attention is at fault, with resulting falling-off in the quality of performance, more especially in attack.

Even to an unpractised eye it may be obvious that the patient in a groggy state is making feeble and uncoordinated movements, that his limbs are ataxic, and that he is inefficient and vulnerable. He is, as they say, "out on his feet." At this point the referee may stop the fight. The victim may remain indisposed for the next few days, with headaches, postural dizziness, and imbalance. During this time

he may be morose and taciturn, muddled regarding recent events, and perhaps tremulous and dysarthric. This condition passes, and the boxer ordinarily returns to his *status quo ante*. It is arguable, however, that he has suffered a certain cerebral affront, for one groggy state is apt to follow another with succeeding contests. The suggestion, indeed, that an accumulation of groggy states leads to a permanent punch-drunk clinical picture is not to be considered far-fetched. Perhaps, then, we could translate the layman's term "groggy state" into "remitting commotio cerebri."

Illustrative Cases of the Groggy State

The following case notes illustrate the increasing grogginess which may follow a particular contest or series of contests.

Case 12.—This man would feel groggy for days after each contest, with his eyesight getting worse temporarily each time. He had particular difficulty in judging distances. This is why he eventually packed up boxing.

Case 13.—"I seemed to go dead, and not to feel the punches. It would now take me two or three days to get over each fight." (Ex-welterweight champion of the West of England.)

Case 14. Latterly he took longer and longer to recover from each fight, because of headaches, defective memory, and impaired speech. His wife did not approve of his boxing and persuaded him to give it up. (Ex-lightweight professional boxer with punch-drunkness in which headaches and irritability were conspicuous.)

Case 15.—A former welterweight champion of Lincolnshire, aged 30, used to recover from his contests promptly and has even boxed on two consecutive days. Latterly he would remain stiff for some days after each contest. After two years his record deteriorated, especially when he got to London, where he found the style of boxing was different, with more "in-fighting." He stopped boxing for four years, but took it up again when he joined the Navy. In his last contest he went down several times in the fourth round, but he finished the fight "not feeling right" . . . his "limbs felt like rubber" and he complained of a thick head and a sore neck, and he could not sleep. Early morning headaches followed, with severe postural giddiness, irritability, tearfulness, poor memory, fatigue, and lack of interest. Examination brought out that his emotivity and a gross dysarthria were evident.

Case 16.—A man aged 29, never quick on his feet, he could always "take it," and ordinarily "did twelves" (as he put it when questioned on the length of the contests he fought). He packed it up because of his headaches. After one fight he became so unsteady on his legs that he was accused of being drunk. Towards the end of his boxing career he would feel queer for about a week after each fight.

Case 17.—A man aged 28; two weeks before entering hospital he staggered so much in the ring that the audience howled him down and the promoter declared him drunk. In hospital he presented a picture somewhat resembling disseminated sclerosis. Three weeks after his discharge from hospital he fought Paolino in Paris for the heavyweight championship of Europe (this was in 1932), but he was knocked out at the first blow and the crowd stormed the ring.

Case 18.—This man, aged 25, had been four times middleweight champion of Wales and sparring partner to Jack Petersen and to Len Harvey. About six months before coming into hospital he received some blows from Jack Petersen. He had to fight again two days later, but gave up after three rounds because of weakness in his arms. His next fight was a fortnight later; he gave up after the second round because of weakness and tremulousness of his limbs. His manager thought he was drunk. A doctor told him never to box again. He seemed to improve after a month's convalescence in Swansea, but, still being unsteady, he went into the National Hospital, where he was found to be punch-drunk.

Case 19.—A heavyweight aged 31 was knocked out "through the ropes" in 1945 and was dazed for the next 24 hours. The right leg was found to be weak immediately after his fight and continued so. Within the day or two following this same fight his right hand began to shake: the left hand started to tremble some six months later. He was hospitalized seven years later, a typical severe punch-drunk.

Case 20.—A delinquent mild punch-drunk, interviewed in prison, gave up boxing at the age of 20 because he was not feeling himself. He felt drunk although he had taken nothing in the way of alcohol: his head would be in a swim after each fight.

Case 21.—A Royal Navy welterweight, aged 22, matched against a tougher opponent, was struck heavily over the heart in the second round, causing him to feel dizzy or groggy. Shortly after he got a severe blow to the side of the head, flooring him for a count of nine, when he rose and resumed the fight. He could remember vividly every incident up till then; but after that his memory was a blank. Apparently he finished the second round, and in the third round he received heavy punishment, being knocked down 10 times, striking his head on the floor more than once. His next recollection is being on the deck of his ship about an hour later, feeling dizzy and sore about the stomach. Two weeks later he became ill with headaches, vertigo, and vomiting, and was hospitalized. Investigation showed old blood-staining of the C.S.F.

Conclusions

There is much in boxing to interest a practising neurologist, and special attention should be focused upon (1) the phenomenon of groggy states as occurring during or after a contest, and (2) the condition known as traumatic progressive encephalopathy (or punch-drunkness).

Owing to the extreme paucity of pathological data, it is highly desirable that opportunity should be afforded neuropathologists of studying the appearances in the brain of punch-drunk patients.

There is a scope for further study of boxers by electroencephalographic as well as clinical techniques, at all stages: that is, early as well as late in their careers; and before and immediately after a contest, especially if a knock-out has occurred.

For permission to quote the naval cases I am grateful to the Medical Director-General of the Royal Navy.

FURTHER OBSERVATIONS ON THE MEDICAL ASPECTS OF AMATEUR BOXING

BY

J. L. BLONSTEIN, M.R.C.S., L.R.C.P.

Honorary Medical Officer to the Amateur Boxing Association

AND

EDWIN CLARKE, M.D., M.R.C.P.

Lecturer in Neurology, Postgraduate Medical School of London

The medical aspects of boxing continue to attract attention in both the medical and the lay press. Recent attacks on the sport (Duggart, 1955; Summerskill, 1956) have aroused further controversy, and the reports of death (Rottgen, 1955; Pampus and Müller, 1956; Müller, 1956) and of possible brain damage (Taylor, 1953; Geller, 1953; La Cava, 1954; Brandenburg and Hallervorden, 1954; Soeder and Arndt, 1954; Pampus and Grote, 1956) repeatedly raise the question of the advisability of allowing youths to indulge in what would appear to be a dangerous and unjustifiable recreation. We therefore thought it worth while to review the boxing injuries, especially those to the head, encountered in the London Amateur Boxing Association contests during the past season, as an extension of a previous report (Blonstein and Clarke, 1954).

Material

During the period of seven months (October, 1955, to April, 1956, inclusive) there were approximately 300 tournaments representing about 3,000 boxing contests under the control of the London Amateur Boxing Association, and these involved almost 5,000 boxers. According to the medical welfare scheme instituted two years ago (Blonstein and Clarke, 1954), all contestants who have been concussed or have suffered lengthy amnesia are rested for at least one month, the exact period depending upon the estimated severity of the injury. It was therefore possible to trace with ease all the boxers who had been knocked out during the season. Those who had been more severely concussed or who had been knocked out more than once were selected for special study. There were 29, and their ages ranged from 17 to 26 years; 23 had been knocked out twice and 6 had been severely concussed on one occasion.

Method

First an attempt was made to classify the boxers according to the severity of their injury, as judged by events in the ring. The following groups could be identified.

Group I: "Out on the Feet."—Following a head blow the boxer was unable to defend himself, was obviously dazed, and staggered about the ring or rested on the ropes.

Group II: Mild Knock-out.—Those who were knocked down and could not rise before the count of 10, but who, although dazed, were not unconscious for more than a few seconds.

Group III: Moderately Severe Knock-out.—Those rendered unconscious, and carried to their corner, where they quickly recovered.

Group IV: Severe Knock-out.—Those remaining unconscious for periods greater than Group III.

This classification accounted for only 26 of the 29 cases, for at times there was a disparity between the observed actions of boxers and the amnesia estimated subsequently.

As the behaviour of the boxer in the ring is obviously of considerable importance, a grouping based on this rather than total traumatic amnesia alone was selected. Both, however, were recorded in every instance.

Each of the 29 boxers was given a careful neurological examination after the responsible contests, and an electroencephalogram (E.E.G.) was carried out. Seven had the E.E.G. within two weeks of the knock-out and 22 had it three to four weeks afterwards. The difficulties in arranging this examination for amateur boxers have been discussed previously (Blonstein and Clarke, 1954); a recording immediately after a bout was never practicable.

Results

The 29 boxers represented 0.58% of all boxers active during the 1955-6 season, so that, roughly speaking, in each 100 contests there was one such person involved. Their distribution according to weight was: heavyweight, 4; light heavyweight, 7; middleweight, 5; light middleweight, 4; welterweight, 2; light welterweight, 3; lightweight, 1; featherweight, 1; bantamweight, 1; flyweight, 1.

As would be expected, the boxer's weight varied directly with the frequency and severity of knock-outs. The grouping relative to the severity of the knock-out in 26 cases was: group I, 6 cases; group II, 7 cases; group III, 7 cases; and group IV, 6 cases.

In these youths the central nervous system was normal when examined soon after the head injury and no E.E.G. abnormalities were detected in any of them.

The three cases that could not be included in the suggested classification are described individually because they illustrate some of the varieties of memory loss encountered.

Amnesia may occur without an obvious knock-out. One boxer completed his bout and was given the decision on points, but in the dressing-room he complained of headache and had amnesia for the whole contest and its sequelae. On examination the left pupil was larger than the right, but the nervous system was otherwise normal. He had received several blows to the jaw, but had not fallen, and his condition during the contest had given rise to no comments or anxiety, despite the fact that he had no memory of events in the ring. His E.E.G. was normal, but he was not allowed to box for one month. This case points out the disparity that may exist between the boxer's behaviour and his subsequent amnesia.

Sometimes the head blows may be trivial but the combined amnesia (retrograde and post-traumatic) may be disproportionately large. In the second case, a youth who was unconscious for only a few seconds during his contest was confused and forgetful the next day. Instead of going to his usual place of work he travelled to a different town. The nervous system and E.E.G. were normal. There is reason to believe that his lengthy amnesia was in part "functional" in origin.

A delayed loss of consciousness has been observed, and in the following case it closely resembles that described by Denny-Brown (1941). A boy was "out on his feet" at the end of the first round and the contest was stopped. He complained of double vision on looking to the left, but had a shower and his refreshments. About half an hour later he became unconscious and was removed to hospital, where he regained consciousness 12 hours later. There were no abnormal neurological signs and the E.E.G. was normal. This boy made a complete recovery, but has been advised to give up boxing permanently.

The E.E.G. was therefore normal in each of the 29 boxers and the neurological abnormalities were extremely few. If loss of memory alone in the 26 cases is considered without reference to the suggested grouping, three youths had retrograde amnesia of up to one hour and in seven the post-traumatic amnesia lasted from half an hour to three hours. The maximum period of unconsciousness, however, was half an hour.

During the 1955-6 season there were no skull fractures, and injuries elsewhere in the body were few. One boxer suffered a spontaneous pneumothorax, another fractured a fibula, and there were 11 cases of fractured metacarpals. Cuts of the supraorbital ridges and cheeks occurred approximately twice in every tournament; not a single case of fractured nose or serious eye injury has been reported.

Discussion

Medical control of boxing, both amateur and professional, is of vital importance if the sport is to continue, and recent reports indicate the prophylactic measures used or suggested in various countries (Labignette, 1954, in France; Egan, 1954, in the U.S.A. (see also Ferlino, 1952); Schwarz, 1955, in East Germany; Henner, 1955, in Czechoslovakia; Graham, 1955, in Great Britain; Medved, 1955, in Yugoslavia). We are concerned here with the amateur boxer only, and it is obvious that youths at school, at work, or in the armed Forces who are indulging in the sport as a pastime rather than as a profession must be given the maximum of protection; an impeccable medical service is therefore mandatory.

We have described elsewhere the scheme adopted by the London Amateur Boxing Association (Blonstein and Clarke, 1954), and it would appear from a survey of a season's boxing that damage to the brain, claimed to be severe by most opponents of the sport, may not be a serious objection when medical supervision is adequate. By clinical and electroencephalographic means we have detected no acute or subacute disabilities resulting from boxing blows to the head, and injuries elsewhere in the body on the whole have been few. A survey of casualties in other sport over a similar period of time would be of interest; it seems that in New York, for example, it is more dangerous to play baseball or football than to box (Gonzales, 1951).

That deleterious cerebral changes may occur in amateurs after an interval is a possibility that has by no means been excluded by this study. There have been allegations that it is inevitable; but there is in fact very little, if any, evidence to support them. There is probably more to indicate the reverse. Thus in our experience the "punch-drunk" syndrome has never been observed in amateur boxers (Blonstein and Clarke, 1954), and, furthermore, there are many men in the various professions who, although keen amateur boxers in their youth, have demonstrated by their careers that a cerebral deficit has not ensued. However, a follow-up over a long period of time has not yet been carried out in either professional or amateur boxers, so that the precise frequency of the "punch-drunk" state is unknown. On the whole it seems that the much-publicized pugilist's dementia is in amateur boxers as unlikely as the deleterious effects of "athlete's heart" in non-professional athletes.

The popular concept that each major head blow produces a petechial haemorrhage in the boxer's brain has been fostered by Martland (1928), who was one of the first medical observers to describe the "punch-drunk" syndrome. But, as Kaplan and Browder (1954) have pointed out, there is no pathological verification of this. Evidence from animal investigations (Windle, Groat, and Fox, 1944), however, suggests that a blow sufficient to induce unconsciousness, as well as heavy blows that do not, will produce histological changes in the form of cell death. It follows that if these changes take place in the human brain, repeated stimuli of the same nature will eventually bring about clinically detectable brain degeneration such as that seen in the professional pugilist after a long and misguided career (Brandenburg and Hallervorden, 1954); that a very severe closed head injury in man will produce white-matter degeneration has recently been shown by Strich (1956).

So far as the present considerations are concerned there are two objections to this assumption. In the first place, the juvenile brain, like any other young organ, can presumably adapt itself to the small amount of cell loss, if this in fact takes place. The second point is the more

important, because if there is a strict medical control of amateur boxers the possibility of extensive and repeated neuronal destruction will not exist and the argument indicting boxing on account of the cerebral end-results will therefore be groundless and unnecessary. Thus according to the London Amateur Boxing Association laws, boxers who are repeatedly knocked out, who suffer lengthy amnesias on several occasions, or who are severely concussed are excluded from further contests.

There is another aspect of the medical service, and this is to explore all possible measures that will help to safeguard the non-professional boxer. As well as our report on the use of the E.E.G. as a prophylactic aid, other authors have published their results (Ardito, 1954; Soeder and Arndt, 1954; Larsson *et al.*, 1954; Medved, 1955; Pampus and Grote, 1956). Kaplan and Browder (1954) made an extensive study of professional boxers, and they, like most other authors and ourselves, found little or no evidence of permanent brain changes. Records taken soon after a bout in which the boxer received a lot of head blows were usually normal, and a few men who were followed for up to three years whilst boxing regularly developed no E.E.G. abnormality. Permanent cerebral deficits, although they no doubt occur, seem to be very difficult to detect by the methods of investigation at present available, and are in any case probably rare. Kaplan and Browder (1954), when evaluating the relative merits of the information obtained from these investigations, arrange them in the following order of usefulness: past medical history, physical fitness, past boxing performances, and finally the E.E.G. With this we would agree, and it is obvious that a decision concerning a boy's boxing future can be reached only by considering all the available evidence.

At the moment, all the possible information concerning boxing head blows must be amassed, and observations on the amnesia of the concussed boxer is of considerable importance. The retrograde and post-traumatic memory losses are both indications of the severity of the blow (Russell and Nathan, 1946), but they must be assessed with reference to events observed by onlookers. Thus, a lengthy amnesia without the external appearances of loss of consciousness should be considered equivalent to a state where the boxer is obviously unconscious.

The grading of head blows received in the ring is not easy, and we have attempted to provide a classification that seems to include most cases of concussion. It is possible that as we acquire more knowledge some modification may be necessary, but at the moment the recording of both objective and subjective information is justified.

Much more information on boxing amnesia, however, is required, and, as well as the immediate retrograde type, the behaviour of more distant pre-traumatic memories may be important (Williams and Zangwill, 1952). It seems possible that assessment of the total traumatic amnesia will be more important than the neurological examination, the E.E.G., or other tests in detecting the first signs of the deleterious effects of boxing upon the brain—if such will ever result from amateur boxing.

The increase of medical interest in amateur boxing that is evident all over the world is of considerable importance. It is helping to eradicate the prejudices and misconceptions that dominate most discussions on the subject. At the same time, it will improve and popularize the medical welfare of youths who indulge in boxing as a recreation and in particular will protect them from chronic cerebral damage, if this can be proved to be a consequence of amateur boxing. The medical problems of the amateurs are under constant review and new knowledge acquired from the sport or from elsewhere will be made use of where appropriate.

With regard to the more fundamental objections to boxing as a sport, we have nothing to add to previous statements (Blonstein and Clarke, 1954), except to comment upon the interesting fact that the emotions said to be displayed in the ring and condemned by the opponents of boxing are often evident in their belligerent verbosity.

Summary

Boxing injuries encountered in 3,000 London Amateur Boxing Association contests during 1955-6 are assessed.

Only 29 boxers (0.58%) were severely concussed or knocked out more than once. The results of neurological and electroencephalographic examinations were normal in all. Other injuries were very few.

A classification of boxing head injuries is suggested and the importance of traumatic amnesia stressed.

Doubt is cast upon the possibility of chronic cerebral changes in amateur boxers who are protected by an adequate medical service.

In view of the limitations of clinical, electroencephalographic, and other investigations the evaluation of memory loss may be of great importance as a prophylactic aid.

A FATAL INJURY AT BOXING (TRAUMATIC DECEREBRATE RIGIDITY)

BY

MILROY PAUL, M.S., F.R.C.S.

Professor of Surgery, University of Ceylon

A fatal outcome from a punch on the head at boxing is fortunately a rare event, and when it does occur a sportsman who was fighting fit has been lost. The clinical and post-mortem findings in these fatal cases provide a continuous set of observations of the victim from before the beginning of the contest to the post-mortem examination. As the objective of a combatant at boxing is to punch the opponent on the head with sufficient force to drop him to the mat and cause him to remain there till he is counted out by the referee, it is evident that the victim of a "knock-out" drops because he has suffered a concussion of the brain. It is expected that the concussion will last just long enough for the count, and that recovery will be full and complete after this.

In the occasional fatal case the questions arise: has the victim died of concussion? and has he sustained additional injuries to the brain which caused his death? These are questions which could be decided by a post-mortem examination. The fatal accident also provides

the opportunity for investigating the mechanics of a punch delivered by a gloved hand on the head of an opponent who was prepared for the attack, in which the direction and the force of the punch are observed, and the condition of the victim is observed before, at the time of, and after the blow. If concussion be the cause of death, here is a complete picture of the condition. If intracranial haemorrhages have resulted from the blow, the part that these play in determining the fatal outcome can be decided. These features were well presented in the case under review.

Case History

On June 21, 1956, at an amateur boxing meeting open to boxers who had not won a trophy at an intermediate or open meeting, two entrants met for a bantam-weight—118 lb. (53.5 kg.) and under—contest. The victim of the "knock-out," Raymond Perera, was 114 lb. (51.7 kg.) and his opponent 116 lb. (52.6 kg.). Both contestants were 20 years old. The judge, Mr. A. B. Henricus, gave me his observations. The knock-out was delivered shortly after the first minute of the first round. Up to this stage the deceased, Perera, had been leading "lefts" at his opponent and the blow which knocked him out was the first struck by his opponent. It was a right cross which caught Perera on the left side of his chin. Perera appeared to be stunned by the impact, and gradually went dizzier, and slowly slumped down till his bottom reached the canvas. Then he rolled over to one side. He did not appear to be unconscious, and he was raised by his two seconds and helped to walk to his corner.

Mr. A. I. Obeysekera, who was the time-keeper at this meeting, was watching this match between rounds. He observed that when Perera reached his chair he was lying with his limbs fully extended and his jaws clenched, and that he was breathing deeply and audibly like a man sound asleep. To Mr. Obeysekera these appearances were unreal and so unlike those of the victim of a knock-out that he wondered whether the victim was shamming. He had noticed that the victim had never spoken from the time of the knock-out and that he still remained rigidly extended when being lifted into the stretcher for transport to hospital. The knock-out had occurred at 6.30 p.m. I was on duty at 7 p.m. in the casualty ward of the General Hospital, Colombo, when Perera was brought in. He lay on his stretcher breathing deeply as if in deep sleep, his lower limbs were rigidly extended at the hips and knees, and his upper limbs lay by the side of the body rigidly extended at the elbows, with the forearms fully pronated and the fists clenched. Passive movements were resisted by the rigidity, and if the resistance was overcome by force there was movement of the limb, restoring it to its original position. Perera was unconscious, and made no response to a pin tickling the inside of the nostril or pricking the skin of an eyelid.

The left pupil was widely dilated, the right pupil was small. There were no external injuries, no bruises, and no haemorrhage from the nostrils, mouth, or chin. The temperature was 97.4° F. (36.3° C.), pulse full and regular 104, and respirations 20.

At 8 p.m. Mr. C. P. De Fonseka made a trephine hole in the left temporal fossa, and found the dura mater bulged with subdural blood. Incision of the dura mater evacuated 2 oz. (57 ml.) of fluid blood. A second trephine hole in the right temporal fossa showed no extradural or subdural blood. At 11 p.m. the pulse was 88, respirations 38, and temperature 102° F. (38.9° C.). Perera's condition continued to deteriorate and he died at 1.30 a.m. on June 22.

I obtained permission of the coroner to make a post-mortem examination on June 22 at 11 a.m. On turning down the scalp there were diffuse films of coagulated blood on the subepicranial surface of the scalp and on the pericranial surface of the skull extending upwards from the temporal fossae from the surgical incisions in the scalp.

When the vault of the skull was removed, the dura mater covering the whole of the convex surface of the left cerebral

hemisphere was blue from subdural blood, and when the dura mater was incised a thin film of fluid subdural blood covering the convex surface of the left cerebral hemisphere flowed away. The blood was pooled posteriorly, where it bathed the left occipital lobe. The brain was not compressed by the blood. There was no subdural blood over the right cerebral hemisphere. There was a film of subarachnoid blood coating the pre- and post-central convolutions of both cerebral hemispheres extending a little in front of and behind these convolutions as well.

On the left side this film of subarachnoid blood continued into the Sylvian fissure over the island of Reil, and over the outer surface of the left temporal lobe. The medial and inferior surfaces of the cerebral hemispheres had no films of subarachnoid blood. There were no cerebral lacerations. There was about 3 oz. (85 ml.) of dark blood in the posterior fossa, but the cerebellum and the brain stem showed no subarachnoid films of blood and no lacerations, and it is likely that this blood had flowed into the posterior fossa from above.

Sections of the cerebral hemispheres showed no intracerebral haemorrhages or lacerations, but the white matter of both hemispheres was studded with the pinhead orifices of dilated vessels. There were no haemorrhages at these orifices. Sections of the brain stem and the cerebellum showed no haemorrhage or laceration at these sites.

Discussion

The decerebrate rigidity of the victim of this bout presented some striking features. That it came on with the receipt of the blow was evident from the observation that the victim appeared to be stunned and to get dizzier, and that he then slowly slumped down till his bottom touched the canvas, an unusual fall for a knock-out blow which would be explicable on the basis that the decerebrate rigidity had broken the fall. Then, too, the "automatic walk" back to the corner, when he had been picked up and supported by his two seconds, is another phenomenon referable to the state of decerebrate rigidity. The poker-back posture when he was laid down was clear evidence of the state of decerebrate rigidity, as was the maintenance of this posture till the time of death. Experimental transections of the mid-brain have established that decerebrate rigidity is the result of a lesion between the vestibular and the red nuclei. The post-mortem examination showed that there was no visible lesion in the mid-brain, but it did establish that there had been an appreciable displacement of the cerebral hemispheres within the brain case. The subarachnoid haemorrhages on the convex surfaces of both cerebral hemispheres across their waists between their frontal and occipital poles is clearly the result of an upward drive of both cerebral hemispheres against the cranial vault from the blow on the chin being transmitted upwards through the condyles of the mandible. The diffuse subdural blood covering the convex and inferior surfaces of the left cerebral hemispheres must have been from a traction rupture of veins in the subdural space passing from the dura mater to the inferior surface and the lower convex surface of the left cerebral hemisphere. As the punch was delivered on the left of the chin this would account for the greater upward shift of the left cerebral hemisphere rupturing the veins in the subdural space on this side.

The post-mortem findings afford clear evidence of an upward shift of both cerebral hemispheres, and it would be logical to deduce that this had determined the strain in the mid-brain between the vestibular and the red nuclei which had caused the condition of decerebrate rigidity.

In this case the site of the strain in the mid-brain is postulated with precision because of its causing the condition of decerebrate rigidity. The theory that concussion is the result of a strain in the mid-brain just above the red nuclei cannot be postulated with the same certainty, but the evidence of this case in which the strain occurred at a slightly lower level is good evidence for the mid-brain lesion of concussion.

Brain Injuries at Boxing

Boxing is a well-established sport, and the rarity of fatal accidents at boxing and the absence of apparent ill effects in combatants encourage its continuance. Although the head may well receive many punches during a bout, the brain escapes damage. What is the reason for this? It must be that the positioning and tensing of the head and neck, when it is about to receive a punch, prevents the brain from being displaced. In the occasional instance where this protective position is ineffective, the brain does shift within the brain case, and the effects of this are to be assessed by examining the fatal case. The present case details such an examination. The evidence in this case permitted a reconstruction of the mechanics of the injury, and this reconstruction throws light on the mechanics of concussion.

Summary

The case is described of a boxer aged 20 who was knocked out by a blow on the chin and died in consequence. Between the knock-out and the intracranial operation the patient was in decerebrate rigidity.

ANTIGENIC ACTIVITY OF BRITISH
POLIOMYELITIS VACCINE

A REPORT TO THE COMMITTEE ON LABORATORY INVESTIGATIONS OF POLIOMYELITIS OF THE MEDICAL RESEARCH COUNCIL*

During May and June, 1956, three batches of poliomyelitis vaccine were used for the inoculation of 200,000 children in Britain under the scheme organized by the Ministry of Health. The antigenic activity of these three batches was studied in a group of children who were shown to have no detectable antibodies to any of the three types of poliomyelitis virus before their course of inoculations. The group consisted of 196 children between the ages of 1 and 11 years, in five different areas—London, Manchester, Central Scotland, Sheffield, and Southend-on-Sea.

Each batch of vaccine was also tested for antigenic activity in monkeys.

Vaccine

The three batches—designated 4, 5, and 6—were prepared by the Glaxo Laboratories under the direction of Dr. W. Wood from virus strains Brunenders (type 1), MEF-1 (type 2), and Saukett (type 3) by the formalin-inactivation method introduced by Salk. The vaccine differed in its type 1 component from that produced in America, the Mahoney strain having been replaced by a partially attenuated variant of the Brunhilde strain (Enders *et al.*, 1952; Sabin, 1955). Gear (1956) has called this the Brunenders strain.

*Children were immunized and sera collected by Dr. A. Dudgeon, Dr. J. C. W. MacFarlane, Dr. D. O'Brien, and Dr. A. M. Peach (London); Dr. P. B. Stones and the medical staff of the Health Department (Manchester); Dr. N. R. Grist, Dr. W. M. Janieson, Dr. R. C. McLeod, Dr. B. R. Nisbet, and Dr. E. Neil Reid (Scotland); Dr. J. Rendle-Short, Professor C. H. Stuart-Harris, and Dr. D. Tyrell (Sheffield); Dr. J. Greenhalgh, Dr. J. Stevenson Logan, Dr. A. D. Macrae, Dr. Gladys Neill, Dr. R. Pkeworth, and Dr. J. C. Preston (Southend-on-Sea).

Laboratory investigations were made by Miss A. J. Ferguson, Dr. F. T. Perkins, Mrs. K. Russell, and Dr. J. O'H. Tobin, of the Biological Standards Control Laboratory, Hampstead.

The results were analysed and the report prepared by Dr. F. T. Perkins and Dr. J. O'H. Tobin

Titration of Sera

Serial dilutions of serum in Hanks basic salt solution were mixed with an equal volume (0.25 ml.) of virus suspension in Parker 199 solution containing approximately 50 TCID₅₀ of the required type of virus. The mixtures were held at 37° C. for three hours, and then added to tubes containing 6- to 8-day-old monkey kidney cell cultures; two tubes were used for each serum dilution. The inoculated tubes were incubated at 37° C. in roller drums for six days, when the final readings of the cytopathic effect of virus were made and the titre (PD₅₀) of the serum determined. Titres are given as the dilution of serum in the serum-virus mixtures, as recommended by the Committee on Laboratory Investigations of Poliomyelitis.

All sera were titrated, using Brunenders, MEF-1, and Saukett as the test viruses. Twenty post-immunization sera were also titrated for type 1 antibody, using Mahoney as the test virus. They gave similar results to those obtained with Brunenders, the geometric mean titres being 1/90 with Brunenders and 1/70 with Mahoney.

As controls the three British Standard poliomyelitis antisera (to be published) were always titrated in parallel in each set of tests and gave consistent results throughout. Each standard serum has been assigned a potency of 10 units per ml. and, by the method of titration employed in this study, gave on the average a titre of 1/480, 1/806, and 1/960 for types 1, 2, and 3 respectively.

Antigenic Activity in Children

Of the 196 children selected for the study, the majority had their pre-immunization sera taken on the day the first dose of vaccine was given and the remainder within a month before the first dose. The sera were shown to be negative at a titre of 1/8 to all three types of poliomyelitis virus. Seventy-two of the children were injected with batch 4, 66 with batch 5, 53 with batch 6, and 5 with a mixture of batches. Each child received two injections, each of 1 ml., at an interval of three to four weeks. The injections were given intramuscularly into the left deltoid; no untoward reactions were observed in any of the children. Serum was taken on the average two weeks after the second dose

and titrated for antibody to each of the three types. Those sera showing no antibody at 1/8 were retested at 1/2 and 1/4.

Table I gives the results of the three batches of vaccine together in each area and in all areas combined; the combined results are also given in the figure. The results clearly show that almost all children responded; of the 190 whose sera were fully examined, all except two responded to all three types. It is noted that the distribution of type 1 antibody titres in Manchester differed from that in the other areas; of the 33 sera from Manchester, 9

Antibody titres in children after immunization with poliomyelitis vaccine.

TABLE II.—Antibody Titres in Children after Immunization with Three Different Batches of Poliomyelitis Vaccine

Vaccine Batch	No. of Sera	Virus Type	Number of Sera with Antibody Titre of:															Geometric Mean Titre
			<2	2	4	8	16	32	64	128	256	512	1,024	2,048	4,096	8,192	>8,192	
4	72	1	0	0	8	4	9	7	14	12	12	2	1	0	1	0	2	54*
	71†	2	0	0	2	0	2	8	15	13	12	11	4	2	1	1	223	
	72	3	0	0	1	6	8	10	18	10	10	3	2	1	1	1	81	
5	66	1	1	0	2	1	9	15	7	10	8	5	0	1	0	1	6	61*
	61†	2	0	0	0	0	1	3	7	15	16	7	6	4	0	0	2	259
	66	3	1	0	0	2	5	11	11	15	12	4	1	3	1	0	0	101
6	53	1	0	0	0	1	5	7	8	13	9	7	2	0	1	0	0	117
	53	2	0	0	0	0	0	2	9	9	12	10	8	1	2	0	0	270
	53	3	0	0	1	2	2	4	9	10	14	5	5	0	1	0	0	142

In Tables I-III titres of >8,192 were taken as 16,384 in calculating the geometric mean.
* Nine Manchester sera with high type 1 titres were excluded in calculating the geometric mean.
† In the case of six subjects there was insufficient serum to titrate type 2 antibody.

had type 1 titres equal to or greater than 1/8,192 and lay well outside the general distribution curve. These high titres were probably due to infection rather than to vaccination, as an epidemic was occurring there at the time, and have been omitted in calculating the geometric mean response. Considering all areas and all batches of vaccine together, the geometric mean response was 1/72, 1/282, and 1/101 for types 1, 2, and 3 respectively.

The results with each of the three batches of vaccine are given in Table II, and it is evident that the antibody responses to all of them were similar.

TABLE III.—Antibody Titres in Children Under 5 Years of Age and 5 Years and Over After Immunization with Poliomyelitis Vaccine

Age Group	Vaccine Batch	No. of Children	Geometric Mean Antibody Titre to		
			Type 1	Type 2	Type 3
Under 5 years	4	38	73*	291	91
	5	36			
	6	18			
5 years and over	4	35	71*	274	110
	5	34			
	6	35			

From Table III it can be seen that children under 5 years of age responded as well as those aged 5 and over.

Antigenic Activity in Monkeys

The three batches of vaccine were tested for antigenic activity in monkeys by the method in current use in the United States of America (U.S. National Institutes of Health, 1955). A commercial batch of American vaccine, E/2769, kindly supplied by Eli Lilly and Company, was tested at the same time for comparison; this batch was prepared early in 1955, and since then had been stored in the cold without any apparent loss of antigenicity.

For each batch a group of 10 to 12 Rhesus monkeys, weighing between 4 and 8 lb. (1.8 and 3.6 kg.) and with no detectable poliomyelitis antibodies, were given three 1-ml. intramuscular injections of vaccine at intervals of seven days. Sera were obtained seven days after the third injection and titrated for antibody to each of the three types.

TABLE IV.—Antibody Titres in Rhesus Monkeys After Immunization with Poliomyelitis Vaccine

Vaccine Batch	No. of Monkeys Injected	Geometric Mean Antibody Titre to:		
		Type 1	Type 2	Type 3
4	12	52	108	32
5	10	67	54	39
6	11	45	47	30
E/2769	10	47	46	24

The results, given in Table IV, show that the antigenic activity of the four batches was very similar in these animals.

Conclusions

It is evident from the results of the study in children that the poliomyelitis vaccine used in this country in 1956 was able to produce an antibody response to all three types of poliomyelitis virus in a high proportion of children. The results compare favourably with those reported from other countries; they are similar to those obtained in America by Salk (1956) after immunization with two doses of vaccine and decidedly better than those reported from Denmark (von Magnus *et al.*, 1955) after intradermal vaccination.

Although both field and laboratory tests indicate that the three different batches of vaccine were similar in antigenic activity, there is so far insufficient information to decide definitely on what response is required in the monkey test in order to ensure that a vaccine will give a substantial response in children. It will be necessary to test, both in the field and in the laboratory, further batches of vaccine

with differing degrees of antigenic activity before a decision on this question is reached. Antigenicity tests in guinea-pigs (Gard *et al.*, 1956) and cotton-rats (Tobin, 1956) are also being investigated in parallel with the field studies.

Investigations are also to be made of the decline of antibody levels in some of the children who took part in the present study to obtain information concerning when a third booster dose should be given.

Summary

A study of the antibody response produced by the three batches of poliomyelitis vaccine used in Britain in the 1956 immunization programme was made in a group of 196 children who had no detectable poliomyelitis antibodies before their course of inoculations.

The children received two doses of vaccine at an interval of three to four weeks, and antibody response to the three types of poliomyelitis virus was determined two weeks after the second dose. No untoward reactions were observed in any of the children as a result of the inoculations.

All except two of the children produced antibodies to all three types, and the average response to each of the three batches of vaccine was similar.

The antigenic activities of the three batches were also shown to be similar when tested in monkeys and of the same order as that of an American vaccine.

The committee is grateful to the parents who consented to have their children vaccinated, and also thanks the Ministry of Health for the supply of poliomyelitis vaccine.

POLIOMYELITIS STUDIES IN AN ISOLATED SCOTTISH COMMUNITY

BY

A. D. MACRAE, M.D., Dip.Bact.

Virus Reference Laboratory, Colindale, London, N.W.9

During recent years it has been established that poliomyelitis, spread through human association, is widely disseminated throughout the world. Overcrowding and a low standard of living are associated with the early development of immunity which, once established, appears to persist throughout life. Reinfection may occur to bolster up immunity, but Paul *et al.* (1951), from investigation of an isolated Arctic community lacking opportunities for frequent reinfection, have shown that poliomyelitis antibodies may persist in the blood for many years. The development of these antibodies could be temporally aligned with well-separated outbreaks of the disease in the area.

The natural development of immunity to poliomyelitis is less evident in countries and communities with a higher living standard, and many persons of all ages remain fully or partly susceptible to the disease. The introduction of such persons into an area in which the local population has to a large extent been naturally immu-

nized may result in outbreaks of poliomyelitis involving the new arrivals only. Hammon (1949) has reported this occurrence among recently arrived American children and adults in the Pacific island of Guam. From laboratory studies he found that most native children became infected and developed an immunity below the age of 1, confirming that poliomyelitis was widespread, though mainly inapparent, throughout the island. The circulating viruses showed an apparently increased degree of virulence in the presence of a more susceptible population. He commented on the opportunities for studying the behaviour of poliomyelitis presented by such isolated populations.

Poliomyelitis has been a notifiable disease in this country since 1912, but before 1947 no countrywide epidemics had occurred. In a number of areas there have been no reported cases over prolonged periods, owing either to the existence of a widespread immunity or to lack of exposure to virus. Studies of such a community in the Western Highlands of Scotland in which there had been no evidence of poliomyelitis for many years were planned in 1950. It was hoped by the collection of samples of blood and faeces from members of a representative number of households to determine whether poliomyelitis viruses were currently circulating or had been present in the past.*

Selection of Area

Among the points considered in the selection of a community were the following: (1) the relative remoteness from neighbouring villages and restricted means of approach; (2) the relative compactness of the community itself; too much scatter would add to the problems of collection of specimens; (3) the size and age range of the population; around 400-500 with a reasonable proportion

Map of Torridon area

of young people was thought most suitable; (4) the co-operation of the people in supplying information and suitable specimens, and the co-operation of the local medical services; (5) the past incidence of poliomyelitis in the area; (6) any local industries; and (7) the means of transporting specimens to the investigating laboratory.

The area finally selected lay on the north shore of Upper Loch Torridon on the west coast of Ross-shire (see Map). It included the population of Annat, Torridon, Fassag, Corrie, Alligin, and Diabaig. Poliomyelitis had not been diagnosed there within living memory. Approach was by a single road from Kinlochewe, a distance of about 12 miles (19 km.), with the nearest railway station a further 10 miles (16 km.) away at Achnasheen on the route from Dingwall to Kyle of Lochalsh. The local occupations consisted of estate work, crofting, forestry, and fishing. There were few facilities for visitors. Children attended schools in the area up to the age of 11.

*The investigation was planned and the collection of material was organized by Drs. F. O. MacCallum, I. N. Sutherland, and W. C. Cockburn.

The houses in the area were identified on ordnance survey maps and numbered. Lists of the occupants of each house, with details of occupation, age, and school attended if a child, were prepared. In all there were 104 houses with a total population of 294, who had an age range as shown in Table I. Families with one or more children lived in 28 of the houses.

TABLE I.—Age Range of Torridon Population

Years:	0-5	6-10	11-15	16-30	31-50	51-91	Total
Males	13	8	12	21	40	52	146
Females	11	6	6	18	40	67	148
Total	24	14	18	39	80	119	294

Selection of Donors

It was hoped to obtain specimens of blood and faeces from one child in each of the 28 houses, from the youngest child where there were more than one, or failing that from the next youngest, and so on. In addition blood was to be obtained from 30 persons, aged 15 and over, and selected by random sampling from the houses with no children. Specimens of faeces were to be obtained from 12 of these persons. All specimens were to be sent, as quickly as possible after they were obtained by the doctor and nurse, to the nearest bacteriological laboratory. This was 70 miles (112 km.) away, at Inverness. There the serum was to be separated from blood clot and the faeces were to be frozen. The specimens, packed in dry ice, were then to be sent by passenger train to the Virus Reference Laboratory, Colindale.

Collection of Material

An approach, through the doctor and the district nurse, to the persons from whom material for investigation was desired, met with a good response. Specimens of faeces and serum were collected in the spring of 1951, between mid-March and mid-May, and again from the same persons, except for a small number who could not be contacted or who were unwilling, between mid-October and mid-December of the same year. The specimens came from 64 adults and children living in 53 of the 104 houses. There were children under 16 years of age in 25 of the houses. The distribution of the material is shown in Table II. That

samples of serum were not obtained from all children providing faeces was due to difficulty in obtaining blood from some of those under 5 years old. This difficulty had been foreseen, and when it occurred an attempt was made, where possible, to obtain samples of blood from the sibling nearest in age.

Further samples of blood were obtained in the late autumn of 1954 from 19 of the original donors. Of these, four were children up to 5 years old, six were children aged 6 to 10, and three were aged 11 to 15 years; two were adults 16 to 30, and four were aged 31 to 50 years. The aged 16 to 30, and four were aged 31 to 50 years. The intention then had been to bleed (1) those less than 20 years old in 1951, and (2) those over 20 years old with either no old in 1951, and (3) those with either no old in 1951, or with antibody to one type only. Early in 1956, virus or with antibody to one type only. Early in 1956, samples of blood were obtained from the boy (Table III, No. 6) whose faeces yielded the two strains of poliomyelitis virus in 1951, and from his sister. This family had left Torridon for another locality.

Virus Investigations

The investigations consisted (1) in attempted virus isolation from the samples of faeces and (2) in determining whether poliomyelitis antibodies were present in the serum. The material, collected in 1951, was transported to the laboratory and stored there, frozen at -10°C , until 1954, when it was examined.

Faeces.—A 20% suspension of each sample of faeces in buffered saline solution was centrifuged at 5,000 r.p.m. for at least one hour at 4°C . The supernatant fluid was harvested and tested for the presence of bacteria, being ready for virus investigation when bacteriologically sterile. Twenty-four pools, each composed of equal volumes of three suspensions, were prepared; those, and the remaining single suspension, were investigated in tissue culture and in newborn mice. When a virus was detected in a pool the suspensions composing it were individually studied.

Tissue Culture.—Epithelial cells of rhesus monkey kidney grown from minced tissue fragments or from trypsinized cell suspensions were used in the virus isolation and neutralization tests. Lactalbumin hydrolysate medium (Melnick and Riordan, 1952) or synthetic medium 199 (Morgan *et al.*, 1950) supplemented during the initial period of cell growth with 5% normal horse serum was employed. Tubes were incubated in stationary racks at 37°C . For isolation 0.1-ml. amounts of each pool were inoculated into five tubes, which were then observed microscopically at intervals for cell degeneration. The fluids were harvested when this became apparent or after 10-12 days in its absence. Three tissue culture passages were done before a pool of suspension was regarded as negative. Neutralization tests were based on the method of Ledinko *et al.* (1952), using 100 tissue-culture doses (TCD₅₀) of each virus type against increasing dilutions of serum and leaving each serum-virus mixture at room temperature (about 22°C) for at least one hour before inoculation into tissue cultures. The virus strains used were Mahoney (type 1), Y-SK (type 2), and Saukett (type 3). The second samples of serum were tested at a single initial dilution of 1 in 2.5 against the three types of poliomyelitis virus and against the newly isolated Coxsackie B3 strain of virus. Where antibody was present against a type of poliomyelitis virus both samples of serum were titrated in increasing half-log dilutions against that virus. In the antibody titrations of the samples of serum obtained in 1954 and 1956 increasing twofold dilutions were used. The serum dilutions given in the tables are the final dilutions after the addition of virus suspension.

Animal Inoculation.—Litters of mice less than 24 hours old were inoculated subcutaneously with 0.02-ml. amounts of each pool suspension or with individual positive suspensions and tissue-culture fluids. Second mouse passages were done when there was evidence of weakness, tremors, or paralysis in the initial passage. Two rhesus monkeys were inoculated intracerebrally (0.5 ml.) and intramuscularly (2 ml. combined with an equal volume of adjuvant—"arlacel A," "bayol F") with tissue-culture fluids of No. 4 or No. 6 strains (Table III). Three rhesus monkeys, each inoculated intracerebrally (0.3 ml.) with faecal suspension from No. 6, were used in the identification of the newly isolated strains of virus from this child.

Results of Virus Isolation

Seven cytopathogenic agents were isolated on first passage in tissue culture from six samples of faeces from young children (Table III). In each instance the faeces was an autumn sample, the earlier specimens from the same children obtained in the spring being negative, as were the other 67 specimens. Five agents were identified as being strains of Coxsackie virus group B, type 3, by neutralization tests using specific antiserum obtained from Dr. Dalldorf. The cell degeneration produced by these strains occurred in a varying proportion of the culture tubes inoculated with each faecal suspension and characteristically

‡ Paired sera were available from this child; no serum was obtained in 1951 from the others.

developed slowly in the first passage. In the later passages the degeneration appeared more rapidly and was more complete.

In mice inoculated with pooled faecal suspensions, only one pool which contained the strains of virus No. 1 and No. 2 gave rise to signs of infection. In this instance, weakness, tremors, and varying degrees of paralysis developed after seven days in a litter of six, three of which ultimately recovered, surviving beyond a three-weeks period. In a second passage, using a 20% mouse carcass suspension, the effect was similar, with six mice dying and four recovering. When the five individual faecal suspensions containing Coxsackie virus were inoculated into litters of mice the same slowly developing signs of infection were noted in four instances, but inoculation of further litters with positive tissue-culture fluids yielded more rapid and clear-cut results.

The remaining two agents, isolated from the sixth sample of faeces, were identified as being strains of poliomyelitis virus, type 2 and type 3 respectively. The possibility of this occurrence arose when it was found that serum from the monkey inoculated with tissue-culture fluid of No. 6 strain neutralized types 2 and 3 poliomyelitis virus. The separation of the two strains in monkeys and in tissue culture had already been reported (Macrae and Shepherd, 1955).

Results of Serum Neutralization Tests

The distribution of antibody against the poliomyelitis viruses in the various age groups, based on the serum samples collected in the autumn of 1951, is shown in Table IV. Up to the age of 10, four out of 15 children possessed

TABLE IV.—Distribution of Neutralizing Antibody to Poliomyelitis Viruses in Serum* of Persons in Different Age Groups in 1951

antibody, in each instance against one virus type. From the age of 11 onwards, a gradual development of antibody, particularly against virus types 1 and 2, was apparent, although the small number of serum samples from the 16-30 year group does not allow a clear picture of events in this age range to be drawn. After the age of 30 exposure to the three types of virus appeared to have been about equal.

Titration of the paired samples of serum obtained in 1951 were done (1) to determine the individual levels of antibody and (2) to see whether any development of im-

munity against poliomyelitis virus had occurred during the summer. The results of titration, representing the second samples of serum, are shown in Table V; with one excep-

tion (Table VI, No. 2) the titres of the earlier samples of serum showed only minor differences within the limits of experimental error. Of the 19 samples of serum obtained in 1954, 10 were without antibody against any type of poliomyelitis virus; 7 of these were from children who had been less than 10, and one came from a child who had been 15 years old in 1951. The other two sera were from adults who had been 24 and 28 years old.

The remaining nine samples of serum and the two obtained early in 1956 were titrated, together with their preceding 1951 samples, and the results are given in Table VI. These show: (1) that the boy from whom the strains

§ Reciprocal of serum dilution: calculated by Kaerber's method.

of poliomyelitis virus types 2 and 3 were isolated in 1951 had antibody to these types in 1956; (2) that the sister of this boy had developed antibody to type 2 virus before the collection of her second 1951 sample of serum and had also developed antibody to type 3 virus at a later time; (3) that a boy (No. 5) living in a house close to the home of these children developed antibody to type 2 virus between 1951 and 1954; (4) that a girl (No. 3) with a high antibody level against type 2 virus in 1951 showed a four-fold drop in titre by 1954; and (5) that the other antibody levels showed little variation during the three-year period.

The tests with the samples of serum obtained in the autumn of 1951 showed that 12 contained antibody against the Coxsackie group B type 3 virus. These came from six children less than 10 years old and from six adults ranging in age from 26 to 62. These children, including one (Table III, No. 4) from whom a strain of virus was isolated, and one adult had developed the antibody in the interval between the taking of the first and second specimens, the earlier sera being negative. In three adults the antibody was already present in the spring samples of serum, and in the remaining two adults only the autumn samples of serum were available for testing. The children came from scattered houses throughout the community, but, except for one of pre-school age, attended the same school. A strain of Coxsackie B3 virus had also been isolated from the brother (Table III, No. 1) of one of the children.

In tests with the samples of serum obtained in 1954, 10 persons were found with antibody against the Coxsackie B3 virus. Of these, one was a child (Table III, No. 3) from whom a strain of virus had been isolated in 1951, but from whom no serum had previously been obtained; three were children already positive in 1951; and six were from persons, previously negative, with ages ranging from 9 to 38 years and living in houses scattered throughout the community.

Discussion

Torridon, in which no recorded cases of poliomyelitis have occurred, is a sparsely populated and relatively isolated area. It may, however, be reached from London within 24 hours, without difficulty at most times. As in other Highland communities the population is decreasing, owing to the drift away to the towns in search of work and greater amenities. After the age of 11 the children go elsewhere to complete their education; the young adults stay away because of the lack of work, but some return to settle down in late adult life.

The distribution of antibody to the poliomyelitis viruses appears to bear some relation to this. Up to the age of 11 years, 15 of the 38 children available were investigated serologically; 11 of these had no antibody to any type of virus, and four had antibody against a single type. The three children with type 2 antibody were aged 5, 8, and 9 years, the youngest having developed this during the summer of 1951. One child aged 10 had antibody to type 1 virus. In the 11-15 year group, six of the 18 children available were investigated serologically; four had antibody to type 1 virus, one of these having antibody to all three types, one to type 2 virus, and one to type 3 virus also. As the purpose of the investigation was to sample separate households, the extent of infection in siblings was not estimated. It would appear, however, that infection with type 2 virus had occurred in a number of households during the previous ten years and infection with type 1 virus before that, but there had been no widespread distribution of these viruses.

In the 16-30 year group samples of serum from only three persons were obtained. As one person had antibody to all three types of virus and two were completely negative it is not possible to reach any conclusions. After the age of 30 an increasing proportion of persons had antibody to one or more types of virus, probably acquired elsewhere in a number of instances. The antibody distribution in children differs from that found in Bettws-y-Coed, North Wales (Fallon, 1956), an area from which no cases of poliomyelitis had been notified since 1912. There, antibody against the poliomyelitis viruses, particularly types 1 and 2, was found in the sera of children from the age of 1 onwards, and only 6 out of 57 sera from children under 10 were devoid of antibody.

Although the isolation of two strains of poliomyelitis virus from a boy in the autumn of 1951 showed that these viruses were present in the area, there were no notified cases of poliomyelitis in Torridon during 1951 or subsequently. One adult at Kinlochewe, 12 miles (19 km.) away, was transferred to hospital as a suspected case of non-

paralytic poliomyelitis, but no virus was isolated from a sample of faeces obtained while she was in hospital. Serological evidence of recent infection in Torridon was limited to the boy, his sister, and one child from a near-by house who was infected with type 2 virus only. This boy, his sister, and mother had returned to this country from the tropics before the start of the Torridon investigation. No evidence of poliomyelitis infection was found in the material collected in the spring. Whether they had all gone away from Torridon during the summer or whether there had been close contact with relatives or visitors from elsewhere during this time is not known. The age of the children makes it improbable that they had many contacts in the community, hence the limited spread of infection. In addition, there is the possibility, suggested by Dalldorf (1952), of interference with the spread of poliomyelitis virus by Coxsackie B viruses.

Outbreaks of Bornholm disease in 1951, in some instances associated with Coxsackie B3 virus, were reported from Scotland and England (Swain and Mitchell, 1953; Disney *et al.*, 1953). The disease was prevalent in Ross-shire during the summer and autumn, starting on the east coast and spreading westwards. From the Torridon area 13 cases were reported to the medical officer of health (personal communication), including four who were donors of specimens in this investigation. Except for one donor whose serum contained no demonstrable antibody against the Coxsackie B3 virus in either 1951 or 1954, the cases occurred in houses in which evidence of infection with this virus was obtained either by isolation or by antibody development. The laboratory findings support the probability that the clinical illness in Torridon was associated with this type of virus.

The five strains of Coxsackie virus isolated came from young children, three being from near-by houses and two from well-separated houses. One of these was also a combined post-office and shop, the child's father being postmaster, shopkeeper, and, in addition, ferryman and warden of the local youth hostel. The serological findings confirm that infection was widespread, and the combined results are a contrast to the picture with the poliomyelitis viruses. They also serve as a model of what might happen with poliomyelitis, given suitable conditions.

Summary

An investigation of the semi-isolated community of Torridon, in the Highlands of Scotland, for evidence of infection with poliomyelitis is reported. No clinical cases of poliomyelitis have ever been reported from there.

Out of a population of 294 living in 104 houses, samples of faeces, serum, or both were obtained in the spring and again in the autumn of 1951 from 64 persons living in 53 of the houses. Emphasis was placed on obtaining specimens from the youngest child in each family selected. Further samples of serum were obtained in 1954 from 19 of the original donors.

Strains of Coxsackie B3 virus were obtained from five young children living in separate houses, and strains of poliomyelitis virus types 2 and 3 were isolated from one young boy in another house.

The development of antibody against types 2 and 3 poliomyelitis virus during these studies occurred only in the sister of the boy from whom the viruses were isolated, although serum from the boy himself, obtained five years after the virus isolations, did also contain these antibodies. One other child from a near-by house to these children developed antibody against type 2 virus only.

The distribution of antibody in the serum of donors indicated that immunity to poliomyelitis developed

relatively late in life, but that antibody levels, where present, showed little variation over a three-year period.

Serological evidence of widespread recent infections in children and adults with Coxsackie B3 virus corroborated reports of Bornholm disease in the area.

I am indebted to Drs. F. O. MacCallum, I. N. Sutherland, and W. C. Cockburn for advice and encouragement; to Drs. R. D. Martin, D. MacRae (since deceased), J. Landess Horne, Josephine W. Shepherd, H. MacPherson, H. Williams, and the district nurse for their co-operation; and to Dr. G. Dalldorf for the Coxsackie B antiserum.

DEATHS FROM POLIOMYELITIS AMONG BRITISH DOCTORS

BY

RICHARD DOLL, M.D., M.R.C.P.

Member of the Statistical Research Unit of the
Medical Research Council

AND

A. BRADFORD HILL, C.B.E., F.R.S.

Professor of Medical Statistics, London School of Hygiene
and Tropical Medicine; Honorary Director of the
Statistical Research Unit of the Medical
Research Council

In our study of lung cancer and other causes of death in British doctors in relation to their smoking habits we have observed 34,494 medically qualified men over nearly five years—that is, from November, 1951, to September, 1956, a total of a little more than 165,000 years of exposure.* Over this time and in these 34,494 medical men there have been recorded eight deaths from poliomyelitis (including one certified as acute poliomyelitis). In relation to the size of the population at risk eight is a very small number. Yet it is greatly in excess of the number that would be expected to occur if doctors were dying of poliomyelitis at the same rate as adult males in the general population of Great Britain. Applying to our population of medical men these general population rates in the ten quinquennial groups from age 20 to age 70 (no deaths occurred in the general population over the age of 70) gives an expectation of only 0.83 deaths. It may be that persons in the higher social classes are rather more at risk of contracting poliomyelitis than those in the lower social classes. That would be in accordance with some modern beliefs—though we know of no statistical evidence in this country in its support. But even making them three times as vulnerable we would not expect more than two or three deaths to put against the eight observed. It therefore seems that doctors are specially at risk either of contracting poliomyelitis or, having contracted it, of dying from it.

*In our previous report (Doll and Hill, 1956), the total number of years of exposure observed was referred to as 148,686, but at that time data were available for deaths occurring only until March, 1956.

All those who died were relatively young men. At time of death their ages (last birthday) were 28, 30, 30, 32, 36, 37, 39, and 41. In their work there was no evidence of special risk—for example, in a laboratory. Their last known appointments were hospital casualty officer, hospital medical officer, chest physician, orthopaedic hospital officer, and general practitioner (4). These appointments were widely scattered—London (2), Middlesex, Berkshire, Kent, Staffordshire, Yorkshire, and Lincolnshire. In time, on the other hand, the deaths were curiously concentrated, since five of them occurred in August and September, 1952. The poliomyelitis season in this country is such that one would expect deaths to be specially concentrated in those months, but in each of the 1953 and 1956 seasons there was but one death of a doctor from poliomyelitis and in 1954 and 1955 there was none. The eighth death occurred at the end of the 1951 season (January, 1952). On the other hand, the total number of adult male deaths from poliomyelitis in Great Britain in 1952 (98) was the same as in 1953, not very different from the number in 1955 (105), and only about double that in 1954 (46 deaths) and, it seems likely, 1956.

Summary

The evidence given here suggests that men between the ages of 25 and 45 who are practising medicine in Great Britain are at special risk of dying of poliomyelitis. The actual number of deaths recorded (8) is small in relation to the number of men at risk (nearly 35,000), but at the rates of the general population not more than one death would have been expected to occur.

INVESTIGATION OF NON-ULCER DYSPEPSIA BY GASTRIC BIOPSY

BY

A. WYNN WILLIAMS, M.D., D.C.P. (Lond.)

Senior Lecturer in Pathology, University of Edinburgh

FELICITY EDWARDS, B.M., M.R.C.P.

Research Assistant, West Middlesex Hospital, Isleworth

N. F. COGHILL, M.A., M.B., M.R.C.P.

Physician, West Middlesex Hospital, Isleworth

Large numbers of patients with dyspepsia come to hospital, and often, in spite of appropriate investigations, no cause for it can be found. Although symptoms may abate when a patient learns of negative findings they often persist, and treatment may be difficult and unsatisfactory. A nervous cause of the indigestion may be suspected, but it is difficult to prove. In fact, dyspepsia of unknown aetiology constitutes a notable clinical problem.

Gastritis has long been suggested as a cause of non-ulcer dyspepsia, but in common with others we have found its diagnosis by gastroscopy far from certain (Wirts *et al.*, 1951; Shallenberger *et al.*, 1951; Palmer, 1952; Debray *et al.*, 1953; Selesnick and Kinsella, 1953). The suction biopsy tube introduced by Wood *et al.* (1949) offered a new means of obtaining information

about the gastric mucosa in dyspepsia, and we have used it for this purpose. Details of the modified instrument and method, together with illustrated descriptions of the commoner mucosal lesions, have already been given (Coghill and Wynn Williams, 1955a, 1955b).

By dyspepsia we mean a condition in which abdominal or thoracic symptoms other than dysphagia occur in relation to eating. In this paper non-ulcer dyspepsia (N.U.D.) implies the occurrence of such symptoms when (N.U.D.) implies the occurrence of such symptoms when no ulcer can be found in an oesophagus, stomach, or duodenum not previously subjected to surgical intervention. Patients with anaemia, hiatus hernia, oesophageal reflux, carcinoma of the stomach, or hepatic, biliary, pancreatic, intestinal, renal, or cardiac disease were excluded.

Classification of Histopathological Changes in Gastric Mucosa

In our examination of 1,043 biopsy specimens from 467 patients with different disorders we observed changes in which were mainly, although not entirely, inflammatory in character. Different classifications of gastritis have been suggested (Schindler, 1947; Magnus, 1952; Palmer, 1954), and these vary in complexity. The following simple classification, which is based partly on that of Motteram (1951), was found to be most useful. It is to be especially noted that in our classification the changes refer to body ("fundic") mucosa.

Chronic Superficial Gastritis.—There is atrophy of the glands in their superficial part and infiltration of the stroma in this region with numerous inflammatory cells, mainly plasma cells and lymphocytes.

Chronic Atrophic Gastritis.—Glandular atrophy is complete or almost so, and there is a variable amount of infiltration of the stroma with inflammatory cells similar in type to those seen in chronic superficial gastritis. Intestinal heterotopia ("metaplasia") commonly occurs, and pyloric gland heterotopia is also of frequent occurrence.

Gastric Atrophy.—The mucosal changes are the same as in chronic atrophic gastritis, but inflammatory cells are inconspicuous.

"Hypertrophic Gastritis."—This unsatisfactory title refers to a group of rare and ill-understood disorders characterized by a marked proliferation of epithelial or stromal cells, or both (Schindler, 1947; Palmer, 1954; Fieber, 1955). In a single example, proved by partial gastrectomy, we were unable to diagnose the condition from biopsy specimens obtained subsequent to operation.

In many patients there were abnormalities in the gastric mucosa which were so slight that classification into any of the groups we have mentioned was not possible. Consequently it was necessary to introduce a fifth group.

Miscellaneous Minor Mucosal Changes.—The glandular pattern is normal, but the surface epithelium or the stroma, or both, are abnormal. The alterations include irregularities in the size, shape, staining properties, and numbers of surface epithelial cells, and oedema and a mild excess of inflammatory cells, usually plasma cells and lymphocytes, in the stroma. The excess of inflammatory cells, in particular, was a common finding.

Material

After excluding patients in whom a cause for the symptoms was found outside the oesophagus, stomach, and duodenum, 775 new subjects with dyspepsia were seen as out-patients in a medical unit over the three years from July 1, 1952, to June 30, 1955—an average annual rate of 258. This figure comprised 25.7% of all new out-patients attending the unit. The corresponding figure for all new general medical out-patients attending the hospital was about 20%.

To assist diagnosis every patient had a barium-meal examination with appropriate investigation of oesophagus and cardia. When there was doubt about the result the examination was repeated and gastroscopy was performed when indicated.

Of the 775 patients with dyspepsia, 459 (59.2%) were men and 316 (40.8%) women. Investigation revealed a likely organic cause for the dyspepsia in 307 (39.6%)—duodenal ulcer, 195 (25%); gastric ulcer, 79 (10%); gastric and duodenal ulcers, 7 (1%); hiatus hernia, 16 (2%); oesophageal reflux, 3; gastric carcinoma, 3; cardiospasm, 2; oesophageal ulcer, 1; volvulus of stomach with eventration of the left diaphragm, 1.

Thus there were 468 patients, forming 60.4% of the whole group, in whom no peptic ulcer could be found, and in whom other causes of dyspepsia were not suggested by the clinical findings or were excluded by appropriate investigations. Of the patients with N.U.D. 251 (53.6%) were men and 217 (46.4%) women.

Gastric biopsy specimens were obtained from 200 of 564 consecutive new out-patients with N.U.D. seen after July 1, 1952. Fourteen had had a peptic ulcer in the past, but none was present at the time of biopsy, although symptoms persisted. Mild overt haemorrhage of the upper alimentary tract had occurred recently in three patients, but in none was notable anaemia present. Attempts at gastric biopsy were made on less than half the patients with N.U.D. There were several reasons for this. Some patients failed to return after their x-ray examination, some were too old (Coghill and Wynn Williams, 1955b), and some declined the investigation because they felt better, or for other reasons such as a dislike of swallowing tubes. Some patients with N.U.D. in whom gastric biopsy was performed were grouped under different categories—for example, because of anaemia, as the subject of further studies—and have not been included in this series.

Results

Of the 200 patients with N.U.D. from whom biopsy specimens of the gastric mucosa were obtained, 134 (67%) were men and 66 (33%) women. The mucosa was classified as normal in 90 (45%); 72 (36%) were placed in the miscellaneous group, 9 (4.5%) were classed as chronic superficial gastritis, and 29 (14.5%) were classed as chronic atrophic gastritis. There were no examples of gastric atrophy in the series. In 14 (48%) of the cases of atrophic gastritis the mucosa showed signs of intestinal metaplasia. In 13 patients (6.5% of all cases) multiple specimens demonstrated notably different histology in the same patient, and each case has been classified as showing the more severe of the changes found.

Thus in 110 (55%), rather more than half the patients examined, there was evidence of gastritis. Of these, 72 had only minor changes (miscellaneous group). Major abnormalities (superficial and atrophic gastritis) were found in only 38 patients (19% of the whole N.U.D. group).

Sex.—The distribution between the sexes of patients with normal and different types of abnormal mucosae is shown in Table I and Fig. 1. Fewer women than men were examined, chiefly because fewer presented suffering from N.U.D. and more declined the examination or were unsuitable for

N=Normal. M=Miscellaneous minor mucosal changes. SG=Chronic superficial gastritis. AG=Chronic atrophic gastritis.

It is generally acknowledged that dyspepsia is a common complaint, and that in a large proportion of cases no cause can be found. Edwards and Copeman (1943) failed to demonstrate a peptic ulcer in 50% of 436 dyspeptic patients in the Army, while Avery Jones and Pollak (1945) classified 41% of a group of 1,522 patients with gastric symptoms into the category of "non-ulcer dyspepsia." Friedman (1948), reviewing "functional dyspepsia" in the American forces, reported a 10 to 60% incidence in various series of patients, the average incidence for a total of 13,000 patients being 52%. Doll *et al.* (1951), in a survey of 5,951 men and women at work, found 25.4% with N.U.D. compared with 5.6% with peptic ulcer. In our series no cause for the dyspepsia was discovered in 60% of 775 out-patients presenting with this symptom. We have found miscellaneous minor histological changes in the gastric mucosa in 36% of 200 patients with N.U.D. and superficial or atrophic gastritis in 19%. The significance of these findings depends on several factors.

RESPIRATORY VIRUS INFECTIONS IN HOSPITAL AND IN GENERAL PRACTICE, 1954-6

BY

N. R. GRIST, M.B., B.Sc., M.R.C.P.Ed.

AND

R. G. SOMMERVILLE, M.B., Ch.B.

WITH THE TECHNICAL ASSISTANCE OF

H. G. CARSON, F.I.M.L.T.

From the Virus Laboratory of the University Departments of Bacteriology and of Infectious Diseases, Ruchill Hospital, Glasgow

In continuation of previous laboratory studies of respiratory illness, tests for a wider range of virus infections were made in a series of patients admitted to hospital and also in cases of milder illness seen in general practice during the winter seasons of 1954-5 and 1955-6. This paper presents evidence of infections with influenza viruses of types A, B, and C, an agent related to the Sendai strain of newborn pneumonitis virus ("influenza D," Jensen *et al.*, 1955), and the adenovirus group (Rowe *et al.*, 1953).

Methods

The population investigated included 167 patients admitted to pneumonia wards of Ruchill Hospital from July, 1954, to April, 1955, 70 admitted to baby pneumonia wards from November, 1954, to May, 1955, and 98 adults and 44 children under 2 years old admitted to these wards from November, 1955, to April, 1956, inclusive. Tests were also conducted in 105 cases of suspected influenza seen in general practice from December, 1954, to April, 1955, and in 92 similar cases seen in the corresponding five months a year later in the course of schemes for the detection of influenza in the community during vaccine trials of the Medical Research Council (M.R.C. Committee, 1955). A number of additional cases were examined in the course of investigations of outbreaks of respiratory illness. Serum samples were taken during the early and late stages of illness. Garglings for attempted virus isolation were collected with autoclaved skimmed milk or saline with added broth. During the 1955-6 season, respiratory secretions of infants were collected from the nose or throat by sterile cotton-tipped swabs which were subsequently extracted each in a few millilitres of broth for one hour at 37° C.

In general, the cultural and serological techniques were those described in previous papers (Grist, 1955; Grist and Landsman, 1955). For attempted virus isolation, embryonated eggs were inoculated by the amniotic route; at least two passages were made before specimens were regarded as negative.

Sera were examined by small-volume complement-fixation (C.F.) tests and by haemagglutination-inhibition (H.I.) tests. Soluble antigens were used in C.F. tests for influenza A and B; in some experiments soluble antigens prepared from locally isolated strains of virus were used. A fixation period of 90 minutes at 37° C. was employed with adult sera, but with sera from infants the cold overnight method was used. Antigens from several of the following strains of virus were used for H.I. tests: PR8 (type A), A/Scotland/1/53, A/Scotland/26/54, A/Scotland/31/56, Lee (type B), B/England/52, B/Scotland/28/55, and the 1233 strain of type C virus (Taylor, 1949). The Sendai strain of newborn pneumonitis virus was received from the World Influenza Centre of the World Health Organization. Allantoic-fluid antigens of this virus were used in C.F. and H.I. tests; positive and negative control sera for C.F. tests were received from the Virus

Laboratory of the School of Public Health, University of Michigan. Type 4 adenovirus (Hilleman and Werner, 1954), together with positive control serum, was received from the Virus Reference Laboratory, Colindale. Adenovirus group antigen was prepared from HeLa cell cultures showing complete degeneration after infection with this virus; the cultures were frozen, thawed, centrifuged at low speed to remove debris, and the supernatant fluid was heated to 56° C. for 30 minutes and stored at 4° C. for use as antigen in the small-volume cold overnight C.F. test. Sera were tested for agglutination of streptococcus M.G. by a standard method similar to that employed at the Virus Reference Laboratory, Colindale. Titres are cited as reciprocals of initial serum dilutions in C.F. and H.I. tests and as reciprocals of final dilutions in streptococcus M.G. agglutination tests.

Results

Influenza

Evidence of influenza infection indicated by fourfold or greater rising titres in serological tests was found during the periods shown in Table I. In common with the rest of

Britain, Glasgow experienced an outbreak of influenza B during the winter of 1954-5. A few type A infections detected during April, 1955, heralded the following winter's outbreak of influenza A, which was associated with virus C infections as in the outbreak two years before (Grist, 1955). No influenza infections were found at times other than those shown in Table I. As might be expected, a higher proportion of serologically positive cases was found in the general-practice group than among the miscellany of cases admitted to the pneumonia wards, but very few of the infants showed rising titres of antibody. Thus, during the months when type A or B infections were detected, a specific serological diagnosis of influenza A or B was made in 42% of the general-practice cases, and in 12% of adults, but in only 3% of young children in the hospital series. Two type B strains of influenza virus were isolated during the first winter from garglings collected from children involved in an outbreak of illness in a Glasgow school for the deaf in January, 1955. Dr. A. Harboe, of the World Influenza Centre, reported that these strains closely resembled those sent to the Centre from other countries during the previous two years. During the same period outbreaks of influenza were reported from Ayrshire, and serological evidence of type B infection was found in four out of five cases from which paired sera were sent by Dr. C. D. Rigg, general practitioner.

During the second winter outbreak eight strains of virus A were isolated: these viruses were identified by Dr. A. Isaacs, of the World Influenza Centre, as Scandinavian subtype A strains similar to those isolated in Glasgow in 1953 and 1954. Two of these viruses were isolated from garglings from adults suffering from clinical influenza and six from throat swabs of infants or young children admitted to the baby pneumonia ward, of whom two aged 1 year showed fourfold or greater increases in antibody to type A virus. Of the other four children, two aged 3 years gave positive

serological reactions in the earliest serum samples and in the second serum of one; no second serum was available from the other child. The remaining two infants were 3 months old: very weak positive reactions were given by the sera of one and no reaction was found with the sera of the other at a dilution of 1/2 in the cold overnight C.F. test with soluble antigens prepared from PR8 or from current (A/Scotland/26/54) strains of virus.

Table II, constructed from the records of adults in both hospital and general practice series from whom paired sera were examined by both C.F. and H.I. tests, shows that these

TABLE II.—Results of Influenza C.F. and H.I. Tests of Adult Sera

Season and Type of Influenza	Results of C.F. Tests	Results of H.I. Tests	
		Fourfold or Greater Rising Titre	No Rise of Titre
1954-5 B	Fourfold or greater rising titre ..	28	3
	No rise of titre ..	8	176
1955-6 A	Fourfold or greater rising titre ..	24	15
	No rise of titre ..	8	142

tests were of similar efficiency. Five more cases of influenza B were diagnosed by H.I. than by C.F.; of 31 cases tested by H.I. with two type B antigens, all showed significant increases of antibody titre with current virus antigen (B/Scotland/28/55) and 30 did so with antigen of the Lee strain. Only 62% of type A infections gave diagnostic reactions with both tests, and seven more were detected by C.F. than by H.I.; only antigens from recently isolated strains of virus were used in H.I. tests for influenza A.

A specific serological diagnosis of influenza A or B based on rising titres of antibody was made in 34% of the general-practice cases. When sending blood for examination the practitioners were asked to classify the patients as either "typical" or merely "probable" cases of influenza, basing the distinction on their own clinical judgment. Virus A or B infection was confirmed serologically in 41 (31%) of "probable" and 26 (39%) of "typical" cases.

Newborn Pneumonitis Virus

The detailed results of experience with this agent will be reported separately (Sommerville, to be published). Fourfold or greater rising titres were found by one or both of the C.F. and H.I. tests in three adults admitted to pneumonia wards and also in six of the general-practice cases of suspected influenza (Table III). Of these nine cases of antigenic experience, four were found in the 1954-5 season; the other five occurred during the following winter.

" Influenza " "	172	6	70	1	120	0

Adenovirus Infections

C.F. tests with the group antigen were performed with negative results in 103 cases admitted to adult and 32 admitted to baby-pneumonia wards; a rise in titre from <8 to 64 was found in 1 of 70 general-practice cases tested (Table III). One infant pneumonia case admitted in November, 1955, had a C.F. titre of 32 in both serum specimens, suggestive of recent infection. Further evidence of infection with a virus of this group was found during investigation of an outbreak of respiratory illness in a children's residential nursery in Paisley in mid-January, 1956. Eight children aged from 9 months to 4 years became ill on January 14 with

fever followed by the development of pneumonia with marked illness and copious nasal and post-nasal discharge. Serological investigations gave no evidence of infection with the viruses of influenza A, B, C, newborn pneumonitis, psittacosis, or Q fever. No influenza virus was isolated from throat swabs by egg inoculation, but in one instance an agent which produced the cytopathogenic effects and gave the C.F. reaction of a member of the adenovirus group was isolated in tissue culture.

The results of C.F. tests on serum from the children (Table IV) show that antibody was detected in the first two sera of the child from whom virus was isolated and that at least

TABLE IV.—Evidence of Adenovirus Infection in Residential Nursery

Age of Child (Years)	Virus Isolation from Throat (17/1/56)	C.F. Titres of Sera Tested with Adenovirus Group Antigen

a.c. = Anticomplementary. N.T. = Not tested.

one other child had some antigenic experience. These findings do not prove that an adenovirus was responsible for the wave of illness in the nursery, although negative C.F. reactions do not exclude the possibility, since Balducci *et al.* (1956) have reported instances of infected children whose sera contained no demonstrable complement-fixing antibodies but nevertheless neutralized the homologous strain of adenovirus isolated. Serological evidence of infection with an adenovirus was also found during investigation of an epidemic of keratoconjunctivitis on Clydeside in the early months of 1956.

Streptococcus M.G. Agglutination Tests

Of 372 cases tested (Table III), none had antibody titres of 40 or greater or showed significantly rising titres except one man aged 24 years who was admitted to the pneumonia ward in March, 1955. Titres of 10, 160, and 320 were found with sera taken on the 4th, 7th, and 15th days of illness respectively; the serum of the 7th day gave a cold agglutination titre of 256. Clinically, the illness was an atypical pneumonia of gradual onset, with right lower lobar consolidation and without leucocytosis.

Discussion

These investigations showed the continuing seasonal activity of influenza viruses in and around Glasgow and again illustrated the tendency of type A and B viruses to become active in alternate years. Virus C infections were again found only during the epidemic of influenza A. Serological evidence of infection with an agent related to the newborn pneumonitis virus, for which the name "influenza D" has been proposed by Jensen *et al.* (1955), was found mainly during the height of the outbreak of influenza A. Significantly high but unchanging titres in the tests for infections with these four viruses were found mainly during and after the periods when cases with fourfold or greater rising titres were detected.

Little evidence of specific viral aetiology for respiratory infections of infants admitted to hospital was found in the present study, but our experience again indicated the greater difficulty in demonstrating serum antibodies in this age group. Not only is the antibody response of infants highly specific for the infecting virus, as compared with the broader response of the antigenically more-experienced adult, but also their antibodies react more weakly than those of older subjects in the C.F. test with influenza antigens (Anderson *et al.*, 1953). In Glasgow, Russell (1956) has found that the period of maximum notifications of pneumonia in children under 1 year old often precedes by some weeks the

seasonal outbreak of influenza which coincides with peak notifications of pneumonia in adults. Similar observations that maximal respiratory illness in young children may not coincide with outbreaks of influenza were reported by Stuart-Harris *et al.* (1949) and by Garrow and Fawcett (1953). The epidemics of acute bronchiolitis in infants in 1951, 1953, and 1955, observed by Heycock and Noble (1956), were all in the pre-Christmas season (Heycock, personal communication), whereas influenza epidemics usually occur later in the winter. It seems likely that influenza viruses are not the main agents responsible for the winter seasonal increase in serious respiratory illness of infants. Nevertheless, influenza infection was detected in several infants in the present study; the clinical aspects of their illnesses will be described in a separate report (Thomas, to be published).

McDonald and Andrews (1955) investigated diagnostic methods in an influenza vaccine trial and concluded that assessments based on purely clinical grounds were apt to underrate while those based on purely serological data were apt to exaggerate the protective power of the vaccine. They recommended that the assessment should be based on the numbers of cases diagnosed as influenza on clinical grounds during the limited period when laboratory tests showed that influenza was present in the community. The general-practice study described above was organized primarily in connexion with vaccine trials. Both hospital and general-practice investigations indicated the activity of influenza viruses in Glasgow during similar periods. A higher proportion of serologically positive cases was found among those seen by the practitioners, and during the second winter influenza A was detected earlier and for a longer period in this group than in hospital. On the other hand, laboratory investigation of patients admitted to hospital with acute respiratory illness is more easily organized, and earlier studies at this laboratory have confirmed that the results of such tests reflect the influenza experience of the community as judged by other criteria (Grist and Landsman, 1955).

The standard C.F. test with soluble antigen was again found to be a convenient and satisfactory method of diagnosis in adults, though an additional 23% of infections were detected when this test was supplemented by H.I. tests. The difficulty of clinical diagnosis of influenza is illustrated by the similarity in the proportions of confirmed cases in the groups considered "typical" and "probable" influenza by the general practitioners. It should be understood that each practitioner was encouraged to submit specimens from two patients a week whose illnesses might conceivably be influenza in origin. This was done in order to secure a representative sample of minor febrile and respiratory disease throughout the study, and doubtless resulted in some dilution of influenza with other cases. Nevertheless, the "typical" group did not contain a significantly higher proportion of cases in which laboratory tests indicated specific infection with influenza virus A or B.

Evidence of infection with members of the adenovirus group has been reported in Britain by Zaiman *et al.* (1955), Andrews *et al.* (1956), and Balducci *et al.* (1956). In the present study these infections were infrequently found except during investigation of an epidemic of keratoconjunctivitis. Rising titres of C.F. antibody were found by Balducci *et al.* (1956) in 3 out of 67 adults with pneumonia or bronchitis in a Sheffield hospital, whereas none of 103 similar cases in the Glasgow hospital study showed a rising titre. The pathogenicity of these viruses for man is incompletely defined, but in this country they have now been associated with the syndromes of febrile catarrh, pharyngo-conjunctival fever (Bell *et al.*, 1955), and epidemic keratoconjunctivitis.

Atypical pneumonia accompanied by the development of cold agglutinins and agglutinins for streptococcus M.G. has continued to be uncommon in Glasgow since these investigations of pneumonia cases began in 1950. Glasgow did not appear to share the epidemic experience of this disease in 1954 reported from East Anglia and London by Wormald *et al.* (1956), Wood (1956), and Garrow (1956).

Summary

Examinations for virus infection were made in 197 cases of suspected influenza seen in general practice and in 265 adults and 114 children admitted to pneumonia wards during the winters of 1954-5 and 1955-6.

Cases of influenza B were detected in all groups during the first winter.

In the second season an outbreak of influenza A occurred; during this period were found several influenza C infections and also instances of antigenic experience with an agent related to the Sendai strain of newborn pneumonitis virus.

Few adenovirus infections were detected except in cases of epidemic keratoconjunctivitis, but a virus of this group was isolated during investigation of an outbreak of respiratory illness in a children's nursery.

One case of atypical pneumonia with agglutinins to streptococcus M.G. was found.

The investigation showed the practicability of detecting the time and type of influenza outbreak by serological tests of cases selected in general practice or admitted to hospital with the diagnosis of pneumonia.

Combined complement-fixation and haemagglutination-inhibition testing revealed more influenza cases than either test alone. The weak immune response of infants made serological diagnosis difficult.

We thank the following practitioners, by whom the general-practice study was carried out: Dr. W. Blair, Dr. W. K. N. Dr. T. F. Stewart, Dr. A. Clarke, Dr. S. Dunn, and our clinical colleagues, particularly Dr. Mary Thomas; to Dr. Public Health Department, Paisley, and Dr. T. S. Wilson, of the Health and Welfare Department, Glasgow, for assistance in the investigations of outbreaks of illness; to Dr. C. H. Andrews, of Virus Reference Laboratory, Mill Hill, Dr. B. E. Andrews, of the University of Michigan, U.S.A., for supplies of seed virus and control sera; and to our colleagues Lillias G. MacGregor and Helen E. Larminie for assistance with tissue-culture studies.

A film entitled "Hearing Tests in Cerebral Palsied Children" has been made at the Centre for Spastic Children, Chelsea, in co-operation with the audiology unit of the Royal National Throat, Nose, and Ear Hospital. It shows some of the methods and difficulties in testing these children. The film is silent, 16 mm., and 650 ft. (198 m.) in length. A script to accompany the film is available or a lecturer can be supplied. The film is available from the Centre for Spastic Children, 61, Cheyne Walk, Chelsea, London, S.W.3.

INFECTION WITH SENDAI VIRUS IN AN OUTBREAK OF RESPIRATORY ILLNESS

BY

G. B. BRUCE WHITE, M.R.C.S., Dip.Bact.

P. S. GARDNER, M.B., M.R.C.S., Dip.Bact.

Virus Reference Laboratory, Central Public Health Laboratory, Colindale

AND

R. E. HOPE SIMPSON, M.R.C.S.

Director, Epidemiological Unit (Public Health Laboratory Service), Cirencester, Glos.

In February, 1956, an outbreak of respiratory infection, suspected to be due to an influenza virus, occurred in a hospital for the chronic sick and infirm of both sexes (many of limited intelligence). A small section of the establishment also contained rooms for the destitute. In the next month, among 180 patients, 67 cases (25 male, 42 female) were recognized, of which 21 proved fatal. The staff consisted of two part-time doctors, a matron, and 65 full-time and part-time nursing staff, none of whom had an attack of respiratory infection other than minor colds during this period. Specimens of serum were sent to the laboratory for confirmation of influenza virus infection, but no material was collected for virus isolation.

At the same time there were cases of clinical influenza among residents of the town and among nurses at the local cottage hospital. In several of these the diagnosis was confirmed as influenza virus A infection by complement-fixation (C.F.) tests with their sera. When the sera from 41 patients at the "chronic sick" hospital were examined (38 pairs, 3 single convalescent) by C.F. tests and haemagglutination-inhibition (H.A.I.) tests, only 13 of 38 (34%) had rising titres (9 of them fourfold or greater) suggestive of recent infection with influenza virus A. All gave negative results in the streptococcus M.G. agglutination test and in routine C.F. tests with influenza B and C, psittacosis, adenovirus, and *Rickettsia burnetii* antigens.

At this time a strain of Sendai virus became available at the Virus Reference Laboratory. This virus, said to be a cause of pneumonitis in infants, was isolated originally in Japan. Complement-fixing and haemagglutinating antigens had been prepared to test sera from infants suffering from acute bronchiolitis with spasm in 1955-6. None of these tests had provided evidence of Sendai virus infection, but interesting results were obtained when the same antigens were used to investigate the outbreak in the hospital for chronic sick.

Materials and Methods

The strain of Sendai virus, W.I.C. 12827, was kindly supplied by Dr. Isaacs, of the National Institute for Medical Research, Mill Hill; it had come originally from Dr. Ackermann, School of Public Health, Ann Arbor, Michigan. The strain had had 12 mouse, one rat, two mouse, and 14 egg passages; it had undergone two further egg passages at the Virus Reference Laboratory. The complement-fixing and haemagglutinating antigens consisted of undiluted allantoic fluid derived from 10-day-old fertile hens' eggs inoculated allantoically with 0.1 ml. of a 10^{-4} dilution of stock seed virus. After incubation for three days at 95° F. (35° C.) the

eggs were chilled overnight. Fluids containing haemagglutinating virus were pooled, and clarified by centrifugation at low speed.

The strain of mumps virus used in the course of the investigation was that of Enders, E63/2, which had had many egg passages. Haemagglutinating and "virus particle" complement-fixing antigens were prepared by the allantoic inoculation of 8-day-old fertile hens' eggs with 0.1 ml. of a 10^{-2} dilution of stock seed virus. The eggs were incubated at 95° F. (35° C.) for five to six days. They were then chilled and the allantoic fluids were harvested from those eggs containing haemagglutinating virus in high titre. The pooled fluids were spun at 20,000 r.p.m. for one hour after low-speed clarification, and the deposit was resuspended in normal saline in one-tenth the volume of the harvested fluids.

Sodium azide was added as a preservative (in a final concentration of 0.08%) to both mumps and Sendai complement-fixing and haemagglutinating antigens. The optimal dilutions of the antigens for use in the C.F. tests were determined by means of chequerboard titrations with known positive sera.

C.F. tests were carried out in "perspex" plates with cups, using 0.1-ml. quantities of inactivated test serum, complement, and antigen; 2½ M.H.D. of complement were used and fixation of reagents took place for 1½ hours at 37° C. Then 0.2 ml. of 1% sensitized sheep red cells was added and lysis was allowed to occur for a further half-hour at 37° C. Suitable controls were put up with the test, and all results were read next morning after standing at 4° C. overnight.

Sera tested for haemagglutination-inhibiting antibody were first treated for 18 hours at 37° C. with receptor-destroying enzyme (R.D.E.), and after inactivation at 56°-58° C. for one hour were adsorbed in the cold with a suspension of fowl red blood cells which were subsequently removed by low-speed centrifugation.

Haemagglutination-inhibition titrations were carried out in W.H.O. plastic haemagglutination plates (World Health Organization, 1953) employing 0.2-ml. doubling dilutions of the prepared sera in normal saline. Then 0.02 ml. of virus suspension (containing four agglutinating doses of virus) and 0.02 ml. of 7% fowl red blood cells were added to each serum dilution, and the results were read after mixing and standing for 30 minutes at room temperature. Suitable controls were set up with each series of tests.

Results

In consequence of the small number of patients at the hospital providing results suggestive of recent infection with influenza virus A it was decided to retest their sera with a number of other virus antigens. On testing the sera of those

elderly patients serologically negative for influenza virus A for their ability to fix complement with Sendai virus preparations, recent infections with this agent were suggested when five patients were found to have rising antibody titres (Table 1); two other patients gave positive results at a dilution of 1:16 in both specimens (patients H and F,

Table II). In addition, the laboratory technician (patient Tec. K) who had collected blood from patient Ba suffered later from a mild respiratory illness and his sera showed rising antibody titres with Sendai virus only. Further examination by C.F. and H.A.I. tests of all remaining sera available from the hospital inmates, and other patients from the town, showed that in all probability a number had been infected recently with Sendai virus, including some who had suffered in addition from an influenza virus A infection. Table II shows those patients with elevated but unchanging antibody titres to Sendai virus, including some with rising antibody titres to influenza virus A.

Examination of further samples of sera (third specimens) collected about three months later confirmed this opinion. The Sendai virus complement-fixing antigen, which had the same constitution as the haemagglutinating antigen—that is, both were undiluted allantoic fluid—gave reproducible results from day to day with sera collected for the investi-

gation. In addition, rising titres of haemagglutination-inhibiting antibody always appeared as such on repetition of the tests, but the actual titres obtained tended to vary somewhat when the titrations were repeated on different occasions. This rendered impossible the determination of an H.A.I. baseline value for the detection of patients who had suffered from a previous infection, and from whom only one serum was available or whose paired sera showed unchanging antibody titres. It was not possible to determine exactly the times at which Sendai virus infection started and stopped in the hospital, but the first specimen from Ba, apparently the first case, taken supposedly on the third day of illness, January 20, was already positive at a dilution of 1:8; the sera collected in June (third specimens) from 29 patients providing negative results in February showed no evidence of further rises in antibody titre, with the exception of patient R, whose titre in the third specimen may not be significant because it could not be tested at the same time as the previous specimen. R was also the only patient in whom there was evidence of influenza A virus infection between the first week in March and the third bleeding in June (Table II).

The serum of one of the medical officers, collected in June, did not contain any complement-fixing antibodies at a dilution of 1:8 for influenza virus A antigen, but gave positive results at this dilution with both Sendai virus and mumps "virus particle" antigens. The significance of these findings cannot be interpreted at the moment (see below). Too few sera were obtained from the nursing staff to be able to determine the presence of infection among them.

The sera of 8 of 49 (16%) blood-transfusion donors from the town, collected in June, had Sendai virus complement-fixing titres of 1:8 or higher (five at 1:8 and three at 1:16), suggesting the possibility of infections with this virus in the local population.

While this work was in progress Dr. G. K. Hirst, of New York, visited the laboratory and reminded us that Sendai virus was similar in some respects to Newcastle disease virus. Although Jensen *et al.* (1955) found no serological cross-reactions between Sendai virus and the virus of mumps, the patients' sera were tested for antibody with mumps complement-fixing "virus particle" (V) antigen, which has an antigenic relationship to Newcastle disease virus (Jungherr *et al.*, 1949). It was found that of the six patients in whom rising Sendai virus complement-fixing titres could be demonstrated the sera of five had no complement-fixing antibody at a dilution of 1:8 when tested with mumps V antigen. The sixth patient had an unchanging titre of mumps V antibody of 1:8 in the first two specimens (Table I). The sera of five elderly patients (G, K, H, F, and R, Table II) showing unchanging Sendai virus complement-fixing antibody titres of 1:8 or higher were tested with mumps V antigen, and complement-fixing antibody was found to be absent at a dilution of 1:8.

None of the sera which gave negative results at a dilution of 1:8 in the Sendai virus complement-fixing test (including those with high haemagglutination-inhibiting antibody titres) had mumps V complement-fixing antibody at this dilution. The sera of four patients from the hospital for whom rising Sendai virus haemagglutination-inhibiting and complement-fixing antibody titres could be demonstrated gave negative results when retested with mumps V antigen for haemagglutination-inhibiting antibody.

Among 800 patients with illnesses of all descriptions from whom pairs of sera were received in 1956, five patients were found whose sera showed fourfold or greater increases in complement-fixing titre with Sendai virus and negative (titres <1:8) or non-rising complement-fixing titres with mumps "virus particle" antigen. The sera of these five patients gave negative results when examined routinely for antibodies to influenza viruses A, B, and C, psittacosis, adenovirus, *R. burnetii*, lymphocytic choriomeningitis virus, and streptococcus M.G. One of the patients was an adult with an influenza-like illness, and four were children with respiratory infections.

Discussion

In 1953 Kuroya and Ishida described the isolation of a virus from the lungs of a fatal case of pneumonitis in an infant by intranasal inoculation of mice. This virus was isolated subsequently by other Japanese workers from different laboratory stocks of mice, hamsters, and swine. Subsequent investigations (on volunteers) by Japanese workers confirmed that the virus could cause severe pneumonitis in children.

Jensen and his colleagues (1955) found serological evidence of the presence of the virus in the U.S.A. Five cases were identified, but no isolations of virus were made. The results of our preliminary serological surveys of single sera suggest that infection with the virus may not be uncommon in England, but more work is needed to ascertain the significance of these tests. The precise relationship between mumps V and Sendai antigens is being investigated at the moment. It is for this reason that all our suspected cases have been tested with mumps V antigen.

It is of interest that the recent addition to the myxo group of viruses, the "croup agent," isolated by Chanock (1956) in Cincinnati, U.S.A., and by Beale *et al.* (1956) in Toronto, also gives some serological cross-reactions with the mumps virus, but not with Sendai virus.

Summary

In an outbreak of respiratory illness in a hospital for the chronic sick, six patients (five old people and one technician) who developed rising titres of complement-fixing antibody to Sendai virus were observed.

Preliminary surveys show that antibody to Sendai virus is not uncommon in Southern England.

We wish to thank Dr. F. O. MacCallum for his active help and advice in investigating the outbreak and in preparing this paper. We are also indebted to Dr. Preston, Deputy Director, and the staff of the Regional Transfusion Centre, Oxford, for supplying specimens of blood from local donors; and to the laboratory staff at the Memorial Hospital, Cirencester, for the collection and dispatch of specimens.

SUXAMETHONIUM CHLORIDE ADMINISTRATION AND POST- OPERATIVE MUSCLE PAIN

BY

D. D. B. MORRIS, M.B., F.F.A.R.C.S., D.A.
Senior Anaesthetic Registrar

AND

C. H. DUNN, F.F.A.R.C.S., M.R.C.S., D.A.
Senior Anaesthetist

West Middlesex Hospital, Isleworth, Middlesex

A great deal has been written in praise of suxamethonium chloride ("scoline") as a muscle relaxant in clinical anaesthesia, stressing its freedom from side-effects such as bronchospasm, tachycardia, and fall in blood pressure. In many ways suxamethonium is the ideal relaxant: the rapid onset of complete relaxation followed by the quick return of full muscle power has made it very popular for endotracheal intubation, orthopaedic manipulation, and short abdominal operations. The ideal conditions produced for intubation have undoubtedly reduced the incidence of minor trauma to lips, tongue, and teeth, and of sore throat. One of its principal disadvantages, that of prolonged apnoea, has received so much attention as to obscure other side-effects which produce considerable anaesthetic morbidity.

It is the purpose of this paper to call attention to muscle pain and stiffness, in some cases of great severity, following the use of suxamethonium in patients who are discharged from hospital within 48 hours of operation.

Churchill-Davidson (1954) first drew attention to muscle pains after suxamethonium administration, but this received little attention in the literature; some writers denied that it even occurred. It has been noted that patients kept in bed for two to four days after operation rarely complain of post-operative muscle pains. In the present investigations dental patients discharged the day after operation were chosen. The investigations were designed to show the incidence of post-operative muscle pain, to make an estimate of its severity, and to try to find some simple means of preventing it.

Technique

The patients were premedicated with "omnupon" and scopolamine, or morphine and atropine, in doses appro-

priate to their age, weight, and physical condition. Induction was with 0.5–0.75 g. of thiopentone 5%, immediately followed by suxamethonium, 50–75 mg., and naso-tracheal intubation. Maintenance was with nitrous oxide, oxygen, and trichlorethylene. On the Nosworthy card was recorded the occupation of the patient, the dose of suxamethonium, and its speed of administration, divided into fast, medium, and slow. The resulting fasciculations were recorded as strong, moderate, and weak, and any particular muscle group strongly affected was noted. The patient's shoulders, chest, abdomen, and legs were bared in order to observe this accurately. The patients were seen the day after operation, when they were discharged, and five days later in the out-patient department, when they attended for routine dental follow-up. The site of any muscle pain or stiffness, its severity, and any spontaneous observations of the patient were recorded.

Control Series

In all, 73 patients were anaesthetized in the way described and followed up. The results were: 25 (35%) complained of pain and/or stiffness on day of discharge; 52 (72%) complained of pain and/or stiffness when seen in out-patient department; and 16 (22%) complained of severe pain and/or stiffness.

The relationship of pain and stiffness to the degree of fasciculations was studied. There seems to be no clear-cut correlation between strong fasciculation and the development of severe pain and stiffness afterwards. Some cases in which the fasciculations were weak developed severe pain and stiffness. One case is of particular interest in this connexion. The only visible fasciculation was an isolated jerk of the rectus muscle, and the patient complained post-operatively that she felt as if she had been "kicked in the belly by a horse." However, when seen in the out-patient department five days later she had experienced generalized aching for three days after discharge. Likewise, there seemed to be no definite relationship between the occupation and the state of physical fitness of the patient. Many athletic patients developed pain, and a blacksmith's striker complained of severe shoulder pain.

Our results are thus in close agreement with Churchill-Davidson's figures—that is, 72% of cases developed pain and stiffness. Our incidence of severe pain was, however, much lower: 22% as compared with 42% approximately. This difference can be explained on the basis that Churchill-Davidson's cases were out-patients, immediately ambulant after operation, whereas ours were in bed for 24 hours after operation. The longer the patient remains in bed after operation the less likely he is to develop suxamethonium pain. One patient, an architect, who had undergone five dental operations before this investigation and developed suxamethonium pain after each one, gave a very interesting account of this phenomenon. He had observed that if he kept still and made no sudden movements he was free of pain; but any activity, such as getting up out of a chair, was painful. Patients quiescent in bed after operation may not notice any discomfort. The figures from the control series show this clearly. Many patients who have no pain on the day of discharge develop it later when they return home. The incidence of pain in patients seen in the out-patient department is twice that on the day of discharge.

Experiments with Modified Technique

The following modifications of anaesthetic technique were made in an attempt to abolish muscle pains:

1. *Chlorpromazine Hydrochloride Experiment.*—Chlorpromazine hydrochloride has a direct paralytic action on skeletal muscle (Burn, 1954). It was hoped that it might modify the painful after-effects of suxamethonium. Chlorpromazine hydrochloride, 50 mg., was given intramuscularly with the premedication. A further 25 mg. was given intravenously on arrival in the theatre, followed by 0.25 g. of thiopentone, 50–75 mg. of suxamethonium, nitrous oxide, oxygen, and trichlorethylene. Fourteen cases were anaesthetized. The results were: 7 (50%) complained of

pain and/or stiffness on the day of discharge; 8 (56%) complained of pain and/or stiffness when seen in the out-patient department; and none complained of severe pain and/or stiffness. Although this series of cases was very small, administration of chlorpromazine hydrochloride did not seem to influence the incidence of post-operative pain, and the experiment was abandoned on account of the drowsy condition of the patients post-operatively, which in some cases persisted on the morning of discharge.

2. *D-Tubocurarine Chloride Experiment.*—In 65 cases Gray's test dose of D-tubocurarine (5 mg.) was given intravenously before the thiopentone and suxamethonium induction. It is important to observe the effects of these test doses, as a sensitive patient might develop a mixed block on subsequent suxamethonium administration. All of our cases developed ptosis, but none showed hypersensitivity. Visible fasciculations were not abolished in every case; in the few in which they did occur they were weak and transient. The results were: 2 (3%) complained of pain and/or stiffness on the day of discharge; 15 (22%) complained of pain and/or stiffness when seen in out-patient department; and 3 (5%) complained of severe pain and/or stiffness. Churchill-Davidson, in a much smaller series of cases, using 40 mg. of gallamine triethiodide in place of 5 mg. of D-tubocurarine, found that 40% complained of muscle pains, as compared with 22% in this series. There is no doubt that the administration of 5 mg. of D-tubocurarine effectively reduces the incidence and severity of post-operative suxamethonium pain, and is a simple practical measure. The case referred to above in which the patient had experienced suxamethonium pain from five previous anaesthetics underwent a further five dental operations during the investigations. In each of these inductions 5 mg. of D-tubocurarine was given before the thiopentone and suxamethonium induction as described, with complete relief of post-operative muscle pain.

3. *D-Tubocurarine Post-suxamethonium Experiment.*—In order to prove that 5 mg. of D-tubocurarine before suxamethonium is the effective measure in reducing muscle pains, 5 mg. of D-tubocurarine was given after the suxamethonium in 25 cases. No modifications of fasciculations were seen; this was expected, as suxamethonium acts more rapidly than D-tubocurarine. The results, as expected, correlate closely with the control series: 7 (28%) complained of pain and/or stiffness on the day of discharge; 19 (76%) complained of pain and/or stiffness when seen in the out-patient department; and 4 (16%) complained of severe pain and/or stiffness.

4. *Slow Administration Experiment.*—In 27 cases suxamethonium was given at the rate of 10 mg. per 30 seconds until apnoea occurred. When administered in this way fasciculations are greatly reduced in strength. The results were: 12 (44%) complained of pain and/or stiffness on the day of discharge; 20 (74%) complained of pain and/or stiffness when seen in the out-patient department; and 8 (30%) complained of severe pain and/or stiffness. Some of the most severe cases occurred in this group. One female patient was confined to bed on her return home and was so stiff and aching that her relatives had to lift and turn her over in bed. Bourne *et al.* (1952) state that where fasciculations are vigorous post-operative stiffness is more likely. This series shows conclusively that the degree of pain bears no relationship to the strength of visible fasciculations. Six patients who complained of severe pain had no fasciculations at all.

5. *Procaine Experiment.*—Procaine produces neuromuscular block by inhibiting production of acetylcholine at the end-plate. In 25 cases 10–20 ml. of 1% procaine was given intravenously before the thiopentone and suxamethonium induction. The results were: 2 (8%) complained of pain and/or stiffness on the day of discharge; 11 (44%) complained of pain and/or stiffness when seen in the out-patient department; and 3 (12%) complained of severe pain and/or stiffness. Procaine administration does seem to have some influence on suxamethonium

muscle pain, but is a clumsy method and not so effective as D-tubocurarine. Procaine administration is time-consuming and suffers from the danger that it may prolong the action of suxamethonium, since they are both destroyed by the same enzyme.

Discussion

It is evident from the results of the investigations that suxamethonium is responsible for considerable post-operative discomfort when a patient is discharged home within 48 hours of its administration. After the patient has been up and walking around for about eight hours, aches and pains start, lasting two or three days; in some cases they are severe and may last for as long as six days. A common description by patients is to say, "I feel as if I had been kicked in the belly by a horse," or "trampled on by a herd of elephants": a tough young man will say, "I feel as if I have been in a brawl." Many patients have called in their own doctors for advice and treatment. The condition usually goes unrecognized, and various diagnostic labels are attached, such as "Fibrositis" or "You must have been in an awkward position on the table."

From the statistical results and from interviews with these patients in the out-patient department it is our firm opinion that suxamethonium should be given up as a relaxant in those cases where the patient is discharged within 48 hours of operation, unless previously modified with D-tubocurarine. Suxamethonium is often the relaxant of choice for a difficult intubation or a manipulation in a very muscular individual, and in these cases the likelihood of suxamethonium pain can be greatly reduced by the use of 5 mg. of D-tubocurarine before the suxamethonium.

Summary

229 cases undergoing dental operation were given suxamethonium chloride ("scoline") for endotracheal intubation, and the incidence of post-operative pain attributable to the drug was investigated.

Slow administration of suxamethonium does not reduce the incidence and severity of post-operative muscle pain.

The only practical and convenient measure to reduce this muscle pain is the administration of 5 mg. of D-tubocurarine or 40 mg. of gallamine triethiodide before the suxamethonium.

We are indebted to Mr. H. Mandiwall, consultant dental surgeon, and Mr. D. A. Brown, senior hospital dental officer, for their co-operation in conducting these investigations.

For the first time a section devoted to hospitals will be included in the annual Congress of the Royal Society of Health, which is being held at Folkestone from April 30 to May 3. This section will be presided over by LORD INMAN, Chairman of Charing Cross Hospital. Another innovation will be a forum consisting of a general practitioner, two medical officers, the medical director of a London hospital, and a health visitor, which will discuss questions concerning the health and welfare of the family. During the Congress papers will be read on such subjects as world nutrition, new methods in food preservation, absenteeism in industry, marriage and mental health, slum clearance, food hygiene, fluoridation of public water supplies, and atmospheric pollution. To commemorate the tercentenary of the death of William Harvey, Sir ARTHUR MACNALLY will deliver a special lecture entitled "William Harvey—His Influence on Public Health." Provision has also been made for an overseas forum at which late papers from foreign delegates will be given.

GENERALIZED ARTERIAL CALCIFICATION OF INFANCY

BY

A. C. HUNT, M.D.

Lecturer, Department of Forensic Medicine, the London Hospital Medical College

AND

D. G. LEYS, D.M., F.R.C.P.

Senior Physician, Children's Department, Farnborough Hospital, Kent

In some 40 reported cases of arterial calcification of infancy the proved occurrence in siblings has been described once (Menten and Fetterman, 1948). We report a further example of siblings affected by this disease. It has been described in children of either sex from the age of 1 day to 27 months, usually in the first six months of life. The clinical history and post-mortem appearances in most of the reported examples in early infancy are very similar. The children are born to apparently healthy young parents. The pregnancy and birth are normal, and there is no evidence of abnormal consumption by mother or child of poisons or poisonous dosages of calcifying substances. The infant thrives at first, then, after a few hours, or at the most a few days, of acute symptoms, succumbs from cardiac ischaemia. The symptoms are refusal of feeds, painful rapid respiration, abdominal distension, and heart failure. Occasionally, as in the first of our cases, an electrocardiogram may show the picture typical of coronary occlusion.

Although the clinical manifestations are usually attributable to blockage of the coronary arteries, the calcification affects large and medium-sized arteries throughout the body, and hence we have used the term "generalized arterial calcification."

This is not the only cause of cardiac infarction in infancy, but the syndrome forms a well-defined clinical entity.

Case 1

A male child was born on July 11, 1949. The mother was aged 19 and the father 20; both were in good health with no significant medical history. Both were English and not consanguineous. The child was delivered normally in hospital after an uneventful pregnancy and weighed 7 lb. 13 oz. (3.5 kg.) at birth. He cried vigorously. There was difficulty in establishment at the breast owing to retracted nipples, and the infant was therefore bottle-fed (dried milk). The mother noted no disturbance of any kind until four days before readmission to hospital on August 9, 1949, the infant then being 4 weeks old. The first symptom was refusal of food, and this was followed by vomiting and rapid breathing. The family doctor did not think the child was seriously ill until the day of admission, when respiration became much more difficult.

On arrival at hospital the infant was extremely ill, cyanosed, and pale, with a respiration rate approaching 100, temperature 100° F. (37.8° C.), and heart rate 180–200. The liver was enlarged, but there was no oedema. The clinical diagnosis was of acute infection, possibly accompanied by paroxysmal tachycardia. The cardiogram showed inversion of the T waves and elevation of the ST segment, typical of coronary occlusion. The leucocyte count was 7,000, of which 50% were polymorphonuclears. X-ray examination of the chest showed some mottling at the bases. Antibiotics and digoxin were prescribed, but the infant died a few hours later.

Case 2

A third child (a girl) was born at home on October 28, 1955, after a normal pregnancy—a second child (a boy) having been born in 1954. Delivery was spontaneous, and the infant appeared healthy. She was breast-fed and showed no signs of illness until 24 hours before admission to hospital on November 26, then being 4 weeks old. The first symptom was refusal of food, and this was followed by vomiting, the passing of two or three loose stools, and rapid grunting respiration. On admission the infant was cyanosed, pale, and collapsed, with a heart rate of 180, enlargement of liver and spleen, and oedema. There were crepitations over both lungs. The infant died within a few hours.

Post-mortem Examination

Both children were well nourished and externally normal. The most outstanding lesion internally was the calcification of the coronary arteries. The first 2–3 cm. stood out hard, white, and tortuous from a faintly mottled pale-red epicardium. The external iliac, femoral, popliteal, axillary, and brachial arteries were rigidly calcified in almost their whole length, but no other calcification was seen with the naked eye. In Case 2 all of the viscera were radiographed after removal, and, besides the sites already mentioned, calcification was obvious in the mesenteric arteries and in the lingual arteries. The heart of the first child was enlarged (40 g.), predominantly by left ventricular thickening, and the myocardium was firm and light red. In Case 2 the heart was of normal size (23 g.) and the anterior wall of the left ventricle was pale and slightly mottled, the pallor being most pronounced in the inner third. The anterior columnae carinae were flattened. In Case 1 the valves were normal, but in Case 2 there were five minute dark flecks on the contact margin of the posterior mitral cusps. Macroscopically the aorta was normal.

The kidneys were normal to the naked eye. The bones and their epiphyseal lines in Case 2 showed no abnormality macroscopically or microscopically. Only the upper pair of parathyroid glands were found in Case 2 despite a prolonged naked-eye and microscopical search. The two found were of normal size and microscopically appeared normal by the criteria of Gilmour (1947). The parathyroid glands were not examined in Case 1.

Microscopical Appearances

Arteries.—The vascular changes in both children were in all major respects similar, although there were minor variations in the degree of involvement at different sites. In addition to the arteries in which calcification was visible, either by naked eye or radiologically, smaller arteries, such as the pericapsular vessels of the thyroid and suprarenals, and arteries in the pancreas and thymus, often showed slight degrees of calcification. The relationship of the calcification to elastic tissue emphasized particularly by Stryker (1946) was very obvious. There was a remarkable predilection for the internal elastic lamina. The minimal lesion was a fine incrustation on each side of the elastic strand, and there were all degrees between this and large irregular masses of calcification distorting the media, with great fibrous intimal proliferation even to the extent of completely obliterating the lumen. In most of the large masses fragments and lengths of elastic tissue could be demonstrated with suitable staining. A common finding was straight bars of calcification along the course of the elastic lamina with loss of the characteristic wavy appearance, and a slight degree of intimal thickening. The pulmonary arteries showed calcification in the elastic strands throughout the media, but no large masses and no intimal changes. A few elastic fibres in the media of the aorta were focally encrusted with calcified material. The affected elastic was at varying levels in the thickness of the aortic media, and sections of all parts of the aorta showed the change. There were no changes in the cerebral vessels. Minimal lesions were present

in the common carotid arteries in Case 1. The elastic laminae remote from the areas of calcification appeared normal.

Heart.—The myocardium of the enlarged heart in Case 1 showed slight patchy interstitial fibrosis, most marked in the subendocardial third and in the papillary muscles, and a few small areas of recent muscle necrosis. In Case 2 there was less fibrosis and more extensive recent infarction, mainly in the anterior wall of the left ventricle. The flecks on the mitral valve consisted of fibrin and red cells, and the valve itself was normal.

Kidneys.—There were amorphous masses of calcification in a few scattered glomeruli in both cases. These masses projected inward from Bowman's capsule and distorted the glomerular tuft. In sections stained with periodic-acid-Schiff the calcification was clearly related to the basement membrane of the capsule, which split to enclose it.

No calcification was found histologically in any other sites, including the gastric mucosa, the pulmonary alveolar walls, and the endocardium.

Examination of the Mother and Surviving Sibling.—This was made clinically, radiologically, and electrocardiographically, and no abnormality was detected. Their serum calcium, blood inorganic phosphorus, and plasma cholesterol were normal.

Discussion

The differential diagnosis clinically between the effects of generalized arterial calcification on the heart and the manifestations of such conditions as glycogen-storage disease, interstitial myocarditis, endocardial fibroelastosis, and aberrant coronary arteries may be difficult. It has been suggested by Cochrane and Bowden (1954) that radiography of the neck may show the arterial calcification.

The aetiology of generalized arterial calcification of infancy is unknown. There is a possibly distinct small group of cases in which primary renal disease may have produced metastatic calcification. Hydronephrosis was found in two children (Bryant and White, 1891; Andersen and Schlesinger, 1942) and congenital renal hypoplasia in one (Cochrane and Bowden, 1954).

A congenital abnormality of the arterial wall and an abnormality of calcium metabolism are the most likely alternatives to account for the remaining cases, and in our opinion the latter is the more probable. The possibility of vitamin D overdosage has been excluded in the majority, although the possibility of hypersensitivity to the vitamin cannot be disproved. The parathyroids have been normal in the few cases in which they have been examined, and no lesions have been found in the bones.

The serum calcium level has been estimated in life in only one example of primary arterial calcification without primary renal disease, and was normal—10.8 mg. per 100 ml. (Traisman *et al.*, 1956). This isolated estimation in a single case cannot be regarded as of great significance.

The predilection of the calcification for elastic tissue has been thought to indicate a primary abnormality of this structure (Stryker, 1946); it has been suggested that the calcification of the arteries in the children with primary renal disease was coincidental. However, calcification round elastic laminae has been described in renal rickets (Shelling and Remsen, 1935), and we have observed a similar picture in material from seven young adults with chronic renal disease and metastatic calcification in the collection of the Bernhard Baron Institute of the London Hospital. In four of these a prominent feature was arterial calcification, most commonly in the form of diffuse calcification of the media, but frequently with a narrow darker staining deposition of calcium against the internal elastic lamina. In all seven cases there were fine incrustations and bars of calcification related to the internal elastic laminae in medium and small arteries closely resembling the lesions of generalized arterial calcification of infancy. It appears that in any state of metastatic calcification the arterial

elastic laminae are particularly liable to have calcium deposited round them.

The presence of calcification in the kidneys in many examples of arterial calcification of infancy, either in the glomeruli or in the tubules, suggests that the condition may be part of a generalized metastatic calcification rather than a dystrophic one.

Lightwood (1932) reported widespread arterial calcification in a mentally retarded dwarfed child of 26 months with calcification at sites other than the arteries and kidneys, and with increased density of the bones. The serum calcium was 11 mg. and the blood inorganic phosphorus raised to 6.68 mg. per 100 ml. This case may indicate an aetiological connexion of at least some of the cases of generalized arterial calcification with the severe form of infantile hypercalcaemia described by Fanconi and Girardet (1952), Schlesinger *et al.* (1952), and others.

Furthermore, deposition of calcium in relation to "degenerated" elastica in lingual, meningeal, and renal arteries has been described in a child of 26 months with the severe type of infantile hypercalcaemia (Schlesinger *et al.*, 1956, Case 9).

Until some information becomes available on the biochemical changes in life in generalized arterial calcification of infancy, it is unlikely that any more will be known of its aetiology. It appears from Menten and Fetterman's (1946) cases and ours that the condition may have a familial incidence.

Summary

Two cases are reported of sudden death in infancy from general arterial calcification occurring in a family. Little is known of the aetiology of the condition.

We thank Dr. F. E. Camps for allowing us to use his post-mortem records and material from Case 1.

"The Flour (Composition) Regulations, 1956, require that all flour, other than wholemeal, shall contain minimum quantities of certain nutrients, including vitamins B₁ and B₂, and iron and chalk. Some of these nutrients are partly removed during milling operations, and the lower extraction flours now being sold require, in many cases, the artificial addition of such substances in order to bring the total amounts in the flour up to the minimal quantities laid down by the Regulations. The nutrients are added by millers in the form of a so-called 'master mix' containing all of them in such amounts as to ensure that if the level of one of them in the flour is of the correct order the remaining ones will also normally be present in the required quantity. From the analytical point of view it will be therefore usually necessary to determine only the amounts of one or two of the nutrients present, and to assume, fairly justifiably, that if these are found to be in the correct proportions the others will be likewise. Four samples of flour were examined during the quarter as a preliminary trial. Three of them were of incorrect composition."—Report of the Birmingham City Analyst.

Medical Memoranda

Primary Dislocation of the Left Shoulder-joint in the Boxing-ring

In the course of a light-heavyweight bout between R.A.F. College, Cranwell, and Cambridge University a cadet was seen suddenly to hold his left elbow with his right glove and to be completely disabled. The round ended almost immediately, and he subsided into the chair in his corner in great pain.

It is often difficult to see some decisive incident in the ring (hence multiple judges as well as a referee), and in this instance I was "stymied" by the referee and saw nothing. As I climbed up to investigate, a colleague in the front row helpfully hazarded the opinion that the man had dislocated his shoulder. On examination this "spot" diagnosis was seen to be perfectly correct, with the classical flattening of the deltoid region and the bulge of the head of the humerus anteromedially and subcoracoid. It was not the moment or the place for bothering the patient about the detailed mechanism whereby this extraordinary happening had come about. I was puzzled because, in boxing, the left upper limb is mainly concerned with the safe piston-like movements of leading and guarding, in which no considerable abduction is involved. It would have been much more explicable in the case of the right shoulder-joint, where wide abduction occurs in swinging a right hook to the jaw. Moreover, this was not a recurrence. The man had never dislocated his shoulder before, and so lacked the notorious tendency to recurrence. I wrote to the patient and to the S.M.O. at Cranwell R.A.F. College, asking if they could throw any further light on the dislocation, and I also questioned his opponent, our own light-heavyweight.

The cadet replied: "It was very difficult, as I didn't actually feel it happen at all. The only sensation was of not being able to raise my left arm, and then I thought it must be cramp. I didn't realize the shoulder was dislocated until I returned to my corner at the end of the round." He continued: "I have asked independently all the members of the team who were watching, and . . . it appears that . . . I attempted a left hook, and while my arm was fully extended (my punch having missed) he hit my arm with a right-hand punch."

The opponent confirmed this missed hook, and stated that he himself had a very sore right ulna from the violent impact of his own upthrusting forearm blow in warding off the said hook.

COMMENT

It would appear that the patient's left shoulder-joint was relaxed, with flaccid muscular control, at the moment when his arm was widely abducted and the blow missed. Simultaneously the Cambridge man violently forced the arm much further upwards, bruising his own forearm, and levering the head of the humerus downwards out of its shallow socket and through the capsule of the joint.

It is hardly necessary to recall that the stability of the shoulder-joint (with its shallow glenoid cavity providing little or nothing to hold the head of the humerus) depends on the tension of the tendons passing under, over, or through the joint and the elastic compressing pull of the muscles acting upon it. The dislocation happened at the moment of misfire, when all these structures were relaxed.

I have never seen this accident in the boxing-ring before, during thirty years at the Cambridge ringside, nor have I heard of it elsewhere. It would seem that primary dislocation of the shoulder-joint in the boxing-ring is an extremely rare accident, comparable in rarity with dislocation of the hip-joint at "rugger" (Woods, 1949).

R. SALISBURY WOODS, M.D., F.R.C.S.,
Honorary Medical Officer,
Cambridge University Boxing Club.

Agranulocytosis During Treatment with an Amoebicide

A case of agranulocytosis developing in the course of treatment of amoebiasis with "camoform" is described. It appears to be the first time in which such a haematological change has been noted during camoform medication.

CASE REPORT

In November, 1955, in Calcutta, an Englishwoman aged 27 complained of abdominal discomfort and dyspepsia. She had never been ill before. She had one child aged 15 months. On clinical examination no abnormality except moderate obesity was found. A stool examination revealed mucus and a few precystic and cystic forms of *Entamoeba histolytica*, no cellular exudate, and no ova. A blood count showed: erythrocytes, 4,510,000; Hb, 12.6 g./100 ml.; leucocytes, 5,200 (polymorphs 70%, lymphocytes 27%, monocytes 0%, eosinophils 3%). Her urine contained no abnormality. Camoform, one tablet (250 mg.) four times a day, was prescribed. On the fifth day of treatment her temperature was 101° F. (38.3° C.), and she had mild photophobia and mild pains in the limbs and neck. On the following day the fever had abated to 100° F. (37.3° C.), and she had very little photophobia or pain. She did not complain of sore throat and no pharyngeal abnormality was found on examination. On that day her leucocytes numbered 2,300 (polymorphs 71%, lymphocytes 24%, monocytes 3%, eosinophils 2%).

Camoform treatment was stopped after a total of 16 tablets (4 g.) had been taken. On the sixth day the leucocytes had further decreased to 2,000 (polymorphs 56%, lymphocytes 40%, monocytes 2%, eosinophils 2%). On the seventh day the lowest readings were obtained: leucocytes, 1,200 (polymorphs 56%, lymphocytes 40%, monocytes 1%, eosinophils 3%).

The patient was admitted to hospital on the sixth day and treatment instituted. Penicillin was given eight-hourly in doses of 400,000 units intramuscularly (crystalline penicillin G procaine 300,000 units, with buffered crystalline penicillin G potassium 100,000 units) for five days. "Pent-nucleotide," 10 ml. daily, was given intramuscularly for the first three days. Cortisone acetate, 150 mg. daily in divided doses, was also given for four days. Afterwards the dose of cortisone acetate was gradually reduced. On the third day of this treatment the leucocytes rose to 1,800 (polymorphs 68%, lymphocytes 30%, monocytes 1%, eosinophils 1%), and there was a consistent improvement onwards. Five days later a blood count showed: erythrocytes, 4,250,000; Hb, 12 g./100 ml.; leucocytes, 5,100 (polymorphs 54%, lymphocytes 34%, monocytes 2%, eosinophils 10%). Four months later the patient was still well.

COMMENT

In a series of 20 cases Barrios (1954) reported no haematological toxic signs, though three of his patients developed anorexia, transient albuminuria, or headache. Abdominal pain, headache, nausea, dizziness or vertigo, sweating, or palpitation were observed in East Africa by De Mello and De Mello (1955), but they, too, do not report any blood dyscrasia. In Honduras, Hoekenga and Batterton (1954) gave camoform, 1.5 g. daily for seven days, to a series of 18 patients with amoebiasis, with no ill effect.

We have used camoform in a large number of cases of amoebiasis, but this case of agranulocytosis is the only one in which a serious toxic reaction followed the use of the drug.

Acknowledgment is made to Professor B. P. Tribedi for his help in performing laboratory investigations; to Messrs. Parke, Davis and Co. Ltd.; and to the Librarian of the Royal Society of Medicine for aid in surveying relevant literature.

Reviews

ANATOMY AND PHYSIOLOGY OF
GALEN

Galen on Anatomical Procedures. Translation of the surviving books with introduction and notes by Charles Singer. (Pp. 289+xxxvi; illustrated. 37s. 6d.) London, New York, Toronto: Oxford University Press for Wellcome Historical Medical Museum. 1956.

This translation by Dr. Charles Singer of Galen's *De Anatomica Administrationibus* is a very useful addition to the publications sponsored by the Wellcome Historical Medical Museum. In it we have what is essentially Galen's "Little Cunningham," for the book is a translation of a series of lecture-demonstrations on anatomy and physiology given at Rome in the year A.D. 177. The greater part of it comprises a dissecting manual, not of the human but of the monkey or ape, as Galen himself freely acknowledges. This is not to say that Galen did not have access to human material in his studies, for he indicates quite clearly that he had worked on the human skeleton—and there are other hints that he knew something of the soft parts. Such knowledge must have been obtained as occasion offered, and so he officially advises his students to dissect either the Barbary ape or the rhesus monkey, which seemed to him most like the human in structure. Professor Singer has very carefully assessed the problem to which of these two creatures the majority of Galen's dissecting instructions refer—and he believes that the animals used were rhesus monkeys. Accordingly the text has been illustrated by relevant figures from the excellent monograph by Hartman and Straus (*The Anatomy of the Rhesus Monkey*, 1953), which do much to assist the reader.

One of Galen's difficulties was that of nomenclature, especially with regard to the muscles. There were few "official" names for many structures when he wrote, so his descriptions may seem rather verbose and the structures difficult for us to identify, the more so since his observations do not refer to the human; but Singer has interpolated the modern names in the text, and in a series of notes has shown the essential differences between monkey and man for those who know little of comparative anatomy. Much of the value of the translation stems from this scholarly work. Galen, however, was not only an investigator of the dead body; he constantly refers to observations on the living human where wounds or disease are present; and, again, he practised operations on animals in attempts to understand the mode of the circulation and respiration. In this he showed the essential linkage between anatomy and physiology as two subdivisions of one science.

This book should be in all medical libraries; it would be worth while for postgraduate and undergraduate students to study it at their leisure, and to learn from it that the sciences of anatomy and physiology are not of such recent development as they may think, and reflect on the heritage to which they are successors.

J. S. BAXTER.

THE HEART AND ITS DISORDERS

Cardiology. By William Evans, M.D., D.Sc., F.R.C.P. Second edition. (Pp. 574+x; illustrated. 92s. 6d.) London: Butterworth and Co. Ltd. 1956.

Diseases of the Heart and Circulation. By Paul Wood, O.B.E., M.D., F.R.C.P. Second edition. (Pp. 1,005+xxxviii; illustrated. £5 5s.) London: Eyre and Spottiswoode Ltd. 1956.

That new editions of two books emanating from the National Heart Hospital should appear in the same month is a testimony to the authority, ability, and industry of their distinguished authors. Both dedicated to Sir John Parkinson, the doyen of British cardiologists, both nurtured and maturing in the same stable, yet were there ever such dissimilar but attractive twins?

William Evans claims to write for the student requiring a concise statement of modern views. Dogmatic, personal, steeped in the clinical outlook, more than a trifle prejudiced at times, but always vastly stimulating, his book sets out his views with a deep conviction and a burning fervour. This is the gospel according to Evans. Not the least praiseworthy of his many attributes is the author's nonconformist attitude, which should serve to arouse the critical powers of the more experienced postgraduate. A most commendable, original, but unorthodox book by a great clinical teacher.

Paul Wood writes primarily for the graduate, and modestly claims that his volume is not intended for the consultant cardiologist. In point of fact few physicians—cardiologists or not—can afford to dispense with this book, which provides a comprehensive survey, unique in its scope and outlook. Similarly, surgeons, now entering this field in increasing numbers and not averse to advice, will find the help and guidance they require. The author brings to the bedside a vital dynamic approach, based primarily on the application to man of the physiological techniques which have revolutionized our concepts of circulatory mechanisms over the past 20 or 30 years. Facts and figures, opinions and hypotheses, are criticized and analysed with a masterly assurance. This is the naked truth according to Wood. In breadth of outlook, in the blending of clinical experience with the results of technical procedures, and in their welding together, a sound critical and constructive judgment is revealed. There is no better presentation of the advance in our understanding of circulatory disease than this masterly survey from the pen of Paul Wood—an outstanding achievement which brings great credit to British cardiology.

A. RAE GILCHRIST.

NON-VENEREAL GENITAL DISEASES

The Nonvenereal Diseases of the Genitals: Etiology, Differential Diagnosis and Therapy. By Fritz T. Callomon, M.D., and John F. Wilson, B.S., M.D., M.S. (Pp. 382+xiii; illustrated. 95s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1956.

This is a book by two dermatologists who have undertaken to give a detailed comprehensive description of all the non-venereal affections of the genitalia, whether localized to that area or forming part of more generalized conditions. They have covered a wide field, and some of their descriptions, especially of dermatological conditions, are excellent. Disproportionate attention is, however, paid to the rare and unusual, of which the description is in some cases unduly discursive, with the result that the book is far longer than the subject-matter really requires. Its chief value will be as a book of reference, and as such it is particularly commended to venerologists, for all kinds of lesions which have nothing to do with venereal infection are apt to present in the clinic for venereal diseases. There is also much of interest to the dermatologist, the gynaecologist, and the urologist.

The sections on treatment are valuable and in most instances well up to date. In general the English is lucid enough, but it is sometimes quaintly phrased, almost as though it had been translated too literally from a foreign language. There are a number of typographical errors which careful proof-reading might have corrected, and the references, though large in number, are not always accurate and seem to show a bias, perhaps determined by a nostalgic devotion to out-of-date German literature. Many of the illustrations are excellent, but others are not so. Those readers who feel able to afford the considerable cost of a personal copy will be rewarded with a book that is well printed and produced on excellent paper, and subject-matter which contains much of interest. It could, however, have been much better done, for when the authors deal with some subjects outside the immediate scope of dermatology, such as non-gonococcal urethritis, the standards of achievement are very indifferent.

AMBROSE J. KING.

CLINICAL ORTHOPAEDICS

Clinical Orthopaedics—No. 7. Edited by Anthony F. DePalma, with the assistance of the associate editors, the board of advisory editors, and the board of corresponding editors. (Pp. 354+x; illustrated. 60s., or 48s. to subscribers.) Philadelphia and Montreal: J. B. Lippincott Company. London: Pitman Medical Publishing Company, Ltd. 1956.

The subject-matter in No. 7 of this series is bone tumours and injuries resulting from motor accidents. There are, in addition, an appreciation of Bloodgood's work and a few chapters on general orthopaedic subjects, including central fracture of the acetabulum. There is not a textbook description of all bone tumours, but those of interest are chosen, either because there has been particular study of such growths as chordoma and osteoid osteoma, or because the advance of knowledge is slow, as in the case of the sarcomata. Copeland writes on tumours of cartilaginous origin, and Jaffe and others on osteogenic sarcoma. It is reported that solitary and multiple osteochondromata and chondromatosis of joints may acquire malignant changes. The history of several types of sarcomata is well described. Biopsy is advocated to provide accurate diagnosis rather than the assumption that the manipulation during examination is a more potent factor in dissemination than the operation. The round-cell sarcomata are separated into types, and it is stated that correct diagnosis is essential, as the cell type of the neoplasm determines the nature of the appropriate treatment. There are reports on 107 fibrosarcomata and 32 aneurysmal bone cysts from the Mayo Clinic and of a chondroblastoma of the talus from Texas.

Ample material was available for the study of several aspects of motor injury, such as the time intervals between injury and death, the crush syndrome, and the injuries of young and old. Readers will be interested in chapters on head, chest, and abdominal injuries. The information on residual disabilities will be accepted, but the opinion expressed on the withholding of a driving licence on medical grounds is unlikely to meet with approval in this country.

These volumes continue to contain high-grade information, and the illustrations, especially the reproductions of radiographs, are excellent.

DISEASES OF THE SKIN

An Introduction to Dermatology. By G. H. Percival, M.D., Ph.D., F.R.C.P., D.P.H. Twelfth edition. (Pp. 374+vii; illustrated. 45s.) Edinburgh and London: E. and S. Livingstone Ltd. 1956.

The Edinburgh school of dermatology is well established, having been founded by William Allan Jamieson and carried on by his successor, the late Sir Norman Walker. Both wrote textbooks on diseases of the skin and made the Edinburgh teaching more generally available. It is now over half a century since Sir Norman Walker's first edition of *An Introduction to Dermatology* was published. Professor Percival, who holds the only chair of dermatology in the British Isles, collaborated with him in the production of the tenth edition, and nine years ago was solely responsible for the eleventh. Since then additional antibiotics, the discovery of A.C.T.H. and cortisone, and the appearance of other new therapeutic agents have made a new edition essential and welcome.

In the twelfth edition the arrangement of the contents is unchanged, the chapter headings being precisely the same as before. There are 25 more pages and six more figures. In a book of this kind the illustrations are of great importance. Almost without exception these are excellent, and it is remarkable that 188 of them are in full colour. The book is well balanced in its consideration of both common and rare conditions. It is, moreover, essentially practical in its approach, and once more can be warmly recommended to medical students and general practitioners, for whom it is written.

S. T. ANNING.

PHYSICAL AIDS IN PLASTIC SURGERY

Physical Methods in Plastic Surgery. By Joseph P. Reidy, M.A., M.B., B.Ch.(Cantab.), F.R.C.S. General editor of physical medicine series: William Beaumont, M.R.C.S., L.R.C.P. (Pp. 69+xiii; illustrated. 12s. 6d.) London: The Actinic Press. 1956.

Although the physiotherapist, the occupational therapist, the remedial gymnast, and the rehabilitation expert may all have their parts to play in the team which is concerned with the treatment of patients requiring reconstructive or plastic procedures, it is often extremely difficult to define their existing activities. These, in any case, will vary from patient to patient and from condition to condition. Instead of producing a dry catalogue of the possible remedial procedures, the author has written an informative little book containing a series of simple descriptions of the commoner surgical methods which the plastic surgeon may employ, together with an indication of some of the conditions for which they are likely to be used. The whole is well illustrated by line drawings and photographs, and throughout an indication of the particular activities of the physiotherapist is given. On the other hand, the book will have an equally wide appeal to both nurses and medical students, and it is for this reason that one can almost wish that its title were more indicative of its contents.

R. MOWLEM.

PARASITOLOGY

Introduction to Parasitology. With Special Reference to the Parasites of Man. By Asa C. Chandler, M.S., Ph.D. Ninth edition. (Pp. 799+xiv; illustrated. 68s.) New York: John Wiley and Sons, Inc. London: Chapman and Hall, Ltd. 1955.

Some 35 years ago the first edition of this book was published with the title *Animal Parasites and Human Disease* to present human parasitology in a readable popular form for general readers. It was immediately accepted as an introduction to parasitology for academic purposes; in successive editions, of which this last is the ninth, the scope was widened to include the lower animals as well as man, in order to emphasize the general principles of parasitology that may not be obvious when the parasites of only one host are considered. The approach is primarily biological, stressing the importance of the parasites, their life-cycle, epidemiology, pathogenicity, immunology, and the applied aspects of prevention and control. Taxonomy is considered only so far as is necessary to give an understanding of the general relationships of the parasites. The book is more concerned with fundamental principles than with the details that would interest a specialist.

A comprehensive and integrated account is given of the relevant fields of protozoology, helminthology, and medical entomology, and this approach is most desirable in giving a general introduction to subjects which are so intimately related. The spirochaetes are included with the protozoa, since some are transmitted by arthropod vectors, and arthropod-borne bacteria, rickettsias, and filterable viruses are considered together. Parasitic diseases that are of increasing current interest in the world, such as leptospirosis, amoebiasis, schistosomiasis, onchocerciasis, and leishmaniasis, are dealt with more fully, and the general sections on immunity, insecticides, etc., have been largely rewritten. The guidance given to the literature on parasitology is particularly valuable.

There are occasional statements with which those intimately concerned with particular subjects may not agree, and since this edition was compiled there have been important advances in onchocerciasis and in infections with *Loa loa*, *Wuchereria malayi*, and *W. pacifica*; but this is inevitable in a subject which is developing so rapidly. This new edition succeeds even better than the last in presenting parasitology to the novice as a fascinating integrated study of living organisms, and is a book which may be read with new pleasure by the parasitologist.

VIRUSES MADE TO ORDER

The relative simplicity with which the plant viruses can be handled has recently led to outstanding advances in the understanding of their structure, and it is no exaggeration to say that it is now possible to take a virus particle to pieces and put it together again without at the same time ending its existence as an infective entity. Tobacco mosaic virus is an exceptionally favourable object for study, since it can be prepared from infected tobacco plants in large quantities and obtained in crystalline form, a circumstance which enables its structure to be investigated by the powerful method of x-ray diffraction. G. Schramm, G. Schumacher, and W. Zillig¹ showed that the rod-like particles of virus could be broken down into sub-units by treatment with alkali, and that the sub-units could then be recombined into particles of protein which were of the same size and shape as the original virus, although they were no longer infectious. The sub-units could be further separated from each other by electrophoresis to yield a number of distinct fractions, and when these fractions were examined under the electron microscope an odd assortment of objects came to light. There were virus rods with one or more sections missing out of their middles, and held together by a central filament which evidently ran throughout the whole length of the rod. The missing bits were also in evidence as disks with holes in the middle. From studies of the chemical composition of the virus it seemed probable that the disks were made of protein and were strung upon a central filament of ribonucleic acid. Now protein and nucleic acid are chemical substances of distinctive properties which can be separated and treated by standard chemical procedures, and H. Fraenkel-Conrat and R. C. Williams² have been able to prepare each com-

ponent in a fairly pure state. The protein was precipitated with ammonium sulphate and the ribonucleic acid was obtained by treating the virus with detergent; after purification the protein and the ribonucleic acid were obtained as separate solutions. No trace now remained of the structure of the original virus rods, and the two solutions were not infectious when rubbed on to the leaves of tobacco plants. But when the solutions were mixed an opalescence gradually developed on standing; examination in the electron microscope revealed that rods had reappeared, and that they resembled the rods of tobacco mosaic virus in all respects except that they showed greater variation in length. Moreover, when this material was inoculated on to tobacco plants it was found that 3% of the rods were infectious, and produced the distinctive lesions of tobacco mosaic virus.

In further experiments³ protein of standard tobacco mosaic virus was combined with ribonucleic acid prepared from certain strains of virus which produced distinctive symptoms, and the reconstituted virus was then inoculated on to tobacco plants. In all cases the lesions which resulted were those characteristic of the strain of virus which supplied the ribonucleic acid. In one instance investigated in further detail the progeny virus which developed in the plant was identical with the parent which donated the ribonucleic acid. It is therefore evident that hybrids can be produced *in vitro*, and the experiments further afford an elegant demonstration that the genetic characters of the virus reside in the ribonucleic acid and not in the protein. The practical aspects of the reconstitution process have been studied by B. Commoner and his colleagues,⁴ and by paying careful attention to details it was possible to raise the yield of infectious rods to nearly 10%. They also made an observation of far-reaching implications. Ribonucleic acid extracted from normal tobacco mosaic virus could be separated into three fractions by chromatography, and when these fractions were recombined with virus protein and inoculated on to tobacco plants the three types of reconstituted virus particle produced symptoms which differed widely from those characteristic of the normal virus. The genetic behaviour of the virus had evidently been modified by the procedure, and three new viruses had in effect been created in the test-tube.

The experiments reported so far have all been carried out with ribonucleic acid obtained from tobacco mosaic virus itself, but it now appears that the virus protein will also combine with ribonucleic acid from other sources. The biosynthesis of ribonucleic acid has been studied by S. Ochoa and his colleagues,⁵ and they have found that the nitrogen-

fixing bacterium *Azotobacter vinelandii* contains an enzyme, named by them polynucleotide phosphorylase, which will cause adenosine diphosphate and other nucleotide diphosphates to polymerize into a long chain of nucleotide units. The product may be regarded as a highly artificial form of ribonucleic acid, artificial in that it does not consist of all four types of nucleotide arranged in a sequence of genetic significance. In spite of this it has now been found⁶ that the protein of tobacco mosaic virus will combine with this material as well, forming rods which are indistinguishable from those of the virus itself. These rods were not infectious for tobacco plants, but it can be fairly claimed that they represent a close approach to a synthetic virus, which lacks infectivity only because it has been supplied with the wrong key for unlocking the metabolism of the host cell.

What applications could this work have in the field of human and animal virology? The material is far less favourable to work with, but it has recently been reported that poliomyelitis⁷ and Coxsackie⁸ viruses can be crystallized, and crystalline arrays of particles have been seen in sections of cells infected with adenoviruses.⁹ It is possible that these viruses have a structure as simple as that of tobacco mosaic virus, and the examination of their crystals by x-ray diffraction will soon enable this point to be settled. If they in their turn can be separated into components and recombined, the manufacture of synthetic animal viruses *in vitro* may become possible. Many years may pass before this is achieved in practice, but it offers the possibility of obtaining non-pathogenic variants by a controllable procedure, without having to wait for spontaneous mutants to arise. The use of synthetic viruses prepared in this way might greatly advance the prevention of such a disease as poliomyelitis.

NON-ULCER DYSPEPSIA

Biopsy has often helped clinical progress during the past twenty years. The development of needle biopsy of the liver, originally described by P. Iversen and K. Roholm,¹ has led to notable improvements in the diagnosis of hepatic disease and in the interpretation of the pathological changes occurring. Recently renal biopsy, which was introduced by P. Iversen and C. Brun,² has been developed in Chicago by R. M. Kark and R. C. Muehrcke³ into a reliable technique and has already cast light on the diagnosis, pathogenesis, and treatment of renal disorders. Most biopsy studies of the stomach have sprung from the work of I. J. Wood and his colleagues in Melbourne.⁴ In 1949 they described a method of obtaining biopsy speci-

mens of gastric mucosa by passing a flexible tube into the stomach, sucking a knuckle of gastric mucosa into a lateral hole in a small metal cylinder at the distal end of the tube, and then cutting it off by means of a cylindrical knife running within the first cylinder. Their studies confirmed the critical importance of chronic atrophic gastritis and mucosal atrophy in pernicious anaemia and its neurological complication, subacute combined degeneration of the cord. Many centres with much experience of the megaloblastic anaemias now include gastric biopsy as part of their routine investigations.

At page 372 of the *Journal* this week Dr. A. Wynn Williams and his colleagues at the West Middlesex Hospital describe the results they obtained from studying gastric biopsy specimens from a large number of patients suffering from so-called non-ulcer dyspepsia. They use this term to describe dyspeptic symptoms related to the intake of food and occurring in the absence of any focal lesion of the stomach or duodenum (such as ulcer or cancer) and of disease elsewhere, such as in the gall-bladder, appendix, and colon. Such patients represent a formidable challenge to physicians. They are very numerous, as may be seen from the fact that F. Avery Jones and H. Pollak⁵ found that two out of every five patients with gastric symptoms do not suffer from peptic ulcer, and in the majority of these patients it is impossible to make any firm diagnosis. More recently, S. Lipetz and colleagues⁶ have found that patients with non-ulcerative dyspepsia are even more common in an urban general practice than are patients with peptic ulcer.

Wynn Williams and his colleagues divide the histological changes seen in gastric-biopsy specimens into several categories—normal, chronic superficial gastritis, chronic atrophic gastritis, mucosal atrophy, and minor mucosal changes. In company with other workers they find that atrophic gastritis becomes steadily more common with advancing years. By contrast, the proportion of patients showing superficial gastritis and minor mucosal changes stays relatively constant in all age groups; this finding agrees with that of Wood's group of workers in their latest report.⁷ There are two possible explanations for this difference between relatively mild mucosal changes on the one hand and the severe disturbances of chronic atrophic gastritis and mucosal atrophy on the other.

¹⁰ Atkins, L., and Benedict, E. B., *New Engl. J. Med.*, 1956, **254**, 641.

One is that the lesser changes are precursors of the more severe, so that the proportion of patients showing the lesser changes stays constant with advancing years because entrants to the group are roughly balanced by subjects who develop the more severe changes. Alternatively, the lesser mucosal changes can be regarded as not being a significant departure from normality. This does not seem likely in view of the finding that the lesser mucosal abnormalities are associated with an appreciable diminution in the secretory power of the stomach, this group of cases lying intermediate between the "normal" group and those with atrophic gastritis which show severe loss of secretory power.

Wynn Williams and his colleagues have not been able to attach any specific significance to the various mucosal changes met with on gastric biopsy. At the moment, therefore, this procedure does not seem likely to enter into routine medical practice for the investigation of dyspepsia. It has become plain that patients with a normal specimen obtained at gastric biopsy can suffer from non-ulcer dyspepsia, and it is equally plain that a patient's stomach may be the seat of chronic atrophic gastritis without his having a single gastric symptom. Moreover, combined gastroscopic and biopsy studies have shown some startling discrepancies.⁸⁻¹⁰ The condition of chronic hypertrophic gastritis, once confidently diagnosed at a glance by gastroscopists, is found to yield a specimen of normal mucosa more often than not. In other words, the type of gastritis most prone to be associated with dyspeptic symptoms turns out not to be "gastritis" after all. The fact that precise clinical significance cannot yet be assigned to the varieties of gastritis in the causation of dyspepsia does not vitiate the value of making careful observations on the state of the gastric mucosa in disease. It is to be hoped that the West Middlesex Hospital group will be able to observe the future progress of many of their patients with superficial gastritis and minor mucosal changes to see if these changes evolve in time into the more profound disturbance of atrophic gastritis and mucosal atrophy, which, if generalized throughout the stomach, is the primary lesion in pernicious anaemia.

BOXING INJURIES

That boxing is by no means the innocuous sport that some suppose it to be is apparent from the attention paid in recent years to the injuries sustained in the ring by both amateurs and professionals. The subject has previously received attention in these columns,¹ and four papers in the present issue refer to various aspects of the problem. Dr. Macdonald

Critchley gives a comprehensive review of the subject, illustrating his account with numerous case histories; Drs. J. L. Blonstein and E. Clarke discuss the ill-effects observed in 29 amateur boxers who were severely concussed or knocked out more than once in a seven-month period; Professor M. Paul describes a fatal injury in a young amateur boxer; and Mr. R. Salisbury Woods reports a curious case of dislocation of the shoulder-joint. Boxing enthusiasts have made much of statistics which suggest that the incidence of serious injury is less than in many other sports such as football and skiing; on the other hand, boxing is unique in that the intention of the boxer is to damage his opponent and, if possible, to render him unconscious. Such superficial signs of injury as the flattened nose, the cauliflower ear, and the scarred, hypertrophied eyebrows are insignia of the boxer's trade. Serious damage to muscles and peripheral nerves is a rare occurrence, and so also is fatal cardiac contusion. The local effects of foul blows (the "rabbit" punch to the nape of the neck, testicular bruising from a punch "below the belt," and renal haemorrhage from the kidney punch) have occasionally to be treated, but it is the injuries which may result in damage to intracranial structures and to the eye which constitute a serious threat to life and livelihood.

Fatalities resulting from injuries in the ring, though uncommon, are being reported more frequently, and Critchley remarks that over 200 had been described up to 1950. Most of these have been attributed to intracranial haemorrhage, usually in the subdural space, but it is remarkable how often surgical evacuation of a subdural haematoma has failed to save the patient's life. In Paul's case, such a collection was found and evacuated, but the patient showed severe decerebrate rigidity from the moment of injury and it seemed probable that mid-brain damage had occurred, even though no definite histological changes were found in this region. As E. Jokl² has pointed out, the ordinary knock-out may be due to a transient effect of the blow upon the brain stem, and irreversible damage to this area, without striking histological change, is possibly responsible for some fatalities. It should also be remembered that death may result from the secondary head injury which results when the boxer's head strikes the floor.³

The punch-drunk state, so graphically described by Critchley in his paper, has long been recognized as a serious cause of progressive physical and mental

deterioration in professional boxers whose standard of performance has fallen off, resulting in increasingly frequent knock-outs. This condition of traumatic encephalopathy is often unhappily progressive even after the subject has abandoned the sport; it has previously been attributed to multiple petechial haemorrhages in the brain, but recent histological studies⁴ have revealed a diffuse cerebral atrophy with changes like those of presenile dementia. Euphoric dementia with dysarthria and ataxia is seen in the fully developed case of punch-drunkness, or there may be extrapyramidal manifestations of Parkinsonian type. As Critchley points out, the "groggy state," in which the boxer, "out on his feet" during the contest, is subsequently confused and amnesic, may become increasingly severe after successive bouts and may be a prelude to punch-drunkness. Blonstein and Clarke assert that in their experience the punch-drunk syndrome has never been observed in amateur boxers, but Critchley reports an amateur champion who developed its characteristic signs. While it is clearly true that the risks of amateur boxing are slight compared with those of the professional sport, the prolonged amnesia which Blonstein and Clark describe in some of their cases clearly differs only in degree from the "groggy state."

The many and varied eye injuries which may occur in the boxer have been comprehensively reviewed by J. H. Doggart.⁵ Among the most important are corneal trauma, scleral rupture, tears of the iris, iridocyclitis, cataract, subluxation of the lens, vitreous haemorrhage leading to retinitis proliferans, and retinal detachment which is rarely amenable to surgery. Doggart also describes a patchy choroidal degeneration ("cauliflower choroids"), as well as orbital fractures, glaucoma, and direct damage to the optic nerve. Many of these lesions represent a serious threat to vision. In fact, the list of possible injuries in boxing is a formidable one, but the medical authorities supervising both professional and amateur boxing are advising many sensible precautions in an attempt to limit their occurrence. Serial E.E.G. recordings can be of value in detecting early evidence of cerebral damage, but frequent clinical review by experienced observers, with particular attention to the occurrence and duration of amnesia, may be equally satisfactory. Although much evidence exists to justify the opinion expressed by Blonstein and Clark that amateur boxing in particular is remarkably safe, occasional catastrophes will certainly continue to occur, and it is important that all concerned with the sport, and particularly the boxers themselves, should be aware of the risks involved. Many will feel that the benefits derived from boxing outweigh its dangers, but this

opinion will be hard to sustain unless every reasonable step is taken to minimize the risks of permanent disability, particularly that resulting from injury to the brain or eye.

BILIRUBIN

Forty years ago van den Bergh¹ showed that gall-bladder bile and serum from patients with obstructive jaundice reacted directly with freshly prepared, diazotized sulphanic acid to give an intense purple colour, whereas serum from normal subjects and from patients with haemolytic jaundice reacted only after the addition of alcohol—that is, indirectly. It appeared that the bilirubin formed by the breakdown of haemoglobin was altered in some way by its passage through the liver, but until recently no satisfactory explanation has been forthcoming to explain the van den Bergh reaction. Perhaps the most popular theory was that the indirect-reacting pigment was bound to protein, from which it was released by the addition of alcohol, while the direct-reacting pigment was free bilirubin. Electrophoretic studies, however, showed that both pigments migrate with the serum proteins, and are probably lightly attached to the albumin fraction. A recent detailed analysis² has finally disposed of the view that different bilirubin-protein complexes are responsible for the two reactions. An alternative theory, that a chemical change takes place in bilirubin during its passage through the liver, remained unproved, and it was suggested that the liver produces a catalyst which is responsible for the rapidity of the direct reaction.

The pioneer work of P. G. Cole and G. H. Lathe,³ using the technique of reverse-phase chromatography, has finally settled the question whether there are one or two bilirubins. They found it possible to separate two distinct pigments—a fast moving, water-soluble substance which gives the direct reaction, and a more slowly moving, indirect-reacting pigment, which is identical with crystalline bilirubin. Later work has shown that the direct reacting pigment is made up of two distinct components.⁴ Unfortunately these are extremely unstable, a fact which has hindered their identification. Now two papers have appeared almost simultaneously, one from England and the other from the U.S.A., which provide an important clue to their probable nature.^{5,6} Chromatographic analysis of the more stable azo-pigments reveals that the direct-reacting bilirubins are glucuronides, which can be converted to bilirubin (indirect-reacting pigment) by treatment with alkalis or with β -glucuronidase. This is a discovery of great general interest. It is well known that many substances are conjugated on their passage through the liver. This has been termed "detoxication" because it applies

particularly to toxic materials, but there is good evidence that naturally occurring substances—for example, certain steroids—are treated in the same way. Bilirubin appears to be a further example. A. White and colleagues⁷ state that “the enhanced solubility in water incident to glucuronide formation . . . may well render them [conjugated substances] more readily dispensable by the body.” This would explain the classical clinical observation that bilirubin appears in the urine in obstructive but not in haemolytic jaundice. Glucuronides are not the only compounds available for conjugation, and there may well be other types of bilirubin complex. For example, bile acids are readily demonstrable in the direct-reacting material, and the capacity of bilirubin to form complexes with taurine has recently been reported.⁸

It looks as though a satisfactory explanation of the van den Bergh reaction is available at last. While of great theoretical interest, the clinician may well ask if these findings have any practical value in the elucidation of jaundice. It is probably fair to say that at present the test is rarely helpful, because there are simpler ways of differentiating obstructive from haemolytic jaundice. In parenchymatous jaundice, for which a reliable test is badly needed, the reaction is complex and often equivocal, though if the speed with which the colour develops is taken into account it may be useful in some cases.⁹ It seems possible, however, that a study of the bilirubin complexes in disorders in which the liver cell is damaged may yield data which could be applied to the diagnostic problems of the clinician.

DOCTORS' DISEASES

Some data showing that British medical practitioners may be at special risk of dying from acute poliomyelitis are reported by Dr. R. Doll and Professor A. Bradford Hill at page 372 of the *Journal* this week. The authors have derived them from the death certificates of certain doctors who died in the five years 1951–6. Among 34,494 doctors who had provided particulars for these authors' prospective investigations into the relation between smoking and lung cancer were eight men who, in this five-year period, died from poliomyelitis. While the number is small, it seems to be about ten times as large as it would be if medical men experienced the same death rate from this disease as men in the whole population. The difference is striking, and it does suggest that poliomyelitis can with some certainty be added to the list of diseases to which medical practitioners are unusually susceptible. One of these is coronary heart disease. J. N. Morris and his colleagues¹ showed that middle-aged general practitioners are about twice as likely to die from this cause as are men of comparable age in the population as a whole. In the U.S.A. leukaemia has been shown to be more prevalent among radiologists than other physicians,² but evidence in

Britain is lacking. Deaths registered in England and Wales in 1950 analysed by social class showed a steep decline in mortality from leukaemia from class 1 (in which doctors are grouped) to class 5 for men as well as women.³ But unfortunately, though we are more than half-way to the next census, no full occupational mortality tables based on the 1951 census have yet appeared. Some recent figures from the U.S.A. show a relatively high death rate for diabetes mellitus among doctors,⁴ though their significance to the British scene is debatable.

In seeking an explanation for the unusually high number of deaths from poliomyelitis in their sample of medical practitioners Doll and Bradford Hill mention the belief that people in the higher social classes may be more likely than people in the lower to contract the disease. As they say, no statistical evidence in this country supports it. Nor does living in a healthy environment seem to raise the risk of contracting the disease, as has been suggested, for Bradford Hill and W. J. Martin⁵ found no correlation between infant mortality rates and incidence of poliomyelitis in England and Wales. Possibly the clue lies in the inescapable obligations that so often fall to the medical man to fulfil. Doctors may contract the disease no more often than laymen, but, because they keep working too long, pay the penalty of succumbing to a more severe attack.

HEALTH SERVICE SUPPLEMENTARIES

There is nothing new in a supplementary estimate for the cost of the Health Service being presented to Parliament; in fact, it has been the exception rather than the rule for Ministers to keep within their original estimates. There are two main reasons for this. One is that in a period of rising prices the spending authorities are faced throughout the year both with a bigger outlay on goods and with claims for higher pay from those providing services. The second reason is that no other department of state, in estimating its expenditure, has to cope with such an unpredictable and uncontrollable demand for its service as has the Ministry of Health. In the early years of the Health Service it was the unexpected demand that made nonsense of the original estimates of the Service's cost. In recent years it has mainly been the need to pay higher wages and salaries that has raised the estimates. Both factors have led to the supplementary estimate for 1956–7, which was presented last week, though increased remuneration is dominant.

The net total of the supplementary estimate (that is, after allowing for an increase in superannuation contributions and savings in certain items such as the poliomyelitis vaccination scheme) is nearly £27m. for Great Britain. All the main branches of the Service share in this increase:

<i>Extra Amount Needed</i>			
	£		£
Hospitals ..	15,008,000	Pharmaceutical service ..	8,089,000
Local health authorities ..	1,227,000	Dental service ..	1,635,000
General medical services ..	2,946,000	Supplementary ophthalmic service ..	801,000

The hospitals, as is only to be expected, account for over half the net total of the supplementary, and in fact a supplementary estimate was heralded at the very beginning of the financial year with the announcement last April of new scales of pay for nurses, including mental nurses, and midwives. Since then there have been Whitley awards to ancillary workers and to administrative and clerical staff. For England and Wales these awards, costing an extra £4½m. a year for nurses and about the same amount for the ancillary staffs, account for about £10m. of the extra £13½m. needed to maintain the hospitals in this financial year. The balance is made up by higher prices for goods consumed, such as food and fuel, which account for £2½m., and by an extra £1m. which the hospitals have to pay in rates as a result of the revaluation of their premises.

The supplementary estimate of nearly £3m. in the cost of general medical services mainly represents the extra amount due to general practitioners as a result of the increase in their expenses. The remainder is accounted for by more payments into the central pool for maternity services, the treatment of temporary residents, and so on. Higher remuneration, especially of nurses, is responsible for almost all the increased cost of the local health services. In the remaining branches of the Service it is a bigger demand from the public that is the chief reason for their cost being higher than was originally estimated. This increased demand is reflected most clearly in the extra sums needed for drugs. Under a new agreement chemists are made a slightly bigger allowance for the cost of containers, but the bulk of the additional £8m. needed is to meet an increase in the number and average cost of prescriptions. An even larger supplementary bill for drugs would have been presented had it not been for the change in the prescriptions charge from a shilling a form to a shilling an item, which is estimated to save £1½m. this year. For some reason the cost of prescribing per head of the population seems to have been more stable in the past year north of the Border than in England and Wales.

COMPOUND ASPIRIN AND STEROID TABLETS

Since the Ministry of Health announced the availability to general practitioners of the newer cortisone analogues prednisone and prednisolone some pharmaceutical manufacturers have been drawing the attention of doctors to the supposed advantages of tablets containing a combination of one or other of these substances with aspirin in a fixed dosage. Advertisements have stated that the combination has a greater anti-inflammatory action than the steroid alone. There is no proof whatsoever of this. In the early days of cortisone investigation claims were put forward that such substances as insulin and *p*-aminobenzoic acid were “cortisone spacers,” but these claims were not upheld, and so far

no substance has been found to enhance the action of the older or newer steroids.

In one advertising leaflet the indications for the combined tablet are given as rheumatoid arthritis, osteoarthritis, gouty arthritis, bursitis, tenosynovitis, myositis, fibrositis, and neuritis. There is little convincing evidence that oral steroid therapy is of any value in osteoarthritis or in the non-articular varieties of rheumatic disease which involve bursae, tendons, muscles, or nerves. As steroid therapy causes adrenal involution it should be used only where there is a clear indication of its value. A few reports have shown that cortisone or the newer analogues may be helpful in attacks of gout where colchicine is contraindicated, but their main value in the field of rheumatic diseases is in severe active rheumatoid arthritis. Controlled trials by the Joint Committee of the Medical Research Council and Nuffield Foundation¹ and by the Empire Rheumatism Council² have shown that in the average case of rheumatoid arthritis steroid therapy is unnecessary, since progress is as good with aspirin. In severe cases, when other methods of treatment have failed to halt the progress of the disease, W. S. C. Copeman and his colleagues³ have shown the value of long-term treatment with cortisone under careful medical supervision. W. S. C. Copeman and O. Savage⁴ have estimated that only 10% to 20% of cases of rheumatoid arthritis should be considered for steroid therapy.

There would seem to be no advantages and some disadvantages, as Dr. F. Dudley Hart has pointed out in a letter at p. 398 in this issue, in combining 0.5 mg. of prednisolone with 5 grains (0.32 g.) of aspirin. For mild cases of rheumatoid arthritis 60 grains (4 g.) of aspirin is an average dose, and this would provide only 6 mg. of steroid—an amount unlikely to have any suppressive effect on the arthritis. In a severe case requiring steroids the average maintenance dose of prednisone or prednisolone is 15 mg. per day, and if that were given by the combined tablet the patient would have to take 30 tablets and 150 grains (10 g.) of aspirin a day. In other words, such tablets, in spite of being the most expensive form of aspirin yet devised, contain steroids in amounts which are quite inadequate for effective treatment.

HUNGARIAN MEDICAL REFUGEES

A special fund is being opened to help those medical men and women who have recently had to flee from Hungary. This week in a letter at p. 398 the Chairman of Council of the B.M.A. earnestly solicits the help of all doctors on behalf of these unfortunate colleagues, of whom about sixty have reached Great Britain, while many more are in Austria. He suggests that doctors may if they wish earmark their contribution to be used in Austria; for the medical profession there, through the Austrian Medical Association, has already made great sacrifices to help the refugees. A certain amount of assistance has already been provided from B.M.A. funds,⁵ but all that doctors individually can give will be most gratefully received.

FATAL HOSPITAL FALLS

BY

GAVIN THURSTON, M.R.C.P., D.C.H.

Barrister-at-Law; H.M. Coroner, County of London
(Western District)

The incidence of fatal hospital falls is not high, but the matter deserves notice from the standpoint both of prevention and of the risk of litigation. These aspects are, of course, interdependent. The kind of accident caused by falls on polished floors is well recognized and is not dealt with here. This article is concerned with falls, often suicidal, from windows and roofs.

In six months in the West London Coroner's district six such falls have occurred. The area includes 40 hospitals with roughly 13,800 beds. Postulating an 80% bed occupancy and an average length of stay of 20 days per patient, this gives an annual population at risk of about 100,000. The risk of a fatal fall from a window is therefore about 1 in 8,000. Not all the cases are overtly suicidal, but it is of interest to compare this figure with the current suicide rate of 1 in 10,000 in the general population. The six falls occurring during the six months under review seem to represent an unusually high incidence. Against the factor of closer supervision must be set the nature of the hospital population, consisting as it does of sick people who may be temporarily upset by pain, toxæmia, or biochemical disturbances, to say nothing of psychological troubles. During this time no fatal fall occurred among those occupying the 4,000 beds for mental patients.

Case Reports

Case 1.—Two days after an abdomino-perineal resection of the rectum for carcinoma a man aged 66 climbed out of bed at 6.30 a.m., scaled a radiator, and got out of a narrow opening in a window. He fell to the ground and died of multiple injuries. He had been somewhat mentally confused during the preceding night, but not unduly so for an elderly man recovering from a severe operation. The nurses on duty, quite reasonably, did not consider the possibility of such an athletic action, which was carried out under their eyes with such speed that they could not stop him. He was in an open ward. In view of his disordered mental state it was doubtful whether the conscious intention of self-destruction existed, and an open verdict was returned.

Case 2.—A male hospital employee aged 63, while convalescent from cholecystectomy for gall-stones, developed functional retention of urine, for which he had an indwelling catheter. He was distressed by this. At 12.30 a.m. he was missed from his bed and was found to have made his way to a staircase and thrown himself from a window on the floor above the private room which he had occupied. It was clear that he had deliberately killed himself, and the verdict was in accordance with this.

Case 3.—A woman aged 54, who had had bilateral adrenalectomy for carcinomatosis from carcinoma of the breast, was in hospital, in a private room, to have her cortisone dosage balanced. She had had much distressing treatment and knew she had carcinoma. Superficially she did not seem to have been unbalanced mentally. She had had several attacks in which she had become giddy and had staggered while walking. At 3.30 p.m. she fell from a high-silled window just outside her room door. In view of a history of breathlessness and the giddy attacks it was not possible to exclude accident, and an open verdict was returned.

Case 4.—A woman aged 41 was suffering from alcoholism and had had several epileptiform fits, for which she was being investigated in hospital. She was in a general ward and was described as being rather euphoric and facetious and confused at night. Treatment consisted of large doses of vitamin B, paraldehyde, 5 ml. six-hourly, and phenobarbitone, 3 gr. (0.2 g.) intramuscularly if required. During her third night in hospital she seemed more confused than usual and announced her intention of going home. An extra nurse was detailed to look after her. Early in the morning she got out of bed, gathered her belongings, and said she was going to call a taxi. Despite remonstrance she went down the stairs, accompanied by the nurses, who were still remonstrating with her; suddenly she stopped, threatened the nurses with a piece of iron which she had picked up, and slipped through a staircase window on to a flat roof. Still followed by the nurses, she made her way along the roof and climbed a wall at the end. This was thought to be at ground level, but was in fact some distance above a yard. She fell and was killed. The verdict was accidental death.

Case 5.—A man aged 22 with Crohn's disease had been in various hospitals for several months and had had extensive resection of the ileum. During the course of the illness he developed symptoms of anxiety and depression and was admitted to a mental observation hospital. After a time he was thought fit to return to the general ward for further treatment of his somatic disease. He did not then show signs of mental confusion. At 6.30 a.m. he was seen to go to the lavatory, and bid good morning to one of the nurses quite cheerfully. He was soon missed, and was found lying dead on the pavement several stories below the lavatory window. This window was of the casement variety and so situated that accidental falling was impossible. At the inquest the finding was that he had killed himself.

Case 6.—A man aged 68 had had an operation for implantation of radium seeds for inoperable carcinoma of the pancreas. He had had a previous operation and much medical attention. He was aware of the diagnosis. He had been in hospital 12 days, made no complaint, and suffered no pain. At 6 p.m. he went to the lavatory and threw himself from the window. A note written on the edge of a newspaper was found, making clear his intention. The verdict was that he had killed himself.

Discussion

These six cases show the kind of risk involved. It may be recorded here that the three suicides as found at inquest were the only suicides in hospital during the six-months period. Other methods of committing suicide, such as coal-gas poisoning, drugs, and hanging, are clearly less likely in hospital in view of the practical difficulties, so the window-jump must be regarded as the chief danger. Only a small number of cases are recorded, but they are cited to indicate the risk. Any person with hospital experience could add to them, and no particular hospital seems unduly vulnerable. It is easy to be wise after an event, but reasonable precautions should be taken to avoid this kind of death. The problem should be taken into account in planning the design and layout of new hospitals. No claims were made against the hospitals in which these deaths took place, but it is known that liability has been alleged in similar cases. If a claim is made it would be necessary for the hospital authority to show that a reasonable standard of care had been taken to avoid such incidents. What is reasonable would be assessed by referring to current hospital practice; but this is not inflexible, and would cease to be a guide in the presence of some proved danger. Attention to the following points is suggested.

Perhaps the outstanding feature of these cases is that in no instance was the window-fall expected; and the paucity of such events from mental hospitals, where organization is geared to the ever-present possibility of suicide, indicates the importance of the staff being aware of the risk.

It has been noticed that suicide, including cases of self-destruction that lie on its borderland, is often associated with convalescence from major operations, especially where there has been deprivation of an important viscus. The psychopathology of this is outside the scope of this article. It is suggested that patients who show signs of unusual behaviour in these circumstances, even if it is only slight, should be regarded as possible suicidal risks and be placed in a ward on the ground floor. They certainly should not be left in side wards or private rooms without a special nurse. If a psychiatric opinion has been sought and removal to a mental hospital advised, the usual delay associated with administrative obstacles must be eliminated. It has been noted that the nursing staff can more easily supervise a patient in an open ward; but even this, as shown in Case 1, is no guarantee of security, although the risk is clearly diminished. It is not thought that increase of staffing by night or day would make much difference to fatal falls from windows: the patients in these six cases all fell at a time when ward activity was slight.

Precautions of a structural kind seem more practical, though there would be difficulties where buildings are old and financial resources are slender. It should be impossible to open windows more than 9 in. (23 cm.) at the bottom in upstairs wards, staircases, and corridors. Casement windows could likewise be limited. Where this is not feasible, bars should be fitted to afford at least a temporary obstacle to egress from windows. In the case of lavatories, it should not be possible to bolt the door from the inside. Instead, a large indicator showing "engaged" or "vacant" would be suitable.

In the present state of hospital design and routine it does not seem that any further precautions would be expected by a reasonable person.

Summary

The risk of fatal falls from hospital windows is described and illustrated.

Awareness of the risk is important and should be inculcated in nursing staff.

Simple structural precautions are suggested.

MEDICAL ETHICS IN WARTIME

CODE AND EMBLEM ADOPTED BY W.M.A.

The World Medical Association, at its tenth general assembly last autumn, adopted a "Code of Medical Ethics in Wartime" drafted by a joint committee of the International Red Cross, the International Committee on Military Medicine and Pharmacy, and W.M.A. itself. The World Health Organization was represented on the committee as an observer. W.M.A. also adopted an emblem, recommended by the same committee, for civilian doctors (and others) to wear in wartime. National medical associations are now being asked by W.M.A. to approve and support the code and the emblem. The matter is due to be considered shortly by the B.M.A.

Code of Medical Ethics in Wartime

The provisions of the "Code of Medical Ethics in Wartime" are as follows:

1. Medical ethics in time of war is identical with medical ethics in time of peace, as established in the International Code of Medical Ethics of the World Medical Association. The primary obligation of the doctor is his professional duty; in performing his professional duty the doctor's supreme guide is his conscience.
2. The primary task of the medical profession is to preserve health and save life. Hence it is deemed unethical for doctors to: (a) give advice or perform prophylactic, diagnostic, or therapeutic procedures that are not justifiable in the patient's interest;

(b) weaken the physical or mental strength of a human being without therapeutic justification; (c) employ scientific knowledge to imperil health or destroy life.

3. Human experimentation in time of war is governed by the same code as in times of peace; it is strictly forbidden on all persons deprived of their liberty, especially civilian and military prisoners and the population of occupied countries.

4. The forbidding of the medical procedures in points 2 and 3 is mandatory under all circumstances regardless of decisions to the contrary issued by either a *de jure* or a *de facto* authority.

5. In emergencies the doctor must always give the required care impartially and without consideration of sex, race, nationality, religion, political affiliation, or any other criterion. Such medical assistance must be continued as long as necessary.

6. Medical secrecy must be preserved by the doctor in the practice of his profession.

7. Privileges and facilities afforded the doctor must never be used for other than professional purposes.

Rules Governing the Care of Sick and Wounded, Particularly in Time of Conflict

1. Under all circumstances every person, military or civilian, must receive promptly the care he needs without consideration of sex, race, nationality, religion, political affiliation, or any other criterion. Any procedure detrimental to the health, physical or mental integrity of a human being is forbidden unless therapeutically justifiable.

2. In emergencies doctors and associated medical personnel are required to render immediate service to the best of their ability. No distinction shall be made between patients except those justified by medical urgency. Services may be refused if other doctors are rendering their services.

3. The members of medical and auxiliary professions must be granted the protection needed to carry out their professional activities freely. The assistance necessary will be given to them in fulfilling their responsibilities. Free passage will be granted whenever their assistance is required. They will be afforded complete professional independence.

4. The fulfilment of professional duties and responsibilities shall in no circumstance be considered an offence.

5. In fulfilling their professional duties the medical and auxiliary professions will be identified by the distinctive emblem of a red serpent and staff on a white field. The use of this emblem is governed by special regulation.

Medical Emblem

It is clear from the fourth Geneva Conventions and Conferences, states W.M.A., that the protection of the Red Cross emblem applies only to doctors, ancillaries, and medical installations in military organizations. Hence, in time of war, the civilian doctor, his assistants, and civil defence units not under military control are without such protection. The new emblem, suggested by the joint committee and approved by W.M.A., is for them to wear. It consists of a red staff and serpent on a white field. The staff is represented by a vertical line, the serpent by a sinuous line, overlying the vertical line, with two undulations on the left side and one on the right (see diagram).

The ultimate success of this emblem and the Code of Ethics as a guarantee of protection for civilian doctors will largely depend, states W.M.A., on the support they receive from national medical associations.

Dr. W. A. HORNE, medical officer of health of Glasgow, has some remarks to make in his Annual Report for the year 1955 about infestation with bed bugs. In that year 15,000 houses in rehousing schemes were inspected and evidence of infestation was found in 66 (0.44%). Twenty years before the percentage of infested houses was 9.2. The use by the disinfection unit of D.D.T. and "gammexane" is said to give every satisfaction in the eradication of this pest. The total number of "apartments" treated for infestation by bugs in 1955 was nearly 3,000.

Correspondence

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

Hungarian Medical Refugees

SIR,—The many problems presented by the Hungarian refugee doctors have been considered by the Council of the Association, and it is with the full approval of the Council that I now appeal to the profession for subscriptions to a fund to provide assistance for them.

A particularly heavy burden has fallen upon Austria, as will be seen from the following letter, recently received from the Austrian Medical Association.

"Dear colleagues,

"You have certainly heard about the events which happened in Hungary, our neighbour-country, and that the people of Austria helped the refugees with all efforts, achieving great sacrifices. You will realize, however, that so small a country as Austria is not able to help alone for long and therefore asked the freedom-loving world for assistance. Also the doctors of Austria, who certainly are not too well off, helped the Hungarian refugees by giving them free medical treatment and by raising large sums for the general relief funds. However, another problem arose affecting the doctors of Austria, and for the solution of which the co-operation of the medical profession is needed. Among the Hungarian refugees there are many doctors, and the Medical Board of Vienna sponsored a collection to provide a gift of 500 Austrian schillings (20 dollars) for every one of our colleagues. However, the number of the Hungarian doctors increased and is still increasing. Up to date (December 28, 1956) 560 Hungarian doctors called at our office and the Medical Board of Vienna had to raise a loan to continue the financial support given to them. However, we are now at the end of our financial means and therefore ask you to help the Hungarian doctors. We are convinced that, once you have heard about the misery of the Hungarian doctors, the willingness to help your colleagues will be in your country as great as in Austria.

"However, *Bis dat qui cito dat*!

"Will you please transmit financial support for the Hungarian doctors to the Österreichische Ärztekammer, Erste Österreichische Sparcasse, Wien 1, Graben 21, Konto No. 889,685.

"Thank you very much for your co-operation in the name of our Hungarian colleagues."

The Council would particularly like to be able to give prompt assistance to the profession in Austria, which has already shown great generosity to the many refugee colleagues now in that country. It is proposed that a part of the money subscribed should be used to relieve distress among the relatively small number of refugee doctors from Hungary who have come to this country—most of them on their way to other parts of the Commonwealth or to America—but subscribers may earmark their contributions for transmission to Austria if they so wish.

I have no doubt that very many doctors have already subscribed to one or another of the general relief funds, but I hope that some may be able and willing to subscribe again to a special fund for medical refugees, and I appeal especially to any who may not yet have contributed to any fund for refugees from Hungary.

Subscriptions should be sent to me at B.M.A. House, Tavistock Square, London, W.C.1, and cheques should be made payable to the "B.M.A. Hungarian Relief Fund."—I am, etc.,

London, W.C.1.

S. WAND,
Chairman of Council.

Prednisone and Prednisolone

SIR,—In view of the fact that prednisone and prednisolone are now generally released to the profession, your excellent leader (January 26, p. 215) on the subject was most timely and instructive. Judging by the many brochures on the subject issued by various drug houses since then it

seems necessary to underline certain of the points made in your leader, for, acting on the different instructions given in the brochures, the practitioner may run into real trouble, particularly as regards gastric intolerance. Dyspepsia is common in steroid therapy, and these new delta compounds are no exception; a patient should always be asked regarding previous dyspepsia and gastric investigations before starting therapy. Most clinics using these substances since they became available to hospitals eighteen months ago have seen haemorrhage or perforation at least once.

The dosage level should be considered one-fifth that of cortisone; the number of tablets required daily remains, therefore, the same if one changes a patient from tablets containing 25 mg. of cortisone acetate to tablets containing 5 mg. of prednisone or prednisolone. Much of the improvement seen in the clinical condition on changing a patient from one drug to the other may lie in actual increase of dosage, some workers assuming the substances are effective in a dose ratio of 1:3 or 1:4. We have learnt with cortisone to restrict the dosage to the lowest effective level, and in treating rheumatoid arthritis, for instance, daily dosage of cortisone nowadays practically never exceeds 100 mg. and is usually 75 mg. or lower. The equivalent dosages of prednisone and prednisolone are 20 and 15 mg., and though this dosage can be, and should be, increased in the short-term treatment of emergencies, such as severe status asthmaticus, the daily dose in continued suppressive therapy should be under 20 mg., except in conditions dangerous to life.

It offends the lovers of champagne that the bubbles in that delightful wine should be removed by special whisks before making champagne cocktails; it offends my common sense that prednisone and prednisolone, whose main virtue lies in causing less sodium retention than cortisone, should be recommended in some brochures for the treatment of adrenal deficiency, but only in conjunction with deoxycortone. As stated in your leader, the delta substances, because of their very slight salt-retaining properties, are not suitable for the treatment of cases of Addison's disease or the adrenalectomized subject; cortisone or hydrocortisone are to be preferred here, with, in salt-losing cases, fluorohydrocortisone. There is no particular virtue in medicine in removing one property in manufacture so that a second drug must be administered in practice.

Finally, a word against compound analgesic cum steroid tablets. If a given dose of prednisone or prednisolone is mixed with an analgesic substance in a compound tablet it may easily lead to over- or under-dosage of one or other substance. Aspirin is so readily available and widely used that it seems unnecessary to invent yet another compound tablet.—I am, etc.,

London, S.W.1.

F. DUDLEY HART.

Prednisone and Nasal Allergic Disease

SIR,—During the last few years I have been lucky to have the opportunity of helping to assess the value of corticosteroids in the treatment of allergic disease of the nasal cavities and para-nasal sinuses. In particular, corticotrophin, cortisone, and hydrocortisone both as solids, suspensions, and in free alcohol solution have been used. They were given either systemically, by local spray, or by local injection under reasonable conditions of controlled trial. No real evidence of lasting or even temporary benefit in a majority of the cases has resulted from this work, so that enthusiasm had flagged somewhat by the time prednisone became available for clinical trial in hospital.

It is therefore most encouraging to find preliminary studies showing that prednisone in small systemic doses can be of real benefit. So far, selection of patients has been strictly limited to the very worst and most intractable cases, usually with polypi and unresponsive to all other forms of treatment. Out of 14 patients treated after removal of gross polypi, 12 have been completely relieved of symptoms, many of them during the first two or three days, and in four cases the sense of smell has returned after many years' absence.

Dosage begins with one 5-mg. tablet three times a day and is proportionately reduced over the next month until a minimal effective dose is found. In several, this appears to be only 5 mg. every other day. Relapses occur when the treatment is discontinued, and so far the longest consecutive period of treatment of any patient is four and a half months.

Such treatment is likely to be purely palliative and has been used in only a small number of the most severe cases. But these early clinical results have been so heartening, and the gratitude of the patients so impressive, that I feel they should be recorded.—I am, etc.,

London, W.C.1.

HENRY J. SHAW.

Safety Factor in Car Design

SIR,—As we see the results in hospitals, road traffic accidents as a class cause the most serious injuries, have the highest mortality rate, and are associated with more permanent disabilities than any other type of accident. In 1954 such accidents accounted for 5,010 deaths in Great Britain.

The mortality rate from similar accidents in 1954 in the German Federal Republic, France, and Italy (each with populations comparable but lower than our own) were respectively 11,565, 7,539, and 5,281. Undoubtedly there are many factors contributing to these considerably higher figures than our unenviable record. One may well be the popularity in those countries of small low cars of extremely light construction. Since petrol rationing and the resulting increase of such cars in this country, both of foreign and home make, we have already treated many serious and two fatal injuries in users of such vehicles.

Many years of hospital experience have shown² that, from the car-users' (safety) angle, car design and solid construction are important factors. Four good wheels, a few feet of steel between the driver and what he hits in head-on collisions, stoutly constructed body work as a protection against side-swipe accidents and overturning, a safe design of steering-wheel and dashboard, splinter-proof glass, and a car at least high enough to give its driver a good view of the road ahead and its crossroads, are all important factors in safety car design.

From the safety angle, the increasing popularity of small, low, and very lightly constructed cars is to be deplored. A saving in petrol may be bought at too high a price.—I am, etc.,

Birmingham.

Tuberculosis in Glasgow

SIR,—Drs. W. F. Tyrrell and J. Smith have written an interesting and valuable epidemiological study in their paper on pulmonary tuberculosis in north Glasgow (*Journal*, December 22, 1956, p. 1451). It should be of interest to all part-time tuberculosis consultants. Among their most striking results was a definite contact history in 77.6% of the male cases and 75.4% of the female cases, and of a familial nature in the high figure of 88.5% of cases. To obtain such figures the intensity of the contact investigations must have been great but worth while. The following paragraph among their conclusions deserves special mention: "This work has given us some general impressions which we feel may be of value to other workers in the field. For example, we find that visits by the chest physician to the homes of new patients give the health visitor a feeling of greater interest and encouragement, with the added advantage that such visits serve to reinforce, and occasionally redirect, her activities to the best advantage. We also found that home visits made in the evening were most productive in eliciting information and in establishing rapport with the members of the household. Moreover, at such times recalcitrant contacts were found to be in a more

amenable state of mind and willing to discuss the reason for their reluctance to be examined. As our figures show, this reluctance could usually be overcome as a result of our methods, which, however, sometimes involved a considerable number of visits."

The authors state, "Overcrowding, poverty, and Irish nationality were found not to be significant factors," and correlate this with Bradbury's¹ well-known, quite different findings in his Tyneside study. Here, surely, like is not being compared with like. In 1932 the country had some three million unemployed, and Jarrow on Tyneside was a real black spot. Visiting that area then was to see real abject poverty, with housing mostly of the "box house" type, with eight rooms and eight families, the staircase turning right and left into complete darkness; the smell of vermin; rat-gnawed wainscoting; male patients in bed spitting on to newspaper; and children swarming about in squalor and dirt. Glasgow in 1956 was not a distressed area, and is not comparable with Jarrow in 1932, either in its economic conditions or the housing.—I am, etc.,

Church Stretton, Salop.

G. LISSANT COX.

Incidence of Venereal Disease

SIR,—It is obviously most desirable to know the true incidence of venereal disease in this country, and from this viewpoint the inquiry instituted by the B.M.A. Venereologists Group Committee (*Supplement*, January 12, p. 19) is to be welcomed. However, attention must be called to the statement that there has been a big fall in the number of new cases attending the V.D. clinics. As far as we can ascertain there has been no significant decrease in these numbers, as the average number of new patients attending the clinics in England and Wales in the years 1921–5 was approximately 76,000; in 1934–8, 100,000; and in 1952–5, 97,000. In 1956 the number of cases attending during the first three-quarters of the year totalled 74,000, so that the probable average for the five-year period 1952–6 will be in the region of 98,000.

It is true that early syphilis is rare and late syphilis is also decreasing in most areas, as would be expected. The incidence of gonorrhoea remains disturbingly high, and in some areas, including Birmingham and district, is tending to reach epidemic proportions. This is partly due to immigration, but also, we feel, due to the failure of the medical profession to tackle the problem of gonorrhoea from the aspect of the community as a whole. We feel that many cases of gonorrhoea, and probably a few cases of syphilis, are treated by general practitioners. This they have every right to do, but we wonder if in all cases they follow up the contacts or retrieve defaulters. It is also not generally appreciated that gonorrhoea in the female is frequently symptomless, and that in very many cases there are no significant signs. As a result of this attenuated reaction to infection in females cultural investigation is always necessary in possible contacts.

The above points, we feel, are important factors in the continuing high incidence of gonorrhoea, and practitioners who treat cases of this infection should realize that they have a greater responsibility than that of curing the individual patient.—We are, etc.,

Birmingham, 4.

W. FOWLER.

The Hurt Brain

SIR,—In company with millions of viewers, I have watched with interest the series of programmes on the television concerning mental health under the title "The Hurt Mind." I was greatly astonished and considerably disturbed to hear the doctor who presented the series state that syphilis affecting the brain could now be cured with ten injections

of penicillin. Unfortunately, this view seems to be widely accepted in mental hospitals, and yet I feel quite sure that few venereologists would support this statement. It is true that in many patients the symptoms are relieved and greatly improved by such a course of treatment, but that is far from establishing a cure. I fear that these same magic powers are attributed to a short course of penicillin not only by psychiatrists but by many others in the various ancillary branches of medicine, and one cannot too loudly decry this view.—I am, etc.,

Liverpool.

E. E. PREBBLE.

Asphyxia due to Faulty Apparatus

SIR,—Having read with interest the letters by Dr. W. N. Rollaston (*Journal*, September 15, 1956, p. 658) and Dr. C. Langton Hewer (*Journal*, September 29, 1956, p. 766) titled "Asphyxia Due to Faulty Apparatus" prompts me to publish the enclosed photograph, which is self-explanatory. Luckily the patient suffered from no ill effects except for some temporary cyanosis.

It looks as if anaesthetists must not only examine the patency of endotracheal tubes and T-pieces but airways as well before they embark on an anaesthetic.

Surely the lesson to be learnt from this photograph is that airways should not be cleaned with pledgets of cotton-wool but by a proper brush on a wire holder.—I am, etc.,

Farnham Royal, Bucks.

F. J. RUSSELL STONEHAM.

Treatment of Acute Appendicitis

SIR,—The recent discussion on the conservative treatment of acute appendicitis has occurred at an opportune moment so far as emergency treatment on the high seas is concerned. This week the national dailies have graphically told of the predicament of Captain R. S. Paton, of the *Tahsinia*, who was confronted with a serious case of acute appendicitis in one of his crew. According to the news accounts, he was 700 miles from land and with no hope of skilled help being immediately available. In answer to his messages for advice he was told to operate. Bear in mind this was a ship of 5,680 tons, pitching and rolling in the teeth of an Atlantic gale. There was no anaesthetist and the captain had no medical qualification, but it is alleged he was advised to plunge into the patient's abdomen to look for he knew not what. Wisely he decided to disregard advice, wear ship, and make full speed for land, believing that the circumstances for his first exploratory laparotomy were not propitious.

Following Mr. Eric Coldrey's account (*Journal*, December 22, 1956, p. 1458) of his method of conservative treatment of acute appendicitis, it would seem proper to revise the *Ship Captain's Medical Guide* and to give a detailed method of conservative treatment to be applied in all cases of acute appendicitis when no surgeon is carried aboard. This should enable the patient to be carried in safety to skilled medical help and save the predicament which beset Captain Paton. It is, of course, by no means unknown for captains to embark on surgical treatment of sick or injured members of the crew when no skilled help is at hand. In the days of

sail many captains became of necessity physicians, surgeons, and accoucheurs according to the demands of the occasion.

Twenty years ago I sailed in a windjammer whose Finnish mate, Lars Persh, told me of a surgical occasion in his previous ship. He was sailing in the Erikson-owned windjammer, the *Olivebank*, and when about a month from Australia and two months from England a member of the crew had symptoms of acute appendicitis. The captain decided to operate and Persh assisted him. Another member of the crew gave the chloroform. Although he made a good opening in the S.W. corner of the belly (as it is described in the *Ship Captain's Medical Guide*) they failed after prolonged search to find the appendix. The captain sewed everything up in one layer, using fine twine, and the patient recovered sufficiently to walk off the ship some weeks later. My friend, the mate, was well used to doing minor surgery and had plenty of confidence. He would have been quite happy to operate on me had the occasion arisen. On my voyage I had to operate on a septic hand which had gone beyond further conservative treatment, and I sampled some of the minor problems of working in such surroundings. The weather was bad and the ship was in stone ballast, which caused everyone and everything to be thrown from side to side. Nothing would stop still. The patient was held in a bunk while I gave him hexobarbitone and a member of the crew endeavoured to hold me against the bunk for steadiness. Bowls, syringes, etc., rolled in all directions. The lighting was bad. Add to this the need for a laparotomy, a volunteer anaesthetist giving his first chloroform administration, and a lay operator making his first acquaintance with the inside of the peritoneal cavity, and there seems a sound argument for adopting conservative treatment of the acute appendix on the high seas.—I am, etc.,

Sheffield, 8.

E. C. ATKINSON.

SIR,—It was with great interest that I read Mr. Eric Coldrey's paper (*Journal*, December 22, 1956, p. 1458) advocating a conservative approach to the treatment of acute appendicitis. I have been engaged in emergency surgery for over twenty years and have performed the operation of appendicectomy, very rarely with drainage, on some thousands of cases at all ages and all stages of the disease. Surely the introduction of antibiotics has not abolished the old surgical dictum, "Where there is pus, let it out." The observation of Professor F. A. R. Stammers (*Journal*, January 26, p. 225) on frozen pelvis as a result of antibiotic therapy with consequent stricture of the rectum should be enough to condemn this method of treatment. I personally consider it dangerous teaching for house-surgeons and registrars to enter the practice of surgery with the idea that in the presence of infection with pus formation antibiotic therapy is the be-all and end-all of treatment.—I am, etc.,

Swansea.

J. RUSSELL HUGHES.

SIR,—Your correspondent, Dr. G. I. Alexander, states as follows in his letter (*Journal*, January 5, p. 46): "I seem to remember that during the war a directive was issued by the Admiralty that under no circumstances was appendicectomy to be attempted at sea—the results of keen young chaps operating in destroyers had been so bad." No instruction of this nature was issued by the Medical Director-General and I have no knowledge of any directive of this nature having been issued. I cannot conceive any circumstances in which such an instruction would be sent. As the conditions under which such emergency action would arise cannot be foreseen, a directive on such a matter might have fatal consequences. This is not intended to be an entry into the lists of *pro* and *contra* appendicectomy. Professional freedom as regards treatment in the Royal Naval Medical Service is a much-prized duty and privilege. It would be a great pity if it were to be thought that arbitrary directives are issued governing the conduct of that professional duty.—I am, etc.,

London, S.W.1.

R. C. MAY,
Medical Director-General
of the Navy.

Abnormal Haemoglobin

SIR,—I was interested in your review of the abnormal haemoglobin situation (*Journal*, January 5, p. 34). May I be permitted to comment? During a three-month period last year I examined the blood of a number of West Indians and Africans who have recently become resident in S.W. London. The majority were out-patients and not, to my knowledge, first-degree relatives. By electrophoresis and sickling tests the haemoglobin composition of 204 subjects was determined as follows: A, 167 (82%); S, 1 (0.5%); C, 1 (0.5%); A+S, 29 (14%); A+C, 5 (2.5%); S+C, 1 (0.5%); total abnormal haemoglobins, 37 (18%).

These findings confirm that a considerable incidence of abnormal haemoglobins may be found in such a population. It seems important to recognize this fact because the presence of haemoglobin S may be responsible for a wide variety of non-haematological syndromes. For example, in this series (none of whom presented with any haematological symptoms) the patient in whom S only was found by electrophoresis, a 29-year-old housewife and mother of two children, presented with Perthes's disease of the hip. Unfortunately, no family study could be made and we cannot state whether the condition was homozygous or heterozygous, in the latter case coupled with thalassaemia. In sickle-cell thalassaemia the haemoglobin A production of the heterozygote can be suppressed. The combination of sickle-cell trait with thalassaemia is likely in this instance because, in addition to S, there was 36% foetal haemoglobin. Similarly, the combination of S+C haemoglobin was found in a young man who underwent splenectomy for enlarged painful spleen. Both these conditions are presumed to be the result of intravascular sickling, a condition which may give rise to vascular occlusion in almost any organ of the body. Patients may, on account of this, present with such conditions as haematuria, pyrexia, jaundice, abdominal pain, and various neurological lesions. I suggest, therefore, that elucidation of haemoglobin type is required in any anaemia or inexplicable syndrome occurring in patients of West African ancestry.—I am, etc.,

London, S.E.1.

J. A. M. AGER.

The Black Sheep

SIR,—Your leading article on Sonne dysentery (*Journal*, January 26, p. 217) draws attention to the likelihood of transmission of infection through the handling by children of infected lavatory seats.

The reputation of the lavatory seat for transmitting disease, like its owner, has had its ups and downs for years, and up to recent times it has been thought that such blame as it has received has resulted largely from its limited scope for hitting back. However, there is now good reason to believe that Sonne dysentery, trichomoniasis, and syphilis through the secondary rash can be transmitted by this means.

The answer to the problem lies in the provision of the squatting type of water closets. These have the following advantages: (1) the feet are the only part of the anatomy to have contact with the lavatory; (2) the lavatory can be cleansed with a water jet from a hose-pipe; (3) absence of upward splash; (4) the squatting position maintains better tone of the abdominal and perineal muscles; (5) more effective evacuation. It may be thought that prejudice against such water closets would make them unacceptable in this country, but nevertheless the two local authorities I serve have provided them in certain of their public conveniences, and a large factory here has adopted this style for its labourers.—I am, etc.,

Dartford, Kent.

J. H. HUDSON.

SIR,—May I send you two clues which may help to solve the mystery of the black sheep (*Journal*, January 26, p. 217)? (1) The cheaper lavatory paper now consists largely of what Dr. Samuel Johnson called "interstitial vacuities," through which the faeces can hardly fail to contaminate the right hand. (2) In the days of the high cistern the handle on the dangling chain lay more conveniently

accessible to the uncontaminated left hand. The modern cistern, built low and flushed by a button or small lever, is more easily manipulated by the contaminated right hand. Even among the very U. flushing precedes washing.—I am, etc.,

London, W.1.

RAYMOND GREENE.

Fatal Reactions to Local Anaesthetics

SIR,—Your annotation on fatal reactions to local anaesthetics (*Journal*, February 2, p. 276) rightly points out the danger of these drugs, especially when applied topically in the dosage normally used. However, as I pointed out in a previous letter (*Journal*, May 28, 1949, p. 957), there appears to be evidence that, in the case of amethocaine as well as cocaine, the real danger is idiosyncrasy rather than overdosage. My experience of toxic reactions has been increased by only one case since the four I mentioned in 1949, but in every one of these convulsions have developed at an early stage in the preparation of the patient for bronchoscopy or laryngoscopy. Case 4, as previously reported, had less than 10 mg. of amethocaine following 1 mg. of cinchocaine, and the highest dosage in the five probably did not exceed 50 mg. when allowance is made for the solution left on swabs or expectorated. No case has occurred late in a difficult bronchoscopy or bronchography in which use of the bronchial spray may almost double the normal dosage of anaesthetics.

Experience here appears to confirm the belief that premedication with a barbiturate reduces the incidence of these reactions. We had nine years' immunity after adopting such a scheme. However, as case 5 proved fatal in spite of thiopentone and artificial respiration with oxygen, we will use lignocaine in future, but will not relax our normal precautions—barbiturate premedication, thiopentone, and a Boyle's machine at hand.—I am, etc.,

Market Drayton, Salop.

A. CLARK PENMAN.

Mild Endogenous Depression

SIR,—I was most interested in Dr. C. A. H. Watts's account of the mild endogenous depression (*Journal*, January 5, p. 4). As a retired consultant psychiatrist, I am filled with admiration at Dr. Watts's "clinical insight" into these conditions, and I would like any remarks I may make to be regarded as complementary to his paper rather than critical. I could not agree more with Dr. Watts's contention that these patients must be treated with patience, sympathy, and understanding. But, having said that, instead of "waiting for three months," I would suggest the enormous benefit most of these patients would get from the immediate giving of 4 or 5 E.C.T.s. In the majority of cases there would be no need for the patient to enter a mental hospital. Most mental hospitals now give such treatment freely to out-patients, and in some instances the treatment may be had in the psychiatric out-patient department of a general hospital.

In dealing with any form of depression the adjective mild, in my opinion, is a risky one to use. The most careful examination may miss the depth of the depression, and what may be a mild depression to-day may be a very severe one to-morrow. Therefore, I do not think the practitioner (or psychiatrist) should subject himself to all the worries of the possible outcome of such cases, but should seek the immediate help of E.C.T. (E.C.T. by no means removes the necessity for sympathetic understanding and support—in fact, if given without the latter, it will usually be found to be very unsatisfactory.)

It is difficult to understand what Dr. Watts means by his "anxious patient" who is "rational and he can follow with interest a logical argument" (so, too, can most depressives). If he means uncomplicated anxiety hysteria, then of course we are dealing with an entirely different condition where E.C.T. would be quite valueless, and where, in my opinion, the treatment of choice is suggestion, which, correctly given, should be almost instantaneously effective. But exceeding care is required here in diagnosis, and it should be remembered that the anxiety hysteric, while perhaps full of

fears and anxieties of, as a rule, all sorts of bodily ailments, does not exhibit any of the classical triad (depression, sleeplessness, and tearfulness), either alone or in combination, of depressive states. It cannot, I think, be too strongly borne in mind that the latter symptoms, in any combination, connote a breakdown, and not a "psychological aberration" which will immediately respond to any form of psychotherapy.—I am, etc.,

Northampton.

ROBERT THOMPSON.

Neostigmine-resistant Curarization

SIR,—The recent spate of correspondence in your *Journal* on the subject of neostigmine-resistant curarization leaves me bewildered and not a little anxious. As a surgeon, I am wondering whether one can any longer, with a clear conscience, leave the choice of anaesthetic to an anaesthetist. It may be that the time has come to reconsider the advantages and disadvantages of regional analgesia, and to avoid tampering with the patient's vital functions. Each of your correspondents voices a different opinion as to the root cause of his troubles, but the fact remains that several fatalities are admitted, and, unless a solution is forthcoming, many more may be expected. What distresses me most is the lamentable lack of precise description in most of these reports. Your *Journal* reaches every corner of the globe, but of what possible use can such letters be if the cardinal facts are omitted? You, Sir, and your advisers are not blameless in this matter. It is your editorial duty to ensure that the relevant facts are supplied, so that their publication may stimulate healthy and helpful criticism and the high scientific level of your *Journal* may be maintained.

One correspondent reports five cases with extreme vagueness. The notable omissions are: (1) the amount and nature of the relaxant given; (2) the method by which the dose was assessed; (3) whether the drug was given in a single dose or repeated at intervals; (4) whether a CO₂ absorber was used; (5) the proportions of gas and oxygen; (6) blood-pressure readings; and (7) the age, weight, and muscular development of the patient. Given these very pertinent findings, it is at least possible that somewhere in the world a fellow anaesthetist might be able to offer more than a feeble conjecture as to the cause of the condition.

Two other correspondents advance a possible explanation, and submit four case reports, again very incomplete. In the first, the statement is made that the dose of relaxant was not excessive. To my mind, Sir, that bald statement requires supporting evidence. How was the dose assessed? And what was the dose? Further, what proportions of anaesthetic gases were used? Was attention paid to the tidal and minute volumes respired? Was an efficient CO₂-absorber used? What were the findings as to colour, pulse, and blood pressure? Their second case recovered after two hours of artificial respiration, and is summarily dismissed without a single detail, incredible as it may seem, as to the anaesthetic. Such a case might be highly illuminating if fully reported. Their third case report omits to state the proportions of gases used, the amount of relaxant, whether a CO₂-absorber was used, details as to tidal and minute volumes, and the facts as to colour, pulse, and blood pressure. The fourth case report has similar omissions.

It seems to me that such anaesthetists are forgetting their elementary physiology in their search for a scapegoat. I believe that the relaxants are safe if used in the correct dosage; that this dosage should be assessed in the light of many factors, such as age, sex, muscular development, weight, and state of health; that the estimated dose can be easily checked by feeling the resistance offered by the re-breathing bag to manual compression; and, finally, that the reported complications can be avoided by correct dosage, by attention to the fundamental factors of tidal volume, minute volume, and adequate intake and output of oxygen and CO₂ respectively, and not by sanguine reliance on antidotes.—I am, etc.,

Johannesburg, S. Africa.

M. ARNOLD.

SIR,—While not wishing to drag out this correspondence, I would like to congratulate your last contributor, Dr. J. A. Scanlon (*Journal*, February 2, p. 283). His point of view savours of common sense and clinical acumen, qualities which are apt to be sadly lacking nowadays. As anaesthetists, we are constantly asked to deal with hopeless cases. The surgical mind appears to be incapable of accepting defeat: modern anaesthesia is apparently innocuous to the patient, and cases are operated on which have already reached a "point of no return." But before that point is reached there is a stage where operation will save life, and it is then that my less spectacular method (*Journal*, December 1, 1956, p. 1303) will prove effective.—I am, etc.,

Glasgow, S.4.

ALBERT CHRISTIE.

Translumbar Aortography

SIR,—May I comment on the interesting paper by Mr. H. Gaylis and Dr. J. W. Laws (*Journal*, November 17, 1956, p. 1141) and the subsequent correspondence? As a result of their experimental work Gaylis and Laws advance the theory that aortic dissection from intramural extravasation following translumbar aortography was largely responsible for some of the serious complications previously attributed to toxicity of the various injection media. It is true, as they point out, that there are many instances in which all the contrast medium has been injected into one branch without ill effect and that some of the reported complications have been associated with extravasation. On the other hand, there are just as many instances in which no ill effect has ensued following the extra-aortic or intramural injection of dye, and there are good grounds for accepting the toxic effect of these media on various tissues. Their theory, however, cannot be refuted, and goes far to explain dissection as a factor in some of the complications, but I incline to agree with Dr. David Sutton (*Journal*, January 26, p. 225) that "toxicity of the medium when given in excessive doses is the major factor in such accidents."

At least four factors must be taken into account in the explanation of complications following aortography—namely, technique of puncture, type of medium, quantity of medium, and injection pressure. Dr. Sutton, in his criticism of the technique used by Mr. Gaylis and Dr. Laws, advocates the use of a test dose to ascertain the position of the needle point. While this will reduce the risk of injection into one main branch, I agree with Gaylis and Laws, supported by Lindgren,¹ that it does not completely obviate the possibility of intramural extravasation occurring during the main injection. In an experience of 500 translumbar aortograms performed mainly (95%) for renal diagnosis I have found that when extravasation occurs it is usually as a result of imperfect positioning of the needle before injection. This is largely a matter of technique and should be, to a great extent, avoidable. In practice, the surest method to avoid this mishap is to effect puncture by a needle alone and not by one connected to a closed saline system. In this way the needle may be rotated through a full circle of 360 degrees and adjustment made so that a free pulsatile stream of blood is obtained throughout the whole manoeuvre. It is imperative that such a free flow of blood is obtained before injection is made.

As regards the various opaque media, the modern organic iodide compounds, while a great advance on sodium iodide, are not completely free from toxic effect. I insist on a routine intravenous test dose for toxicity and sensitivity, and do not place complete reliance on a previous uneventful excretion urogram in which a different strength if not a different drug may have been used. Sodium acetrizate 70% ("urokon") has proved, in my hands, the most satisfactory medium so far. I consider large quantities of dye, such as 70–100 ml., to be excessive. The use of more than 20 ml. is no more necessary or desirable in renal angiography than in intravenous urography. In practice I never use more than 18 ml. for renal angiography or aortography, this amount being quite adequate provided reasonably rapid injection is carried out. Further, in the event of extravasa-

tion, it is not unreasonable to assume that the effects will be proportional to the quantity injected.

The most important single factor in the production of good aortograms consists of the rapid introduction of the dye, and there is little doubt that the pictures produced using moderate mechanical pressure are superior to those obtained by hand pressure alone. Dr. Sutton, however, appears to condemn the use of pressure injection and states that such instruments "can be extremely dangerous in other and unskilled hands." This is certainly true, but such a criticism applies to the use of almost every piece of apparatus in the medical armamentarium, and I think the position is fairly summed up in respect of aortography in general by the editorial comment on arteriography² that translumbar aortography should be employed "as a diagnostic adjunct by carefully trained personnel" (my italics). The use of excessive pressure such as 3,000–4,000 mm. Hg attained by some gas-air machines is to be condemned, but few articles on this subject state the actual pressures used for injection. The lever apparatus and technique which I use have been described elsewhere³ in which 15–18 ml. of dye is injected in one second. This requires a pressure of 800 mm. Hg through a No. 16 S.W.G. needle, which I do not consider excessive compared with a pressure of 500–600 mm. Hg over a period of three seconds required by hand pressure to introduce the same amount. Experiments with this injection pressure showed that the rise in intra-aortic pressure was less than 10 mm. Hg and had no detectable effect on the cardiac cycle. While I may have been fortunate in the absence of any significant complications in this series, I attribute this largely to the small quantity of dye used for injection.—I am, etc.,

Glasgow.

Breasts from Bird-seed

SIR,—The interest which has been shown in the device which I described in my previous letter, "Breasts from Bird-seed" (*Journal*, March 17, 1956, p. 628), indicates the real need which exists for a better form of mammary prosthesis. The purpose of this further communication is to describe an improved pattern, which is now on the market, possessing the mechanical advantages of the bird-seed model but free from its obvious drawbacks.

It may be remembered that the original model consisted of a cloth bag loosely filled with bird-seed, which was inserted into an ordinary brassière. The design of the new one is identical except that "polystyrene" granules are used as a filling instead of bird-seed. The patient who first used the bird-seed model has tried this one out and has found it to be equally satisfactory. It is now going into production, and I understand that a patent has been applied for. It has been given the name of "malpro," and may be obtained, in limited quantities at present, from Eunice A. Morris, 62, Church Street, Blackpool.

The polystyrene granules which are used are similar in size and weight to bird-seed, and so they provide the shifting quality and the exact counterpoise which are needed (see my previous letter). They are non-absorbent and resist boiling, so that washing the prosthesis presents no problem. Although they burn in the open fire, they are not highly inflammable. In conclusion, may I reply to two points which were raised by "Interested Victim" in her letter (*Journal*, April 14, p. 862)? First, although cotton-wool is a satisfactory substitute in ladies of modest proportions, it is quite inadequate in the majority of cases, because it is much too light to retain its place and to counterbalance the other side. Secondly, the discomfort in the immediate post-operative period which she has experienced from the standard models is largely due to their fixed shape and lack of resistance—i.e., a lack of the very shiftiness which has caused such fun.—I am, etc.,

Blackpool.

D. K. LENNOX.

Non-united Fracture of Scaphoid

SIR,—In two successive orthopaedic clinics at the R.A.F. Hospital, Nocton, recently, six new cases of established non-union of a fractured carpal scaphoid were referred for diagnosis and treatment. While the number was unusually high it did serve to emphasize the steady stream of such cases encountered. Disability from this lesion is variable, but more often than not manual workers are handicapped by pain, a weakened grip, and restricted mobility, while a skilled craftsman can become seriously disabled. In almost every case the fault lies in premature reassurance of the patient in the surgery or the casualty department as his "sprained wrist" is strapped. This reassurance may have been encouraged by an x-ray report of "No bone injury" within a few days of injury. A confirmatory radiograph twelve or fourteen days later (when clinical suspicion should have remained) was not taken.

A non-united fracture of the scaphoid offers considerable difficulties in management. Degenerative osteoarthritic changes are often well established by the time the patient presents for treatment, and there is, unfortunately, no single procedure available that will guarantee union and/or abolish disability in all cases. It is for these reasons, Sir, but above all for the distressingly high incidence of this largely avoidable lesion, that I beg leave to raise this subject in your columns. I realize only too well that this problem has long been widely appreciated. Our experience, however, does seem to underline the value of occasional emphasis on this diagnostic problem.—I am, etc.,

Lincoln.

K. R. J. DE BELDER.

Herpes Zoster and Chicken-pox

SIR,—I recently had a case of herpes zoster in one of my patients followed later by chicken-pox in her daughter, aged 21 years. I reviewed the recent comprehensive article on this subject by Dr. R. M. McGregor (*Journal*, January 12, p. 84), and felt that my observations on these cases might strengthen the view that there is some connexion between the two conditions.

The patients in question went away on holiday over Christmas and returned to Liverpool on New Year's Day. Two days later (January 3) the mother developed severe pain in the right hypochondrium radiating through to the back, associated with a feeling of nausea, and this was considered most likely to be an attack of biliary colic. A curious feature is that for three nights the pain recurred at approximately the same time—2 a.m.—although during the day she could bear the pain. I called out a consultant physician on January 4, who agreed that biliary colic was the cause, due to over-indulgence in rich food while on holiday. He suggested I call in a surgeon if there was no improvement in her condition. This I did on January 5, and, although he considered the diagnosis of biliary colic most likely, for the first time it was noticed that she had some vesicles in the region of the umbilicus, in the line of the tenth right intercostal nerve. It was felt advisable to admit her to hospital for Graham's test, which proved negative, and the herpes zoster lesions appeared in typical fashion. After a week she returned home. On January 23 her daughter developed a severe attack of chicken-pox, from which she is convalescing at present.

I feel that in these cases exposure to infection took place during the holiday, and there is presumptive evidence that there is approximately twenty days' difference between the incubation period of chicken-pox and herpes zoster, as both the mother and the daughter must have been exposed to the same source of infection. An interesting feature of the case is that some years ago the mother's father had severe herpes zoster at the same time as his son had chicken-pox. I have seen several cases of herpes zoster in the last few years, but regret that my note-taking has not been as thorough as that of Dr. McGregor, who must be congratulated on his most excellent article. As a point of interest, a recent case of herpes zoster was in a patient suffering from

Hodgkin's disease, and I would welcome any suggestions as to the possible associations between the two conditions.—I am, etc.,

Liverpool, 7.

R. H. BRACEY.

SIR,—I was interested in Dr. R. M. McGregor's article on herpes, chicken-pox, and cancer (*Journal*, January 12, p. 84), and since reading it have come across a small outbreak I feel worthy of mention.

The father of a family of grown-up children was diagnosed as having herpes ophthalmicus on January 5. Sixteen days later his married daughter, who lives in the same house, had chicken-pox. Only four days after this her young brother of 17 was similarly diagnosed. A young married woman and frequent visitor of the family, who lived two houses away, contracted chicken-pox on the same day as the daughter. So far as we are aware there have not been any other cases of herpes or chicken-pox in this fairly isolated village for many months. And the patients concerned have had no known contact with these diseases outside their village.—I am, etc.,

Charing, Kent.

RAYMOND CASTLE.

Hereditary Factor

SIR,—The report by Dr. Mary E. Carter on two siblings diagnosed as acute lymphatic leukaemia (*Journal*, February 2, p. 265) is particularly interesting to me, because in 1953 I saw a woman of 45 with typical chronic myeloid leukaemia, who had lost identical twins with acute lymphatic leukaemia 20 years earlier. The literature on the possible hereditary factor in leukaemia by Guasch¹ does not contain any similar information, but it may well be that my three cases were coincidental.—I am, etc.,

London, W.1.

A. PINEY.

Pregnancy Sickness

SIR,—I am encouraged to add my mite of personal observation to that of Dr. Doreen S. Ball (*Journal*, December 22, 1956, p. 1487) and Dr. P. G. Cronk and Dr. Muriel Dalby (*Journal*, January 5, p. 49). My medical school is known for its antenatal training, and I anticipated a pregnancy without emesis or toxæmia, with well-being, a "natural" birth, and full breast-feeding, as being the right of a wanted pregnancy and a calm, sensible approach. So eager was I to conceive that I thought myself pregnant before I was, though of course the symptoms did not include sickness. Does pseudocyesis ever include emesis? The first sign of pregnancy was slight giddiness and that a casual throat clearing or cough made me retch at about six weeks. All day nausea and retching attacks developed; flavours went wrong; my mouth seeming to be coated with stale fat, which drove me to eat citrus fruits. Nausea, occasional vomiting, and wrong flavours persisted till delivery. I never felt well and had mild pre-eclamptic toxæmia at 30 weeks.

In labour I had no fear, was completely confident in my doctor and nurses, and had my husband with me. The familiar uterine contractions were painless, but accompanied by a sharp pain in the sacrum, this becoming unbearably severe even with pethidine. The pain had no component of pressure, distension, ache, or drag, and was not like intestinal colic. Relaxation did not ease it. The second stage was comparatively easy. The baby was by my side during the lying-in period, and breast-feeding seemed the easiest and happiest thing, but after two months the supply declined and was not revived by 14 days' religious expressing.

Such experiences open one's mind to try to observe instead of merely applying teaching. Any patient's account published by Dr. Grantly Dick Read and followers describes feeling some very strong sensation during labour, which is not pain. What is it? I am sure that only a few "trained"

mothers achieve painless labour (I have not personally known of one), while a few "untrained" mothers have painless labours anyway. Are there any comparative figures? I do not decry antenatal training in the least, but so much depends on the personalities of those who attend women in labour. I have heard a nurse answer an appeal from a distressed woman with, "You've been taught to relax—get on with it," then leaving her alone. It is the absence of fear that is all-important.—I am, etc.,

Emsworth, Hants.

ANN PARKER.

Methyltestosterone Therapy

SIR,—In response to the request of Drs. G. L. Foss and S. L. Simpson (*Journal*, December 15, 1956, p. 1426) we wish to report an additional case of jaundice due to methyltestosterone. A female patient, aged 50, diagnosed as a case of hypopituitarism, was admitted to Sheffield Royal Infirmary and treated with methyltestosterone linguets (20 mg. daily) from March, 1953. In July, 1953, she became deeply jaundiced, and three months elapsed before the patient returned to her normal colour. The results of liver-function tests between the onset of jaundice and December, 1953, are tabulated below.

The main abnormalities are a raised serum bilirubin and alkaline phosphatase with a normal thymol turbidity. Two weeks after the jaundice became evident the patient's haemoglobin fell to 7.4 g./100 ml., and, though no frank melaena was observed, the stools contained occult blood at this time.

Date	Thymol Turbidity	Serum Bilirubin (mg./100 ml.)	Serum Alkaline Phosphatase King-Armstrong Units	Serum Albumin (g./100 ml.)	Serum Globulin (g./100 ml.)
1953					
July 16	1		42		2.2
" 30	<1	37	37	4.1	
Aug. 10	<1	22	23		
" 20	<1	13.8	20	4.3	2.3
" 28	<1	10.4	18		
Sept. 2	<1	6.9	17		
" 9	<1	5.0	16	4.9	3.0
" 15	1	3.6	15	4.7	2.3
" 24	1	1.8	11		
Oct. 14	2	2.5	7		
" 21	2	1.6	12		
Dec. 2	1	0.8	8	5.0	3.1

After transfusion and oral iron the anaemia was corrected, and repeated examination of the stools showed that they contained no occult blood. The interval between starting the drug and the onset of jaundice is in keeping with most of the cases reported by Werner and others,¹ who also found the serum alkaline phosphatase to be raised. The case reported by Wood² had a normal serum alkaline phosphatase.

Since recovering from jaundice the patient has been well and treatment with methyltestosterone has not been resumed. The number of reported cases is small, and the complication is so rare that it should not be regarded as a contraindication to using this drug.—We are, etc.,

Tobacco-cancer Problem

SIR,—If Dr. Lennox Johnston (*Journal*, January 26, p. 228) is correct, as I believe he is, in asserting that tobacco smoking is essentially a manifestation of nicotine addiction, there seems to be a simple solution to the cancer-smoking problem: nicotine could be presented in some bland vehicle providing characteristic and pleasant sensations of taste, flavour, touch, etc. For the edentulous, a flavoured sucrose pastille might be suitable, but for others some non-fermentable (non-cariogenic) substance would be preferable—e.g., sorbitol, as in diabetic sweets, or chiclé gum sweetened if necessary

Obituary

D. R. MacCALMAN, M.D., F.R.C.P.Ed.

Professor Douglas MacCalman, formerly Nuffield professor of psychiatry at the University of Leeds, died after a prolonged illness on January 31 at the age of 53.

Douglas Robert MacCalman was born on December 4, 1903, in Strachur, Argyllshire, the son of the Rev. D. M. MacCalman. Brought up in the north-west Highlands, he never lost his deep affection for that remote and lovely part of the country, and the influence of those years was always apparent in his own quiet and courteous manner. He was educated at Glasgow Academy and then at the

University of Glasgow, where he graduated M.B., Ch.B. in 1929, winning the Hunter medal in pathology. As with many other sons of the manse who have studied medicine, he was at an early stage in his career attracted to psychological medicine. Soon after qualification he took up appointments in psychiatry in the United States, first at Phipps Clinic, Johns Hopkins Medical School, Baltimore, under the late Professor Adolf Meyer, and then at the Boston Psychopathic Hospital, under the direction of another illustrious Scot, Dr. McFee Campbell, professor of psychiatry at Harvard. Having come under the tutelage of two of the most eminent psychiatric teachers of our time, MacCalman was well fitted to return to this country and assume a position of leadership at an early age. In 1932 he was appointed medical director of the Notre Dame Child Guidance Clinic in Glasgow and assistant physician at the Victoria Infirmary, having in the previous year proceeded to the M.D., with high commendation in psychiatry. In 1935 he was invited to become general secretary of the Child Guidance Council in London, where he enhanced his reputation not only as an able clinician but as a man of outstanding academic and administrative ability.

The institution, in 1938, of the Crombie-Ross lectureship in psychopathology at Aberdeen University was an important new development, for it was the intention of the founder and of the university to extend teaching and research in psychological medicine into the general teaching hospital and to enlarge the mental health service by setting up out-patient clinics for adults and children. Dr. MacCalman was the first and only holder of this appointment, which carried with it the honorary status of assistant physician at the Aberdeen Royal Infirmary and the Aberdeen Hospital for Sick Children. Throughout the war years the new department was gradually built up in face of wartime restrictions, shortage of staff, and the like. Additional duties in connexion with the emergency medical services were placed on his shoulders. Despite these great handicaps and the mounting burden of private practice, he succeeded in establishing himself and his subject in the north-east

[Kemsley Picture Service]

with saccharin. I suggest a sweet or sweetened solid vehicle because those who are giving up smoking often find the use of ordinary or diabetic sweets helpful, but I imagine that some other consistency and taste, or combination of tastes, would be found equally pleasant if it were especially associated with the pleasure derived from nicotine, in the same way that a degree of bitterness that would otherwise be objectionable is pleasant in some drinks containing caffeine or alcohol.

Such a solution to the cancer-smoking problem might possibly lead to an increase in nicotine poisoning, but it surely deserves consideration. The ideal solution, of course, would be the discovery of some perfectly harmless but identically satisfactory substitute for nicotine itself. I doubt if education, propaganda, and legislation will themselves do much to prevent tobacco-smoking. Even middle-aged doctors obviously prefer to run the risk of cancer rather than forgo the pleasure of absorbing nicotine from tobacco smoke. Prohibition could only be accepted, if at all, when every possible effort to find a constructive solution had failed, and this is very far from the case at present.—I am, etc.,

London, S.W.10.

Check the Dose

SIR,—The anticoagulant drug phenindione is familiar under the trade name "dindevan" as scored tablets in one strength only—50 mg.—from which dosage schedules in multiples of 25 mg. may be arranged. There is now a need for a weaker strength if advantage is to be taken of the more accurate stabilization of patients by means of Owren's¹ modified method of estimating the "one-stage prothrombin time." The advantages claimed for this method of controlling anticoagulant therapy are that it is sensitive to dosage increments of 10 mg. and thus it is possible to stabilize patients whose dosage requirements do not coincide with multiples of 25 mg.; trends towards overdosage are obvious and the correct dose can often be decided two or three days earlier than with the older method.

The makers are ready to supply a 10-mg. tablet of dindevan to meet this need. With this new strength, however, difficulties for the prescriber and pharmacist may arise. The *British Pharmacopoeia*, 1953—Addendum, 1955, directs that, "if the quantity [of phenindione] contained in a tablet is not stated, tablets containing, in each, 50 mg. shall be supplied or dispensed." If this directive were followed, the pharmacist would supply tablets which might be five times the strength of those intended.

So that there may be no doubt as to what should be supplied, prescriptions or orders for this drug should state the precise dose in milligrams or the strength of the tablet required.—We are, etc.,

ROSEMARY P. BIGGS.

Wellcome Floating Laboratory

SIR,—Under the heading "Benefactions by the Wellcome Trust" (*Journal*, February 2, p. 295) there occurs the following statement: "... probably the first floating laboratory to be made was the one built in 1907 to the order of the late Sir Henry Wellcome. It was used on the Nile by members of the staff of the Gordon Memorial Hospital, Khartum."

There has, in fact, never been a hospital in Khartum called the Gordon Memorial Hospital. The floating laboratory was given by Sir Henry Wellcome to the Wellcome Tropical Research Laboratories, which he had himself founded in 1902–3. It was first used by the director, the late Sir Andrew Balfour. The floating laboratory was loaned to me for several months in 1915 when I was dealing with a devastating epidemic of cerebrospinal meningitis in the then White Nile Province of the Sudan.—I am, etc.,

London, W.1.

H. C. SQUIRES.

region with such success that the fruits of his work are still being gathered to-day. It was singularly appropriate that when it was decided to create a professorial department in Aberdeen Dr. MacCalman should become the first incumbent of the chair. In the next three years the unit was extended and the teaching programme completely reorganized, so that now a comprehensive course of over 100 hours is given to the undergraduates during their third to fifth years of study. His opinions were much sought after in the early days of the National Health Service, and his vision contributed greatly to the close integration of the mental health service in the north-east region.

In 1948 he decided to apply his great gifts to a new and larger sphere when appointed the Nuffield professor of psychiatry at the University of Leeds. Here again he built up a university department, both in its teaching and in its research functions. He organized the training scheme for the University of Leeds diploma in psychiatry and advised the regional hospital board on the organization of its mental health service. He was the chairman of the North and Midland Division of the Royal Medico-Psychological Association and a member of many other learned societies and official committees. He was one of the founder members of the Mental Health Research Fund and a Trustee of the World Federation for Mental Health, and he was in constant demand as a lecturer to medical societies, conferences, and lay audiences. One of his outstanding achievements in this connexion was his address to the first World Congress of Mental Health in London in 1948. He was invited to lecture in Finland, the United States, and more recently in Australia, and wherever he went his sterling gifts were apparent. In his early years as a psychiatrist he took part in a large-scale scheme of research into the causation of schizophrenia, and he also made a study of the Rorschach test. He contributed chapters to a number of books and published articles on child psychiatry, education, and neuroses. At the Annual Meeting of the B.M.A. in 1953 he served as vice-president of the Section of Psychiatry. He was elected to the Membership of the Royal College of Physicians of Edinburgh in 1948 and to the Fellowship in 1952.

In recent years ill-health began to impair his prodigious energy, but characteristically he carried on doggedly and without complaint. Though often in considerable pain, he never made reference to it. After a mild thrombotic episode, he eventually decided that he must retire from his chair, but continued in active work, both clinical and academic, almost to the end.

In his younger days MacCalman was an all-round sportsman. He was a fast and elusive wing three-quarter for Glasgow Academicals, and played low-handicap golf until arthritis made this impossible. He had a lifelong interest in gardening, ornithology, and painting, liking nothing better than a painting holiday in Ullapool. An ardent exhibitor of fruit and vegetables at local flower shows, he was always greatly delighted when he won a prize for his products. He was extremely well read, not only in his own subject but in English literature and history.

Professor MacCalman married Helen, only daughter of Dr. J. M. Dawson, in 1935, and she survives him, with one daughter.—W. M. M.

G. R. H. writes: As the first holder of the Crombie-Ross chair of mental health at Aberdeen Douglas MacCalman combined his earlier experience in the mental hygiene

of childhood with his developing interest in the teaching of medical students. This combination of interests he continued to pursue when at Leeds. The attention which the Leeds medical school pays to psychiatry in both its undergraduate curriculum and its final examination bears witness to MacCalman's personal conviction of the importance of this subject in the family doctor's daily work. The existing postgraduate training of psychiatrists at Leeds was continued and developed by MacCalman, and the introduction into the curriculum of the course for the Diploma in Psychological Medicine (Leeds) of teaching on certain aspects of the social sciences and on psychotherapy is evidence of his own broad orientation in psychiatry. Since he had taken up his chair at Leeds in the early days of the National Health Service it was always one of his main aims to strengthen the links between his department in the university medical school, the clinical work of the teaching hospitals, and the psychiatric services of the regional hospital board. Both as a consultant to St. James's Hospital, Leeds, and to the City Council of Leeds, and as chairman of the Mental Health Technical Advisory Committee of the Leeds regional hospital board, he did much to build a closer relationship between the various aspects of the cure and prevention of mental illness in the region.

To those who did not know him well Douglas MacCalman must sometimes have seemed a shy man until his interest in a topic broke through his natural reserve, as it would in discussion, teaching, or public speaking, for which he had a great natural gift. Those who worked with him developed strong bonds of affection with him, and all who saw the way he faced his long and crippling illness admired his great courage. His colleagues and his friends in many countries will feel deep sympathy for his widow and his daughter.

M. B. H. W. writes: I should like to try to express something of my personal concept of and indebtedness to the late Professor Douglas R. MacCalman. In so doing, I am doubtless giving utterance to the thoughts and feelings of the many other psychiatric social workers who have known his encouraging and enabling way with us. Under his aegis as secretary of the Child Guidance Council, a few of us in the 1930's were lent to authorities who wished to start child guidance clinics. We would wish to thank him for his quietly effective support in these ventures and for his sure and careful guidance of our committees. Thanks to his unswerving convictions, out of these small beginnings the present child guidance services have been enabled to grow. In the 1940's, a period of challenge—from without from the rapidly developing mental health services and from within by reason of our growing consciousness of our roles in this field—Professor MacCalman helped many of us individually with our conflicts and problems, never withholding himself when his help was sought. A wider circle will recall his several addresses to the Association of Psychiatric Social Workers: in these he gave full measure of his rich, literary, artistic, humanist self—brilliant and bright—renewing us. It is this quality of renewing, this therapeutic personality, which, as his psychiatric social worker over a period of sixteen years, I feel was his peculiar gift as a psychiatrist; and as I write I recall the many patients, simple and sophisticated alike, who have spoken of this. As a professor, he has been cut off before he could reach his full stature, but for the advancement of psychiatry he imaged the whole; now others must execute the parts. As a colleague he was benign and as a friend he was lovable.

W. H. WILSON, D.M.

Professor W. H. Wilson, emeritus professor of physiology in the University of Cairo, died at the Victoria Hospital, Cairo, on November 14, 1956. He was in his 91st year.

William Hawkins Wilson was born on February 16, 1866, the second son of the late J. C. Wilson, D.C.L., a law tutor at Oxford, and was educated at Radley College

and at Keble College, Oxford, where he was a scholar. In 1888 he obtained a first-class in the Honours School of Physiology and his B.A. degree. From 1888 to 1890 he was science tutor at Keble College and university demonstrator in histology. Deciding to obtain a medical degree, he went on to St. George's Hospital with a scholarship and graduated B.M., B.Ch. in 1893. Before this he had been awarded a Radcliffe travelling fellowship and spent two years studying in Paris, Vienna, Dresden, Munich, and Freiburg in Baden. After qualification he worked as a house-surgeon and house-physician at St. George's. He proceeded to the D.M. in 1903.

In 1895 Wilson was appointed by the Egyptian Government to the post of assistant professor of physiology at the School of Medicine at Kasr-el-Aini, Cairo (afterwards known as the Faculty of Medicine of Cairo University), and he became professor a year or two later, occupying the chair until 1928, when he retired. Later, he was elected emeritus professor of physiology and carried on research work in the physiology department of the faculty and acted as examiner in his subject. He contributed papers on a variety of subjects to the *Journal of Physiology* and other journals, and had made a special study of scorpion venom. During the first world war he remained in Egypt and continued his official duties, also acting as adviser in physiology to the British Army and Air Force. He founded a charitable dispensary at Mataria, Cairo, in 1921, which served a large number of villagers in that area, having a yearly visiting attendance of many thousands. He was a member of the General Board of Health, on which he represented British interests. A member of the British Medical Association for over 50 years, he was president of the Egyptian Branch in 1929–30. He married Kate Hamilton Naylor in 1897; she died in 1935.

C. B. S. E. writes: The late Professor W. H. Wilson, who was appointed to the inspectorate of the Department of Public Health in Egypt in 1895, became much interested in the country, more especially as the increasing national budget permitted of extensive developments in the health service, including the foundation of hospitals and dispensaries in every province, and of the enlargement of the teaching hospital of Kasr-el-Aini, in Cairo. He had a natural sympathy and understanding of the most varied classes of the inhabitants, from his nearest neighbour, Prince Youssef Kamel, to the fellahen workers and small proprietors by whom he was surrounded in Mataria, an outlying suburb of Cairo. There, shortly before the outbreak of the first world war, Professor Wilson and his wife had settled, building a house in a country property; in this he resided until his final illness. His life there was marred only by a disastrous fall during the building of his home, a fall which resulted in serious spinal and internal injuries, crippling him for life so far as locomotion was concerned, but in no way affecting his mental energy or his determination to improve the life of all around him.

At this period he was appointed professor of physiology at the Kasr-el-Aini Medical School, a post in which he remained until superannuated. He continued, however, to take part in the annual examinations until quite recently, when well over his 80th year. The ailments of advanced age further limited his physical capacities, but did not prevent him from flying to England and back in 1955. During his professorship his personal interest in the students provided him with devoted friends among the Egyptian medical leaders in his later years. He conducted much physiological research at the school laboratories. Until three years ago he was also a member of a dietetic research committee of the Public Health Ministry (formerly Department), which laid down rules for the diet in schools, prisons, hospitals,

and for manual workers based on the habits and possible food resources of the country. His close personal touch with working classes living around him, and their women-kind, gave him unusual opportunity to study these matters. In the course of the second world war, when research laboratories were no longer open to him, he invented an instrument to facilitate the sight in night flying, an instrument which was put to use by the R.A.F. He completed the whole work himself in a small wooden hut in his grove of apricot, orange, and almond trees.

His kindness of heart was shown by the fact that on Fridays, his only day free from official work, he opened his doors to the poor and needy in the villages near him, giving them advice, drugs, and money for years. About 36 years ago, with the financial backing of his friend and neighbour, Prince Youssef Kamel, he founded a clinic in Mataria village near his home. In doing this he was supported by some of the best-known medical men in Cairo. He supervised the clinic personally for many years. Fairly recently some official support for it was arranged. Advancing years seriously affected his sight, yet he patiently kept abreast of physiological progress and was ever ready to talk over some new development. During his last days in the Victoria Hospital he had the consolation of visits from several leaders of the medical profession in Cairo, old pupils of his. In spite of the expulsion orders served on the leading members of the English world in Cairo a few days before his death, an English lady was enabled to attend his funeral in company with one or two friends of other communities, including Danish and Egyptian.

H. M. SHELLEY, F.R.F.P.S., M.R.C.P. D.T.M.&H.

Dr. H. M. Shelley, formerly director of medical and health services in Cyprus, died suddenly at sea on January 26 while travelling from Cyprus to Greece. He was 56 years of age and had been ill for some time. He was buried in Athens.

Horace Minton Shelley was born at Bradford on January 11, 1901. From the Intermediate School, Nottingham, he went on to study medicine at Sheffield University. Qualifying in 1923, he joined the Colonial Medical Service in the following year and his first post was in Nyasaland, where he remained until 1939. He took the D.T.M.&H. in 1927 and the M.R.C.P. in 1938, and in 1934 he was elected F.R.F.P.S. of Glasgow. After working for a few years as a pathologist in Nyasaland he transferred to Tanganyika as a senior medical officer in 1939. In 1947 he was appointed director of medical services in Cyprus, where he successfully carried out many reforms and was in charge of the campaign which freed the island from malaria. One of the reasons for the success of this campaign was the friendly relationship which Dr. Shelley established with all his colleagues, medical and administrative. He retired from the Colonial Medical Service in 1952, but continued to live in Cyprus.

An active member of the British Medical Association, Dr. Shelley was honorary secretary of the Nyasaland Branch for six years and president of the Branch from 1934 to 1935. He wrote a small textbook entitled *Epitome of Laboratory Diagnosis and Treatment of Tropical Diseases*, and, having founded the *Cyprus Medical Journal*, he continued to edit it until the time of his death. He married Claire, daughter of Madame Boulenger. She survives him with three children of the marriage.

J. E. G. writes: Dr. Shelley had been ill for several years, and was on his way to seek quieter retirement in South Africa. He had an interesting career, for he was a personality and took a deep interest in many things beside his

work. He boxed as a flyweight for the British against the American universities, and his life was indeed a continual and often successful fight against great odds. He never accepted defeat, and even in a long struggle against a failing heart he seemed to be the attacker. He had more bravery than most men, and rose above his physical incapacity and pain until it mercifully overwhelmed him completely and suddenly. He had dramatic talent and acted on the stage for a time, but mostly this ability was well used in informal medical teaching. Even without his extensive knowledge he would have been impressive. In territories he served in he worked hard and devotedly with the help, and sometimes the handicap, of an imagination not often found in administrators. During his tenure in Cyprus the eradication of the malaria-carrying mosquitoes was completed, and most of this was due to his efforts. He was fond of writing and lecturing, and in addition to his medical writing he wrote fiction and poetry. There are many who will mourn his passing and many whose lives will miss the stimulation of his ideas.

R. W. D. LESLIE, C.B., C.B.E., L.R.C.P.I.

Major-General R. W. D. Leslie, who after a distinguished career in the Army Medical Services, gave valuable help with the organization of the Emergency Medical Service, died at his home at East Leake, near Loughborough, Leicestershire, on January 31, his 74th birthday.

Robert Walter Dickson Leslie was born on January 31, 1883, and was educated at Michaelhouse, Natal, South Africa, receiving his medical training in Dublin. He qualified by taking the Irish Conjoint diploma in 1904. Two years later he entered the R.A.M.C., and when the first world war began in 1914 held the rank of captain. In the twenty years from 1917 to 1937 he rose from the rank of brevet major to that of major-general, holding many important posts in that period. For his services in the first world war, towards the end of which he was an A.D.M.S. in France, he was mentioned in dispatches and appointed O.B.E. in the 1919 Birthday Honours.

Promoted to lieutenant-colonel in 1930, Leslie was deputy assistant director of medical services in India from that year until 1932, and in 1936—having been promoted colonel two years before—he was deputy director of medical services in Palestine and Transjordan. Returning to the United Kingdom, he was in command of the Queen Alexandra Military Hospital, Millbank, until 1937. In that year he became major-general and was appointed deputy director of medical services in Northern Command. He occupied that post until 1941, when he was appointed C.B. and retired from the Army, and from 1939 to 1941 he was an Honorary Physician to the King. During the course of his career in the A.M.S. Leslie contributed a number of articles to the *Journal of the Royal Army Medical Corps*. These included papers on improvements in motor ambulance construction (with Captain G. A. Child); improvised ambulance trains; the medical services in Palestine; and the casualty card scheme in R.A.M.C. field training.

The end of Leslie's military career was by no means the end of his working life. In 1941 he obtained an appointment as a hospital officer in the Emergency Medical Service, and from 1948 to 1954 he was employed as a regional medical officer (No. 3 Region) under the Ministry of Health. For his services in the E.M.S. he was appointed C.B.E. (Civil Division) in the 1946 New Year Honours. Leslie was a member of the Council of the British Medical Association from 1942 to 1948.

He also served on the old Naval and Military Committee of the Association from 1944 to 1948 and on the General Medical Council Committee (1946–8) and the Central Medical War Committee (1947–8). He married Miss Eleanor V. Jackson in 1911, and she survives him.

Dr. RUFUS C. THOMAS, consulting obstetrician and gynaecologist to the Kent County Council, died at his home at Croydon on January 11 at the age of 67. Rufus Clifford Thomas was born at Llantwit Vardre, near Pontypridd, in June, 1889, and was educated at Christ College, Brecon, University College, Cardiff, and at the Westminster Hospital. After qualifying M.R.C.S., L.R.C.P. in 1915 he held the appointments of resident obstetric assistant and senior house-surgeon at Westminster Hospital, and then served for a time in the R.A.M.C. From 1919 to 1927 he was in practice at Newport, Monmouthshire, and while there was elected F.R.C.S.Ed. in 1924. At Newport he was also honorary anaesthetist to the Royal Gwent Hospital, consulting surgeon to the maternity and child welfare clinic, and consulting gynaecologist to the borough council. In 1927 he went to India as chief medical officer to the Maharajah Jamsaheb of Nawangar—"Ranji," the famous cricketer. In India his work was partly administrative, but largely surgical. He left India in 1933 because of illness, and joined the staff of the West Middlesex County Hospital as resident surgeon. Two years later he became obstetrician and gynaecologist at the Mayday Hospital, Croydon, and consultant to the county borough council, and in this post his clinical and administrative skill was used to the full. Some two years after the end of the second world war he accepted a similar appointment under the Kent County Council, with headquarters at Farnborough County Hospital. He was a lecturer and examiner for the Central Midwives Board. Elected a Member of Royal College of Obstetricians and Gynaecologists in 1934, he became a Fellow in 1947, and from that year until 1952 served on the council of the College. He was also a member for some years of its Hospital Recognition Committee. He was president of the Association of Whole-time Salaried Specialists. He leaves a widow and a daughter.

K. G. S. writes: Having worked with Rufus Thomas for nearly twenty years, I feel his loss very keenly. In the early days of our association his acumen in diagnosis and strict attention to detail were at once an example and an inspiration, and there are many who, like myself, owe much to his wise counsel. As a colleague he was always ready with advice, and his wide experience in all branches of medicine made this exceptionally valuable. In addition he had a highly critical appreciation of the legal aspects of his work and was much sought after as a member of various committees. Thomas had a keen sense of humour and an endless supply of anecdotes, but although his hobbies were golf and fishing these subjects were seldom mentioned. He will be greatly missed at Farnborough, especially by those of us who were privileged to enjoy his friendship.

Dr. W. N. GRAY, of Helmsdale, Sutherlandshire, died on January 27, aged 62. William Nicol Gray was born at High Blantyre, Lanarkshire, on August 15, 1894, and was educated at Hamilton Academy. He matriculated at Glasgow University in 1912, his original intention being to become a teacher. His plans were interrupted by the first world war, during which he served first in a munitions factory and then in motor torpedo-boats with the Royal Navy. After the war he turned to medicine and graduated M.B., Ch.B. from Glasgow University in 1922. After holding hospital appointments in Glasgow and Middlesbrough he spent a year as assistant to Dr. W. H. M. Barclay, at Grantown-on-Spey. Though attracted by a country life, he chose to settle in a busy industrial practice in Clydebank in partnership with the late Dr. Thomas M. Strang, a man of outstanding clinical acumen, integrity, and great humanity—traditions which Dr. Gray amply maintained. When the

practice was scattered almost overnight by the fury of the Clydebank "blitz" during the second world war there was widespread dislocation of medical services, and he took up practice again at Helmsdale, where he remained until his death. He leaves a widow and three children, two of whom are graduates in medicine.

R. D. M. writes: In the Highlands outsiders do not always find ready acceptance, but Bill Gray's patent worth, sincerity, depth of understanding, and sense of humour soon made him the friend of all in this scattered area, with its difficult and sometimes snowbound roads. With his passing the Highlands have lost a fine doctor. He identified himself completely with his new parish, even learning Gaelic and later becoming president of the local branch of An Commun Gaidhealach. It would be impossible here to detail the many ways in which Bill Gray served the Highlands during his years in the north. On his shoulders seemed to fall the mantle of that grand old man the late Dr. J. B. Simpson, of Golspie, whom he succeeded as chairman of the Sutherland Insurance Committee. He was also chairman of the Sutherland Division of the British Medical Association and for a year was president of the Northern Counties of Scotland Branch. As a member of the Scottish Committee and the Highlands and Islands Subcommittee of the B.M.A., chairman of the Sutherland Executive Council, of the local medical committee, and of the Highlands and Islands Subcommittee of the Scottish Health Services Council, he undertook a vast amount of extra work and responsibility, as well as many wearisome hours of travel by car and train. Apart from these journeys, he rarely left his practice area. He was a keen fisherman, photographer, and gardener who could coax life out of stones. To his patients, however, he will perhaps always be associated with the struggle to establish the "Hospice" as a small maternity hospital, serving not only his own practice but the rest of the county, particularly the more remote and inaccessible parts. An outstanding all-round clinician with a natural bent for midwifery, he was, moreover, a born teacher; no less than four of his trainees took the D.Obst.R.C.O.G. from this remote country practice. It was a measure of his qualities as a doctor, teacher, and friend that three of his former trainees made the long journey north to join with the sorrowing throng which seemed to include every man in the neighbourhood, who packed the church and streets of Helmsdale to overflowing to bid him sad farewell. In the age of specialization Bill Gray was that fine thing a first-class general practitioner.

Dr. G. W. LLOYD, formerly medical superintendent of the Mayday Hospital, Croydon, and subsequently a general practitioner at Thornton Heath, Surrey, died at the Mayday Hospital on January 28. He was 74 years of age. George William Lloyd was born at Brough, East Yorkshire, on August 1, 1882, and was educated at Hull Grammar School and at St. Bartholomew's Hospital, qualifying M.R.C.S., L.R.C.P. in 1905. After holding a resident appointment at the East Suffolk and Ipswich Hospital he went into a country practice at Alsager, in Cheshire, and while there obtained the London degrees of M.B., B.S. in 1911. He proceeded to the M.D. in 1917. During the first world war he served in the R.A.M.C. from 1914 until he was invalided out of the Army in 1917, and for the next few years was assistant medical superintendent of St. Giles Hospital, Camberwell. From 1922 to 1929 he was medical superintendent of the Mayday Hospital, Croydon. He returned to general practice in 1929, this time at Thornton Heath, and continued in this work until he retired in 1954. A year or two after he had had a stroke. As a young man Dr. Lloyd was a good athlete. He played Rugby for the first fifteen at Bart's and represented the hospital at boxing. In later life his interests were shooting, fishing, ornithology, and the rearing of gun-dogs. He married Miss Elsie Rigby-Jones, of Liverpool, in 1909, and had five sons and one daughter. His eldest son and his son-in-law are both doctors.

Dr. T. M. BODY, who was in practice at Middlesbrough for nearly fifty years, died at Marton-in-Cleveland, Yorkshire, on January 28 at the age of 80. Thomas Munn Body was born at Wittersham, Kent, on December 13, 1876, the son of John Body, J.P., and was educated at Tonbridge School and at St. Bartholomew's Hospital. After qualifying M.R.C.S., L.R.C.P. in 1902 he held the appointments of house-surgeon at the Norfolk and Norwich Hospital and the Royal Portsmouth Hospital and accompanied the Anglo-Liberian Boundary Commission as medical officer. He settled in general practice at Middlesbrough about 1908, and shortly afterwards went into partnership with Dr. John Hedley, succeeding to the practice on Dr. Hedley's death. During the first world war he served as a captain in the R.A.M.C. in France, Mesopotamia, and India. Returning to his practice after the war, he became a prominent figure in the public life of Middlesbrough. He became deputy lieutenant of the North Riding of Yorkshire in 1947, an appointment he regarded not only as an honour to himself but also as one for the medical profession in general. Since 1918 he had been a Justice of the Peace for Middlesbrough, and throughout the second world war he was chairman of the North Riding Territorial Association. He had been chairman also of the committee for the care of mental defectives and of a medical recruitment board at Middlesbrough and president of the Betterment Association. A member of the British Medical Association for forty-five years, he was chairman of the Cleveland Division in 1925–6.

Dr. G. O. MONTGOMERY, who was in general practice at Croydon, Surrey, for some 30 years, died at his home there on January 31 at the age of 63. Geoffrey Owen Montgomery was born in Tasmania on August 31, 1893. He enrolled as a student at University College, London, in 1914, but joined the Army on the outbreak of the first world war. Commissioned in the Green Howards in 1915, he served in France for four years. On return to civilian life he resumed his medical training, and qualified by taking the London Conjoint diploma in 1923. Two years later he obtained the London degrees of M.B., B.S. After holding the resident posts of house-surgeon, house-physician, and obstetric assistant at University College Hospital he became resident medical officer there. In 1927 he joined a firm of doctors at Croydon, and worked in that practice until the time of his death. Among the appointments he held were those of physician to the Croydon General Hospital and medical officer to the Post Office. A keen Territorial officer, he was in France with the British Expeditionary Force in 1940 as commanding officer of the 133rd Field Ambulance, with the rank of lieutenant-colonel. In 1941 he was promoted colonel, and, after serving as assistant director of medical services in the Anti-Aircraft Command, was given the command of a general hospital, first in West Africa and afterwards in India. For his services to the Territorial movement he was awarded the Territorial Decoration in 1955. His cheerful, kindly, and unselfish nature will always be remembered by all who came into contact with him, and a large circle of colleagues, friends, and patients mourn his passing. He leaves a widow and one son and one daughter, to whom our sincere sympathy goes out in their great loss.—E. M. C.

The obituary of Mr. C. L. GIMBLETT was printed in the *Journal of February 2* (p. 288).

Dr. A. G. SALAMAN writes from Saffron Walden, Essex: When Charles Gimblett came here during the war under the E.M.S. scheme we in these parts met a man of great charm. A complete disregard for pomp was one of his outstanding characteristics. He had an untiring enthusiasm from which he seemed to derive enormous fun even when doing the simplest eye test, and his eagerness to guide us G.P.s through the more treacherous mazes of ophthalmology was a delight to experience. I well remember an occasion when my wife took our son, aged 5, to see him. Gimblett sat solemnly at his desk and asked for symptoms. My son said, "I can't

hardly see nothing at all." With great seriousness Gimblett wrote on the case card: "Patient says, 'I can't hardly see nothing at all.'" He then summoned the patient over in order to sign the statement, which he did in large spidery letters. His vision proved to be normal. Those of us who knew Gimblett remember him as a very human person who, when practising his specialty, never forgot that the owner of the eyes he was examining was a human being too.

Medical Notes in Parliament

DIMINISHED RESPONSIBILITY IN MURDER CASES

The Homicide Bill, emerging without alteration from the committee stage, was given a third reading in the House of Commons on February 6—the voting was 217 to 131—and sent up to the House of Lords.

Mr. R. A. BUTLER moved the third reading in his first speech as Home Secretary, and in so doing sought to put the Government's proposals in a new setting. The Bill represented some progress, he said, since it swept away the doctrine of constructive malice and enlarged the defence of provocation; but, more particularly, in its adaptation to English law on the doctrine of diminished responsibility it would enable the courts to take account of the great strides that had been made in the understanding of the human mind, and to avoid treating as murder killings for which the accused ought not to be held wholly responsible. This, he went on, was all part of the new approach to the problems of the mind which would exercise both the Home Office and Parliament in the future. This unexplored territory of the mind would be perhaps one of the most exciting of the adventures before the human intellect; it was as important in the human sphere as nuclear development was in the scientific. He invited in anticipation the support of the House in any further moves in the direction of the humanizing and understanding of relationships.

This part of his speech at any rate was welcomed by the Opposition, though their general opinion of the Bill was that for the sake of party unity the Government had missed the opportunity of what could have been a great measure of penal reform. Mr. SYDNEY SILVERMAN (Nelson and Colne, Lab.) moved the official amendment against the third reading which, while welcoming the removal of some anomalies in the law of murder and the abolition of the death penalty from some offences, refused assent to a Bill which "fails to satisfy the public sense of justice, and is in defiance of the principle which the House has already approved—namely, that the death penalty for murder no longer accords with the needs or the true interests of a civilized society."

Indefinite Sentences

Dr. REGINALD BENNETT (Gosport and Fareham, Con.) said he felt considerable unease of mind about Clause 2. A verdict reduced to manslaughter automatically on proof of diminished responsibility meant the introduction of a new code on which the courts would have to decide these matters which would exist simultaneously—and in conflict—with the McNaughton Rules. Which of these two mechanisms was to be invoked? If there was *prima facie* abnormality of mind, did a charge of murder still stand? If it was evident from unopposed medical evidence before a trial that the prisoner's mental state was in other ways deranged, did the indictment drop to manslaughter? The greater difficulty was of deciding on what basis and to what degree there was irresponsibility. The provision in Clause 2 was whether the accused "was suffering from such abnormality of mind (whether arising from a condition of arrested or retarded development of mind or any inherent causes or induced by disease or injury) as substantially impaired his mental responsibility for his acts or omissions." The McNaughton Rules test was whether the accused was suffering at the time

from such a defect of mind as to be unable to appreciate the nature of his act or the fact that it was wrong. Which standard came first? Which was to be a criterion? If a person was found guilty of manslaughter there could be little purpose in sending him to a psychopathic institution, with a finite sentence.

The East-Herbert institution being built was not likely to be effective or to give anything like the results that the Herstedvester Institution in Denmark was giving, unless they were prepared to agree that for curative purposes the mentally afflicted offender must be sent to such an institution for an indefinite sentence, with the varying degrees of probation that would follow it as his rehabilitation became more complete. If the McNaughton Rules applied, a man found to be suffering from a defect of reason would go to Broadmoor, which was automatically an indefinite sentence. If, however, his defect of mind—maybe even the same defect—was found to justify a sentence for manslaughter, he would go down for seven years, and there would be no consideration of any treatment for his mental state except such as was incidental to an ordinary term of imprisonment.

Mr. J. E. S. SIMON, Under-Secretary, Home Office, saw the introduction of the defence of diminished responsibility as possibly the greatest change that was being made in the law of England. Among other factors, it provided a criterion which took cognizance of the fact that there were many degrees of mental responsibility for crime. The relation between the two defences, of insanity and diminished responsibility, he suggested was this. The accused man might, on the face of it, be unfit to plead. That was generally determined initially by the prosecution, although it might be raised by the defence, and a jury was empanelled to decide whether the man was fit or unfit to plead. Only if the man was fit to plead did any question of these defences arise, and then it was a matter for the man: it was for him to say whether he would raise a defence which would lead to a verdict of "Guilty but insane," or a defence which would lead to a verdict of manslaughter by raising a question of diminished responsibility. The one was under the McNaughton Rules; it was a complete defence, and the verdict was "Guilty but insane," equivalent to "Not guilty." The diminished responsibility defence would lead to a verdict of "Guilty," but "Guilty of manslaughter." It did not necessarily follow that the man would be sentenced to a fixed term. It was entirely a matter for the judge's discretion, on the evidence given to him after the verdict, whether he passed a sentence for life if he could not determine the time necessary to treat the prisoner successfully. He could sentence the convicted man to a term of years. Equally he could, if he wished, put him on probation for the crime of manslaughter, and make it a condition in a proper case that the man should submit himself to psychiatric treatment, or any other medical treatment, for a suitable time.

Poliomyelitis Vaccination

Mr. M. TURNER-SAMUELS (Gloucester, Lab.) asked the Minister of Health on February 8 whether, in view of the fact that the remuneration to general practitioners for carrying out the responsible duties and complicated arrangements required to collect, store, and administer the vaccine and keep the necessary records in connexion with inoculation against poliomyelitis was unreasonably low, he would increase the present inclusive fee of 5s. for the two inoculations required in each case to a more reasonable figure. Mr. D. VOSPER stated that the vaccination would be performed as part of the general practitioner's comprehensive medical care of his patients for which he received remuneration from his local executive council. The additional 5s. fee was to be paid by the local health authority for the record of vaccination. This was the present fee for records of other forms of immunization, and was agreed between representatives of local authorities and of the medical profession.

Analgesia

Mr. R. W. SORESENSEN (Leyton, Lab.) asked what further advance had been made in the use of analgesia and the supply of apparatus for this purpose in hospitals and in domiciliary practice; and, in the light of experience during the past year, what was the merit and cost of triline, as compared with analgesia, in respect of confinements. Mr. VOSPER replied that no information was available about the use of analgesics in hospitals or by general practitioners. In 1955 inhalational analgesics were administered by domiciliary midwives in 75% of the confinements attended by them, compared with 72% in 1954, and the number of sets of apparatus in use rose from 6,489 to 6,764. He was advised that triline served broadly the same clinical purposes as gas and air, but the apparatus was more easily transportable. The costs of the types of apparatus in general use were broadly comparable. The use of triline, he stated, was on the increase. At the end of 1955 about 256 triline sets were in use, and this had risen at the end of 1956 to about 900.

Health Centres

Mr. J. K. VAUGHAN-MORGAN, Parliamentary Secretary, Ministry of Health, informed Mr. W. T. PROCTOR (Eccles, Lab.) on February 4 that eight new health centres had been provided under the Health Service since July, 1948. In addition, premises were taken over in July, 1948, by six local authorities so that general medical or dental services could be continued there. Current restrictions on capital expenditure rule out further provision for the time being. The new centres were: Faringdon, Berks; William Budd, Knowle West, Bristol; Woodberry Down, Stoke Newington, London; John Ryle Health Centre, Clifton Estate, Nottingham; Harold Hill, Romford Aveley, Thurrock, Essex; Hesters Way Estate, Cheltenham; and Alderman Jack Cohen Health Centre, Sunderland.

Pay Variations

Dr. DONALD JOHNSON (Carlisle, Con.) asked the Minister whether he was aware that the average earnings of general practitioners supplied by his department was comprised of wide variations; and whether he would give a breakdown of such an average. Mr. VOSPER, in reply, said that the breakdown of earnings for which he asked was not available.

Mr. J. A. LANGFORD-HOLT (Shrewsbury, Con.) asked what was the average salary received by doctors working whole-time for the Health Service after deduction of income tax. Mr. VOSPER told him also that this information was not available.

Dental Council's Rebuff

Mr. BARNETT JANNER (Leicester, North-west, Lab.) asked for a statement on the availability of dental hygienists for the general public in accordance with the provisions of the Dentists Act, 1956.

Mr. VOSPER replied that some dental hygienists were already employed in the local authority and hospital dental services, but they could not work with dentists in dental practice until permitted by regulations made under the Dentists Act, 1956, by the General Dental Council. The General Dental Council had asked the Privy Council to approve draft regulations which provided that dental hygienists should not be allowed to work in private practice until such time as the requirements of the local authority and hospital dental services were in the opinion of the General Dental Council satisfied. This limitation would not appear to accord with the intentions of Parliament, as expressed during the passage of the Bill, and the proposals had therefore been referred back to the General Dental Council for further consideration.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending January 26 (No. 4) and corresponding week 1956.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

† Includes primary and influenza pneumonia.
§ Includes puerperal pyrexia.

Vital Statistics

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases (deaths for influenza) of certain diseases notified weekly in England and Wales (great towns for influenza). Highest and lowest figures reported in each week during the years 1947-55 (influenza, 1952-5) are shown thus ----, the figures for 1956-7 thus ———. Except for the curves showing notifications in 1956-7, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

Infectious diseases were more prevalent in England and Wales during the week ending January 26. Rises in the numbers of notifications included 1,352 for measles, from 8,175 to 9,527, 569 for whooping-cough, from 2,664 to 3,233, 158 for dysentery, from 477 to 635, 136 for scarlet fever, from 693 to 829, and 56 for acute pneumonia, from 516 to 572.

The largest rises in the incidence of measles were 373 in Lancashire, from 1,931 to 2,304, 202 in Lincolnshire, from 62 to 264, 174 in Northumberland, from 472 to 646, 166 in Surrey, from 238 to 404, 144 in Durham, from 666 to 810, 130 in Essex, from 673 to 803, and 107 in Cumberland, from 142 to 249; the chief exceptions to the general trend were falls of 126 in Yorkshire West Riding, from 610 to 484, and 72 in Oxfordshire, from 159 to 87. The largest rises in the number of notifications of whooping-cough were 63 in Suffolk, from 36 to 99, 47 in Lancashire, from 297 to 344, and 40 in Kent, from 168 to 208. The largest increases in scarlet fever were 45 in Shropshire, from 2 to 47, due to an outbreak involving 44 persons in Bridgnorth R.D., and 35 in Essex, from 30 to 65. Only one case of diphtheria was reported, 3 fewer than in the preceding week.

27 cases of acute poliomyelitis were notified, and these were 9 fewer for paralytic and 5 fewer for non-paralytic cases than in the preceding week. The largest returns were 3 cases in the counties of Lancashire, Essex, and Hertfordshire (Stevenage U.D. 2).

The rise in the incidence of dysentery was due to an increase in established outbreaks rather than to new centres of infection. The largest returns were Lancashire 121 (Stretford M.B. 49, Liverpool C.B. 13), Warwickshire 89 (Coventry C.B. 47, Birmingham C.B. 20), Yorkshire West Riding 80 (Bradford C.B. 14, Sheffield C.B. 14, Leeds C.B. 12, Keighley M.B. 11); Yorkshire East Riding 45 (Kingston-upon-Hull C.B. 42), London 40 (these cases were scattered through 15 boroughs), Nottinghamshire 35 (Arnold U.D. 18, Nottingham C.B. 15), Northumberland 29 (Alnwick U.D. 13), Staffordshire 22 (West Bromwich C.B. 13), Surrey 21.

Week Ending February 2

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 865, whooping-cough 3,302, diphtheria 5, measles 13,008, acute pneumonia 661, acute poliomyelitis 37, dysentery 1,097, paratyphoid fever 10, and typhoid fever 3.

Isle of Man Census

The total population enumerated in the Isle of Man at the 1951 census was 55,253, representing a net gain since 1931 of about 6,000 persons. 1,229 visitors were enumerated in the Isle of Man, and 1,306 persons enumerated in the United Kingdom stated that their usual place of residence was in the Isle of Man. It is estimated that 55,437 persons were usually resident in the Isle of Man at the census date.

Householders were asked to state whether they had exclusive use of, shared with another household, or were without piped water supply within the house, cooking stove or range, kitchen sink, water-closet, or fixed bath. 55% of

household arrangements, and a further 14% had all except a fixed bath; these figures compare with 52 and 19% for England and Wales.

The population of the island was on the whole a little older than that of England and Wales. 13.9% were aged 65 and over, compared with 10.9% in 1931. The figures for England and Wales were 11.0 in 1951 and 7.4 in 1931. The ratio of females to males in the Isle of Man was higher than in England and Wales, the numbers of females per 1,000 males being respectively 1,144 and 1,082. A striking feature of the returns was the increase since 1931 in the proportions married, particularly among younger people. At age 20-24 there were 169 males married per thousand as compared with only 96 in 1931, and 401 females per thousand compared with 169.

Total fertility in the Isle of Man was somewhat higher than in England and Wales. There were 173 live-born children per 100 married women under age 50, compared with 169 in England and Wales. Current fertility rates (percentages of married women under age 50 bearing a live-born child in the year ending April 8, 1951) were slightly higher in the Isle of Man (10%) than in England and Wales (9%).

The number of people returned in 1951 as able to speak Manx (all of whom could speak English also) was 355 for the whole island, compared with 4,657 in 1901, 915 in 1921, and 529 in 1931.

Medical News

Radiological Practice.—The Minister of Health and the Secretary of State for Scotland have now appointed the promised committee under Lord ADRIAN's chairmanship to review current practice in diagnostic radiology and the radiotherapy of non-malignant conditions, and it has started its work. The committee's appointment was recommended by the Medical Research Council subcommittee responsible for the preparation of the Council's report on *The Hazards to Man of Nuclear and Allied Radiations* (Cmd. 9780, H.M.S.O., 1956). Besides reviewing current practice in the two fields of radiology mentioned, the committee is asked to submit recommendations to the Ministers. The members of the committee in addition to Lord Adrian are: Professor J. C. McC. Browne (professor of obstetrics and gynaecology, London), Sir Horace Evans (director, medical unit, London Hospital), Mr. R. J. G. Grewcock (dental surgeon, London), Professor R. J. Kellar (professor of obstetrics and gynaecology, Edinburgh), Dr. Peter Kerley (director, x-ray unit, Westminster Hospital), Dr. D. R. Maitland (radiologist, Royal Infirmary, Edinburgh), Professor W. V. Mayneord (professor of medical physics, London), Professor J. S. Mitchell (professor of radiotherapeutics, Cambridge), Mr. C. Naunton Morgan (surgeon, St. Bartholomew's Hospital), Dr. Kenneth Robson (chest physician, St. George's Hospital), Mr. T. Holmes Sellors (thoracic surgeon, Middlesex Hospital), Mr. G. R. Seward (dental surgeon, Ilford), Professor F. W. Spiers (professor of physics, Leeds), Professor E. J. Wayne (regius professor of the practice of medicine, Glasgow), Professor Charles A. Wells (professor of surgery, Liverpool), and Professor B. W. Windeyer (professor of radiotherapy, London).

Research on Smoking and Lung Cancer.—Following a question in Parliament this month about public expenditure on research on smoking and lung cancer (*Journal*, February 9, p. 350), the Tobacco Manufacturers' Standing Committee has released, by agreement with the Medical Research Council, some details from the latter's report on the projects supported from the Tobacco Manufacturers' research fund. The report covers the year which ended on October 31 last. During that period the total expenditure from the fund was £51,679, of which £28,679 was non-recurrent and £23,000 recurrent. This brings the total so far spent

from the £250,000 fund to £68,679. (The fund was accepted by the M.R.C. three years ago.) The major grants made from the fund during 1956 were for the expansion of the work at St. Bartholomew's Hospital on atmospheric pollution, and for the establishment of a group at Exeter to study the chemistry of tobacco smoke. In addition, states the report, "there are other important projects which have only just got under way." In America the Tobacco Industry Research Committee there announces that it made grants to the value of \$566,000 during 1956, bringing the total sum allocated since the latter part of 1954 to \$1,380,000.

World Federation for Mental Health.—The executive board of the World Federation for Mental Health has been meeting in London, and on February 7 the Federation's United Kingdom committee held a press reception in honour of Dr. MARGARET MEAD, this year's president of the Federation. She was introduced by Dr. J. R. REES, director of the Federation. Earlier, on January 30, Dr. Mead had delivered the British Psycho-Analytical Society's eighth Ernest Jones lecture at the Royal Society of Medicine, and on February 8 she gave a public lecture on "Mental Health in a Changing World" at County Hall. Dr. Mead, whose work on primitive cultures is well known from her books, is now particularly concerned with the impact of social forms and cultural changes on the development of character. She is associate curator of ethnology at the American Museum of Natural History in New York. Among those who attended the reception were Dr. BROCK CHISHOLM, of Canada, W.H.O.'s first director-general, Dr. F. FREMONT-SMITH, medical director of the Josiah Macy, Jr., Foundation, New York, and Dr. EDUARDO KRAFF, of Buenos Aires, chief of W.H.O.'s mental health section.

Polish Surgeons Visit Britain.—Two Polish surgeons, Dr. WITOLD RUDOWSKI, chief surgeon at the Radium Institute, Warsaw, and Dr. BRONISLAW PRASZALOWICZ, senior surgeon at the Institute of Haematology, Warsaw, and deputy editor-in-chief of the Polish State Medical Publishing House, have been visiting Britain under British Council auspices. They arrived on February 2 and have been seeing hospitals and university departments in London, Manchester, Edinburgh, Oxford, and Birmingham. With them has been Mr. TADEUSZ KLONOWICZ, director of the Polish State Medical Publishing House. Their visit, which is a return of that paid to Warsaw last autumn by Sir ROBERT MACINTOSH, Professor IAN AIRD, and Dr. R. H. DOBBS (see *Journal*, November 24, p. 1230), ends to-day.

Tata Awards for Leukaemia Research.—The trustees of the Lady Tata Memorial Fund invite applications for grants, scholarships, or fellowships for research on diseases of the blood, with special reference to leukaemia, in the academic year beginning on October 1, 1957. Candidates with programmes of research on any aspect of malignant disease which may throw incidental light on leukaemia will be eligible for consideration. The awards are open to suitably qualified investigators of any nationality, working in any country in which it will be possible to make payments.

Grants of variable amount are made for research expenses or to provide scientific or technical assistants for senior workers. Scholarships are awarded for the personal remuneration of workers carrying out approved research under suitable direction; their normal value will be £600 sterling per annum for whole-time research, with proportional adjustment for work on a part-time basis. In addition, the trustees may award one or more Lady Tata Memorial Research Fellowships to workers with considerable research experience; the stipends of these fellowships will be at the rate of £1,200 sterling per annum.

Further particulars and forms of application may be obtained from the Secretary of the (European) Scientific Advisory Committee, Lady Tata Memorial Trust, Chester Beatty Research Institute, Fulham Road, London, S.W.3. Applications must be submitted before March 31, and the awards will be announced in June.

French Government Exchange Scholarships.—Under the terms of a reciprocal arrangement with the Centre National

de la Recherche Scientifique, the Medical Research Council invites applications from British workers in medical science for two scholarships tenable at research institutions in France during the academic year 1957-8. The scheme is intended for young graduates in medicine or science who have already had some experience in a branch of medical science. Candidates must be of British nationality and have at least a working knowledge of French.

The scholarships will normally carry a maintenance allowance within the range of 50,000-70,000 francs a month, according to qualifications and experience, and married men will receive a supplementary allowance (payable in sterling by the M.R.C.). Provision will also be made for travelling expenses to and from the place of work.

Application forms may be obtained from the Secretary, Medical Research Council, 38, Old Queen Street, London, S.W.1, with whom applications must be lodged by March 31.

Polio Vaccination at Wakefield and Burton-on-Trent.—Neither Wakefield nor Burton-on-Trent participated in the Ministry of Health's poliomyelitis vaccination programme last year, as a result of advice given by their health committees. This year they are participating. On December 4 the Wakefield City Council resolved to give children in their area, born between 1947 and 1954, an opportunity to be vaccinated against poliomyelitis. The Burton Borough Council took its decision last April, but it was then too late to register the children for the 1956 vaccination programme.

International Society of Internal Medicine.—Sir RUSSELL BRAIN, P.R.C.P., has been elected president of the International Society of Internal Medicine. He took office on February 1. The Society's next meeting will be held in Philadelphia from April 24 to 26, 1958.

Eli Lilly Fellowship (South Africa).—Dr. H. A. SHAPIRO, as honorary chairman of the selection committee, writes to draw the attention of medical practitioners registered in South Africa but resident at present abroad to the 1957 Eli Lilly medical research fellowship. This fellowship is for research in the United States and provides a net sum of 250 dollars a month together with travelling expenses to and from the place of study. The closing date for applications is April 30. Further details may be obtained from Dr. Shapiro, P.O. Box 1010, Johannesburg.

COMING EVENTS

William Sheen Memorial Lecture.—Sir HARRY PLATT, P.R.C.S., will deliver the Welsh National School of Medicine's sixth William Sheen Memorial lecture on March 6 at 8 p.m. in the Reardon-Smith lecture theatre, Park Place, Cardiff. His subject will be "The Backache-Sciatica Problem."

Royal Society of Health.—Exhibition on "Atoms and Health" at 90, Buckingham Palace Road, London, S.W.1, March 18 to May 31, Mondays to Fridays, 10 a.m. to 5 p.m.

Physical Society.—Exhibition of scientific instruments and apparatus at the Royal Horticultural Society's Old and New Halls, Westminster, London, S.W.1, March 25-28. Tickets from the secretary-editor, 1, Lowther Gardens, London, S.W.7.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Saturday, February 16

KENT PAEDIATRIC AND CHILD HEALTH SOCIETY.—At Children's Department, Farnborough Hospital, 3 p.m., Dr. J. D. Kershaw: Child Health in the U.S.S.R. (illustrated by slides).

Monday, February 18

HUNTERIAN SOCIETY.—At the Mansion House, 8.30 p.m., Hunterian Oration by Mr. A. W. Badenoch: The Surgery that Hunter Changed.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Dr. W. Ritchie Russell: Pn.

UNITED HOSPITALS CATHOLIC SOCIETY.—At 13, Devonshire Place, W., 6.15 p.m., Mr. John Ryan: Family Limitation.
UNIVERSITY COLLEGE LONDON: DEPARTMENT OF PHARMACOLOGY.—At Physiology Theatre, Gower Street, W.C., 5.30 p.m., Dr. T. S. Work: Biochemical Approach to the Problems of Protein Synthesis.

Tuesday, February 19

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. A. L. Greenbaum, Ph.D.: Control of Fat Metabolism.
ILFORD MEDICAL SOCIETY.—At King George Hospital, 8.45 p.m., Dr. James Graham: Planning of Hospital Services on a Regional Basis. Members of Stratford Division, B.M.A., are invited.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. G. B. Dowling: Scleroderma and Dermatomyositis.
ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Professor G. W. A. Dick: Attenuated Virus Vaccines.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—3.45 p.m., Arnott Demonstration by Dr. Frank Stansfield: Anatomy of the Visual Pathway.
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Institute Theatre, 5 p.m., Dr. N. F. Morris: Uterine Blood Flow During Late Pregnancy and Labour.
SOUTH-WEST LONDON MEDICAL SOCIETY.—At Bellinghroke Hospital, Wandsworth Common, S.W., 8.30 p.m., Mr. R. W. Nevins: Ulcerative Colitis.

Wednesday, February 20

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. H. Haber: Localized Disease of the Co.aren.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. H. Nicholson: Corticosteroids in Chest Disease.
INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Mr. A. Clifford Morson: Non-tuberculous Infections of the Urinary Tract.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Dr. J. H. Humphrey: Biochemical Mechanisms Underlying Hypersensitivity Reactions (I).
ROYAL MEDICAL SOCIETY, EDINBURGH.—2.30 p.m., Industrial Visit to Caledonian Distillery, Edinburgh.

Thursday, February 21

AUSTRIAN INSTITUTE, 28, Rutland Gate, S.W.—8.30 p.m., Professor V. Frankl (Vienna): Collective Neuroses of the Present Day.
BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. Honor B. Fell, Ph.D., D.Sc., F.R.S.: Physiology of Skeletal Tissue in Culture.
EDINBURGH CLINICAL CLUB.—At Royal College of Physicians of Edinburgh, 8 p.m., Dr. G. Swapp: Organization in General Practice.
GLASGOW UNIVERSITY MEDICO-CHIRURGICAL SOCIETY.—7.30 p.m., Mr. J. Dunbar: Personalities in Medicine.
HILL END HOSPITAL MEDICAL SOCIETY, St. Albans.—8.45 p.m., Dr. W. Edwards: Changing Picture of Tuberculosis.
HYPNOTHERAPY GROUP.—At Royal Society of Medicine, 8 p.m., Dr. D. M. L. Doran and Dr. I. Hadfield: Hypnototherapy from the Trainee Point of View. A discussion will follow.
LIVERPOOL MEDICAL INSTITUTION.—8 p.m., pathological meeting. Mrs. Edith K. Dawson, M.D.: Mammary Cancer in Young Subjects, with Special Reference to Pregnancy.
LONDON JEWISH HOSPITAL MEDICAL SOCIETY.—At Medical Society of London, 8.30 p.m., Professor C. G. Rob: Surgery of Arterial Disease.
NORTH-EAST CLINICAL SOCIETY.—At Prince of Wales's General Hospital, N., 2.30 p.m., clinical meeting.
NORTH-WESTERN TUBERCULOSIS SOCIETY.—At Clinical Theatre, Manchester Royal Infirmary, 5 p.m., Dr. W. Brockbank: Some Aspects of Asthma.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—3.45 p.m., Arnott Demonstration by Mr. B. E. Greenfield: Functions of the Masseter Muscle. Studies on Normal and Abnormal Subjects.
ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.—At 26, Portland Place, W., 7.30 p.m., Dr. W. S. S. Ladell: Some Physiological Aspects of the Heart Disorders. A discussion will follow.
ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Dr. D. J. Williams: neurology demonstration.
WEST OF ENGLAND CHILD HEALTH GROUP.—At Department of Child Health Lecture Theatre, Bristol Royal Hospital for Sick Children, 5.30 p.m., Dr. J. C. Spencer Ph.D.: Neighbourhood and Family.

Friday, February 22

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. A. D. Porter: clinical demonstration.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. K. Robson: clinical demonstration.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—10 a.m., Mr. G. Flavell: Usual Manifestations of Cancer of the Lung.
ROYAL MEDICAL SOCIETY, EDINBURGH.—8 p.m., address by Professor A. Kennedy: Intercorrelation and Brainwashing.
ROYAL MEDICO-CHIRURGICAL SOCIETY OF GLASGOW.—At Royal Faculty of Physicians and Surgeons of Glasgow, 8.30 p.m., reception and dance.

Saturday, February 23

BIOCHEMICAL SOCIETY.—At Beveridge Hall, Senate House, London University, 11 a.m., Symposium: Structure and Function of Subcellular Components.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Evans.—On December 23, 1956, at Morfa, New Park Road, Holyhead, Anglesey, to Dr. Joan Evans (formerly Wilson) and Dr. Emrys Evans, a brother for David.

DEATHS

Crymble.—On January 26, 1957, Edward Marshall Tate Crymble, L.R.C.P. & S.I. and L.M., of 27, Derby Road, Fallowfield, Manchester.
Kay.—On January 15, 1957, at Boscombe Hospital, Charles Wallace Kay, L.R.C.P. & S.I., L.R.F.P.S.

Macdowell.—On January 16, 1957, Francis Lewis Hartwell Macdowell, L.R.C.P. & S.I. and L.M., Surgeon Captain, R.N. (retired), of The Skips, Sheepscote, near Stroud, Glos.

Newton.—On January 17, 1957, Herbert William Newton, M.R.C.S., L.R.C.P., late of Chester Cottage, Kingsdown, Deal, Kent, formerly of Feltham, Middx, aged 90.

Orchard.—On January 15, 1957, at 458, New Bedford Road, Luton, Beds, Harry Percival Orchard, M.R.C.S., L.R.C.P., late of Brixton, London, S.W., aged 76.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Third Shot of Polio Vaccine

Q.—(1) Does the present evidence suggest that a third inoculation with a Salk-type vaccine is desirable? (2) If so, when is the optimum time to give it, and how long after the second injection does it still remain worth doing? (3) Does it matter if the vaccine used for the third injection, although of Salk-type, is not identical with that used for the first two inoculations?

A.—(1) With the Salk-type vaccines at present available there is little doubt that a third inoculation is needed before a person can be considered adequately immunized. This should be given from six to twelve months after the initial course of two injections spaced four to six weeks apart. By this time the antibody level obtained after the first two injections will be reaching a low level in many of the vaccinated, and the third injection will "boost" it, often to that obtained after natural infection. The fall after this "booster" is very much slower than after the initial course, and antibody will probably remain at detectable levels for at least three to four years.

(2) The ability to respond to a "booster" almost certainly persists longer than detectable antibody, and the third dose can act in this way two to three years after the initial course. As it is not known if the secondary reaction to natural infection is quick enough in these circumstances to prevent any virus reaching the central nervous system, it is preferable not to delay the third injection for more than a year, so that some antibody may be maintained in the circulation continuously. In diphtheria it has been shown that, when the level of antitoxin in the serum is very low, clinical disease may occur before the secondary antibody rise has had time to be effective. Of the inoculated subjects 20% will not respond to the first injection, but do so to the second; a third injection is essential in these people, and this is another reason why it should not be delayed for more than a year.

(3) The type of Salk vaccine used is not important, provided it has been produced under regulations ensuring adequate potency and safety, as the polio viruses fall into three distinct antigenic types with little antigenic variation within each.

Hay Fever Season

Q.—When is the usual hay fever season in Britain, and for how long does it last? To what extent do variations in locality, flora, weather, or other factors influence the time of its onset or its duration? For example, what difference would be expected in the hay fever seasons in Devon and the West Highlands of Scotland?

A.—Grass pollen, the most important cause of hay fever, is most prevalent in the air in England and Wales during the period June 1 to July 15.¹ The hay fever season opens during the last week of May, is at its height in early and mid-June and continues for a variable period (depending on the individual patient's degree of sensitivity), and ends during the latter part of July. The severity of the grass-pollen season is related to the luxuriance of the season's grass crop, which in its turn depends mainly on the rainfall in April and May²; but, since the release of pollen into the air is dependent on bright sunshine, sunny periods are much more conducive to dense grass-pollen clouds—and to hay fever—than are dull ones. During an abnormally sunless, cool, and wet summer only about half as much pollen is released into the air as in a sunny, hot, and dry one. The densest clouds of grass pollen are experienced in the

neighbourhood of meadows of standing mowing-grass during the hours of pollen liberation. This period varies from species to species: in most, though not all, species it occurs in the early morning or the late afternoon. In general, the more remote a particular place is from large areas of cultivated grassland, the lower is the grass-pollen incidence.

No figures are available for either Devon or the West Highlands of Scotland, but to judge from the evidence from lowland and mountain areas, respectively, one would expect Devon to be much more subject to grass pollen than the West Highlands. What evidence there is suggests also that the grass-pollen season opens perhaps 10 days later in Scotland than in southern Britain.

It has been found that very significant quantities of pollen of all kinds are carried from productive areas into non-productive land areas and to a distance of at least 30 miles out to sea.

Varicose Eczema

Q.—Are local applications of cortisone ointment of value in the conservative treatment of varicose eczema? My patient refuses operation. What alternative treatment is advised?

A.—True varicose eczema occurs only in the presence of chronic venous insufficiency with oedema. No local measures will improve the eczema unless the oedema is abolished. Rest in bed will accomplish this, but, although occasionally necessary, it is undesirable for social and economic reasons and because of the risk of thrombophlebitis. Elastic compression is best, though elastic stockings are unsuitable.

Once the affected area is dry, elastic crêpe bandages may be used, but if there is much weeping ichthyol paste bandages covered by elastic adhesive bandages are very efficacious. They should be changed weekly during the weeping stage, which is usually soon passed, and less frequently once a dry glazed surface appears. The Unna's paste type of bandage is not well tolerated in the presence of varicose eczema. During the period of absorption of oedema fluid from an eczematous leg, patches of eczema may appear on other parts of the body, but they usually soon clear up with bland applications.

If the leg is very moist it may be painted with a mixture of talc, zinc oxide, glycerin, and lime water in equal parts, or with silver nitrate solution (1%). Often there is a superimposed infection of the area and it is useful to apply gentian violet solution (1%) as a paint. With dry eczema Lassar's paste spread on thinly with the finger-tip is best. Hydrocortisone ointment or lotion may be helpful but is unnecessary.

Two main reasons for difficulty in the cure of varicose eczema are failure to get rid of the oedema and over-treatment (especially with irritant preparations or such as may provoke allergic sensitization). It must never be forgotten that constitutional causes are likely to be playing a part.

Fusus Oil

Q.—In shops where diesel fuel injector pumps are tested a special oil called "fusos" oil is often used. When the injectors are being tested the atmosphere in the shop may be quite thick with atomized oil for half an hour, say, at one or two periods during the day. Is this harmful to the workers?

A.—Shell fusos oil is a highly refined petroleum oil of low aromatic content. The main reason for using it for the type of work in question is that when gas oil (for diesel engines) is used for fuel pump calibration it tends to give rise to deposits if the pump is then placed in storage for a long period.

There have been some instances of dermatitis where gas oil may have been a contributory factor. It is possible that

fusus oil might similarly affect some susceptible individuals. There is little information on occupational exposures to mists of gas oil or fusus oil, but one case of chronic lipid pneumonia arising from the inhalation of mineral oil has been reported.¹ It is considered sound practice not to expose workers to a mist of Shell fusus A, and tests on injectors are best carried out under a hood with forced draught. Barrier creams are generally available for the use of employees exposed to the oil.

High-fat Slimming Diets

Q.—Is it true that the high-fat low-calorie diets recently advocated for slimming have advantages over the more usual reducing diets?

A.—In the present state of our knowledge it is undesirable to use high-fat low-calorie diets for the purpose of reducing weight. The main features of a reducing diet should be to restrict the carbohydrates, protein and fat being allowed in normal amounts. Certain patients who do not lose weight on these diets can be treated with the high-fat regime.¹

Gustatory Sweating after Sympathectomy

Q.—Shortly after bilateral cervical and lumbar sympathectomies eight years ago a woman began to experience sweating while eating. Though slight at first, the sweating has become severe enough to cause much discomfort and social embarrassment. Sweating is most marked after savoury and meat dishes, but occurs to some extent at all meals. It affects the face, scalp, neck, and upper chest, and is at times very profuse. Is this a recognized complication of sympathectomy, and what treatment is advised?

A.—Gustatory sweating is a well-recognized phenomenon. Like other rarer clinical curiosities such as "crocodile tears" and "gustatory gooseflesh," it has aroused controversy about its physiological basis but no agreement. Three types are known. The first occurs in some normal individuals when they eat certain types of food. The sweating is often accompanied by vasodilatation or lacrimation and is believed by some to be a parasympathetic function like blushing. The second type follows wounds in the neck or face, often in the region of salivary glands, and the third may follow operations on the sympathetic nervous system. An example of the second type was described recently by Young.¹

In the last type—i.e., following sympathectomy—thermoregulatory sweating is absent. Warming the patient causes no sweating in the denervated area. This means that the sweat glands in the area have lost their sympathetic nerve supply, and they might therefore be expected to become supersensitive to acetylcholine, their usual chemical excitant. If then acetylcholine, liberated by the parasympathetic nerves such as those concerned with blushing, etc., on the face, reached these supersensitive sweat glands, it might activate them. Another possibility is that collateral budding might take place from the parasympathetic nerves to the degenerative sympathetic nerve fibres in the area and thus innervate supersensitive sweat-gland nerve-endings. Treatment must therefore be directed to diminishing parasympathetic activity, and anticholinergic drugs should be tried. Tincture of belladonna has been tried in the past, but the side-effects are often unpleasant if the dose is large enough to control the sweating. There are many new anti-parasympathetic drugs now available, and a trial of these in varying dosage offers an opportunity for alleviation. Should this fail the patient should be referred to a centre where the investigation and surgery of the sympathetic nervous system are being studied.

NOTES AND COMMENTS

Penile Smarting After Coitus.—Dr. D. M. O'CONNOR (Loughlinstown) writes: As no more eminent person has apparently done so, may I venture to add a suggestion to your expert's reply on penile smarting after coitus ("Any Questions?" January 12, p. 118)? A search for a renal calculus might reveal a cause for the symptom.

OUR EXPERT replies: I have never seen a patient with smarting after coitus where it was due to a renal calculus. I have been in touch with several urological surgeons and they are of the same opinion. In my reply I stated that an examination should be carried out before the first morning micturition and bath, which would detect any urinary infection. If Dr. O'Connor has seen a case of renal calculus where there was smarting after coitus, the symptom was in all probability due to urinary infection with a concomitant prostatitis and not to the calculus.

Sulkowitch and Fantus Tests.—Dr. B. J. BOUCHÉ (London, S.W.19) writes: In the answer by your expert on the Sulkowitch and Fantus tests ("Any Questions?" December 29, 1956, p. 1559), there are two points calling for correction in regard to Fantus's test, viz.: (1) The pipette, after measuring 10 drops of urine, is washed twice, once with distilled water and again with some of the pot. chromate solution as used in the test; this is obviously for further safety. (2) The number of drops of silver nitrate solution required to give a brick-red precipitate, less one, is the correct number of grammes of sodium chloride per litre of urine. In other words, the number of drops used before the change of colour (not necessarily the formation of a precipitate) indicates the number of grammes per litre. These two are quite minor points.

Treatment of Acne.—Dr. G. ENGLER (Panama) writes: Referring to the inquiry about recent advances in the treatment of acne ("Any Questions?" December 1, 1956, p. 1317), I would like to mention the remarkable results after the administration of rauwolfia preparations. We have been using "rautensin CUP," a Columbian product, a whole root preparation of *Rauwolfia hirsuta* containing 100 mg. per tablet. However, other rauwolfia products may well be equally effective. The average doses of 600 mg. per day resulted in startling improvement in our cases within a period of two weeks. Besides the reduction of blood pressure by about 20 to 30 mm., several patients have observed a decrease in libido.

Infantile Gratification Habits.—Professor R. S. ILLINGWORTH (Sheffield) writes: May I suggest another answer to your correspondent's query concerning the 20-months-old child who is sucking a napkin ("Any Questions?" January 26, p. 240)? My answer would be (1) it is normal, (2) it will stop as she matures, provided only that you do nothing about it. It will not cause permanent deformity of the teeth, provided that it stops by the age of 5 or 6, as it will if no effort is made to stop it.

Correction.—The sentence in Dr. A. S. Playfair's letter (*Supplement*, February 2, p. 50): "Twice in his letter Dr. Glaisher assumes . . . that his relationship has been destroyed through the machinery of the N.H.S." should have read: "Twice in his letter Dr. Glaisher assumes . . . that this relationship has been destroyed . . ."

Books of "Any Questions?" and Refresher Course Articles.—The following books are available through booksellers or from the Publishing Manager, B.M.A. House. Prices include postage. *Any Questions?*, Volumes 2 and 3 (8s. each); *Refresher Course for General Practitioners*, Volumes 2 and 3 (26s. 6d. each inland, 26s. overseas); *Clinical Pathology in General Practice* (22s. 3d. inland, 21s. 9d. overseas).

LONDON SATURDAY FEBRUARY 23 1957

TREATMENT OF ADRENOCORTICAL DEFICIENCY STATES

BY

F. DUDLEY HART, M.D., F.R.C.P.

Westminster Hospital, London

The treatment of adrenocortical deficiency states has been completely revolutionized since the advent of the new adrenocortical steroids. The discovery by Hench, Kendall, and others in 1949 of cortisone as a therapeutic agent marked an advance into a new therapeutic era. Now that adrenal substitution therapy is a practical measure, adrenalectomy for a variety of disorders has become increasingly popular. Total or subtotal adrenalectomy is now orthodox therapy for Cushing's syndrome, and total adrenalectomy has also been extensively used in the treatment of metastatic malignant disease and of malignant hypertension; it has also been empirically performed in the treatment of a number of disorders: diabetes mellitus, schizophrenia, and rheumatoid arthritis, to mention three. Substitution therapy has therefore become a day-to-day problem in the wards of many hospitals, and, as a natural sequence, the treatment of adrenocortical crisis has become more common than it used to be.

The tempo of practical therapeutics is now so rapid that by the time a new effective form of treatment is evolved and applied in medicine its probable successors are already on the scene, as yet incompletely studied and unproved clinically. This is particularly so in the adrenal-deficiency states, where steroid chases steroid across a constantly changing scene. We have passed from the time of high-salt treatment, through the cortical extract era, from the deoxycortone to the cortisone age, and are now in the happy position of having many practical tools, all of proved efficiency. In spite of this, many patients with adrenal deficiency still lag behind somewhere on this therapeutic pathway; to-day brown lethargic Addisonian patients, on deoxycortone alone, resemble the partially treated patients of the pre-1949 era. Such patients are by no means rare even at the time of writing.

The clinical material which forms the basis of this study consists of 150 patients, 5 adrenalectomized for malignant hypertension, 2 for Cushing's syndrome, and 143 for metastatic malignant disease. Details of these 143 cases have been published by Sir Stanford Cade (1954, 1955). Of the metastatic cases, 65 have survived and have been followed-up for more than six months to September, 1956. The number of "survival years" of these 65 cases now totals 85.3. The two patients with Cushing's syndrome are in good health, four and one year after operation. Of the patients with malignant hypertension only one survives after two years; the others lived 10, 12, 19, and 12 months after operation.

The details of these five patients, all under the care of Dr. Swithin Meadows, have been reported by Van T'Hoff (1956).

Sodium Loss, Cortisone Deficiency, and Water Intoxication

The classical symptoms of adrenal deficiency are increasing weakness, lassitude, and inability to respond to any form of stress, followed by vomiting, diarrhoea, prostration, and finally coma. The blood urea rises as the serum sodium falls; the serum potassium rises steadily as the patient becomes depleted of salt and water. These symptoms are, however, found only typically in a minority of patients; in most cases the early signs and symptoms are more subtle and less easy to define.

In the adrenal-deficient subject, particularly in the adrenalectomized subject suffering from metastatic malignant disease, the variables with which the clinician has to contend daily are: (1) the salt-and-water balance; (2) the cortisone requirements; and (3) the activity of the underlying (malignant) disease process.

The clinical and biochemical picture may change rapidly overnight in these severely ill patients. Inter-current infection, extreme pain from involvement of a fresh structure by the neoplastic process, vagaries of appetite and thirst, and, particularly, gastro-intestinal upsets may all rapidly and thoroughly upset the delicate balance of the adrenalectomized subject. The symptoms and signs of imbalance in each of the above—water, sodium, and cortisone—may be very similar; symptoms due to neoplastic extension may also cause a similar clinical picture. To illustrate this point, apathy, anorexia, nausea, and vomiting may be due to water intoxication, sodium loss, cortisone deficiency (absolute from the usual dosage being omitted, or relative in the face of cross-infection or some other stress), or extension of the malignant process. If these symptoms are initiated by extension of the neoplastic process they may in turn cause sodium deficiency and/or water loss and/or hypocorticism (relative cortisone deficiency).

The commonest early symptoms of cortisone deficiency are, in our experience, apathy, lassitude, nausea, anorexia, and a general lack of well-being, followed later by vomiting. The blood urea usually rises, but not invariably at this early stage, and the blood pressure usually, but not always, drops. The pulse usually increases, and the pulse pressure lessens. Exactly the same symptoms and signs may herald sodium deficiency;

Used in adrenalectomized subjects in conjunction with cortisone, glycyrrhetic acid has proved in our hands a weak mineralocorticoid, causing some retention of sodium and chloride, but a stronger water-retaining substance. If dosage of glycyrrhetic acid be raised to 500 mg. daily the cortisone-treated patients will rapidly gain weight and become oedematous; we have twice seen, in our patients, water-loading occurring in the face of persistence of signs of salt deficiency. Galal suggests that this water-loading effect is not mediated through the posterior pituitary, but is

The diagnosis, as mentioned below, must not be confused with that of water intoxication, where the patient has been overhydrated. In the acute form of this (water intoxication) syndrome marked mental disturbances occur, with disorientation, weakness, fits, and even coma; such cases can prove fatal and must be clearly differentiated from the true adrenal crisis before therapy is initiated. In the treatment of adrenal crisis hydrocortisone (free alcohol or hemisuccinate) may be given intravenously; Lundy (1955) has

cortisone was donated by the Medical Research Council. Since this article was written we have learnt that Messrs. Squibb have made 9 α -fluorohydrocortisone available to hospitals in tablets of 1-mg. and 0.1-mg. strength.

USE OF MECAMYLAMINE IN THE MANAGEMENT OF HYPERTENSION

BY

F. H. SMIRK, M.D., F.R.C.P.

Professor of Medicine, University of Otago Medical School, Dunedin, New Zealand

AND

E. G. McQUEEN, M.B., M.R.C.P.

Senior Medical Research Officer, Department of Medicine, University of Otago Medical School, Dunedin, New Zealand

The discovery by Stone *et al.* (1956) that mecamlamine ("inversine"), a secondary amine, has pharmacological properties in many ways similar to those of the quaternary ammonium compounds, which are tertiary amines, is of interest not only in relationship to the properties of the substance itself but also because other secondary amines as yet untested may prove to be more satisfactory as ganglion-blocking drugs than any of those now available.

On the basis of both animal (Ford *et al.*, 1955; Stone *et al.*, 1956) and clinical studies (Ford *et al.*, 1955; Freis, 1955; Freis and Wilson, 1955, 1956; Moyer *et al.*, 1955) it is evident that mecamlamine causes blockade of both sympathetic and parasympathetic ganglia. It differs from the methonium compounds, however, in being readily and completely, or almost completely, absorbed from the alimentary canal. It has also been reported (Freis and Wilson, 1955, 1956) that, contrary to the invariable course of events with the methonium compounds, the continued administration of mecaml-

amine leads to little or no drug toleration, a point of great practical and theoretical interest. The structural formula of mecamlamine (3-methylamineisocamphane hydrochloride) is here shown.

The present study describes our experiences with the use of mecamlamine in the management of 40 cases of hypertension treated for from four to eight months.

Method

Mecamlamine was administered by subcutaneous or intravenous injection and by mouth. The blood pressure was measured by the method recommended by the Committee for the Standardization of Blood Pressure Readings (1939) in order to maintain uniformity with observations published previously on hexamethonium, pentolinium ("ansolysen"), and chlorisondamine ("ecolid") (Restall and Smirk, 1950; Smirk and Alstad, 1951; Smirk, 1953; Smirk and Hamilton, 1956).

Over a period of from four to eight months (average 4.6) 40 patients (20 males, 20 females) have received a trial of mecamlamine. Fundal gradings were or had been grade IV (Keith, Wagener, and Barker, 1939) in five cases, grade III in nine, and grades II or I in the remainder, most of whom had other severe manifestations such as congestive cardiac failure. Twenty-five patients had had treatment with other ganglion-blocking agents previously. In the remainder treatment was instituted with mecamlamine.

Drug Toleration

Before comparing the potencies of mecamlamine and other ganglion-blocking drugs it is necessary to consider whether mecamlamine causes drug toleration. At an early stage it became evident that toleration either did not occur or was present to a comparatively minor degree following the repeated administration of mecamlamine. Indeed, if drug toleration does develop it must do so early in the course of administration of gradually increasing doses; for once a fully effective dose has been discovered there is no consistent change in the dose needed to reproduce the same fall of blood pressure. In some instances the requisite dose has increased somewhat after several weeks or months of treatment; in other instances, somewhat less frequently, the requisite dose has decreased. In Fig. 1 is shown the

FIG. 1.—Effect on blood pressure of identical doses of mecamlamine given intravenously. I.V. (1) shows effect of an initial dose of 14 mg. of mecamlamine given slowly over the period shown, in the posture indicated. I.V. (2) shows effect of the same dose given in the same manner after two weeks of oral therapy, during which time the patient received 14 mg. of mecamlamine twice daily.

result of a test in which the initial effective dose was determined by intravenous titration. This was repeated after two weeks of oral therapy, with the production of an identical response.

Comparison of the Effective Doses of Mecamlamine, Pentolinium, Chlorisondamine, and Hexamethonium

The effective dose of mecamlamine may be compared either with the initial doses of quaternary ammonium compounds or with the doses of such compounds which may be required after repeated administration. In a series of 40 patients treated with mecamlamine the least dose to produce any significant effect was 3 mg., and 5 mg. is a suitable initial oral dose. The effective single oral dose reducing the blood pressure in the standing posture to about 120 or 130 mm. systolic, with corresponding reduction in the diastolic pressure, was 10 mg. or more in 80% of cases.

The duration of action of mecamlamine is in excess of 12 hours. Consequently, when two or more daily doses are given the effect obtained from one dose is influenced by the residue of the effect from the preceding dose. Hence increase of the night dose will have some effect on the level of the blood pressure next morning, and will influence the size of the dose which should be administered then. A fairly good control over blood-pressure levels can be obtained usually by two doses a day, the night dose being, for preference, approximately 30% higher than the morning dose. We have found it an advantage to give a small supplementary dose about 2 p.m., as otherwise there is often a rise of pressure in the late afternoon or early evening. Doses are adjusted in terms of the hypotensive action. The average daily dose in those of our patients who continued on mecamlamine was 33 mg. This average is probably higher than the average daily dose in unselected cases, as about half of our patients on mecamlamine had been selected because of the large dose of pentolinium or chlorisondamine which had been needed to reduce the blood pressure adequately. Among all cases maintained on treatment the highest dose was 70 mg.

By comparison, the effective oral dose of pentolinium per 24 hours at the time of initiation of treatment may vary from 40 to 160 mg., whereas when full drug toleration has been acquired, 60 to 1,800 mg. a day may be necessary, although most patients are controlled with doses of between 160 and 360 mg. a day. Correspondingly effective doses of chlorisondamine are of the order of 25 to 75 mg. at initiation of therapy and 50 to 750 mg. in the fully tolerant patient, and of hexamethonium salts 100 to 300 mg. initially and 300 to well in excess of 3,000 mg. when full tolerance has been acquired.

Direct comparison of mecamlamine with pentolinium was possible in 21 patients. In all of these pentolinium had been administered long enough for full tolerance to develop. Most of these cases had required unusually high doses of pentolinium. In 10 of these pentolinium had been given parenterally, in 11 orally. The results are shown in Table I.

The group originally receiving parenteral pentolinium was made up of patients having in general a particularly high requirement of quaternary ammonium compound. This is reflected in the larger requirement of mecamlamine in this group than of the group previously on oral pentolinium, and of the whole series (33 mg.).

It is of interest to note that oral mecamlamine and parenteral pentolinium, when full tolerance had developed to the latter, were equally potent.

TABLE I

No. of Patients	Average Effective Daily Dose Pentolinium (mg.)	Average Effective Daily Dose Mecamlamine (mg.)
11 10	460 (oral) 39 (parenteral)	32 (oral) 39 "

When hypertensive patients receive two or three doses daily there is usually less variation of the blood pressure throughout the day after mecamlamine than after chlorisondamine or pentolinium. Indeed, in some patients the degree of control which can be obtained by mecamlamine alone is approximately equal to that which can be obtained by chlorisondamine or pentolinium in combination with reserpine. Unfortunately, in some patients the development of side-effects makes it impracticable to administer a sufficient dose of mecamlamine. Our impression of the relationship between control over the blood-pressure level by mecamlamine as contrasted with pentolinium and chlorisondamine is that the best control over blood-pressure levels can be obtained with mecamlamine in those patients who are fortunate enough to be able to tolerate it. Unfortunately, mecamlamine in fully adequate doses is more often associated with prohibitive parasympathetic side-effects than either pentolinium or chlorisondamine. The responses to these drugs are highly individual, some patients for an equivalent degree of control over the blood pressure being more comfortable on mecamlamine, and some on pentolinium, and some on chlorisondamine.

Other Findings

Relationship Between the Effective Subcutaneous and Oral Doses of Mecamlamine.—It has been reported by Freis (1955), Freis and Wilson (1955, 1956), Moyer *et al.* (1955), and Ford *et al.* (1955), that mecamlamine has approximately the same hypotensive action whether administered subcutaneously or orally. Certainly the difference between the subcutaneous and oral doses is very much less than with the various quaternary ammonium compounds. We have found that on the average the oral dose must be a little greater than the parenteral dose in order to produce an equal fall of blood pressure, although in a number of patients the same dose was equally hypotensive when given orally as when given parenterally (Table II, Fig. 2).

Postural Hypotension After Administration of Mecamlamine.—The occurrence of postural hypotension following the administration of ganglion-blocking drugs has been referred to on many occasions. The action of mecamlamine appears to be indistinguishable in this respect from that of quaternary ammonium compounds. The relationship between the extent of the fall in blood pressure in the horizontal posture and the additional fall in the blood pressure which occurs on standing varies from patient to patient.

FIG. 2.—Effect of 8 mg. of mecamlamine intravenously over period shown compared with that of a single oral dose of 8 mg. given to same patient on a subsequent occasion. Effect of posture as shown.

* All cases had received doses of mecamlamine on the previous day and in some cases residual drug action is present.
† Patients with auricular fibrillation having digitalis.

Effect of Mecamlamine on Pulse Rate.—There is no consistent change in the pulse rate following the administration of mecamlamine, except where congestive heart failure or impaired circulatory activity has been improved by its administration. The pulse rate may rise or fall slightly.

Effect of Meals on Hypotensive Action of Mecamlamine.—Just as with hexamethonium, pentamethonium, "M. & B 1863," "Ciba 9295," pentolinium, and chlorisondamine, so also mecamlamine administration is associated with an additional fall in the blood pressure after a meal. Probably this is due to inability of vascular reflexes to compensate for splanchnic dilatation.

Side-effects After Administration of Mecamlamine.—Most of the side-effects which may follow the administration of mecamlamine are of the same kind as those already encountered following the administration of chlorisondamine, pentolinium, and hexamethonium. In addition to the side-effects exhibited by hexamethonium and pentolinium, the administration of chlorisondamine and mecamlamine may lead to vague and indefinable feelings of malaise which make the patients unwilling to continue with the drug, often without their being able to explain exactly the nature of their symptomatology. Such complaints have been rather more prominent with mecamlamine than with chlorisondamine. In an individual patient parasympathetic side-effects such as blurring of the vision, dry mouth, and constipation may be either greater or less with mecamlamine than with

chlorisondamine or pentolinium. We have found that urinary retention has occurred more often after mecamlamine and that nausea and vomiting have been more frequent after mecamlamine and chlorisondamine than after pentolinium. On the other hand, patients who have had attacks of ileus or abdominal distension or other intolerable alimentary side-effects on large doses of pentolinium, necessitating in some cases their transfer to subcutaneous injections, have usually been more comfortable on mecamlamine. In this series of 40 patients, half of whom had been selected for trial because of difficulty with side-effects or with control of blood pressure, the side-effects encountered were of such severity as to cause substantial discomfort in 25 (Table IV).

TABLE IV.—Side-effects of Mecamlamine

Alimentary	Dryness of mouth	11
	Nausea and vomiting	9
	Constipation and abdominal distension	14 (partial ileus in one)
Urinary	Diarrhoea	2
	Dysuria	5 (retention of urine in one)
Visual	Blurring of vision	5

Clinical Appraisal

It must be borne in mind that our experience with mecamlamine has been derived from a group of patients more than half of whom had previously proved difficult to manage with other ganglion-blocking agents and who probably constitute a particularly severe test for any therapeutic regime.

Of the total of 40 patients in whom the trial was undertaken, mecamlamine continues to be used as the ganglion-blocking agent of choice, with or without a rauwolfia alkaloid, in 22. Of the remainder, two died, and in three further cases supply difficulties curtailed the trial. It is of some interest to consider the 13 in whom mecamlamine was abandoned. In one case control of hypertensive cardiac failure was less satisfactory than with the original regime using parenteral pentolinium. In the remaining 12, severity of parasympathetic side-effects was the determining factor. Eight patients reverted to other ganglion-blocking agents (three parenteral pentolinium, three oral pentolinium, one oral chlorisondamine, one oral "139.C.55"), one was satisfactorily managed on reserpine alone, and three defected from treatment, an unusual event for this clinic.

Since tolerance occurs to a limited extent only, if at all, and since the parenteral and oral doses so nearly correspond, the method of intravenous titration can be used very profitably to initiate treatment. Our experience has been that intravenous administration at the rate of 0.5 mg. a minute with continuous blood-pressure recording is safe and not too time-consuming.

Use of Mecamlamine in Conjunction with Rauwolfia Alkaloids

We have used mecamlamine in conjunction with reserpine (0.5 mg. or less in 24 hours), rescinnamine (0.75 mg. or less in 24 hours), or canescine (1 mg. or less in 24 hours). We have encountered no difficulties in using these combinations of drugs. Smaller doses of mecamlamine suffice when rauwolfia alkaloids are administered concurrently. The extent of the potentiation of ganglion-blocking activity requires further study, but the initial impression is that it is of the same order as that observed after pentolinium.

Summary

Mecamlamine, a secondary amine, exhibits in man the pharmacological properties characteristic of a ganglion-blocking drug. In contrast with quaternary ammonium compounds, mecamlamine is well absorbed

*N'-(5-cyano-5'-diphenylpentyl)-N':N'-N'-trimethylethylene-l-ammonium-2-morpholinium sulphate (Burroughs Wellcome and Co.).

from the alimentary canal, so that the oral dose is little more than the parenteral dose. The degree of drug toleration is slight, and is not sufficient to cause difficulty in determining the requisite dose of the drug. The action is more prolonged than that of pentolinium or of chlorisondamine, so that the degree of control over the blood-pressure level is better, provided that a sufficient dose can be administered. Adequate control over the blood-pressure level is hindered in some instances by the occurrence of parasympathetic side-effects, which appear to be rather more prominent in most cases than those we have encountered with pentolinium. There are, however, individual differences in patients such that, with equal falls of blood pressure, side-effects may be less in some patients when they are treated with mecamlamine and less in others when they are treated with pentolinium.

Mecamlamine may be used satisfactorily in combination with rauwolfia alkaloids. Delayed toxicity has not been encountered with mecamlamine during our experience of eight months.

This work was supported in part by the Life Insurance Medical Research Fund of Australia and New Zealand. We wish to acknowledge the generosity of Messrs. Merck, Sharp, and Dohme in the supply of mecamlamine, and to thank Miss Noeleen Richardson for her assistance with the secretarial work.

Q FEVER DOWN THE DRAIN

BY

M. G. P. STOKER, M.D.

Department of Pathology, University of Cambridge

There is nothing very original about Q fever contracted in the laboratory. Since the early days of research on this disease in Australia and the United States infections have regularly occurred in institutes where live organisms (*Rickettsia burneti*) have been handled, although the incidence has probably diminished since vaccination was introduced in 1948 (Smadel *et al.*, 1948). In most published accounts the mode of infection is apparently airborne, sometimes after transport on clothing (Oliphant *et al.*, 1949; Beeman, 1950), and often after very short exposure.

The main purpose of this paper is to describe two infections in the Department of Pathology, Cambridge, by a route which this highly versatile organism has not previously succeeded in exploiting. Since the investigation of Q fever has now ceased in the department, the opportunity is also taken to review briefly other infections which occurred among members of the staff while the work was in progress.

General Arrangements and Vaccination Procedure

Research on Q fever was carried out in a set of three rooms on the top (third) floor of the department, in an animal-room and post-mortem room on the same floor, and in five small huts on the roof.

Serological investigation of Q fever began in 1947, but living strains of *R. burneti* were not handled until October, 1949. From this date until March, 1955, the rickettsia was grown in large numbers for production of antigen and other purposes. All those who worked in the Q fever laboratory itself were given a course of two or three injections with vaccine kindly supplied by Dr. H. R. Cox, of the Lederle Laboratories. From December, 1953, vaccination was extended more widely to those who were known to visit the laboratory, and, in all, 31 of a total of 83 members of the staff of the department were vaccinated.

Vaccination was not more extensive, because of limitation of supply and also because a chronic sterile abscess sometimes formed at the site of inoculation. In two individuals this progressed to form a discharging sinus which took many months to heal. This complication is thought to occur more frequently after booster injections (Meiklejohn and Lennette, 1950), so these were not generally given.

No cases of Q fever were identified between 1949 and 1953. Between October, 1953, and July, 1954, however, five members of the staff developed typical attacks of Q fever, which were confirmed serologically. Investigation failed to reveal outside sources, and it was assumed that infection took place within the department.

Several outbreaks of Q fever in other laboratories have followed the first growth of *R. burneti* in the yolk sacs of chick embryos, which yield very highly infective material. The number of eggs harvested and the method of processing in Cambridge had not varied much since 1949, however, and the onset of laboratory infections in late 1953 seemed to coincide more with an increase in the number of workers who were handling the organisms, even though, with one exception, they did not themselves succumb.

Of the five individuals who developed Q fever, four (patients B, C, D, and E) worked elsewhere in the building and were unvaccinated. They had all been in their occupations for a number of years. The remaining patient (A) had recently arrived to work on Q fever and was consequently vaccinated. Two patients (D and E) were infected together from a blocked drain. The remainder were unconnected sporadic infections.

Sporadic Laboratory Infections (Not Associated with the Blocked Drain)

Patient A received 1-ml. injections of vaccine on January 4 and 11, 1954. On January 21 he harvested yolk sacs heavily infected with *R. burneti*. On February 11, 21 days after this exposure, he developed Q fever. Complement-fixing antibody was absent on the third day, but appeared on the fourth day—very much earlier in the course of the disease than is usual—and was presumably due to the previous vaccination. The attack was nevertheless moderately severe, until after chlortetracycline was given on February 15.

It is clear that insufficient time had elapsed between completion of the course of vaccination and exposure to large numbers of rickettsiae.

Patient B worked in the histology department on the first floor. Eighteen days before the onset of his illness, on February 21, 1954, he briefly entered the Q fever laboratory to deliver a message. He had no other contact that could be discovered, and it seems highly probable that he was infected during the few seconds that he was in the laboratory.

Patient C, who became ill on October 4, 1953, also worked in the histology department on the first floor. Although he lived in the country no obvious source of *R. burneti* to which he was exposed could be discovered outside the department. He paid occasional visits to the Q fever laboratory, but could remember none during the probable period of exposure. He had contact, however, with one of the assistants in the Q fever laboratory who often took tissues (not infected with *R. burneti*) for sectioning, and it is possible that the rickettsia may have been carried in the clothes or hair (see Beeman, 1950).

Laboratory Infections from the Blocked Drain

Patients D and E both developed Q fever on July 2, 1954. Since they did not meet outside working hours and had no obvious contact with external sources of *R. burnetii*, it seemed likely that they were both infected in the department and at the same time. D had been in charge of the media and autoclave rooms for many years. E worked in the histology room, but he occasionally helped D with autoclaving when there was a lot to be done.

Material from the Q fever laboratory was sometimes taken to D's autoclaves, but until autoclaving was complete it was handled by Q fever laboratory staff and not by D himself. Moreover, E had not been assisting with the autoclaves during the period when infection probably occurred. D did go upstairs to the door of the Q fever laboratory, but not inside, on June 8 or 9 (23 or 24 days before the onset of his illness), but E claimed that he had not been near the Q fever laboratory at this time.

On June 11 at the probable date of infection, 21 days before the onset, a drain had been opened in the media room, flooding the floor. Both D and E were present, and subsequent inquiries strongly suggested that they were both infected at this time.

Diagram of relevant part of waste-water-drain system in the Department of Pathology. X=Junction which often became blocked. Y=Trap to main drainage.

including the media room on the first floor, collecting the waste water from lateral drains.

The lateral drain in the Q fever laboratory on the third floor was almost horizontal and the flow was very slow, so that it often became blocked at the junction (X) with the vertical drain and had to be opened at this point to be cleared.

The drain was blocked and cleared in this way on June 10, but on June 11 the obstruction recurred. This time it was lower in the vertical pipe and could not be cleared from the junction (X) in the Q fever laboratory. No clearing-points were present lower in the vertical drain for removing this obstruction, and the pipe was therefore cut open as it descended through the media room. This procedure, which had never been necessary before, released a flood of black sludge on to the floor of the room.

Twelve individuals were present or entered the media room shortly afterwards to see what was going on. Of these twelve, one had had Q fever previously (patient B) and three had received Q fever vaccine. Of the remaining eight susceptible individuals who were exposed, two developed Q fever (patients D and E). Serum was obtained later from four of the six susceptibles who remained well, but there was no antibody rise to suggest asymptomatic infection.

It seemed probable that patients D and E were infected by inhalation of droplets containing *R. burnetii* from the deluge of sludge. Specimens of sludge were therefore collected from the junction of the horizontal and the vertical drain in the Q fever laboratory (X) and from the trap at the bottom of the pipe (Y). These specimens, which were taken in November, 1954, were centrifuged at 2,000 r.p.m. for 10 minutes, and the supernatants were mixed with penicillin and injected into guinea-pigs. *R. burnetii* was isolated in this way from the sludge at the top of the drain, but not from the trap at the bottom.

Viable rickettsiae had not been deliberately poured down the sink in the Q fever laboratory. Infected glassware and other equipment, as well as discarded egg and animal tissues and infected fluids, were normally autoclaved, and some pieces of special apparatus were boiled. An exception was made for Tenbroeck tissue grinders and Waring blenders, however. The heavy coating of yolk which usually remained after processing of eggs made it extremely difficult to clean these pieces of apparatus after sterilization by heat. They were therefore soaked in lysol (approximately 5%) overnight, then were washed in the sink. In earlier investigations of the inactivation of *R. burnetii* by disinfectants (Malloch and Stoker, 1952) lysol was easily the most effective of those tested at room temperature. 1% lysol reduced the infectivity of yolk-sac suspensions by a factor of more than a million in three hours, at room temperature.

Nevertheless the most likely source of the living rickettsiae in the drain was the lysol-treated material. This may have occurred through a mistake in the time of inactivation or the concentration of lysol, which was not accurately measured, or through failure of the disinfectant to penetrate large lumps of yolk tissue. Once in the drain the lysol would rapidly be diluted out, and surviving organisms might remain embedded in the sludge for many months.

Undiagnosed and Asymptomatic Infection of Department Staff

In view of these attacks of Q fever an attempt was made to find out if asymptomatic or undiagnosed infection had occurred more widely than was suspected while work on *R. burnetii* was being carried out.

Of 83 members of the staff in October, 1954, 31 had been vaccinated. Excluding the 5 patients and 10 others who were not available, specimens of serum were obtained from 68 individuals and tested for Q fever antibody by the complement-fixation test.

Of 42 unvaccinated members of the staff, four had antibody (two at 1/5, one at 1/10, one at 1/20). This could have been due to unrecognized infection in the department, but the numbers were too small to show a significant increase over the proportion of the general adult population (blood donors) with antibody. There is no suggestion that unrecognized infection was at all common in the department.

Twelve out of 26 of the vaccinated group had antibody at 1/5 or greater. Antibody was present in all the six vaccinated individuals who were heavily exposed to the rickettsia in the Q fever laboratory, but in only 6 out of 20 of those who were rarely exposed.

Summary and Conclusions

Two Q fever infections in the Department of Pathology, Cambridge, are described: these occurred by an unusual route. A review is also given of other infections which occurred among the staff.

Except for Patient A, the laboratory infections occurred amongst unvaccinated individuals who had a rare and unlucky experience of the rickettsia. It is curious, however, that no infections were ever detected among those of the staff who had close contact with the Q fever laboratory but were nevertheless unvaccinated.

In 1953, before vaccination was offered more widely, nine unvaccinated workers from an adjoining laboratory were sharing a refrigerator in the Q fever laboratory, which they repeatedly entered. None developed either clinical or serological evidence of infection. On the other hand, Patient B entered the laboratory for a few seconds and later succumbed to the disease.

This effect might be due to chance or individual variation in susceptibility. It is possible, however, that small repeated infections produce an immunity which is not detectable by conventional tests for antibody.

The resistance of *R. burnetii* to adverse environmental conditions has allowed its transfer to new hosts by varied and often devious routes. The two infections, which resulted from contamination of the drain-pipe, suggest that the possibilities are not exhausted, but it is fortunate that the circumstances of this particular incident are unlikely to recur frequently.

I am grateful to Professor H. R. Dean for permission to publish this paper.

A SURVEY OF DIABETES IN WEST CORNWALL

BY

C. T. ANDREWS, M.D., F.R.C.P.
Physician, West Cornwall Clinical Area

The objects of this survey were (1) to determine the incidence of diabetes in the West Cornwall clinical area, which is an isolated geographical entity with a population of a quarter of a million, largely shut off from the rest of England by Bodmin Moor; and (2) to find out to what extent the diabetic patient constitutes a load on the community. In assessing the second object four main agencies were considered: the home, the district nurse, the general practitioner, and the hospital service.

Incidence

Approximately one-third of the population has been surveyed through general practitioners, the doctors taking part being chosen so as to obtain an even geographical distribution and a balance between town and country practices.

In the spring of 1953 preliminary invitations were sent to 55 general practitioners, and a subsequent letter invited each one who agreed to co-operate to survey his list and complete a short questionnaire (see Appendix). In this way figures were obtained covering the practices of 48 doctors distributed from near Land's End to Camelford and Bodmin. These varied in size from just over 500 to one partnership of nearly 13,000. The results are given in Table I. The rate per 1,000 is seen to be 5.6. The incidence varied within the practices surveyed from 3.2 to 8.4 per 1,000.

Of the 593 patients accepted as diabetics, the diagnosis had been confirmed in 579 by attendance at a diabetic or general medical clinic, by blood-sugar investigation, or by previous investigation as a hospital in-patient. The

remainder were accepted after careful scrutiny, and, in some cases, after personal discussion with the doctor making the return. No significant difference was found in the predominantly rural and predominantly urban practices. A cross-check on these findings was made by counting the number attending general medical and

TABLE I.—Incidence of Diabetes in West Cornwall

Total population of West Cornwall	266,389
No. of list patients surveyed	104,827
Percentage of total population surveyed	39.2
Total number of diabetics found	593
Number of diabetics per 100,000 population	565.7
Estimated number of diabetics in West Cornwall	1,507
Percentage attending diabetic or general medical clinics	77.4
Estimated total number attending diabetic or general medical clinics	1,167
Actual number found attending	1,141

diabetic clinics, and the number (1,141) was found to accord closely with the estimated figure obtained from the general-practitioner returns (1,167).

Very little information is available on the incidence of diabetes in this country. During the second world war the necessity to obtain a medical certificate for special rations afforded an opportunity of arriving at an approximate figure. In 1947 it was thought that nearly all diabetics were availing themselves of the extra allowances. The incidence calculated from medical certificates in this year was 231 per 100,000 for England and Wales. It is possible, however, that many of the milder diabetics in rural areas did not avail themselves of the special rations.

The advent of the National Health Service has made it possible to enlist the help of the general practitioner in investigations of this type. In a recently published survey of the work of eleven practices covering the years April, 1952, to March, 1954, it was found that the annual rate of patients having consultations for diabetes varied from 2 to 7 per 1,000 population within the practices investigated. The average annual rate for all the practices was 3.6.

A partial explanation of the high incidence of the disease in Cornwall is provided by a study of the population structure. In this area approximately 19% of the population is aged 60 or over, as compared with 15% for the rest of the country. As diabetes predominates in the older age groups a higher incidence would be expected. A more powerful reason is probably provided by the isolation of the area, with consequent inbreeding in the past. Isolation in West Cornwall has meant a great deal more than lack of intercourse with the rest of England. The small fishing village and rural township have kept themselves apart to a degree rarely seen in the rest of England. Local geography has fostered this isolationism, for many of the coastal villages even to-day have no more than one bus a day or even one a week.

Sex Distribution

The distribution between the sexes is given in Table II, and is compared with that derived from a count of special ration certificates for the whole of the country in 1947. It will be seen that the sex distribution in Cornwall closely follows that of England and Wales as a whole. The

TABLE II.—Sex Distribution

	Males		Females	
	No.	%	No.	%
General-practitioner survey	234	39.5	359	60.5
Old clinic cases	173	39.3	267	60.7
Present Truro Clinic	178	36.9	304	63.1
England, 1947 (special ration certificates)		38.0		62.0

slightly greater predominance of female patients at the clinics as compared with the general-practitioner survey may be explained by the fact that the principal clinic in the area is held at 10 a.m., so that men in jobs may have some difficulty in attending.

Age at Onset

In relation to the load on the community it is necessary to consider the age at which the disease first produces symptoms and the manner of its presentation.

The average age of onset as determined from the case records of 901 clinic patients was 52 years. The age of onset in relation to sex shows a striking difference between male and female diabetics (see Chart). The female curve rises

Chart showing age at onset of diabetes in males and females.

sharply to a peak in the sixth and seventh decades while the male curve is flatter. Of greater interest perhaps is the relative preponderance of males in the first four decades and the tendency for this preponderance to reappear in extreme old age. The effect of this on the incidence of the disease in the over-70 age groups is accentuated by the tendency in West Cornwall for the female diabetic to die at an earlier age than the male (see below). The striking excess of females in the sixth and seventh decades is well known and accounts for their overall preponderance in the survey (60.5% in a total of 693 cases).

Mode of Onset

The material used for this part of the investigation was the case records of 573 clinic patients, in nearly all of which the history had been taken with this investigation in mind. It will be seen from Table III that the classical symptoms of thirst, polyuria, and weight loss constituted the reason for seeking advice in only 41.4% of the cases. Incidental illness and routine examination together account for the first attendance of 13.5% of all the cases attending. Some of these were picked up by shrewd general practitioners looking after minor illness such as influenza at home. Most, however, were diagnosed on admission to hospital for illness in no way associated with diabetes. Routine medical examination for life assurance, for the Services, or for employment led to the diagnosis of 3.7%.

TABLE III.—Mode of Onset in 573 Cases

Classical (thirst, polyuria, weight loss)	237 (41.4%)
Incidental illness	56 (9.8%)
Eye complications	38 (6.6%)
Pruritus and eczema	53 (9.2%)
Skin sepsis (including foot sepsis)	46 (8.0%)
Weight loss alone	30 (5.2%)
Routine examination	21 (3.7%)
Lassitude alone	12 (2.0%)
Neuritis	9 (1.6%)
Coma or pre-coma	20 (3.5%)
Gangrene	20 (3.5%)
Other	31 (5.4%)

A consideration of these groups raises the question of whether there are not in the community to-day many diabetic patients more or less symptom-free and therefore undiagnosed. While it is true that many of this group on direct questioning admitted having symptoms of diabetes such as polyuria, they were not such as to bring them to medical attention. It seems likely, indeed, that routine urine testing of the whole community would lead to a further substantial addition to the figure of incidence in this area at least.

The figure for skin sepsis includes also cases presenting with foot sepsis. All but one of the cases of gangrene were of the lower limb. Several of the 20 cases presenting in coma or pre-coma appear to have had no symptoms suggestive of the disease till a few days before the onset of coma.

Use of Clinics

Information was obtained on this subject from the answers to the questionnaire. They show that 77.4% of all patients attend either a diabetic or a general medical clinic (Table IV). Some were attending more than one clinic at

TABLE IV.—Attendance at Clinics

Total number of diabetics found (G.P. survey)	593
Information re clinic attendance not given	26
Remainder	567
Attending clinics	445 (78.5%)
" diabetic clinic	418 (73.7%)
" general medical clinic	21 (3.7%)
" other clinics	11 (2.0%)
Hospital in-patients	26 (4.6%)

the same time—for example, diabetic and chest. Some were regarded as still attending the clinics though in-patients at the time of the survey.

The extent to which the clinics were used varied widely, and this variation appeared to bear no relation to geographical accessibility. For example, in one large practice returning 63 patients all but three of these attended the diabetic clinic four miles away. In the same town the attendance rate from another doctor's practice was 18%. It was clear that a small proportion of the general practitioners regarded themselves as competent to look after their own diabetics and referred to the clinics only those presenting special problems.

It might be thought, particularly in a sparsely populated rural area, that age would exert a considerable influence on attendance, but this is apparently not so. The average age of those attending the clinics is 64, of those not attending 65. Of the 120 patients shown as not attending the clinics in the general-practitioner returns, 50 (41.7%) were males and 70 (58.3%) females. These figures show a slightly greater attendance rate for females than for males in proportion to their total numbers.

Problems of the Home

These are mainly those constituted by special diet, insulin administration, and intercurrent illness. Of these, the dietetic problem gives rise to least anxiety in the minds of diabetic patients. Of 501 patients investigated at the Truro Clinic, 100 (20%) were adhering to a strict dietetic regime (Lawrence line ration scheme); 363 (72.4%) were observing some dietetic restriction short of this; and 38 (7.6%) might be regarded as observing no dietetic restrictions.

It is probably true to say that the problem of diet constitutes a handicap to no more than 20% who adhere to a strict regime. The problem of insulin administration, however, is of a different order. Of the clinic patients, 18% are found to require no insulin, 37% use one type, and 45% two types (generally soluble and protamine zinc) daily, while 5% of all patients attending require more than one injection of insulin daily. Thus insulin administration constitutes a problem in 82% of all cases, and amongst this number the problem is of several grades from the point of view of domestic responsibility. The patient who requires one injection daily of one type of insulin is much less of a problem than the patient who has to manipulate two separate phials, while the patient who requires two daily injections may be much restricted in activity if she is not able to cope with the problem herself.

Table V shows the home arrangement for insulin administration in 383 patients attending the Truro Clinic. It shows that the problem confronting the female patient is solved through a wider variety of agencies than that of the male. The number of patients regularly giving their own injections is 80.4% of the males and 62.5% of the females. For those, however, who are unable to give their own injections the wife proves more valuable to the helpless

TABLE V.—Insulin Administration in 383 Cases

	Males		Females	
	No.	%	No.	%
Self	111	80.4	153	62.5
Wife	18	13.0	—	—
Husband	—	—	26	10.6
Father	1	0.8	1	0.4
Mother	—	—	1	0.4
Daughter	3	2.2	27	11.0
Son	2	1.4	8	3.2
Neighbour	1	0.8	9	3.7
Nurse	2	1.4	20	8.2
Total	138		245	

Nurse gives 5.7% of all insulin injections. 69% of all patients give their own insulin.

husband (13%) than the husband to a dependent wife (10.6%). The helpless female patient in fact chooses from a wide range of assistance of which daughter, husband, and district nurse are the most important. The helpless husband tends to rely exclusively on his wife, and usually only when a widower does he resort to help from other agencies.

The figure of 5.7% of all injections given by the district nurse is probably too low. In country districts she plays an important part in the training of the patient or a relative in insulin administration. This applies particularly to the milder diabetic who is stabilized as an out-patient. This phase ended, she generally ceases to attend except for the small percentage who are dependent on her for daily insulin. There are some, however, who require a supervisory visit once a week or oftener, and on these occasions the nurse usually gives the insulin. In some cases where measurement of the correct dose constitutes the main problem she may fill the syringe and leave it for the patient herself to administer the next day. In some cases of defective eyesight a member of the household measures the dose and the patient gives the injection.

The commonest reasons given for inability to administer their own insulin were defective eyesight, nervousness, and general frailty of old age. Though defective eyesight was the commonest reason given it often seemed to be mainly an excuse to cover lack of courage. The relationship to age was very definite, as shown by Table VI. From this

TABLE VI.—Age and Inability to Give Own Insulin

Age Group	0-9	10-	20-	30-	40-	50-	60-	70+	Total
Total on insulin	4	6	8	25	42	90	115	93	383
Dependent on others	3	1	0	2	4	18	33	52	113
%	75	16.6	0	8	9.5	20	29	56	29.5

it is seen that dependence on others for insulin administration increases numerically in each decade from the third and that more than half of those over 70 are dependent on others for this service.

Intercurrent Illness

How much illness does the diabetic patient have? In an attempt to answer this question 483 patients passing through the clinic at Truro were questioned at each quarterly attendance during 1954 regarding illness in the previous three months. The investigation has now been continued, and has been completed for the year 1955, during which 663

TABLE VII.—Days in Bed 1954 and 1955

	Males		Females	
	1954	1955	1954	1955
None	139 (77.7%)	216 (82.4%)	214 (70.4%)	317 (79%)
1-7 days	14 (7.8%)	15 (5.7%)	27 (8.9%)	24 (6%)
8-15	19 (10.6%)	25 (9.5%)	55 (18.1%)	50 (12.5%)
Over 15 days	7 (3.9%)	6 (2.3%)	8 (2.6%)	10 (2.5%)
Total	179	262	304	401

patients were questioned. The results are set out in Table VII. At the onset it became clear that in dealing with the older age groups it was extremely difficult or impossible to obtain a true measure of morbidity. Many of the patients are frail or infirm. Standards based on fitness for work or confinement to the house have little meaning in a group in which many are over working age or are housewives doing a limited job of work in their own homes. In the end it was decided to inquire about days spent in bed through illness. Two main reasons for this inquiry were (1) such illness constitutes a load on the home to a much greater extent than that which does not require rest in bed, and (2) it is a measurable entity which the patient can easily remember.

From this investigation the fact emerges that 73% of all patients had no illness requiring rest in bed in the year 1954 and that the proportion was rather higher for 1955, a year in which less respiratory illness and fewer fractures of the lower limb occurred. These figures might not be so good if they included diabetics not attending the clinics. This point is discussed below.

The figures also include time spent by clinic patients in hospital. Owing to the large number of hospitals involved it has not been possible to determine this figure accurately for clinic patients, but the hospital requirements of the total diabetic population of the area are discussed in a later section.

It will be seen that illnesses of one to five weeks predominated in the females in both years reviewed. This was due almost entirely to the greater tendency to fracture of the lower limb and abdominal operations in this group.

TABLE VIII.—Principal Causes of Incapacity During 1954 and 1955

	1954	1955
No. of patients questioned	483	663
Total No. of bed days, all patients	2,385	2,727
Average for all patients attending the clinic	4.9	4.1
" laid up	18.2	21
Total No. of patients confined to bed	131	130
Respiratory infections: colds, influenza, bronchitis, sinusitis, pneumonia	666 days	632 days
Percentage of all bed days	27.9	23.2
No. of patients affected	42	43
Recognized diabetic complications: coma, pre-coma, hypoglycaemia, cataract extraction, skin sepsis, gangrene	370 days	377 days
Percentage of all bed days	15.5	13.8
No. of patients affected	26	28
Abdominal operations	307 days	276 days
Percentage of all bed days	12.9	10.1
No. of patients affected	12	10
Fractures and other injuries	249 days	82 days
Percentage of all bed days	10.4	3.0
No. of patients affected	7	4
Cardiovascular disease	171 days	262 days
Percentage of all bed days	7.2	9.6
No. of patients affected	5	9
Rheumatism, fibrositis, backache	55 days	58 days
Percentage of all bed days	2.3	2.1
No. of patients affected	6	5
Infectious fevers	149 days	118 days
Percentage of all bed days	6.3	4.3
No. of patients affected	7	6
Pulmonary tuberculosis	0	310 days
Percentage of all bed days	0	11.3
No. of patients affected	0	2

Table VIII gives the time spent in bed with the principal groups of illness. It amplifies Table VII and shows that the average number of days during which a clinic patient was laid up was 4.9 and 4.1 respectively for the years 1954 and 1955. There was a slight predominance of illness in the females: this was more definite in the year 1955, in which the average duration of bed illness was 3.6 days for males and 4.5 for females. In this respect the findings agree with those of the general-practitioner survey recently published by the General Register Office (1956).

An analysis of the illnesses shows that those which predominate in the lives of diabetics are not the recognized complications of diabetes but the sort of illnesses prevalent in the general community of corresponding age, with some diabetic complications added. These latter account for only about one-seventh of all bed days.

The predominance of respiratory ailments in a group which includes a large percentage over 60 is not surprising.

The small figure for pulmonary tuberculosis emphasizes the comparative infrequency of this disease in the controlled diabetic to-day. The incidence of gall-bladder disease is certainly much higher than the figure given under this heading suggests. It could be assessed accurately only by radiological examination of a large number of diabetic patients. No figure is given for the incidence of hypoglycaemic reactions. These are very common, and it is probable that in the course of seven years nearly every patient has experienced hypoglycaemic symptoms. In an educated diabetic community, however, these seldom amount to much except in the brittle unstable diabetic, who constitutes a problem in every diabetic clinic.

The main figures showing the work of the district nurse for diabetics are set out in Table X. The principal information that emerges from this investigation is that the district

Total No. of district nurses involved	98
No. of diabetic patients in the area (estimated)	1,507
" " visited in 1954	228
Percentage of all diabetics visited	15.1
Total No. of general nursing visits to all sick patients in the area in 1954	135,468
Total No. of visits paid to diabetics	25,068
Percentage of total visits paid to diabetics	18.5
No. of visits per diabetic patient visited	110

No. dependent on district nurse for daily insulin	96
Percentage of all diabetics in the area	6.4

As already suggested, some of those whom the district nurse regards as dependent are not in fact given the daily injections by her. She may visit the patient on one day, give the injection, and leave a further dose ready for administration the next day by a member of the family or by the patient. The number of patients in whom insulin administration is a combined operation between nurse, patient, and family would appear to be considerable.

The amount of work done for diabetics in the area by general practitioners is set out in Table XI. A large number of general practitioners failed to answer this section of the

Females	275	1,267	4.6	1,356	4.9

There was wide variation in the amount of visiting and surgery attendance from patient to patient and from practice to practice. For example, one patient was returned as

In association with the figure of 49% of patients requiring some domiciliary visiting during the year by the general practitioner should be considered the figure from Table VII of 70 to 82% of patients having no days in bed. From this it seems clear that a large number of the doctors' visits are made to patients who are not confined to bed. The patient, for example, with an attack of bronchitis or a sore foot will stay indoors and send for the doctor, but he will often weather the illness in his armchair by the fire. Further

The last section of Table XI compares the attention given to male and female patients at home and at the doctor's surgery. It will be seen that while the male diabetic gets most of his attention at the doctor's surgery the female patient gets it mainly at home. This is no doubt related to the fact that men can more readily arrange to fit in surgery attendances on the way to and from work. It is, however, in contrast to experience at the clinics, where the tendency is for a better attendance of women than men in proportion to their overall numerical distribution.

What are the hospital requirements of diabetic patients? Why do they go there and how long do they stay? The answers to these questions were sought by inviting each of the 22 hospitals in the area to supply information regarding diabetic admissions during the year 1954-5 and by taking a census of diabetics in hospitals in the area on a day in November, 1955. Table XII shows the result of the first of these investigations. About 42% of those seeking admission to hospital did so for reasons not directly associated with the diabetes. This is not surprising in view of the findings for illness in the home. The diabetic picture is, however, more prominent in Table XII than in that of home illness (Table VIII). This is largely accounted for by the large number who have to come in for initial stabilization. The comparatively low incidence of respiratory ailments contrasts sharply with the high figure for illness in the home. This is in keeping with the general trend of medical care to-day, for the general practitioner can usually cope with such ailments even in the diabetic patient unless severe complications arise.

Diabetic Causes		Non-Diabetic Causes

		Other	10
			85

From a study of all the hospital figures it is possible to hazard a guess at the bed requirements for diabetics which may serve as a guide to those planning diabetic units. On

the basis of an average stay of 14 days a 15-bed unit in this area should be able to cope with approximately 300 admissions per annum, which is 73 in excess of the total admission figure for the area for the year 1954. Approximately three-fourths of the admissions were to medical wards, so that, given an even admission rate, 12 beds could deal with all medical admissions. There are, however, seasonal fluctuations, so that the actual range of bed occupancy for medical diabetics is from 5 to 18. There are also generally some patients waiting for admission. Taking all these factors into consideration, it seems reasonable to suggest a figure of one medical bed for every 100 of the diabetic population. The provision of a similar number of long-stay beds to cope with social and special clinical problems seems necessary.

Table XIII shows the cause of death, so far as can be ascertained, of 76 diabetics who have died in this area in the past three years. The figures were obtained partly from a follow-up of all diabetics who cease to attend the

TABLE XIII.—Recorded Causes of Death in 76 Diabetic Cases

clinics at Truro and Redruth and partly from a search of hospital records. It is believed that these are more accurate than those obtained from registration returns. Joslin *et al.* (1952) estimate that in the United States only about two-thirds of diabetics who die have their diabetes mentioned on the death certificate. It seems probable that the practice here is similar.

The figures in the third column provide a comparison with those derived from the Registrar-General's (1955) returns for Cornwall for the year 1954. It seems surprising that there is not a greater incidence of death from cardiovascular and renal disease in diabetics than in the general population. The series, however, is a small one, and it is possible that the figures might look substantially different if the investigation were extended for 10 years. The number of deaths from diabetic coma (seven in three years) is small, but could probably be further reduced with better liaison between hospital and general practitioner. In a concentrated urban area, with good hospital facilities for dealing with this emergency, deaths from diabetic coma might well be eliminated.

Table XIV shows the age at death of 129 cases (50 men and 79 women) for which this information was available. It is worth noting that the peak decade for deaths is the

TABLE XIV.—Age at Death of 129 Patients

Age:	0-39	40-49	50-59	60-69	70-79	Over 80

Women	2	1	16	32	26	2
Total	4	3	24	43	44	11

Average age at death: men, 68.9 years; women, 66.1 years.

eighth for men and seventh for women. The average age at death of the 50 men was 68.9 years and of the 79 women 66.1 years; for both sexes it was 67.1 years. The figure compares with that of 61.9 years given by Joslin *et al.* (1952) for 656 of their own patients. We are, however, dealing with an older population in West Cornwall, which may partly explain the high average age at death. It should be remembered also that the figures given are derived from a follow-up of clinic patients personally supervised: the

figures for the whole diabetic population would almost certainly be less favourable.

A study of registration figures for the administrative County of Cornwall for the year 1954 discloses the fact that 54% of male deaths and 67% of female deaths occurred at 70 or over. The corresponding figures in this diabetic series are 54% (male) and 35% (female). It appears, therefore, that diabetes as seen in Cornwall has a definite effect on the expectation of life in the female patient, but little or no effect on that of the male.

Summary

In a survey of diabetes in West Cornwall the incidence of the disease has been found to be 5.6 per 1,000 of the population. This figure is high in comparison with previously published figures for the country as a whole.

The sex distribution (3 female : 2 male) follows that of the country as a whole.

An attempt has been made to measure the load on the community by assessing the work done by general practitioners, district nurses, hospitals, and the patients' relatives and families.

A study of the age of onset shows a tendency for males to predominate up to age 40, with a striking excess of females in the sixth and seventh decades. There is a tendency for male predominance to reappear in old age.

Less than 50% of the patients present with the classical symptoms of thirst, polyuria, and weight loss.

Seventy-seven per cent. of the patients attend a general medical or diabetic clinic.

The problems of the home are mainly those of insulin administration and intercurrent illness: 80% of male and 62% of female diabetics requiring insulin administer it themselves.

For those unable to give their own insulin the wife usually provides the necessary assistance for the helpless husband; to the dependent female patient help is most often given by the daughter, district nurse, or husband.

More than three-fourths of the patients attending the clinics had no illness requiring rest in bed during the course of a year. The average number of days spent in bed with sickness was 4.9 in the year 1954 and 4.1 in 1955. The female patient tended to have rather more illness than the male. Respiratory illnesses predominated in the home. Diabetes and its complications were responsible for only 15.5% and 13.8% of all days in bed in the two years investigated.

The district nurse visits 15.1% of all diabetic patients in a year and is responsible for daily insulin administration in about 6.4% of all patients.

The general practitioner sees the average diabetic patient 10 times in the year. He is consulted by 91% at some time during the year. Home consultations predominate for women and surgery consultations for men.

The commonest reason for admission to hospital was initial stabilization: 42.5% of all admissions were for reasons not connected with the diabetes.

It is suggested that one medical bed for every 100 of the diabetic population is required in this area.

Cardiovascular disease was responsible for death in more than half of 79 patients followed up. The disease in Cornwall appears to affect the expectation of life in the female but not in the male. The age at death for both sexes was 67.1 years.

I am indebted to the 48 general practitioners who co-operated in this survey; to Miss A. White, who provided the information on the work of the district nurses; and to the hospital secretaries and matrons for figures of diabetic admissions.

APPENDIX : QUESTIONARY SENT TO G.P.s

Patient's initials.....
 Present age if known.....
 Sex.....
 Whether attending a clinic:
 (a) Diabetic clinic.....
 (b) General medical.....
 (c) Other.....
 Whether at present a hospital in-patient:
 (a) General medical ward.....
 (b) Chest hospital.....
 (c) Geriatric service.....
 (d) Mental hospital.....
 (e) Other.....
 If no hospital contacts, diagnosis based on:
 (a) Previous hospital investigations.....
 (b) Symptoms and urinary findings.....
 (c) Blood-sugar examination.....
 During 1954 how many visits did this patient require:
 (a) Home visits.....
 (b) Surgery attendances.....
 Is this patient at present having insulin?.....
 Number of list patients surveyed.....
 Number of diabetics found.....
 Private diabetic patients under your care.....

OUTBREAK OF STAPHYLOCOCCAL INFECTION IN A SURGICAL WARD

BY

R. A. SHOOTER, M.D.

J. D. GRIFFITHS, F.R.C.S.

JOSEPHINE COOK, M.B., D.C.H.

AND

R. E. O. WILLIAMS, M.D.

From the Departments of Bacteriology and Surgery and the Children's Department, St. Bartholomew's Hospital, and the Central Public Health Laboratory, Colindale

Outbreaks of staphylococcal infection in surgical wards are not very uncommon, but they are rarely recorded in print. This is partly because opportunities are not often available for extensive investigation, and in consequence the source of infection can rarely be traced. Nevertheless, the paucity of published records makes more difficult the study of new outbreaks as they occur.

It so happened that the outbreak described in this paper could be investigated in some detail, and, perhaps for this reason, we have been able to indicate a possible way in which infection may have been spread.

Clinical Features

The surgical unit concerned consisted of an operating theatre and a male and a female ward, each containing

25 beds. The wards were large and airy and the beds were spaced approximately 6 feet (1.8 m.) apart. Before May, 1956, sporadic cases of staphylococcal infection had occurred in both wards. On May 2 a wound-book was begun in order that a more reliable measure of the incidence of sepsis could be obtained. Against each patient's name was entered the name of the surgeon, details of the operation, and the condition of the patient's wound during convalescence. Wounds in which pus could be seen were regarded as septic; patients whose operations were through infected areas were excluded in assessing the sepsis rate.

Between May 2 and June 25, 86 clean operations were performed: three of the patients died post-operatively from causes unrelated to sepsis; of the remaining 83 patients, 24 developed sepsis in their wounds (Table I). Most of this

TABLE I.—Sepsis Developing in Clean Wounds, May 2 to June 25, 1956

sepsis was in the male ward, where 18 out of 43 patients became infected as compared with 6 out of 34 women. Six children brought from the children's unit in another part of the hospital to the operating theatre and returned after operation had no septic complications. *Staphylococcus pyogenes* was recovered in culture from 17 of the infected wounds. From two coliform bacilli were grown, and from five no swabs were taken.

Seven of the male patients developed staphylococcal infection of sites other than the operation wound, including five chest infections and three urinary infections. Finally, by June 25 three patients were found to have staphylococcal enteritis, and, because of this and the number of other infections, it was decided to stop operating, and the male ward was closed.

In addition, the male ward contained six patients operated on before May who, before or during May, became infected with staphylococci. Of these six, one had a pelvic abscess, two had infected wounds, two had urinary infections, and three had chest infections. One of these last patients developed an abscess involving most of the upper lobe of the left lung.

Staphylococci Responsible for Infection

The staphylococci isolated from infected wounds were all of a strain of *Staph. pyogenes* resistant to penicillin, streptomycin, and tetracycline, but at first sensitive to chloramphenicol and erythromycin. Later, as a result of treatment, variants resistant to chloramphenicol or erythromycin appeared. Twelve of the 17 staphylococci isolated from lesions were typed by the bacteriophage method and all were found to belong to one type, with the phage-sensitivity pattern 47/53/75/77. Some strains were lysed only by phages 53, 75, and 77, and some by 75 and 77 alone, but all were considered to belong to the same type. There was no correlation between these minor variations in phage-sensitivity pattern and the change in antibiotic sensitivity. Staphylococci that were not tested, but had the same sensitivity to antibiotics, were considered to belong to the same type in view of our failure at that time to find any strain with the same characteristics but belonging to a different phage type. With one exception, all the staphylococci isolated from patients with infective complications belonged to the epidemic type.

In the case of enteritis, chest infection, and urinary infection the staphylococci were plainly acquired in the ward. The source of the staphylococci infecting the wounds was not so clear. The majority of infections were thought on clinical grounds to be theatre infections, an early rise in temperature and pus developing deep in the wound being the main criteria.

Staphylococci in the Operating Theatre

In a report of post-operative wound infection occurring in another unit in this hospital (Shooter, Taylor, Ellis, and Ross, 1956) the opinion was expressed that infection originated from air-borne organisms sucked into the theatre from adjacent wards. There seemed less reason to incriminate air in this case.

There was some suction of air into the theatre from the corridor outside, but this was less than in the unit described before, and the total bacterial air counts in the theatre were substantially lower. Search for staphylococci in the theatre air showed a variety of types to be present. On May 30 50 cu. ft. (1.416 cubic metres) was sampled, and six staphylococcal colonies were recovered, five of which belonged to the epidemic type. Examination of 50 cu. ft. (1.416 cubic metres) of air on June 6 yielded three staphylococcal colonies, none of the epidemic type, and a further examination of 540 cu. ft. (15.29 cubic metres) of air on June 20 yielded 26 staphylococcal colonies, only 2 of the 25 typed being of the epidemic type.

Altogether the 35 staphylococci isolated included 15 different phage types. If the wound infections had been chiefly due to air-borne bacteria the staphylococci cultivated might have been expected to reflect the diversity of types present in the theatre air. The fact that they did not suggested some other source of infection.

A clue to this source was given by the examination of nasal swabs from the theatre team. Swabs were taken from 17 members of the team, including surgeons, nurses, students, and the orderly, and from seven of these swabs *Staph. pyogenes* was recovered. From only one person, however, were staphylococci of the epidemic type isolated. Examination of this individual's movements strongly suggested that he was concerned with infection of the wounds. Of the 45 operations in which he took part 21 resulted in infection. On the other hand, of the 38 patients operated on in his absence, only three became infected, and of these one was infected with coliform bacilli, and the other two may have been ward infections. Furthermore, he had been on leave from May 14 to 27, and during this time, with the exception of the wound infection due to *Bacterium coli*, no patients operated on developed septic wounds.

The surgical members of the unit worked as two teams, and it was possible that infection was the result of some difference in technique or came from some other person. This appeared improbable in view of the failure to detect any other carrier of the appropriate staphylococcus, and was not supported by a more detailed analysis of the wound-book. The team to which the carrier did not belong carried out 29 operations, three of which were followed by sepsis. The other team, with the carrier, performed 54 operations, and 21 of these patients developed infected wounds. However, of these 54 operations, 40 were done in the carrier's presence, and 20 of the 21 infections came in this group. Of the 14 patients operated on in his absence, only one became infected, and that infection was due to *Bact. coli*.

On three occasions the carrier was examined after he had been wearing rubber gloves; his hands were moist, and staphylococci of the epidemic type could be recovered from the fingers and the insides of the gloves. The same finding was recorded after preliminary washing of the hands with soap and water and a scrubbing-brush. In two of these experiments he was dressed in clean surgical uniform and incarcerated in a sterile room for 10 minutes. On neither occasion were staphylococci of the epidemic type

recovered from the air. Such staphylococci were, however, isolated from the air when he was shut in the room in his ordinary clothes. The carrier yielded a heavy growth of staphylococci from his nose on all the occasions on which he was examined; his faeces also yielded numerous staphylococci of the same type.

Staphylococci in the Wards

During this investigation there was less wound sepsis in the female ward than in the male ward, only 6 women out of 34 developing septic wounds, as compared with 18 out of 43 men. There was still, however, a suggestion that the carrier in the theatre was concerned, since of the 15 operations on female patients which he attended four were followed by sepsis, whereas of the 18 when he was absent only two wounds were infected, and in one of these the cause was *Bact. coli* and the other was almost certainly a ward infection. The patients in the female ward were also free from staphylococcal complications.

In the male ward *Staph. pyogenes* was carried in the nose by 7 out of 10 nurses, but only one of the strains was found to be of the epidemic type. This nurse, and the carrier from the surgical team, constituted a source of infection in the ward, but a very much more prolific source was provided by the patients themselves. This applied particularly to the patient with an extensive lung abscess who was present in April and throughout May. During most of the period this elderly man was producing copious sputum which despite treatment contained very large numbers of staphylococci.

Air samples were taken in the ward on May 10, 11, 18, and 22, and June 13 (Table II). In the first samples, other strains besides the epidemic strain were present, but by May 18 the epidemic type was predominant, and it remained so.

TABLE II.—*Staph. pyogenes* in Air Samples Taken in the Male Ward, May 10 to June 13, 1956

June 13	450	13.00	623*	22/22

* Estimated number on phenylphthalein phosphate plates: coagulase tests done on 158.

In all the samples counts of general bacteria ranged between 19 and 51 colonies per cubic foot (0.028 cubic metre) of air.

Air collected on June 17 in the corridor joining the male and female wards to the operating theatre showed *Staph. pyogenes* to be present. Of 26 strains tested, 10 belonged to the epidemic type.

Further evidence of the large number of staphylococci present in the male ward was given by examination on June 27 of blankets from three patients with staphylococcal enteritis and of eight of the bed curtains. Both blankets and curtains were tested by the sweep-plate technique (see Blowers, Potter, and Wallace, 1955), and all were found to be heavily infected. Of the many staphylococci recovered, 28 were typed, and all but one were of the epidemic strain.

Closure and Cleaning

In view of the sepsis rate and the simultaneous onset of staphylococcal enteritis in three patients, it was decided on June 28 to cease operating, and to clean and, if possible, disinfect the male ward. All the patients were therefore removed, either by discharge or by transfer to isolation in other parts of the hospital. Movable articles in the ward were disinfected by boiling, treating with formalin vapour, or spraying with sodium hypochlorite solution as seemed

most appropriate. The ward itself was most vigorously cleaned by spraying from ceiling to floor with a power-driven spray of sodium hypochlorite solution (0.17%).

No such steps were taken in the female ward. This was partly because of the better record of the ward, and partly because the result of examination of the air on June 27 was reassuring. Altogether 375 cu. ft. (10.62 cubic metres) of air was examined, and, although 16 colonies of *Staph. pyogenes* were isolated, none belonged to the epidemic type. General bacterial counts were also low, averaging 6.6 per cu. ft. (0.028 cubic metre). The decision not to close this ward was justified by the fact that none of the 39 patients operated on before the unit finally closed on August 22 for redecoration developed sepsis due to *Staph. pyogenes*.

Opening of the Male Ward

During the cleaning of the ward the carrier in the surgical team and the nurse who carried the epidemic staphylococcus left the unit. The ward was opened on July 3 and stayed open until August 22. At first, examination showed a great reduction of the staphylococcal and general bacterial population. For example, the count for the latter ranged between 5 and 10 colonies per cu. ft. (0.028 cubic metre) of air on July 3 and 4. Sweep-plates taken from 10 blankets on July 3 and 4 failed to grow any staphylococci. As the ward was reoccupied bacterial counts rose, and the results of sampling for general bacteria in the air showed a steady climb to a maintained level—approximately 16 colonies per cu. ft. (0.028 cubic metre). This climb was accompanied by an increase in the staphylococci in the ward air (Table III), and a return of the epidemic type.

TABLE III.—Colonies of *Staph. pyogenes* Recovered from the Air of the Male Ward After Cleaning

" 14	75	2.12	29*	

* Includes 18 colonies from 5 cu. ft. (0.14 cu. m.) when a bed was being made.

There was again little to suggest that the staff were chiefly responsible. Nasal swabs taken from 34 members of the unit on August 9, 10, and 11 failed to yield any staphylococci of the epidemic type.

At first the return of staphylococci to the surgical ward was not accompanied by infection. This freedom was, however, only temporary, and infections occurred on July 27 and August 2, 4, and 7. Two of these—an infection around an indwelling catheter and a septic wound—were caused by the type of staphylococcus previously present in the ward. The other two, an enteritis and a wound infection, were due to a staphylococcus of different type. During this time 47 men underwent clean operations.

On August 22 the ward was closed for painting, which had been previously arranged.

Discussion

Outbreaks of staphylococcal infection have been attributed to a variety of sources. Wells and Wells (1936, 1938) and Hart (1937) suggested the possibility of air-borne infection during operations, and, more recently, Blowers, Mason, Wallace and Walton (1955) and Shooter *et al.* (1956) described wound infections which they thought were due to staphylococci from the air of the operating theatre.

In other cases infection was apparently transmitted to the patients by a single carrier, as in the outbreak described by Devenish and Miles (1939). They drew attention to the frequency with which surgical gloves are punctured at operation, and suggested that infection might be caused by staphylococci squeezed through perforations in the gloves.

A third mode of transmission, recorded more for streptococcal than for staphylococcal infection, is from case to case at the time of wound dressing by way of contaminated fingers and instruments (for example, Miles *et al.*, 1940).

In the present outbreak there seemed little doubt that a proportion of the wounds were infected at the time of operation, and glove punctures may well have been the way in which the carrier in the surgical team infected patients, as normally about a third of the gloves worn by members of the surgical staff of the hospital are found to have perforations after use. In retrospect, direct proof is unobtainable, and the possibility that staphylococci from the carrier found their way into the wound by some other route cannot be excluded.

Though in our opinion there seemed to be good grounds for suspecting that the theatre infections originated from a single person, the position in the ward was considerably more complex. The key to the situation seemed to be the great ability of the epidemic staphylococcus to colonize wounds and lungs and other sites. No reliable method exists for testing in the laboratory the disease-producing potentialities of strains of *Staph. pyogenes*, but there is no doubt that some strains are in fact able to spread more readily than others and are more able to cause infection. Our strain showed considerable versatility in the way in which it caused a variety of infections and while the patients were under treatment became resistant to chloramphenicol or erythromycin. It seemed also to be able to establish itself to the exclusion of other strains of staphylococci which had been present earlier. In consequence, not only was it the only strain to be recovered from wounds by mid-May, but it became increasingly preponderant in the ward air (Table II) and was practically the only strain to be recovered from the ward curtains on June 27.

Some of the ward infections may have originated from the male carrier or the nurse, but these two individuals are less likely to have been the cause of some of the other complications; for instance, chest infections or enteritis. Compared with the patients, the carriers must have contributed only a small proportion of the staphylococci present in the ward, and it is tempting to suggest that the start of the epidemic was the elderly patient with the lung abscess. Once established, new victims maintained the staphylococcal strain. To what extent the extensive spread of the staphylococcus should be attributed to inherent properties and to what extent to the efficiency with which two or more particular carriers were able to spread it must remain unknown.

During this epidemic we were able to examine the air for general bacteria and for staphylococci. General air counts appear to reflect largely the activities of the ward and are not necessarily linked with infection. It is misleading to use them alone as a gauge of the effectiveness of measures designed to prevent the spread of infection. Staphylococcal air counts, on the other hand, particularly when phage-typing is available, may be of more help. We used low counts and the absence of the epidemic type in deciding to keep the female ward open, and when more is known it may be possible to estimate the risk of infection in a ward from the number of pathogenic staphylococci present in the environment, and the extent to which they belong to one phage type known to be responsible for infection. Whether this is so or not must depend, of course, largely on whether the staphylococci are actually transmitted to the patients through the air. Further surveys similar to ours are needed to discover whether high air counts precede the transfer of infection or whether they merely reflect transfer that has already happened by other routes.

Another unanswered question in our survey is why the female ward enjoyed its relative freedom from infection. Women are known to be less liable to post-operative chest infection than men, and during this period there was no patient in the female ward disseminating large numbers of staphylococci. Even so, the absence of the epidemic type

in the air collected on June 27 was surprising, and, taken in conjunction with the low general bacterial count, may represent some other factor such as the effect of differences in light or ventilation which we have not recognized.

Finally, the measures taken to disinfect the male ward appear to have been successful in that for a time they eliminated staphylococci and reduced the incidence of infection. From the information available, it is not possible to tell if the epidemic strain of *Staph. pyogenes* was brought back to the ward by a member of the staff from some other part of the hospital, or was brought in by a patient, or came from some unsuspected hiding-place which had escaped disinfection. This staphylococcus had been isolated from time to time in other parts of the hospital.

Summary

During a period of nine weeks, 24 of 83 patients undergoing clean operations in one surgical unit developed wound sepsis and seven developed other staphylococcal infections. All but one of the staphylococci tested from the wounds and other lesions belonged to one phage type.

In many cases wound sepsis seemed to follow infection acquired in the operating theatre, and there was strong evidence implicating one of the members of the surgical team in these infections.

Some cases of wound infection and most of the other infections seemed to have been acquired in the ward. It is suggested that one patient, who had a staphylococcal lung abscess, may have been responsible for widespread dissemination. The epidemic type was found in large numbers in the air and on bedclothes, curtains, etc.; it was carried by only one member of the nursing staff.

We are greatly indebted to Dr. Radmila Skalova, of the Medical Faculty of the University of Zagreb, Yugoslavia, who, while working with a British Council bursary at the Central Public Health Laboratory, gave much assistance with the bacteriological air sampling.

The latest *Life Tables* volume of the Registrar-General's *Decennial Supplement for England and Wales, 1951* (H.M.S.O., 3s.), is based on the 1951 census populations and on the mortality experience in England and Wales as a whole during the three years 1950-2. It shows that the expectation of life of a boy at birth has increased by nearly 15 years in the past 40 years; for a girl the increase is more than 16 years. These increases are largely the result of the immense improvement in infant mortality. In 1910-12 120 of every 1,000 boys born and 98 of every 1,000 girls born died before reaching their first birthday; the corresponding figures for 1950-2 were 33 boys and 25 girls. Women have fared better than men in the improvement of longevity. While for women there has been a continued substantial lightening of mortality even beyond the age of 80, for men the improvement has been much less. For men aged 60 the expectation on 1950-2 mortality is about 14½ years, an increase of only three-eighths of a year on the figure 20 years earlier, whereas for women of that age it is 18 years, an increase of 1½ years. Persons living in England have a higher expectation of life than those living in Scotland or Wales. The rural districts show mortality lighter than the national average. Alone of all the major conurbations Greater London experienced lighter mortality than England and Wales as a whole.

CLINICAL AND LABORATORY ASSESSMENTS OF SENNA PREPARATIONS

The use of standard British pharmacopoeial preparations of senna implicitly assumes that all such preparations will have, for the same dosage, similar laxative effects, and that, subject to individual variation, like effects will be consistently produced by the same dose of the same preparation at different times.

Work directed by one of us (J.W.F.) led to the development of a reliable bioassay procedure, using mice as the test animal (Lou, 1949); and the indications of laxative potency given by this method agree closely with those derived from a physico-chemical method of assay which determines the amount of the glycosides, sennosides A and B, present in different senna preparations (Fairbairn and Michaels, 1950). When applied to standard preparations of senna both these laboratory assay methods strongly suggest that senna pods and different samples of the B.P. liquid extract vary widely in potency: indeed, some of the extracts appear to be virtually inert. Further, B.P. liquid extract of senna appears to lose potency when kept over a period of time (Fairbairn and Saleh, 1953).

These indications, however, are based on laboratory techniques and need not necessarily apply in clinical practice. Although American workers (Miller and Alexander, 1949) have shown that bioassay results agree with laxative effects in humans, their subjects were normal (unconstipated) individuals. We here describe controlled clinical trials designed to measure the relative laxative potency of various B.P. senna preparations in constipated patients in hospital practice and to compare clinical results with the findings of chemical and biological assay. At the same time we have included in the trial a new granular type of senna preparation ("senokot"), for which total retention of the activity of the crude drug, consistency, and stability of potency are claimed (Ryan, 1951). Its laxative efficiency has been favourably assessed by several workers (*Brit. Ency. med. Pract.*, 1956), but no rigorously controlled observations have been reported.

Trial Design

Stage I

In the first stage of the trial, doses of the various senna preparations within the usually prescribed range were given to two groups of patients complaining of constipation; one group comprised expectant mothers in the obstetric wards of a general hospital—that is, "short-stay" patients—the other consisted of patients of both sexes in wards containing some elderly chronic sick—that is, "long-stay" patients. Four preparations were used at two dosage levels. The first levels, representing the average of the B.P. dosage range for the syrups and its approximate equivalent for senokot, were:

- *1. Syrup of senna B.P. (A) 5 ml. (made from 1.25 g. senna pod)
- *2. Syrup of senna B.P. (B) 5 ml. { " " 0.9† g. " " }
3. Senokot granules " 6 g. { " " 0.9† g. " " }
4. Blank syrup (taste and appearance similar to the B.P. syrup of senna).

One dose of each preparation was measured into glass containers. These were numbered in random order and used as required, in that order, in the wards. Any one patient received only one dose. The patient, the physician, and the sister-in-charge did not know the chemical or biochemical activity of the preparations which had been administered. A time limit of 24 hours was given for a bowel action to result. If none was produced, another type of laxative was given. The results of the administration of the senna preparations under trial were recorded on standard forms according to the time, type (full, scanty, or fluid), and frequency of motions.

The second dosage levels for the two syrups were increased by 40% above the first to 7 ml.—that is, approximately the maximum B.P. doses. To avoid drastic purging the dose of senokot was increased by only 25% to 7.5 g.

In the trials at these higher levels the trial procedure was repeated, but the inactive control preparation used was a chocolate granule containing no senna but otherwise indistinguishable from senokot.

Stage II

In the second stage of these trials the design was rather different. To minimize the effect of individual differences in response to laxatives, and to balance the effects of order of administration, each of the four preparations was administered in turn to elderly patients suffering from severe chronic constipation. A latin square type of design ensured that, within each set of four patients, each type of preparation was given once to each patient and once in each order from first to fourth (Table I).

TABLE I.—Order of Administration of Preparations

Patient	1st	2nd	3rd	4th
1	Syrup A	Syrup B	Senokot	Inert granules
2	" B	Inert granules	Syrup A	Senokot
3	Senokot	Syrup A	Inert granules	" A
4	Inert granules	Senokot	Syrup B	" B

Half the patients were given doses at the average levels already indicated, half were given the higher dosages. Inert granules were used as controls throughout this stage. Otherwise the procedure was as before. If, however, no bowel action resulted after at least 24 hours, another type of aperient (not one of those under trial) was given and the trial resumed when the patient next complained of constipation.

To ensure that the dosage of the preparations being clinically assessed had a consistent sennoside content throughout the trials, the same samples of the three preparations were reassayed chemically before the second stage

*The strongest and the weakest (on the basis of chemical and animal assay) of a number of different commercial samples of B.P. syrup of senna examined for this investigation.

†Reduced from 1.25 g. for the syrups owing to the anticipated higher laxative potency of senokot.

TABLE II.—Chemical Reassays of Senna Preparations

Preparation	Mg. Sennoside Content/Aliquot		
	1953	1955	Loss %
Syrup of senna B	0.3	Traces	100
" " A	2.8	1.9	33
Senokot	4.7	5.0	0

began. The results seen in Table II show the changes in sennoside content which had taken place. The apparent loss in potency by one-third noted in one of the B.P. syrups was then compensated for by increasing the average dose from 5 ml. to 7 ml., and the maximum dose from 7 ml. to 9.5 ml. The small sennoside content of the other B.P. syrups had virtually disappeared and no such compensation was practicable. Since the chemical content of senokot showed no loss, the dosage was left unchanged.

Summary of Results

In a preliminary analysis of the results two criteria of clinical potency were used: (1) The percentage of "satisfactory" results—that is, one or more full motions produced within the time limit. Motions described as scanty or otherwise unsatisfactory by the patient were ignored. (2) The total number of motions produced within the time limit without regard to the patient's subjective report.

TABLE III.—Response to Control Preparations

Type of Control	Type of Patient							
	Short-stay				Long-stay			
	No. of Cases	Criteria			No. of Cases	Criteria		
		1	2			1	2	
Syrup	19	42%	1.3	13	23%	0.8	32	33%
Granules	16	63%	0.9	15	53%	0.6	31	58%
Mean	35	53%	1.1	28	38%	0.7	63	46%

Criterion 1: Satisfactory. Criterion 2: Number of motions per patient in 24 hours.

In Table III are compared the results, using each criterion, of the effects of the control substances during stage I in the two groups of patients. The difference in response rates between the two types of clinical case is in line with expectation. The large subjective element in the first criterion is evident in the increase in response achieved simply by substituting the more elegant and novel but inert granular preparation for the syrup type of control. On the other hand, the second criterion shows a satisfactory consistency between the two inert preparations. Partly for this reason and partly because the bioassay method on mice depends on counting the number of extra or fluid motions produced, this second criterion has been used throughout. To match the bioassay technique more closely and to minimize any differences between wards, the final result is expressed as a percentage increase in the number of motions produced by a particular senna preparation over the number produced in the same trial group by the inert control.

Table IV shows the results obtained in the first stage of the trial. As already seen, the response rate is greater among the short-stay patients, but the general trend of the results is similar in the two groups: in total, only the higher doses of one of the B.P. syrups and both doses of senokot produce a laxative effect which is appreciably better than the corresponding inert controls.

In the alternative trial design the individual variation is minimal, but the chronically constipated patient gives a less marked response to laxatives. Table V shows that in these circumstances again only the high doses of one syrup (syrup A) and both dosages of senokot effect any marked rise above the control level. An analysis of variance showed that these results were unlikely to be fortuitous ($P < 0.01$).

It is clear that there are appreciable differences in laxative potency between the various preparations used; it

remains to decide whether these clinical indices agree with the results of chemical and biological assay. Table VI sets out the laboratory and clinical assay results for each preparation arranged in order of the potency as estimated by bioassay. The close correlation between chemical and biological assay methods is obvious. More striking, however, is the relationship seen in Figs. 1 and 2 between chemical

TABLE IV.—Clinical Response to Different Senna Preparations in Different Patients (Mean Number of Motions in 24 Hours)

Preparation	Short Stay			Long Stay			Total Unweighted Mean Control

* Number of patients. † Mean number of motions per patient.

TABLE V.—Clinical Response to Different Preparations in Same Patients (Mean Number of Motions in 24 Hours)*

Preparation	Average Dosage		Maximum Dosage	
	Mean No.	Control	Mean No.	Control
Granule control	0.7	100%	0.4	100%
Syr. senna B	0.7	100%	0.6	150%
" " A	0.6	86%	0.8	200%
Senokot	1.4	200%	1.2	300%

* 16 patients in each dosage group.

TABLE VI.—Correlation of Chemical, Biological, and Clinical Assay Results

Preparations	Mg. Sennosides Dose		Control Response	
	Chemical Assay	Bio-assay*	Different Patients	Same Patients
Syr. senna B (av. dose)	1.3	2.0	71%	100%
" " B (max. ")	1.8	2.8	87%	150%
" " A (av. ")	13.8	22.1	98%	86%
" " A (max. ")	17.5	30.9	164%	200%
Senokot (av. dose)	29.0	51.0	169%	200%
" (max. ")	36.0	65.0	214%	300%

* The bioassay figure is always higher than the chemical assay figure, since the sennoside A and B content represents only about two-thirds of the total biological activity (Fairbairn and Saleh, 1951).

FIG. 1.—Stage I. Clinical and chemical assay results (in different patients).

assay results and clinical response rates where preparations are tested both separately on different patients and serially on the same patient. In the type of patient included in this trial no perceptible rise in clinical response above the control level of 100% occurs consistently with sennoside contents below about 15 mg. per dose.

FIG. 2.—Stage II. Clinical and chemical assay results (in same patient).

Discussion

These clinical trials show how, by careful design and conduct, results of practical value can be simply attained with the use of crude criteria in a relatively minor but important ailment. The nature of the control preparation may be crucial when more subjective patient responses are involved. Changing the inert preparations from syrup to granules can produce a rise in the proportion of "satisfactory" responses from 33 to 58%. It seems better to minimize these psychological influences by using simple objective criteria such as the number of stools produced within 24 hours. For the group of short-stay hospital patients comparisons of preparations allocated separately and at random to different patients will give essentially the same indications as trials where individual variation in response is minimized by serial administration of drugs, in a balanced and randomized design, to the chronically ill.

The analysis of variance set out in Table VII suggests that while order of presentation is unimportant compared with the random variability in response of the same patient

TABLE VII.—Analysis of Variance of Response Rates in Trials on Same Patients (Maximum Dose)

Sources of Variation	Sum of Squares	Degrees of Freedom	Mean Square	Variance Ratio
Difference due to treatments	4.92	3	1.64	4.56*
Personal differences	18.23	15	1.22	3.39*
Order of presentation	1.17	3	0.39	1.08
Random within-person variability	15.16	42	0.36	
Total	39.48	63		

* P. 0.01.

at different times, personal differences in responsiveness are of some account in trial design. This implies that the serial type of trial which minimizes these personal differences is, for this type of patient at least, the more effective test procedure. On the other hand, the greater responsiveness of the younger "short-stay" patient makes such cases more sensitive indicators of differing laxative potencies. Choice of method in clinical trials of laxatives can thus be decided simply on the basis of the number and type of clinical cases

available. Either method will indicate the clinically effective dosage range for the particular type of patient included in the trial.

Of particular importance is the introduction of chemical and biological methods of potency assay where results can be used to grade senna preparations in terms of their likely effect on the constipated bowel in humans.

We would emphasize the agreement between the various forms of assessment, laboratory and clinical, in indicating gross disparities between similar doses of apparently identical standard B.P. syrups. The laboratory tests confirm earlier suggestions of the serious deterioration which may take place in such aqueous preparations. Again, average doses of the two B.P. syrups tested clinically gave no better results than inert syrups. On the other hand, the dry granular preparation tested (senokot) proved to be chemically stable and to have the potent clinical effect which had been predicted from the results of both chemical and biological assay.

Summary and Conclusions

The design and conduct of controlled clinical trials of the therapeutic effect of different senna preparations are described. The results obtained in constipated patients of different clinical types have been compared with the potencies estimated from chemical assay of sennoside content and biological assay based on the laxative action in mice. It was concluded that: (1) Laxatives could be effectively graded by simple clinical trials in both short-stay hospital patients and the more chronically constipated elderly sick. (2) Clinical response rates are in general agreement with the results of both types of laboratory assay methods. Not only do apparently identical B.P. preparations of syrup of senna differ widely in their therapeutic effect, but, at average doses, the B.P. syrups tested were no better than inert controls. Chemical assay confirmed previous indications of deterioration in aqueous B.P. preparations. (3) A dry granular preparation of senna pod (senokot), used in dosages usually prescribed, proved to be chemically stable and to have a potent laxative effect.

We should like to thank the sisters in charge of the wards concerned, Sisters Anderson, Ronaldson, Cawthorn, and East, for their conduct of this trial, and we are indebted to Westminster Laboratories Ltd. for supplies of senokot and the specially prepared inert granules.

Speaking at the Royal Institution in London on February 15, Dr. MARGARET MEAD discussed factors in social evolution. Borrowing, either of isolated traits or of whole patterns of behaviour, was one of the essential mechanisms of human evolution, she said. In 1928-9 she had carried out an anthropological study of a Melanesian village in the Admiralty Islands, and had repeated the study 25 years later. In this time the villagers had established a small "distinctive" with imitation of Western democratic Christian society, with ideas drawn from Christianity, British administration, and the American expeditionary forces. Contact in childhood with adults who were perceived as being of the same order as the children—in this case, their own parents—and dissatisfaction among the adults with the state of their culture, seemed to have been two preconditions of this change. This state of affairs could be contrasted with treating children as lower or imperfect human beings, rearing them with the help of another class such as nurses or teachers, or letting older children or grandparents bring them up.

STANDARDIZED SENNA AS A LAXATIVE IN THE PUERPERIUM A CLINICAL ASSESSMENT

BY

A. S. DUNCAN, D.S.C., F.R.C.S.Ed., F.R.C.O.G.
Professor of Obstetrics and Gynaecology, Welsh National School of Medicine

For many years senna has been regarded as a safe laxative for pregnant and puerperal women. Variability in efficacy from case to case led to diminished use of the drug until in recent years a standardized preparation became available. For this preparation, marketed under the name "senokot," stability and consistency of potency are claimed (Ryan, 1951). A number of favourable reports have now been published (*British Encyclopaedia of Medical Practice*, 1956) and a preliminary trial suggested that senokot might be suitable for use as a routine laxative for puerperal women (Duncan, 1953). In this further clinical trial the laxative effect of cascara and senokot are compared.

Spontaneous Bowel Movement.—As a preliminary step 100 consecutive puerperal women (32 primiparae and 68 multiparae) were observed with regard to spontaneous bowel movement. No laxative was given. The findings are shown in Table I.

TABLE I.—Bowel Movement After Delivery in 100 Cases

	No. of Patients
First spontaneous action on 2nd day	4
" " " 3rd "	22
" " " 4th "	30
" " " 5th "	15
" " " 6th "	4
" " " 7th "	1
" " " 8th "	1
Enema required	23

Design of the Trial

All patients in puerperal ward A were given, as a routine laxative, tab. extract cascara B.P., 6 gr. (0.4 g.), on the morning of the third puerperal day. No further laxative or enema was given for 48 hours.

In puerperal ward B exactly the same routine was followed except that the laxative used was "senokot" granules, 2 teaspoonfuls (equivalent to 11 gr. (0.7 g.) of senna pod). Patients who had been delivered by the abdominal route and 12 patients whose bowels moved spontaneously before the third morning were excluded from the trial. No other exceptions were made.

The interval between administration and bowel movement, and the nature of the first motion, were recorded. The patients whose bowels moved within 24 hours of the dose were regarded as having shown a positive response, and in these the number of bowel movements within the period was noted. These objective observations were made by senior members of the nursing staff. Subjective impressions, such as the severity of colic, were more difficult to assess.

Comparison of the Two Groups

The fact that the two groups are comparable in respect of parity, nature of delivery, and previous history in relation to aperients is shown by Table II.

TABLE II

	Cascara Series		Senokot Series	
	Multip.	Primip.	Multip.	Primip.
Spontaneous delivery without tear	78	14	74	21
Episiotomy, forceps, or tear	21	29	22	31
Total	99	43	96	52

Of the cascara series 37 patients had been in the habit of taking aperients before pregnancy, and a total of 58 had taken aperients during the pregnancy. Of the senokot series 29 patients had been in the habit of taking aperients before pregnancy and a total of 56 had taken aperients during the pregnancy.

Results

The results of the trial are summarized in Tables III-V.

TABLE III.—Response to the Laxative

	No. of Patients

" " " " 12 " 24 "	35	21
Total positive response within 24 hours	80 (56.3%)*	128 (86.5%)*
No response within 24 hours	61	19
Time of response not recorded	1	1
Total No. in trial	142	148

* $P < 0.01$.

TABLE IV.—Nature of Motions in Patients Showing a Positive Response Within 24 Hours

Nature of First Motion	No. of Patients	
	Cascara Series	Senokot Series
Normal	29 (36.25%)	60 (46.9%)
Loose	23 (28.75%)	39 (30.5%)
Watery	3 (3.75%)	16 (12.5%)
Constipated	23 (28.75%)	10 (7.8%)
Not recorded	2	3
Total (positive response)	80	128

TABLE V.—Number of Motions Within 24 Hours of Taking the Laxative

	Cascara Series	Senokot Series
Patients having 1 motion	67	86
" " 2 motions	9	23
" " 3 " "	2	9
" " 4 or more motions	2	10
Total (positive response)	80	128

Resumption of Normal Bowel Habit.—After initial bowel movement 52 of the cascara series and 32 of the senokot series required further aperients or an enema during the puerperium. This is not regarded as significant, because 37 of the cascara series and 29 of the senokot series had been in the habit of taking laxatives regularly even before pregnancy.

Incidence of Gripes.—Of patients who had a positive response within 24 hours, 10 (12.5%) in the cascara series and 22 (17.2%) in the senokot series experienced gripes.

Lactation.—No difference in lactation performance was observed between the two groups. There was no evidence that either laxative had an adverse effect on lactation. Illingworth (1953) suggested that babies may develop diarrhoea when receiving milk from mothers taking senna or cascara. Experimental evidence (Tyson *et al.*, 1937; Friebe and Walkowiak, 1951) shows that senna glycosides do not appear in maternal milk. Certainly in this small series there was no instance of diarrhoea amongst the babies.

Previous History in Relation to Laxatives

For the purpose of comparison of the two groups in the trial a detailed history of the previous use of laxatives was taken. The results of this inquiry are presented as they give an indication of the habits in relation to laxatives in a small sample of married women.

Of the 95 primigravidae, 23 took laxatives regularly before they became pregnant. The drugs used were liquid paraffin in 5 cases, cascara in 5, salts in 4, doctor's prescription in 2, and various (1 each) in 7. During pregnancy a total of 39 primigravidae took laxatives regularly.

Of the 195 multiparae, 43 took laxatives regularly before the present pregnancy. The drugs used were liquid paraffin in 12, cascara in 9, "agarol" in 7, various in 15. During pregnancy 75 of the multiparae took laxatives regularly.

In view of the evidence that liquid paraffin prevents absorption of fat-soluble vitamins it is interesting to note that 43 of the 290 women studied took liquid paraffin regularly during the pregnancies.

Discussion

In the preliminary study it was found that 56 out of 100 patients had spontaneous bowel movements by the end of the fourth puerperal day. The positive-response rate in the cascara series (56.3%) shows no improvement on this. In the senokot series the positive-response rate was 86.5%, and this difference is statistically significant. In these positive-response groups a higher proportion of the senokot series had normal motions (46.9% compared with 36.25%), but also a higher proportion had loose or watery motions (43% compared with 32.5%). On these findings it is clear that with the dosage used senokot was a more effective laxative than cascara. The question arises whether this greater effect was merely a matter of size of dose. The pharmacopoeial dose of tab. extract cascara B.P. is 2-8 gr. (0.13-0.5 g.) (the dose used was 6 gr. (0.4 g.), which is three-quarters of the maximum B.P. dose) and of senna pod B.P. is 10-30 gr. (0.65-2 g.) (the dose used was equivalent to 11 gr. (0.7 g.), which is one-third of the maximum B.P. dose). The laxative effect should therefore have been greater rather than less in the cascara series. The reason for this discrepancy appears to lie in the fact that tab. extract cascara B.P. is unstandardized and contains only part of the original activity of the bark (Fairbairn and Mahran, 1953), whereas senokot is standardized and contains 100% activity of senna pod (Fairbairn and Michaels, 1950). A further point of practical importance is that for a fully active preparation such as senokot the upper limit of dosage for senna pod B.P. (30 gr.—2 g.) may be too high.

No untoward side-effects of the laxatives were noticed apart from gripes. The fact that a higher proportion of the senokot series had gripes is thought to be due to over-dosage, because for the purpose of the trial it was necessary to give the same dose to all patients. Further experience with senokot has shown that an occasional patient experiences severe gripes in spite of smaller dosage, but this has been so infrequent that it has not detracted from the advantages of the drug. The majority of patients expressed the opinion that they preferred senokot to other laxatives which they had used in the past. This might be attributed to the novel form of the preparation in chocolate-flavoured granules. Senokot is also available, however, in tablet form, and a further series of 138 patients was studied under the same trial conditions with the exception that granules were replaced by tablets. The results of this further trial are so similar to those reported above that they are not given in detail. More than half of these patients said that they preferred senna to other laxatives they had used.

The continued use of senokot since the trial was completed has confirmed that it is a very satisfactory laxative for puerperal women. Its value during pregnancy is much more difficult to subject to a clinical trial, but it seems very satisfactory for this purpose. A few patients complaining of severe morning sickness have improved dramatically following regular administration of senokot. The question whether senna is more effective in this respect than other laxatives will require further study.

Summary

In a series of 100 puerperal women who were given no laxative in the puerperium only 26 had spontaneous bowel movements by the end of the third day, but 71 had had spontaneous motions by the end of the fifth puerperal day.

In a clinical trial, extract of cascara in a dose of 6 gr. (0.4 g.) (three-quarters of the pharmacopoeial maximum) was compared with a standardized preparation of senna in a dose of 11 gr. (0.7 g.) (one-third of the pharmacopoeial maximum). With the dosages used the senna ("senokot") was shown to be a more effective laxative.

In the course of the trial it was noted that, of 290 women, 66 had been taking laxatives regularly before they became pregnant and that 43 had taken liquid paraffin regularly during their pregnancy.

I thank Miss G. C. Cruickshank, of the Maternity Department, Western General Hospital, Edinburgh, for her careful supervision of this trial, and Dr. D. H. McVie for his help with the earlier stages. I am indebted to Westminster Laboratories Ltd. for supplies of senokot.

TREATMENT OF HYPOPITUITARISM

BY

R. N. BECK, M.D., M.R.C.P.

Senior Tutor in Medicine, Queen's University, Belfast;
Registrar, Royal Victoria Hospital, Belfast

AND

D. A. D. MONTGOMERY, M.D., M.R.C.P.

Physician to Out-patients, Royal Victoria Hospital, Belfast

Before cortisone became available patients with pituitary insufficiency presented a difficult therapeutic problem, and many died as a result of adrenal crises or hypopituitary coma. All this has now been altered, and the major complications endangering life can readily be prevented by the addition of cortisone to existing methods of therapy. We have shown that patients with Addison's disease can be maintained in good health on cortisone as the sole method of treatment (Beck and Montgomery, 1956), and it is now generally recognized that, provided adrenal gland replacement is carried out, the therapeutic control of patients with pituitary insufficiency is usually satisfactory.

There is still diversity of opinion over what additional treatment, if any, is necessary in the latter. Sheehan and Summers (1954) report on the excellent response obtained in four cases treated with cortisone alone. On the other hand, Perkins and Rynearson (1952), Hart (1953), Querido *et al.* (1954), Whittaker and Whitehead (1954), and others advocate a wider range of substitution therapy and include deoxycortone acetate (D.C.A.), testosterone, and thyroid in addition to cortisone.

With the object of determining the simplest and most effective method of treatment for hypopituitarism, four patients suffering from post-partum pituitary insufficiency were studied as out-patients, and their response to traditional methods of therapy, supplemented with cortisone, was compared with their behaviour when treatment was continued on cortisone alone.

Method

The four patients were treated for periods ranging from 8 to 20 months on combined therapy consisting of D.C.A., sodium chloride, methyltestosterone, stilboestrol, thyroid, and cortisone (combined therapy), and subsequently for periods of 7 to 11 months on cortisone alone. Each patient was carefully assessed at three stages: before treatment started; when D.C.A., salt, testosterone, stilboestrol, and thyroid were withdrawn; and, finally, at the end of the trial period on cortisone. As a safeguard, each patient was interviewed monthly or more often as necessary, and the blood pressure and weight were recorded. At the three major examinations special attention was paid to the following points: energy and capacity for work and recreation; emotional tone, sense of well-being, and mental state; libido; menstruation; incidence and severity of infections; and crises; tolerance of cold; weight and blood pressure; condition of hair and skin; and certain laboratory investigations. The decision to start the trial with combined therapy first, followed by cortisone alone, was made partly because we felt that the withdrawal of a drug providing a measure of relief of symptoms would be more readily noticed by the patients. An additional reason was that several patients were already on a modified form of combined treatment, so it was decided to extend and proceed with this aspect first.

Clinical details of the four patients together with details of treatment given are recorded in Table I.

Results of Treatment

Energy and Capacity for Work.—Profound weakness and lack of energy were characteristic of each case before the clinical trial started. A remarkable recovery was evident with combined treatment, and this improvement was maintained without any deterioration in three cases on cortisone alone. One patient felt well enough to resume her work as a weaver in addition to household duties. Another housewife was able to nurse an invalid relative living at some distance from her home. In the fourth case there was reappearance of asthenia and intolerance to cold, and thyroid had to be restarted seven weeks after its withdrawal.

Emotional Tone, Sense of Well-being, and Mental State.—The patients were depressed and low in spirits before treatment began, and mentally dull or sluggish. All returned apparently to normal on combined therapy, and no change was noticed by the patients, relatives, or physicians when therapy was continued on cortisone alone, except in Case 2, where mental sluggishness, depression, and misery were quickly apparent despite additional cortisone dosage. These symptoms were attributed to lack of thyroid, and they quickly regressed when this was restarted.

Libido.—This was lost in all subjects, and in two there was no improvement throughout the trial with either therapy, but libido had always been weak in these two women. However, one patient noticed some improvement in libido and sexual response with combined treatment, an improvement little altered with cortisone alone. Another patient reported almost immediate improvement in libido and return of orgasm on combined therapy. This was fully maintained with cortisone.

Menstruation.—All had complete amenorrhoea from the onset of their illness until three reported a three to four-day menstrual staining or bleeding during the periods of cyclical stilboestrol withdrawal. One patient (Case 4) did not take stilboestrol very regularly and did not menstruate. There was complete amenorrhoea again when stilboestrol was withheld.

Incidence and Severity of Infections and Crises.—One patient was initially admitted to hospital in coma. The other three had no history of frequent infections or crises before treatment. Since the start of treatment all have remained well and no difference has been apparent between the two forms of therapy.

TABLE I.—Details of Cases

	Case 1, Aged 38	Case 2, Aged 40	Case 3, Aged 48	Case 4, Aged 33
Clinical features before treatment	Severe post-partum haemorrhage 15 years before, with subsequent amenorrhoea. Tired, lifeless, unable to work. Intolerant of cold. Waxy pallor, pubic and axillary hair absent. 17-Ketosteroids 0 mg./24 hrs. B.M.R. -44%. †Radioactive iodine test in myxoedema range (T index 2.1)	Post-partum haemorrhage 17 years before, with amenorrhoea since. Depressed, intolerant of cold. Treated as case of myxoedema with thyroid. Admitted to hospital in semi-coma following respiratory tract infection. Hypoglycaemic. Immediate treatment with D.C.A., cortisone; glucose given. Pre-treatment investigations not done. Subsequent radioactive iodine test in myxoedema range (T 1.55)	15 years' amenorrhoea following post-partum haemorrhage. Unable to work, intolerant of cold. Depressed, no interests. 17-Ketosteroids 0 mg./24 hrs. *Urinary 17-hydroxycorticosterone 0.5 mg./24 hrs. —following corticotrophin stimulation 7.5 mg./24 hrs. B.M.R. -65%. †Radioactive iodine test in myxoedema range (T 0.89)	3 years' amenorrhoea following post-partum haemorrhage. Tired, unable to do housework. Intolerant of cold. 17-Ketosteroid output 2.1 mg./24 hrs. Urinary 17-hydroxycorticosterone and B.M.R. levels unfortunately unavailable, but both were low and the B.M.R. result was below -25%. †Radioactive iodine uptake just above myxoedema range (T 2.9)
Combined therapy—details and duration of treatment	Cortisone 12.5 mg. daily, thyroid 3 gr. (0.2 g.) daily, D.C.A. trimethylacetate and testosterone isobutyrate, 50 mg. each every 4 weeks, stilboestrol 1 mg. daily for 3 weeks out of every four, and NaCl 3 g. daily, for 9 months	Cortisone 12.5 mg. daily, thyroid 2 gr. (0.13 g.) daily, D.C.A. trimethylacetate and testosterone isobutyrate 50 mg. every 4 weeks, NaCl 4 g. daily, for 20 months Stilboestrol, 1 mg. daily for 3 weeks out of every four, for 6 months	Cortisone 12.5 mg. daily for 2 months. Cortisone 25 mg. daily for 7 months For 9 months: thyroid 2 gr. (0.13 g.) daily. D.C.A. trimethylacetate and testosterone isobutyrate 50 mg. each every 4 weeks; stilboestrol 1 mg. daily for 3 weeks out of every four; NaCl 4 g. daily	For 10 months: cortisone 12.5 mg. daily; thyroid 3 gr. (0.2 g.) daily; D.C.A. trimethylacetate and testosterone isobutyrate 50 mg. each every 4 weeks; NaCl 6 g. daily
Cortisone alone and duration	Cortisone 12.5 mg. daily, 7 months	Cortisone 12.5 mg. daily, 7 weeks, then cortisone 25 mg. daily and thyroid 2 gr. (0.13 g.) daily thereafter	Cortisone 25 mg. daily for 11 months	Cortisone 12.5 mg. daily for 7 months

* Measurement of urinary 17-hydroxycorticosteroid output was carried out before and after the intravenous injection of 25 mg. of corticotrophin on two successive days.

† Radioactive iodine uptake test was carried out by measuring the radio-iodine output in urine over successive periods of 8, 16, and 24 hours after an initial oral dose of 10 μ c. of 131 I in accordance with the method described by Fraser *et al.* (1953). They give the T index range in myxoedema as lying between 1.3 and 2.8.

Cold-tolerance.—Intolerance of cold was a major complaint of the untreated patients. All had the well-known characteristics of this symptom—namely, unwillingness to leave the fire, excessive underclothing, and cold extremities. On combined therapy they became normal—undergarments were shed and their extremities felt warm to touch. When treatment was modified and thyroid stopped, three continued to feel normal and did not seem to miss it, but Case 2 relapsed almost immediately and thyroid had to be restarted. Of particular interest is the fact that thyroid was withheld during the month of January, 1955. This and the following two months were colder than usual, so that the apparent normal response to cold in three patients on cortisone alone was surprisingly good.

Electrolytes and Blood Pressure.—It has been previously shown (Beck and Montgomery, 1956) that cortisone will maintain satisfactory electrolyte and blood-pressure control in patients with Addison's disease. It was similarly found that electrolytes and blood-pressure levels of the four patients with hypopituitarism were satisfactorily maintained on cortisone alone (Table II), although it will be seen that there was no significant disturbance in blood chemistry in any case before treatment began. The initial blood pressure was low in three subjects with systolic levels of 100 mm. of mercury or below (Table III). A good response was ob-

TABLE II.—Electrolyte Levels in mEq/litre

	Case 1			Case 2			Case 3			Case 4		
	BT	CT	CA	BT	CT	CA	BT	CT	CA	BT	CT	CA

CO ₂ CP	30	30	28	23	22	26	—	29	29	—	30	30

CO₂CP = Carbon-dioxide combining power.

BT = Before treatment.

CT = Combined therapy consisting of D.C.A., sodium chloride, methyltestosterone, stilboestrol, thyroid, and cortisone.

CA = Cortisone alone—for dosage, see Table I.

TABLE III.—Blood Pressure in mm. Hg

	Case 1	Case 2	Case 3	Case 4
Before treatment	100/60	85/70	110/70	90/65
Combined therapy	120/70	120/75	150/85	110/80
Cortisone alone	130/80	120/75	140/80	105/80

Blood pressures recorded are the averages of numerous recordings made at the three stages of clinical assessment.

tained in all on combined therapy, and the improvement was well maintained when treatment was continued with cortisone alone.

Weight.—Three patients gained 3, 17, and 19 lb. (1.4, 7.7, and 8.6 kg.) on combined therapy. On cortisone alone there was a further gain of 2, 4, and 1 lb. (0.9, 1.8, and 0.45 kg.) respectively. The fourth patient lost 10 lb. (4.5 kg.) on combined therapy, but regained 4 lb. (1.8 kg.) on cortisone alone.

Effects on Skin.—All four patients had dry atrophic skin with some fine scaling, and did not sweat. The characteristic waxy pallor and puffiness of the face associated with loss of pituitary function was well marked. With combined treatment there was considerable improvement. The skin became more supple and its dry scaling quality was replaced by a smooth texture. Three patients noticed recurrence of sweating. The unusual pallor was lost as colour came back to their cheeks and their facial contours resumed a more normal appearance. When treatment was continued with cortisone alone the improvement was maintained in two. One regressed slightly, but the skin of the other (Case 2) returned rapidly to the state existing before any treatment was given.

Effects on Hair.—Very similar findings were experienced regarding hair. Dry, lustreless scalp hair which was rapidly thinning was the finding in each patient. On combined treatment, hair growth improved to a certain extent and eyebrow regrowth was noted in two. All felt, however, that their hair had not returned in quality to that existing before their illness began. Three patients thought that there was no appreciable regression in hair growth or texture when combined treatment was stopped. A definite assessment could not be made for the fourth patient, as thyroid was withheld for only a brief period, and this was clearly too short an interval in which to notice definite worsening in the quality of hair and its growth. There was no change in axillary hair in any patient. Its complete loss in each, prior to treatment, was a feature. Pubic hair was absent or very scanty. Little if any change was noted with either form of therapy.

Electrocardiographic Changes.—All patients had the characteristic electrocardiographic changes associated with myxoedema—namely, low voltage, sinus bradycardia, and flat or inverted T waves. With combined treatment there was distinct improvement in three cases, with increased

voltage and upright or less negative T waves. This improvement was fully maintained in only one patient on cortisone alone; in two others there was definite regression in voltage and T wave formation (see accompanying electrocardiogram); in the fourth case an electrocardiogram was unfortunately not obtained while the patient was on com-

bined therapy, but the graph recorded when she was on cortisone alone showed little change from the pre-treatment appearances. It was clear, therefore, that cortisone had not significantly altered the electrocardiographic pattern in her case.

Discussion

From a study of the patients and their response to treatment it seems clear that the only drugs which played a significant part in their recovery were thyroid and cortisone. In only the following aspects, however, did treatment with cortisone alone seem to be inferior to that provided by combined therapy. Firstly, intolerance of cold and mental depression recurred quickly in one patient when thyroid was withdrawn, but were corrected when thyroid was restarted. Secondly, two patients found that the satisfactory response to treatment made by their skin regressed on cortisone alone. Finally, the improvement noted in the electrocardiogram on combined treatment deteriorated in two when therapy was continued with cortisone, and in one case cortisone failed to improve the electrocardiographic pattern. In each of these aspects the deterioration appeared to be related to withdrawal of thyroid, and where this was recommenced the situation improved.

It is noteworthy that in only one of the cases was it essential to restart thyroid after it was stopped. The other cases continued to do well on cortisone alone, and it was only by careful observation and questioning that any change was apparent in their clinical status. This has also been our experience with three other cases treated on identical lines with those in the trial. In only one of these were the effects of thyroid withdrawal noticeable, in circumstances resembling those in Case 2. Mental apathy set in, she felt cold, and energy declined. All these symptoms were reversed when thyroid was restarted.

It is difficult to understand why in only two cases out of a total of seven, such profound reactions should be experienced following the cessation of thyroid medication. All the patients had clinical evidence of thyroid dysfunction, and, where carried out, basal metabolic rates and radio-iodine tests were in the myxoedema range. In the cases that continued to do well on cortisone alone there was unequivocal evidence of thyroid dysfunction. The only feature common to the two cases under discussion was that both had been treated previously with thyroid, having been incorrectly diagnosed as suffering from myxoedema, while the remaining cases had been untreated when first seen. It may be that the earlier treatment with thyroid had in some way made them dependent or sensitive to the drug so that its withdrawal was quickly followed by symptoms of deprivation. Suppression of the thyroid gland due to long-term replacement therapy would not be a factor in this secondary type of hypothyroidism where deficiency of thyrotrophic hormone is the primary defect.

The well-known improvement that occurs in the electrocardiogram when patients with myxoedema are treated with thyroid, coupled with the improvement noted in the three cases on combined therapy and subsequent regression when thyroid was withdrawn, suggests that thyroid was mainly responsible for the improvement. This action of supplementary thyroid therapy is considered to be important, and to be a further indication for routine treatment with this drug when there is clinical evidence of thyroid gland deficiency.

The stopping of D.C.A. and salt did not apparently give rise to any symptoms, nor could we detect any significant change in the patient's clinical condition. One abnormally high serum sodium level was reduced to the normal range when these were withdrawn. However, as has been previously shown, cortisone is adequate to keep patients with Addison's disease healthy, so that nothing is gained by the use of additional drugs in secondary adrenal failure.

Testosterone is frequently given to patients with hypopituitarism in order to improve strength and energy, and to restore normal sexual libido (Hart, 1953; McCullagh, Skillern, and Schaffenburg, 1954; Williams, 1955). Sheehan and Summers (1954) found, however, that cortisone was

Case 3. Electrocardiogram 17/11/53: before treatment; 27/8/54: after combined therapy for nine months; note improved voltage, T waves now upright in I, II, VF, V3, V5. 7/7/55: off all treatment except cortisone for 11 months; some regression in voltage and lowering of T wave in I, II, VF, and inversion in V5.

more effective than testosterone in the treatment of hypopituitarism, and that the only additional effect obtained when the two drugs were given together was an increase in growth of body hair. Whittaker and Whitehead (1954) gave additional testosterone to the maintenance treatment with cortisone in two male patients, and found increase in libido was produced. No change, however, was noticed in two female patients on the addition of testosterone to their treatment. In this series there was no conclusive proof that testosterone had any effect except to produce unwanted facial hair in one patient, and any general improvement in strength and energy or in libido with combined therapy appeared to be adequately maintained on cortisone alone. From these findings we suggest giving testosterone only to those female patients complaining of loss of libido who fail to improve with a combination of cortisone and thyroid. In male patients, routine testosterone is probably advisable, especially those in the younger age groups.

No definite conclusions regarding the value of stilboestrol can be drawn from this investigation because no detailed gynaecological studies were carried out. It was our impression, however, that stilboestrol made little, if any, difference, and its withdrawal caused no noticeable effect. As a method of treatment, therefore, we would not advise its routine use unless genital atrophy is so severe as to cause symptoms or unless oestrogen-withdrawal bleeding is desired for psychological reasons.

Summary and Conclusions

A clinical trial in which four patients with post-partum pituitary insufficiency were treated for varying periods on combined treatment consisting of D.C.A., sodium chloride, testosterone, stilboestrol, thyroid, and cortisone, and on cortisone alone, is described.

Three patients continued in good health on cortisone alone, while one patient relapsed and had to continue with thyroid.

Cortisone alone was thought to be inferior to combined therapy in respect of minor changes in skin in two patients, regression of the electrocardiogram in two, and return of cold-intolerance in one. It appeared that these changes were related to the withdrawal of thyroid, as they quickly improved when this drug was restarted.

From the study of these four patients and others treated since the trial ended, we regard cortisone and thyroid as the essential drugs to maintain good health in hypopituitarism. While cortisone alone seems to be little inferior to combined therapy, the effect of thyroid on the skin, electrocardiograms, and in some cases (which are apparently often unpredictable) intolerance to cold makes its routine use desirable. D.C.A. and salt therapy are unnecessary and complicate treatment, while testosterone is not advocated as routine therapy in female patients unless libido remains deficient without it.

We thank Professor G. M. Bull for allowing us to treat one of his patients and for his advice; Dr. R. S. Allison, who allowed us to study Case 4; Dr. J. A. Smyth and Mr. D. W. Neill for carrying out the biochemical estimations referred to in this study; and Mr. R. G. Wood for the illustration.

ASPIRIN INTOLERANCE A COMPARATIVE TRIAL OF TWO MODIFIED ASPIRIN PRODUCTS

BY

R. M. VINING, M.B., B.S.

AND

G. D. KERSLEY, T.D., M.D., F.R.C.P.

From the Rheumatism Research Unit, Royal National Hospital for Rheumatic Diseases, Bath

The use of aspirin preparations in rheumatic conditions is often attended by side-effects which preclude full relief of pain. These are gastric symptoms (nausea, heartburn, epigastric pain); salicylism (deafness, vertigo, tinnitus); and allergy (rash, bronchospasm).

Numerous aspirin preparations have been devised to reduce gastric intolerance, which is not without danger (Douthwaite and Lintott, 1938; Hurst and Lintott, 1939; Kelly, 1956) and which is reported to be commoner in rheumatic patients than in others. Femont-Smith (1955) compares the incidence of 26% of 200 rheumatoid cases being intolerant with two other series (Paul, 1943; Tebrock, 1951) where the incidence in non-rheumatic cases varied from 3 to 10%. It is, however, unsatisfactory to compare series of cases from different centres and with different assessors.

In this series an aspirin and glycine preparation ("paynocil") was compared with a citrated preparation ("disprin") in rheumatic patients intolerant of plain aspirin; intolerance in this context being defined as inability because of gastric symptoms to take doses of aspirin sufficient to relieve the rheumatic pain.

Design

The following categories were excluded from the trial: patients receiving cortisone, corticotrophin, phenylbutazone, or colchicine; those allergic to aspirin; and those whose response to treatment was so modified by psychological factors that a reliable assessment was impossible.

The conditions treated included all types of rheumatic disease, with rheumatoid arthritis predominating in both sexes; but most cases of gout and the severest cases of rheumatoid and collagen disease fell into the excluded category requiring more specific treatment.

With these exceptions all patients admitted to research unit beds were given aspirin, 50 gr. (3.2 g.) daily in divided doses, and this dosage was adjusted as necessary until pain relief was adequate, the final dose ranging from 20 to 100 gr. (1.3 to 6.5 g.) daily. Appropriate physical treatment was also prescribed.

Patients showing intolerance were changed to disprin or paynocil, in doses equivalent to the last dose of aspirin, the drugs being chosen alternately on each ward. After further dose adjustment, if necessary, the other product was then substituted for a week (the dose again being altered if necessary), after which the original choice was resumed. Patients were asked for their preference, with reasons. Salicylism was rarely encountered and did not in itself cause us to change the drug; any changes made (for other indications) did not appear to influence this group of side-effects.

Results

Results in men and women are shown separately, but no attempt is made to isolate the conditions treated.

Table I shows that 25% of patients in the series were intolerant to plain aspirin; this agrees with previous reports. The incidence in men and women was similar.

TABLE I

	Men	Women	Total
No. of patients	71	107	178
"intolerant to aspirin"	19	26	45

Table II shows results obtained in the aspirin-intolerant cases. Of 23 given disprin first, 5 preferred it, 10 preferred paynocil, and 8 were indifferent; all the men who made a choice preferred paynocil. Among 22 given paynocil first, opinion was more evenly divided—8 for paynocil, 9 for disprin, and 6 abstaining.

TABLE II

	Disprin Tried First			Paynocil Tried First			All Cases		
	M	F	Total	M	F	Total	M	F	Total
No. of patients	9	14	23	10	12	22	19	26	45
Disprin preferred	0	5	5	5	4	9	5	9	14
Paynocil	5	5	10	3	4	7	8	9	17
Equally satisfactory	1	3	4	1	1	2	2	4	6
"unsatisfactory"	3	1	4	1	3	4	4	4	8

The relative efficacy of the three drugs sometimes differed; four patients found the buffered preparations less effective than plain aspirin, and two found the opposite. Disprin was judged more effective than paynocil in three cases and less effective in one. In this connexion (remembering that the efficacy of salicylates is diminished by alkalis such as sodium bicarbonate, which accelerates excretion) it is noteworthy that two patients in the "unsatisfactory" group experienced improved tolerance without apparent loss of analgesia when every dose (of paynocil in one case and of aspirin in the other) was accompanied by magnesium trisilicate.

One patient who reported that she never took aspirin because of her duodenal ulcer was given paynocil from admission; unfortunately her ulcer symptoms reappeared in a few days, and analgesics had to be withdrawn.

Conclusions and Comment

In this series 45 out of 178 rheumatic patients (25%) could not take adequate doses of aspirin. Of these 45 patients, 37 (82%) responded well to paynocil, disprin, or both. There was a slight majority (17 to 14) in favour of paynocil, but the numbers are too small for this to be significant. Most of those who expressed a preference for one product did so because of marked inability to stomach the other, demonstrating that "one man's meat is another man's poison," and that there is a place for both preparations in the treatment of rheumatism, since one may succeed where the other fails.

Summary

The freedom from gastric side-effects and the analgesic efficacy of two modified aspirin preparations—paynocil and disprin—have been compared in rheumatic patients intolerant of aspirin. Four-fifths of these patients benefited, and two-thirds expressed a definite preference for one or other of these drugs, the preferences being fairly evenly divided between the two. Differences in the analgesic effect were encountered, but no definite pattern emerged. The high incidence of aspirin intolerance in rheumatic patients was confirmed.

Acknowledgment is made to Messrs. Bencard Ltd. for the supply of the aspirin-glycine compound.

Medical Memoranda

Abdominal Periarthritis Nodosa

It is extremely rare for periarthritis nodosa to present as an acute abdominal emergency. However, several cases have been reported which conform to the pattern of gradually increasing abdominal symptoms culminating in an attack of peritonitis, at which stage laparotomy has been performed. The ultimate diagnosis has usually come from the histologist, but three cases are recorded (Manges and Baehr, 1921; Logue and Mullins, 1946) in which the nodules of periarthritis were visible to the naked eye within the peritoneal cavity. We wish to describe a fourth case in which these nodules were visible at laparotomy. Obviously the visibility of the periarthritic nodules depends on their size, and this in turn on the degree of necrosis in the arterial wall, which is one of the variable factors in this disease.

CASE REPORT

A young man of 20 was admitted to St. Mary's Hospital, Portsmouth, on May 13, 1955, with severe epigastric pain. At the age of 9 he had an attack of anterior poliomyelitis which left some residual wasting of the right thigh and leg; in the past year he had had attacks of asthma. For the preceding three weeks he had suffered from intermittent epigastric pain, diarrhoea, and aching pains in the right leg. During this period he had been on a "gastric diet," which had given him some relief. For the 18 hours before admission his epigastric pain had been severe, and he had acute nausea but had not vomited; his bowels had been open normally during that time.

He was thin, pale, and over-anxious. His temperature was 100° F. (37.8° C.), pulse 120, respirations 20. His tongue was clean and moist. The abdomen was tender in the epigastrium and the right hypochondrium; there was widespread moderate abdominal rigidity, with very marked rebound tenderness in the lower abdomen and faint bowel sounds on auscultation. Rectal examination did not reveal any peritoneal tenderness. The respiratory and cardiovascular systems were normal apart from a blood pressure of 148/110 mm. Hg. The urine contained no albumin. An abdominal radiograph showed there was no gas under the diaphragm. His leucocyte count was 17,000 per c.mm., of which 90% were neutrophils and 3% eosinophils.

It was thought that the patient had peritonitis, probably due to a perforated peptic ulcer, and laparotomy was therefore performed, the abdomen being opened through a right paramedian incision (Mr. J. D. Younghusband). There was no free fluid. The first striking finding was that the greater part of the small intestine, and especially the ileum, showed a blotchy, purplish discoloration which was maximal about 2 in. (5 cm.) from the ileo-caecal valve and extended throughout the small intestine with the exception of the upper 2 in. (5 cm.) of the jejunum. Two small round yellow sloughs about half an inch (12.5 mm.) in diameter were present in the bowel wall, indicating imminent perforation. There was little or no fibrinous reaction. The colon was mildly thickened, with generalized faint inflammatory changes. The mesentery, surface of the bowel, and parietal peritoneum were extensively studded with whitish pinpoint nodules; these were best seen in the mesentery of the small intestine and along the peripheral vascular arcades of the mesenteric vessels. Most of the abdominal contents felt gritty because of these nodules. The spleen was not enlarged or affected by the nodules; the liver also was normal. The appendix was not inflamed. The nature of the nodules and the condition affecting the bowel was obscure. The two areas of threatened perforation were carefully oversewn and specimens of the nodules removed for biopsy; the abdomen was then closed. The histological report (Dr. R. D. Clay) stated: "Serial sections of a nodule reveal it to contain a small artery with focal necrosis of the whole thickness of its wall

resulting in a minute aneurysm; this is surrounded by granulation tissue, and the whole is infiltrated by polymorphonuclear and eosinophil cells. The basis of the lesion therefore appears to be a necrotizing arteritis, and a diagnosis of polyarteritis nodosa must be considered."

Post-operative progress was satisfactory, although on May 28 the patient had another severe attack of abdominal pain associated with lower abdominal tenderness, guarding, and a positive release sign. This second attack was treated by a short course of erythromycin, and he made an excellent recovery except for a continued diarrhoea. Sigmoidoscopy revealed "slight patchy reddening of the mucosa and one definite ulcer, with an irregular edge, r-d base, but without a slough." By this time his leucocyte count was 14,800 per c.mm. (12% eosinophils). A left pectoral muscle biopsy was performed (Dr. R. D. Clay) to confirm the diagnosis, and this showed "extensive fibrinoid necrosis of the arteriolar walls, which were densely infiltrated with cells mainly of the polymorphonuclear type. Surrounding the necrotic walls were zones of epithelioid cells, plasma cells, lymphocytes, eosinophil cells, and more polymorphs. This surrounding cellular infiltration was very marked, extending in some areas for a short distance between the muscle bundles. The biopsy thus showed periarteritis nodosa in the acute stage."

The diarrhoea slowly ceased together with some vague abdominal pain of which he had complained. On June 21 treatment with cortisone, 25 mg. twice daily, was begun, and within a week he was stronger; the cortisone was then reduced to 25 mg. daily owing to oedema formation. After three weeks' treatment he was discharged home on the above dosage and continued to remain well apart from two attacks of asthma.

On July 29 he became unconscious after vomiting and was readmitted. The unconsciousness lasted only a few minutes and was followed by irrational and violent behaviour requiring heavy sedation. Later neck rigidity, a positive Kernig's sign, and bilateral early papilloedema developed; a diagnosis of subarachnoid haemorrhage was made and confirmed by lumbar puncture. The blood pressure was 190/145 mm. Hg. The dosage of cortisone was increased to 100 mg. daily for eight days and gradually reduced to 25 mg. twice a day. He recovered satisfactorily from this incident, his blood pressure returning to 140/95 mm. Hg. One further attack of abdominal pain occurred. This was suggestive of peritonitis, but was relieved by sedation. Apart from this incident and slight frontal headaches he recovered well from the subarachnoid haemorrhage. He was eventually discharged on September 20 to continue with cortisone, 25 mg. twice daily. Since then he has remained well, though at no time has his blood pressure been below 140/95 mm. Hg.

COMMENT

Diseases of the abdominal viscera occupy first place in the minds of most surgeons, and it is only natural that they tend to be most commonly diagnosed in cases of peritonitis. Allen (1940) describes a case of abdominal periarteritis nodosa in which perinephric abscess, appendix abscess, and cholecystitis were considered before laparotomy was performed on a presumed diagnosis of penetrating peptic ulcer. Manges and Baehr (1921) thought that their case was one of suppurative retroperitoneal lymph nodes or perhaps a localized peritonitis in the lesser sac. It would appear that patients with abdominal periarteritis nodosa present with a short history of vague abdominal pain—in our case thought to be due to a peptic ulcer; they may also have pains in the muscles and joints and a history of sore throat. Eventually the abdominal symptoms become more marked and signs of peritoneal irritation develop, leading to surgical intervention. The patient usually has a high temperature—100° F. (37.8° C.) in our case—and a marked leucocytosis. Logue and Mullins (1946), in reporting 177 cases of periarteritis, list the most prominent symptoms as fever (81%), leucocytosis (73%), albuminuria (65%), abdominal pain (56%), and hypertension (53%). The presence of albuminuria and hypertension depends on involvement of the renal arteries;

in our case there was a raised blood pressure which has remained constant, but no albumin or red blood cells have been found after repeated urinary examination.

Our thanks are due to Mr. J. D. Younghusband and Dr. R. G. Moore for permission to publish this case.

Operation for Midline Epigastric Incisional Hernia

Although the majority of incisional hernias following midline epigastric incision cause little discomfort and can be supported by a suitable abdominal belt, there are a number with wide divarication of the recti and ballooning of the hernia itself which, because they cause both mental and physical discomfort and in some cases exaggeration of pre-existing chest symptoms, need surgical repair.

Such hernias can, in the main, be prevented by the careful use of unabsorbable suture, but the price is an incidence of stitch sinus which, although varying in the practice of individual surgeons, occurs in a few cases.

For the type of hernia described above I have used the following procedure with unfailing success in some 12 cases.

The scar is excised by an elliptical incision from xiphisternum to umbilicus and the skin on both sides undermined laterally to expose the peritoneum of the sac and the whole of both anterior rectus sheaths to their lateral edges.

The peritoneum is now repaired where it is deficient or weak and the exposed anterior rectus sheaths are dissected off the underlying rectus muscles to form two rectangular flaps, consisting of external and internal oblique aponeurosis, hinged on their medial margins—that is, along the whole lateral margin of each side of the hernial gap. It is important that these flaps should be raised without damage either to the underlying muscle or to the flaps themselves, and that they should include almost the whole width of the sheath. Bleeding, which is usually troublesome, should be dealt with carefully by ligation and suture.

The flaps are now turned over medially on their hinges and sutured with closely placed interrupted sutures of No. 3 plaited silk to the medial edge of the opposite rectus sheath, this being the original but split linea alba forming the hinge of the opposite flap. The security of these sutures is enhanced by folding under the lateral edge of each flap to obtain a double bite. The gap can always be filled in this way with two double-layered aponeurotic flaps—the suture line of each being protected by the intact hinge of its fellow.

The recti, relieved of the lateral pull of the obliques, tend to approximate slightly during the suturing, and this relief of lateral pull can be appreciated later when the repair is healed, when it can be seen that, on straining, the gap tends to close and the remaining deficiency is well controlled by the aponeurotic graft.

The suturing having been completed and haemostasis checked, the skin incision is closed without drainage.

Any subcutaneous serum is aspirated as soon as it forms during the post-operative period; drainage is avoided, to ensure healing by primary union.

ADDENDUM.—Since submitting this article for publication a description of this operation by Professor Charles Wells has been published (*Ann. roy. Coll. Surg. Engl.*, 1956, 19, 316).

I thank Sir Heneage Ogilvie for his advice concerning the preparation of this article.

Gorleston General Hospital.

Reviews

THE LONDON SCHOOL OF TROPICAL MEDICINE

History of the School of Tropical Medicine in London (1899-1949). By Sir Philip Manson-Bahr, C.M.G., D.S.O., M.D., F.R.C.P. (Pp. 328+xiii; illustrated, 50s.) London: School of Hygiene and Tropical Medicine (Memoir No. 11). London: H. K. Lewis and Co. Ltd. 1956.

Within the short period of 50 years the tropics have been converted from a white man's grave almost to a health resort. We are told that it used to be said:

"Beware and betide of the Bight of Benin,
For few come out, though many go in."

Under the changed conditions, however, a doctor who married a nurse and had three children in Nigeria wrote:

"The Bight of Benin is no longer in doubt;
Where two have gone in, now five have come out."

A perusal of this excellent history makes it plain that the London School of Tropical Medicine played a very important part in bringing about this great change. The idea of the school was conceived in the imaginative yet practical mind of Sir Patrick Manson. With the powerful aid of Joseph Chamberlain and Mr. (afterwards Sir) Herbert Read, and the co-operation of the Seamen's Hospital Society, the school was born in a building near the Albert Dock Hospital. Further development took place in the building in Endsleigh Gardens, and it finally entered (in conjunction with the School of Hygiene) into the beautiful building within the curtilage of London University. It triumphed over many difficulties.

The well-produced book in which the story is told comprises four parts. The first tells the plain story in a readable manner; the second gives fascinating short biographies of all those (whether professors, lecturers, technicians, or secretaries) who have played essential parts in the development of the school; the third and final sections give a chronological list of events and an account of the research work and publications of the members of the staff and former students of the school. The whole work is tinged with wit and lit up by flashes of humour. Some of the quotations at the head of sections and chapters are very appropriate. What could be better than these two lines (from Samuel Johnson) to portray Sir Leonard Rogers?

"A frame of adamant, a soul of fire;
No dangers fright him and no labours tire."

I thoroughly enjoyed this book, both for the story it contains and for the many autobiographical interpolations of the author. I take the liberty of quoting one good story. In the old building in Endsleigh Gardens the lecture-room was dark and stuffy. "There was one memorable occasion on one July day when the lecturer was demonstrating a series of statistical tables by means of slides ornamented with yellow, red and blue dots, when he exclaimed to the attendant, 'Turn up the lights and I will talk to them for a bit.' When the light did come on it revealed the whole class of over seventy men, without exception, fast asleep."

One small criticism—there is no index. I should like to add a modern proverb which may be quoted without acknowledgment: "A book without an index is like a country without a map."

ZACHARY COPE.

DISEASES OF THE BREAST

Diseases of the Breast. By C. D. Haagensen, M.D. (Pp. 751+xviii; illustrated £5 12s.) Philadelphia and London: W. B. Saunders Company. 1956.

This is the second important work on breast diseases from an American centre in the last year, but it differs from the former in being an account of the experience of a lifetime in dealing with these conditions. The consequences of this

personal approach are, on the one hand, that the opinions expressed are backed by a vast experience and acquire great value on that account; on the other hand, there is the disadvantage that alternative views are not given so much prominence nor considered with such objectivity as if the author had not had this almost unique experience. The effect is to make the book an object of study for the experienced surgeon and the expert. It is not, however, to be recommended for general reading, nor was it presumably intended for the undergraduate student.

In the section on anatomy the views of Batson on the significance of the vertebral system of veins in the dissemination of breast cancer are given justifiable prominence, and there is a very full discussion of the important subject of lymphatic drainage. On the other hand, the physiology is not very fully discussed. This attitude is reflected in the somewhat inadequate account of the hormone aspects of the treatment of breast cancer, and shows that the author is primarily concerned with the surgical treatment of this condition. An instance of this is the incorrect statement that the presence of hepatic metastases renders a case unsuitable for treatment by adrenalectomy. The author advocates the American practice of self-examination, and he rightly condemns aspiration biopsy, trephine biopsy, and intra-duct biopsy. He will command almost universal agreement when he says that frozen-section biopsy is not adequate to distinguish between the different types of papillary lesion. Dr. Haagensen is an advocate of scrupulous radical mastectomy with skin-grafting in almost every case. The fact that this operation takes between five and six hours might not recommend it to the British school of surgery, which teaches that, with equal care, as satisfactory an end-result can be achieved in half that time and with a lower morbidity. The author's operation for intra-duct papilloma is not perhaps the most elegant which is now available, but it is a great improvement on the hit-and-miss technique of resection of the block of breast tissue in the region from which the blood is thought to be emanating. In the section on tuberculosis of the breast no mention is made of antibiotic therapy, which has completely altered the prognosis of this condition. The advocacy of radical mastectomy for Paget's disease and for the intra-duct cancers in general must command wide support. Finally, the considerable space devoted to the description of biopsy from the bodies of the vertebrae is once more illustrative of the colour which this book derives from the author's personal interests.

The above comments are criticisms of points of detail, which are inevitable when a book is written by an expert who has explored personally so many controversial issues. Taken as a whole, this book is a monument to the life work of a fine surgeon. Although there may be disagreement on certain particular conclusions, this work is informed by scrupulous care and that thoughtful consideration for the interests of the patient which is the mark of a great doctor all the world over.

HEDLEY ATKINS.

PORPHYRIN BIOSYNTHESIS AND METABOLISM

Ciba Foundation Symposium on Porphyrin Biosynthesis and Metabolism. Editors for the Ciba Foundation: G. E. W. Wolstenholme, O.B.E., M.A., M.B., B.Ch., and Elaine C. P. Millar, A.H.W.C., A.R.I.C. (Pp. 308+xii; illustrated, 30s.) London: J. and A. Churchill Ltd. 1956.

This volume records the proceedings of a symposium on the biosynthesis of porphyrins and porphyrin metabolism held at the Ciba Foundation, London, in February, 1955, under the chairmanship of Professor C. Rimington. The subject was last considered in a Ciba Foundation symposium in 1951, when the volume subsequently published bore the title *Isotopes in Biochemistry*. At that time the incorporation of labelled glycine into the haem of circulating blood and the existence of the amino-laevulinic acid cycle were both appreciated, but many gaps existed in knowledge of the

biosynthesis of porphyrins. Because research since that time has been so fruitful, the scope of the new three-day conference had to be limited to the biosynthesis of porphyrins and of haem, and, apart from experimental porphyria, porphyria diseases had to be excluded.

The conference and the book both fell naturally into four main sections: (1) the early stages in biosynthesis, those involving steps before the pyrrole stage; (2) studies involving porphobilinogen; (3) the general role of porphyrins and the binding of iron; and (4) the use of sedormid and allylisopropylacetamide in inducing derangements of porphyrin metabolism. Although firm evidence is available to link glycine and succinic acid as precursors of β -amino-laevulinic acid, and the latter is clearly an intermediary in the formation of porphobilinogen, the steps between porphobilinogen and protoporphyrin are uncertain, though uroporphyrin and coproporphyrin may both be implicated. The stage at which iron enters in the synthesis of haem, and the mechanism of its incorporation, are still uncertain.

The book is well edited, and makes most interesting reading for those anxious to have in an easily accessible form an account of researches spread widely over the original literature.

F. G. YOUNG.

EYE DISEASES ILLUSTRATED

An Atlas of Diseases of the Eye. Compiled by E. S. Perkins, M.B., F.R.C.S., and Peter Hansell, M.R.C.S., F.R.P.S. Foreword by Sir Stewart Duke-Elder, K.C.V.O., M.A., D.Sc., Ph.D., M.D., F.R.C.S. (Pp. 91+ix; plates in colour and black-and-white. 42s.) London: J. and A. Churchill Ltd. 1957.

An Atlas of Diseases of the Eye, by E. S. Perkins and Peter Hansell, attempts to cover the whole range of diagnosis in ophthalmology. Thirty-two pictures are devoted to the lids and orbit, both in their normal and in their pathological aspects; such common conditions as styes and chalazia and such rare affections as naevus flammeus of the face are shown. Affections of the conjunctiva, cornea, and sclera are represented in 36 further illustrations, and a similar number deal with the uveal tract, the lens, and retrolental fibroplasia. The scope of these is shown by the fact that two plates are devoted to gonioscopy and neoplasms of the anterior uveal tract. The two concluding sections depict appearances of the fundus—32 figures show changes occurring in systemic disease, and 64 changes in more localized disease of the eye: in all 96 illustrations forming a useful atlas of the fundus and its diseases. Throughout the work there is evidence of much thought and care, both in the choice of material and in the drawings prepared; no praise can be too high for the reproduction and printing. The explanatory matter is usefully placed opposite the pictures.

ARNOLD SORSBY.

PHYSIOTHERAPY IN PARAPLEGIA

Physiotherapy in Paraplegia. By Elvira P. G. Hobson, F.C.S.P. Foreword by L. Guttmann, O.B.E., M.D., M.R.C.P. (Pp. 110+ix; illustrated. 12s. 6d.) London: J. and A. Churchill Ltd. 1956.

This book is based on a thesis written for the Fellowship of the Chartered Society of Physiotherapy, and as a thesis is commendable. The modern treatment of the paraplegic is considered in all its aspects, and it is here that the book may disappoint the medical reader. Thus it seems inappropriate for a physiotherapist to attempt to report on the strictly medical and surgical problems, for which she can only repeat uncritically what others have said to her. However, for physiotherapists themselves this book gives a useful account of the methods developed by Dr. Guttmann at Stoke Mandeville Spinal Injuries Centre.

W. RITCHIE RUSSELL.

Bibliography on Hearing (London: Geoffrey Cumberlege, 55s.), prepared by the Psycho-Acoustic Laboratory at Harvard under the direction of S. S. Stevens, is a second and enlarged edition of *A Bibliography on Audition* published in 1950. It lists over 10,000 titles of books and papers, arranged alphabetically by author. Following the main list is a subject classification in two parts: the first is an outline scheme under 315 heads, numbered serially; the second, arranged under the numbers of the scheme, lists the authors who have written on each subject. Such an arrangement is open to criticism. The method of using the classification lists to find entries on a particular subject is tiresome. In the second half of the scheme only the surnames of authors are given, and in the case of such common names as Smith this may entail looking through a great many entries to find a particular paper. There is no indication if an author has written more than one paper on a particular subject or if two authors of the same surname have both written papers on it. Considerations of space and printing costs have no doubt dictated the present arrangement; a subject bibliography with an author index would have been more usable. Even so *Bibliography on Hearing* is a valuable work of reference covering all aspects of otology.

The *Annual Review of Medicine* (Vol. 7, 1956) continues to give expert evaluations of progress in a variety of medical and surgical specialties. Although designed primarily for clinical investigators and teachers, it also provides a valuable refresher course for the general and specialist practitioner. It concludes as usual with an exhaustive bibliography of reviews in medicine which have appeared during the past year. It is published by Annual Reviews, Inc., Stanford, California, price \$7.50.

The 58th edition of *Scientific and Learned Societies of Great Britain* (George Allen and Unwin Ltd., 1956, pp. 212, 35s.) brings this valuable reference book up to date once again; the last edition appeared in 1951. Its aim is to include, in classified order, details of all those societies which give educational facilities and/or publish papers or other original material. In the new edition a larger number of societies has been compressed into less space by abolishing the geographical subdivisions and sometimes by omitting names of officers. The price seems high for so small a volume.

Looking back over a varied life of doctoring at home and abroad, Dr. C. V. Nicoll has a number of good stories to tell about medical men, politicians, and others in his book *From a Doctor's Diary* (Wilding, 15s.). Samuel Gee, who was teaching at Bart's when the author was a student there, thought that tobacco smoking was unhealthy and that business men ate and drank too much—traditions alive and kicking to-day. A fellow-student of the author's will arouse the admiration of many for having taken exception to a hectoring examiner and told him he was unfit for the job. However, he apparently had to go elsewhere for his qualifications.

Lecture Notes on the Use of the Microscope, by Dr. R. Barer, is an excellent little book for anyone to study when he first begins to use a microscope. It will also be instructive to the slightly more advanced worker who wants to learn the advantages of Köhler illumination for critical work and how to set up his apparatus to obtain it. The author's elementary account of the optics of microscopes is so designed as to be of use in practice at the bench. The book is published by Blackwell Scientific Publications at 7s. 6d.

The well-known textbook, *Law Relating to Hospitals and Kindred Institutions*, by S. R. Speller, LL.B., has now reached its third edition (1956). Since the Health Service began a number of cases contested in the courts have resulted in alterations to the law. Consequently the author has made a considerable number of changes in his book to keep it up to date. So that it shall not become too unwieldy, he has reduced the text on the Public Health Acts. The book is published by H. K. Lewis Ltd. for 70s.

A group of distinguished contributors have combined in *Progress in Clinical Medicine* (3rd edition) to set out in a practical, didactic style modern views on diagnosis and treatment in many fields of medicine. The subjects covered include infections, diabetes, rheumatism, and diseases of the alimentary, cardiovascular, renal, haemopoietic, respiratory, neurological, and endocrine systems; old people, metabolic disorders, and radio-isotopes come in for special chapters. Edited by Drs. Raymond Daley and Henry Miller, the book is published by J. and A. Churchill Ltd. for 40s.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY FEBRUARY 23 1957

THE CONSTITUTION OF THE B.M.A.

The Representative Body set up in 1953 a Constitution Committee "to examine and report on the present structure of the Association, with special reference to the reorganization of the Representative Body." The report of the Committee is published in this week's *Supplement* and will be the subject of a whole day's debate when the Representative Body meets at Newcastle in July. Mr. H. H. Langston, the Chairman, and his Committee have put the Association in their debt by their painstaking and thorough analysis of the present situation, by the fairness with which they have put the arguments for and against proposals for reform, and by the cogency with which they propose changes in the constitution which will go some way towards meeting the criticisms which have been voiced since the end of the war, and especially since 1948. Many felt that a constitution adapted to the conditions of 1902 would be unlikely to meet the greatly changed conditions of to-day. In particular the Representative Body has grown to such a size as to lead Mr. Langston's Division in Winchester to describe, a few years ago, its meetings "as a shambles—too many members discussing too many resolutions." There have been occasions when on the last day of the meeting important matters had to be hustled through with a haste that allowed hardly any time for discussion. The numbers of the Representative Body rose with the increase in membership of the B.M.A., which grew with but faster than the increase in the numbers of doctors practising in Britain. In 1938 the Representative Body numbered 366 and in 1956 it numbered 500. Can a body this size—the annual Parliament of the B.M.A.—effectively deal with the business of the Association during the four days it meets every year? And the business is no less than that of determining the policy of the B.M.A. The Constitution Committee recommends that the Representative Body should be reduced in number from 500 to 350. The question to be answered is, Will 350 men and women be wiser than 500?, or, at least, be better able to

concentrate on the matters at issue? There would certainly be 150 fewer with a potential right to speak. A more practical question is the difficulty of finding a large enough meeting-place in the different cities of Britain. A more contentious question is that the Representative Body is composed so predominantly of general practitioners that the policy of the Association is determined largely by their interests. The consultants and specialists in particular are uneasy about this. They feel themselves to be, and are, in a minority at a Representative Meeting, and are therefore dependent upon a vote of general practitioners to secure the policies they wish the Association to adopt. The B.M.A.'s constitution is based on a "federation of geographical units rather than an alliance of craft groups," as the Committee puts it, and the Committee sees no reason to change this, but stresses that a Division "should be large enough to include in its membership all the main fields of medical practice." It has taken an important step by recommending that the Central Consultants and Specialists Committee should elect four members of the Representative Body, important because the Committee thus outwardly does something towards meeting a grievance which undoubtedly exists. It notes in its report that at the Glasgow meeting, for example, there were 75 consultant members of the Representative Body as compared with 281 general practitioners.

If consultants and specialists still feel anxious about their position in the constitution of the B.M.A. they should feel encouraged by the Committee's proposals for the reconstruction of the Branches of the Association. It recommends that "the Branches shall be reorganized on a basis corresponding in the main with the areas of the Regional Hospital Boards." In this way hospital staffs will find a B.M.A. focus for their interests and a unit large enough to embrace them effectively. The Branch Council will be able to co-ordinate the opinions of all sections of the profession in its area, and the Divisions and the Regional Consultants Committees will have a common meeting-place for discussion and a common instrument for formulating policy. The Branch Council, the Committee states, "should contain in its membership representatives of all the organized bodies in its area, and so be able to speak with authority on behalf of the profession as a whole." What stands out in this proposal is that it would lead to the establishment of a much closer relationship between hospital staffs and the Association and thus go a long way towards removing the criticism, untenable though it is, that the Association is principally concerned with the welfare and interests of general practitioners. The Committee

does not recommend any change in the present constitution of the Central Council of the B.M.A., consisting of 77 members, of whom 40 members are elected by Branches in Great Britain and Northern Ireland grouped for the purpose. But the proposed reorganization of the Branches, if carried through, might have as one result an increased representation of consultants in the Council.

There is space here to touch upon only a few outstanding matters in a report of remarkable interest. Among others there is the recommendation that a second scientific meeting should be held in the winter, a reminder of the fact that one of the principal aims of the B.M.A. is to promote the medical and allied sciences. It is much to be hoped that members will read and re-read the Constitution Committee's report in this week's *Supplement*. It is the thoughtful product of much hard work. It shows that the B.M.A. is a live organization, alert to its responsibilities in a rapidly changing world. Its publication now, well in advance of the Annual Meeting, gives Divisions ample time to study it and their Representatives the opportunity to join in the debate at Newcastle with prepared minds. Much will depend upon the decisions the Representative Body takes, because it will be laying down the pattern for the future.

MEETING THE NEW MINISTER

A delegation from the Negotiating Committee met the Minister of Health, Mr. D. F. Vosper, on Wednesday this week, and at the time of writing we are ignorant of the results of the meeting. The new Minister has taken office at a time when the profession is deeply disturbed about its relations with the Government and about the conditions in which it works in Britain's National Health Service. With little time in which to grasp the intricacies of the situation facing him Mr. Vosper will have had to lean heavily on the advice of his civil servants; and almost immediately on his appointment he was invited to attend a meeting of the Cabinet. In these circumstances he will inevitably be the spokesman of others, and what he says on the immediate issue of remuneration will be said on the authority of the Cabinet. Whatever the reactions of the profession to this, it will no doubt be fair-minded in its attitude to Mr. Vosper himself at the beginning of his tenure of an office to which many have been called but in which few have chosen to remain.

This week will show whether Mr. Vosper is to adopt the same negative attitude as his predecessors

to the medical profession's claim that its remuneration must continue to be based on the recommendations of the two Spens Committees. It is now being said that the Spens formula is unrealistic and that something new and more flexible must be sought. What at present seems to be inflexible is the Government's attitude to its moral obligation to act on a promise. We do not recall that when the Conservative Party was in opposition in 1948 it raised even one voice against the "unrealistic" nature of the Spens reports. And if the Government to-day tries to evade the issue by calling for a new formula—a more flexible formula—what confidence will the profession have in it in view of the way the Government has treated it since July, 1948? During the past several months our negotiators have patiently asked for a reasonable examination of their case, and have for their pains been fobbed off with a cursory dismissal of it. One result of this has been to bring to the surface a volume of frustration and discontent with many other things than the amount of pay for work done. If—as some people are suggesting—the Spens formula is not flexible enough, neither is the Health Service itself. Doctors feel themselves cased in a rigid structure which inhibits initiative and creative activity.

Basing their claim on the Spens formula, our negotiators have asked for an increase of 24% in the remuneration of those working in the Health Service. If this is rejected the various elements in the Negotiating Committee—we understand—will report back to their constituents. If this is to be done it is hoped that it will be done quickly, so that concerted and united decisions and action may be taken without too much delay. The crisis now facing the profession is for the whole of the profession and not just any one section of it. It must remain united in its collective responsibility not only for its several parts to-day but for the profession of to-morrow.

Many correspondents to this *Journal* rightly insist that the first question to be settled is the present claim for increase of pay in accordance with the Spens recommendations. If the Government refuses to admit their validity, then the relations between it and the profession will be at breaking point. It will have precipitated a crisis that will be of its own making, a crisis of confidence, as it has been aptly called. The present mood of the profession is shown unmistakably by the many resolutions from different parts of the country calling for withdrawal from the N.H.S. if no satisfaction is given. Short of this, a demand might be made for arbitration, a time-honoured method of settling disputes between two groups of people each of which believes it has reason on its side.

GESTATION AND SEX

The idea that the time in the menstrual cycle when intercourse takes place might have some influence on the sex of the child is not a new one.¹ There has been no direct support for this hypothesis, however, and attempts to examine it on experimental animals have given conflicting results.²⁻⁵ Indirect evidence which may have a bearing on the matter has recently been obtained by T. McKeown and B. MacMahon⁶ in an investigation of sex differences in length of gestation of mammals. Their starting-point was the well-established fact that the period of gestation is slightly longer for girls than for boys, and their own observation that the proportion of male children decreases as the period of gestation increases. The relationship was not the same in all the mammals examined. Pregnancy was longer for males than for females in the cow, horse, and possibly the sheep, and appeared to be longer for females than for males in the guinea-pig as well as in man. In commenting on these observations McKeown and MacMahon focused attention on the data for man and the cow, species in which the interpretation is somewhat simplified by the fact that only one foetus is usually present. They suggest that in the cow the most likely explanation of the longer gestation of males is that the proportion of males conceived is higher if mating takes place early in heat; this is to say that in relation to time of ovulation—which occurs after the end of heat in the cow—it is the date of mating which is early and not the date of birth which is late. At first sight this possibility would appear to be ruled out in the case of man, since the sex difference in duration of pregnancy is probably attributable to a difference in foetal weight; second-born females and first-born males are of approximately the same birth weight, and are delivered after about the same period of gestation. But in cattle gestation is dated from mating, whereas in man it is dated from onset of menstruation, and hence provides no information about the time of mating in the cycle. In short, the observations on the cow suggest that sex of offspring may be related to time of mating, whereas the human data are wholly, and inevitably, inconclusive.

This conclusion is necessarily cautious. McKeown⁷ has noted that, if the sex of the child is related to the

time in the menstrual cycle when intercourse occurs, it might explain some of the anomalies of the human sex ratio at birth. There has never been a satisfactory explanation of the fact that the proportion of male births decreases slightly as parental age increases, and that the proportion appears to increase during war. Both observations might be accounted for if the proportion of males conceived is higher in pre-ovulatory than in post-ovulatory matings, since an increase in the frequency of matings would probably tend to increase the proportion of early fertilizations and to raise the sex ratio. In this context the decline in the proportion of male births with increasing parental age is of particular interest. It has never been clear whether the change is associated primarily with age of mother or with age of father, and it is so small that large numbers of observations are required to separate the two influences. A recent report by E. Novitski and L. Sandler,⁸ based on all births of white children in the United States in the years 1947-52, suggests that the age of the father is more important than the age of the mother. If this is true the age trend cannot be attributed mainly to a maternal influence—such as a sex difference in the incidence of abortion—but must also be due to something associated with the father's age. Variation in the relative frequencies of production of X- and Y-bearing sperm is well established in some animals, and is the explanation suggested by Novitski and Sandler. But if time of intercourse in the cycle has an effect upon sex of offspring the slight decline in the proportion of male children with increasing paternal age might result from a decline in the frequency of intercourse rather than from a change in the relative viability or frequency of the two types of sperm.

OXYGENATION IN RADIOTHERAPY

Cellular damage from exposure to x rays is believed to be caused by two different processes—first, by direct "hits" by the ionizing particles on the chromosomes, and, secondly, by ionization of the water contained in the cell with the production of very short-lived oxidizing radicals which inactivate the cellular enzymes and may lead to cell death.¹ The formation of these oxidizing radicals is appreciably increased in the presence of oxygen. The proportion of the cellular damage which can be ascribed to each of these processes is not known, but recent radiobiological research culminating in the work of L. H. Gray and his colleagues² has suggested that the latter is at least as important as the former, if not more so. They showed that the sensitivity of many different types of plant and animal cells to damage by x rays may be reduced, both *in vivo* and *in vitro*, by as much as two-thirds if they are deprived of their normal oxygen supply, but will not be greatly increased in the

presence of excess oxygen. In man the normal environment of most cells contains oxygen at a tension of about 35 mm. Hg, and a rise in the tension will not greatly affect the radiosensitivity; similarly, normally oxygenated tumour cells will not be made much more radiosensitive by increasing the oxygen tension. Many tumours, however, contain large numbers of cells which, because of poor blood supply, exist under almost anoxic conditions.³ It is believed that these poorly oxygenated cells may survive such doses of irradiation as may safely be given to patients, but that if the oxygen tension to which they are subjected were raised to somewhere in the normal range they might become much more sensitive.

In 1954 K. A. Hultborn and A. Forssberg⁴ described four cases of skin tumours in which the concomitant inhalation of oxygen at atmospheric pressure appeared macroscopically to have amplified the effect of irradiation. In the following year I. Churchill-Davidson, C. Sanger, and R. H. Thomlinson^{5,6} reported the results of a preliminary investigation into the effects of irradiating carcinomas in patients breathing oxygen at a pressure of three atmospheres absolute (30 lb. per square inch (2.1 kg. per square cm.) gauge pressure). To obtain results quickly they tried to determine whether the expected increase in radiosensitivity was demonstrable histologically. To do this they treated patients with carcinomas large enough to be divided into two fields for irradiation. One field was irradiated with the patient breathing air at atmospheric pressure and the other with the patient breathing oxygen at three atmospheres in a pressure chamber. Each field was irradiated once only with the same dose of x rays. To compare the effect on the two fields a dose was given which was considered insufficient to kill all the cells. After an interval a biopsy specimen was taken from each field, or the growth was excised, and the pathologist was told where the dividing line between the fields lay but not which field was irradiated in oxygen. Eight patients were treated—four had carcinomas of the lung and four carcinomas of the breast (two were local recurrences after mastectomy). The results were encouraging in that the tissue which the pathologist reported as more damaged was in six cases out of the eight that irradiated in oxygen. This was also probably true in the seventh case, but the conditions of the experiment were not fulfilled, the pathologist having been told, because of some misunderstanding about the dividing line, which tissue was which. In the eighth case no distinction could be made because none of the tumour cells in either field had survived.

At the annual congress of the British Institute of Radiology last December, Churchill-Davidson and his colleagues presented the results of treatment of a further thirty-five patients, who had been given potentially cura-

tive doses of x rays to the whole tumour while breathing oxygen at three atmospheres—the criterion for their selection being that they should, either owing to the tumour's extent or histology, be considered to have little chance of cure by conventional radiotherapy. The apparatus and technique, though experimental, had proved satisfactory and no mishap or immediate complication attributable to the treatments had occurred. The authors stated that, although the results could be regarded only as a preliminary assessment because of the short time which had elapsed since many of the patients had been treated, the initial response of the tumours had in most cases been very much better than would otherwise have been expected in their experience. Nevertheless, they believed that several years' work would be necessary before a final appraisal could be made. The work of P. Howard-Flanders and E. A. Wright⁷ suggests that the addition of oxygen might increase the incidence of radionecrosis of bone and cartilage because of the normally poor oxygenation of these tissues. It is hoped that this difficulty will be overcome by the use of higher energy irradiation, since this is less absorbed in bone and cartilage.

UNSETTLED CHILDREN

The concept of maladjustment in children is so loosely defined that its frequency must necessarily be uncertain. Recent estimates in Somerset, Birmingham, and Berkshire, as reported by the Committee on Maladjusted Children,¹ vary between 5.4% and 11.8% of school-children. This committee, though it embraced a wide definition of maladjustment, seemed to be considering it primarily in relation to child-guidance clinics, paying little attention to children, for example, whose maladjustment brings them before juvenile courts, and encouraging what may be regarded as an undesirable differentiation between the needs of maladjusted and of delinquent children. At least until a year ago 23 counties and 26 county boroughs had no child-guidance clinics, and even if the lowest estimates are accepted existing clinics can hardly be expected to cope with the maladjusted children of their locality.

D. H. Stott, whose previous writings have mainly been concerned with delinquency, has now published a book with the apt title *Unsettled Children and their Families*,² which is directed towards relieving the burden on child-guidance clinics and encouraging teachers and parents to deal more confidently and at an earlier stage with a proportion of their difficult children. He sets out to establish which of the common parental inadequacies matter little or much, to show in detail the kinds of family weakness which give rise to delinquency and to other unsettled behaviour. He lists half a dozen patterns of unsettled behaviour—overdemandingness, withdrawal, depression, and so on—and follows with a dozen "breakdown-producing" family patterns. He has as aids to diagnosis "adjustment pointers," "native-wit schedules," "life-history charts," and "diagnostic

summary sheets"—all of which are to be used by those who are professionally concerned with children but have no formal training in clinical work. He also elaborates ten syndromes of parent-child attitudes, linking up observed behaviour with its meaning for the child. Some readers may think Dr. Stott oversimplifies the problem; he scarcely mentions previous classical work, and he makes some rash statements and alarming excursions into unknown territory. For him "all basic anxieties in children relate to some threat, real or imagined, to membership of the family group." Clinical interviews and the whole body of psychotherapy, individual and group, are rejected. Intelligence tests in clinics should be abandoned entirely. "Depressive reactions" and "irritable, intolerant states" suggest "neurophysical exhaustion" and should be treated by physical rest; even "some of the outbreaks and fits which are now thought to be epileptic" should be treated by "systematic rest-therapy." Enuresis should be looked upon as a "strain illness" of the same order as "infective illnesses of bronchi, ear, nose," and included in the same group are "bad co-ordination and other spastic conditions . . . fits, bad turns."

Nevertheless, there are some useful lessons to be learned from this book. It is probable that teachers and other understanding people, perhaps even parents, could effectively help a far larger proportion of those unsettled children now being sent to child-guidance clinics. In doing so their main need is not a high degree of psychological sophistication but the ability to step outside their immediate relationship with the child and to view the situation objectively. It will not matter very much whether they follow Dr. Stott or the many other authorities who have written on parent-child reaction patterns, so long as they realize that patterns exist, and that each child needs careful observation and assessment in relation to its family. A further point, which should appeal to general practitioners, is that by a confident bearing, a simple, perhaps empirical, prescription, and the prevention of further damage through panic action while Nature completes the cure, a doctor may often be of the greatest help to his patient; and so it undoubtedly often could be with disturbed children. There is surely a need for the child psychiatrist to emerge more frequently from his clinic, in order to help enlightened teachers and social workers to undertake as much of the treatment of unsettled children as possible; and the psychiatrist will have to play the major part in effecting that enlightenment.

EMERGENCY OBSTETRIC SERVICE

Flying squads to give emergency obstetric treatment are now based on 172 maternity hospitals or units in England and Wales. They receive about 3,000 calls per year, or, expressed in another way, their assistance is sought in 10 out of every 1,000 domiciliary deliveries. About three-quarters of the calls are for complications arising during the third stage of labour, but among the other emergencies flying squads are being called on to treat are abortion, antepartum haemorrhage, eclampsia, prolonged labour, undiagnosed malpresentations, mul-

tiple pregnancies, prolapse of the cord, and acute inversion of the uterus. Elsewhere in this issue (p. 455) we report the twenty-first birthday celebrations of the emergency obstetric service at Newcastle upon Tyne, which answered its first call on October 15, 1935, and is thus one of the oldest units in the country. Before the setting up of this service in Newcastle investigations had shown that, while some maternal deaths arose from failure to refer complicated cases to hospital, some women lost their lives as a consequence of their transportation to hospital. This was especially true of patients with the third-stage complications of haemorrhage, retained placenta, and shock—and it was to this group that the obstetric emergency service was primarily directed. An excellent account¹ of the work of the Newcastle service was published in this *Journal* some years ago. In that area it has always been the practice to send out an experienced obstetrician as a member of the team, and this good example has for the most part been followed in other parts of the country. More recently it has been found that invaluable help can often be given by a specialist anaesthetist. In the early days of flying squads there was a fear that obstetricians might be forced by the circumstances of the case "to perform operations at home that would have a wider margin of safety in hospital"²; but according to London experience this fear proved without foundation.³

Though the country is reasonably well served by obstetric emergency services, long distances have to be covered by the flying squads in some regions, with inevitable delay in the treatment of the patient. Consequently the alternative suggestion has been made of distributing emergency equipment among doctors, district midwives, cottage hospitals, or maternity homes—and actually put into effect in the Winchester group of hospitals. Such arrangements will enable transfusion to be given while the flying squad is en route.

With the great reduction of puerperal sepsis, the commonest causes of maternal mortality and morbidity are the toxæmias and haemorrhages. Improved antenatal care and selection of cases for hospital can further reduce maternal mortality and relieve the flying squads of some of their most anxious problems. Early diagnosis and treatment of anaemia, the early detection of pre-eclampsia and hypertension, fuller investigation of the "high head" in relation to placenta praevia before bleeding, immediate admittance to hospital (without internal examination) of every case of bleeding, however slight—all these will make their contribution. So long as domiciliary delivery continues, however, there will be need for efficient service of flying squads. Since the midwife alone attends many patients in need of emergency treatment it would seem reasonable that she should be permitted to summon the service herself in extreme emergency when she is unable to obtain immediate help from the patient's practitioner. Finally, so that full advantage may be taken of the service, executive councils and medical officers of health should keep general practitioners and domiciliary midwives informed

about the location of the flying squads and the method of summoning them to an emergency.

PHYSIOLOGICAL FUNCTIONS OF ZINC

In 1940 D. Keilin and T. Mann claimed to have demonstrated for the first time the physiological function of zinc in organisms.¹ They showed it to be the active part in the molecule of the enzyme carbonic anhydrase. Later workers have shown that this was in fact only the first clue to the varied activities of this widely distributed element. The average human dietary uptake of zinc is 10-15 mg. a day.² A similar amount is excreted in the faeces. Urinary output is relatively insignificant in health. Some patients with albuminuria have been shown to lose more in their urine and to have a negative zinc balance.³ Young male rats fed on a zinc-depleted diet show retarded growth, loss of fur,⁴ and failure of genital development,⁴ but no deficiency syndrome has been recognized in man. These changes may all be secondary to pituitary hypoplasia. Pigs have a relatively high requirement of zinc, and if it is not supplied they develop dermatitis.⁵

Most human organs contain 40 to 200 µg. of the metal per gramme of dry weight.⁶ Normal prostate has been shown to contain about 700 µg. and spermatozoa about 2,000 µg. per gramme.⁷ Several groups of workers have reported that malignant tissues may differ from normal tissues in their zinc content.⁸⁻¹⁰ Zinc has been found not only in carbonic anhydrase but also in uricase¹¹ and in alkaline phosphatase.¹² In recent years B. L. Vallee and his colleagues at Harvard have shown it to be a component of a number of dehydrogenases. By means of statistical methods they related their findings to some important clinical conditions. They showed¹³ that the level of zinc in the serum is reduced in patients with liver cirrhosis of Laennec type, and that this reduction is quantitatively related to the severity of the disease. In two patients who improved clinically under treatment the serum levels of zinc returned to the normal range. Eight patients with infectious hepatitis had normal serum levels of zinc. Hepatic alcohol dehydrogenase and glutamic dehydrogenase, which catalyses the release of ammonia from glutamic acid, are both zinc enzymes. Most of these writers' patients were alcoholics, and accumulation of ammonia is considered to be related to hepatic coma.¹⁴ Consequently their findings give rise to some interesting speculations. In another paper¹⁵ the

Harvard workers show that zinc levels in the serum fall and that the activity of lactic and malic dehydrogenase in the serum increases after myocardial infarction. Some patients with signs of coronary artery disease but none of infarction had normal lactic dehydrogenase activity in the serum. Lactic dehydrogenase certainly and malic dehydrogenase possibly contain zinc; both are related to the liver dehydrogenases. Further work is clearly required to see whether these changes occur in clinically similar conditions.

INTELLIGENCE AND CLEFT PALATE

The intelligence of children with congenital malformations, apart from those such as mongolism in which the brain is directly affected, has been little investigated. There is a clinical impression that mental defect is more common in some instances, but few direct measurements have been made. Professor R. S. Illingworth and Dr. L. B. Birch,¹ of Sheffield, recently made a survey of children with cleft palate all treated by the same plastic surgeon, Mr. Hynes. There were 112 in the original sample who had reached the age of 4 years. Of these, 54 had hare lip and cleft palate and 58 the genetically distinct condition of cleft palate alone. The authors were able to test 61 of these children, 19 were tested by the local authorities, and 17 were not tested but school reports were available for them. No information was to be had on 15, of whom 2 had died. The Terman-Merrill test was used both by Illingworth and Birch and by the local authorities. The mean I.Q. was found to be 95.4, which was significantly different from the assumed mean of 100. Unfortunately no figures were available for the normal test score in Sheffield, and large regional variations in mean intelligence test score are known to exist.² However, of the 80 tested, 3 had an I.Q. below 50, 5 had an I.Q. between 50 and 70, and there were 5 with an I.Q. of over 120. No difference was found between the group with hare lip as well as cleft palate and those with cleft palate alone. The 17 on whom only school reports were available appeared if anything rather less intelligent than the main group.

This evidence that there is a tendency for children with cleft palate to be below average intelligence is borne out by P. Fogh-Andersen's finding in Denmark that 59 instead of an expected 20 children with hare lip and cleft palate were present among 17,000 mentally defective children.³ Illingworth and Birch put forward two possible explanations of their finding. One is that the lower intelligence is due to the same factors, genetic and environmental, as are responsible for the malformation. The other is that there will have been a tendency for independent genetic factors for the deformity and dull intellect to have become associated in the lower strata of society. This second theory, which the authors prefer, is perhaps less probable, since there appears, for example in Fogh-Andersen's Danish study, to be no tendency for the two malformations to be more common in the lower social strata.

ROYAL COLLEGE OF SURGEONS

HUNTERIAN FESTIVAL

As in previous years the Hunterian Oration at the Royal College of Surgeons, Lincoln's Inn Fields, on St. Valentine's Day was followed by the Hunterian Festival Dinner with the President of the College, Sir HARRY PLATT, in the Chair.

The toast of "The College" was proposed by Sir ALBERT RICHARDSON, a past president of the Royal Academy of Arts, who in his speech stressed the importance of anatomy both in art and in the more intimate mystery of surgery. Hunter, he reminded his audience, was not only a great anatomist, but he was also a patron of the arts—he collected good pictures and kept many academicians from starving. He recommended them to do likewise. They had already shown that they had leanings that way in their patronage of an architect and their regard for good pictures, but modern art, he thought, would have to go back again and study anatomy, and the same applied to architecture. He welcomed the association between the arts and the great profession of surgery.

The President on the Rebuilding of the College

The President, Sir HARRY PLATT, who responded to the toast, reviewed the progress made towards the rebuilding of the College. The Nuffield College was now, he said, a heritage, a new heritage for the twentieth century for the College of Surgeons. They had also to record with deep gratitude a number of benefactions. The Wellcome Trustees, whose generous gift of £100,000 had made possible the construction of the beautiful museum which lay above the Great Hall, had given them an additional sum of £35,000 to cover unforeseen costs already incurred in the first stage of their rebuilding programme which had been completed three years ago. Mr. Edward Lumley's gift of £35,000 was no longer shrouded in anonymity, and they thanked him for his support and continuing interest in the affairs of the College. They had also received in the past few months tangible recognition of the great interest shown by leaders of industry in the importance of the College to the nation.

So far he had only spoken of the buildings of the College as an appropriate response to the toast, but their research and teaching activities had inspired new support on a most generous scale. The boards of their two faculties, dental surgery and anaesthetics, had placed research in the forefront of their new activities and ambitions. Of the two, the research department of anaesthetics, already generously endowed, was launched on its career in spacious quarters on the top of the Nuffield College.

Research in the older scientific departments of the College, long established and increasingly expanding, should not have its growing needs overlooked. Their programme of teaching drew students from all parts of the world and they had already outgrown the accommodation in the old College and in the new Wellcome Museum floors. Two years ago, when he had reported on the state of the College, they were looking with confidence beyond the completion of the Nuffield College to the final stage of the restoration and rebuilding of the College—to phase three of the scheme. The first stage of phase three had been designed to provide for extensions to the departments of anatomy and physiology, the new research department in dental science, and logy, the new research department in research in new accommodation for the department of research in ophthalmology. The second stage was to give a much-needed lecture room for teaching departments at present housed temporarily in the Examination Hall in Queen's Square, and, finally, a new Hunterian Museum to display the great collection committed to the care of the College by the nation under the leadership of William Pitt 150 years ago.

Two years ago they saw the new buildings clearly. Their hopes then were high, but they had been brought face to

face with hard facts. Phase 3a would be completed by September, but as a shell only, and there they would be compelled to halt—a breathing-space only, they trusted—until the nation came to realize that the world-wide prestige of British surgical science demanded that the College be restored, extended, and maintained in order that it might fulfil its manifest destination as an academy of surgery, international in its influence and achievements.

Hunterian Oration

Earlier in the day Sir ERNEST FINCH, of Sheffield, had delivered the 89th Hunterian Oration, taking as his subject "The Influence of the Hunters on Medical Education." Both William Hunter and his brother John had been teachers, he said. Coming to London in 1741, William entered St. George's Hospital as a surgeon's pupil. Of his early training he said he had learned much by his ears and almost nothing by his eyes, and therefore nothing to the purpose. His ability to teach was obvious, and by 1746 he was giving anatomy classes and advocating the establishment of a museum of anatomy and surgery for London. John Hunter joined his brother in 1748. During the subsequent years the brothers taught anatomy and conducted research to such good purpose that their school became famous and attracted pupils from all over England and the Colonies. Those pupils, in many cases, returning to their native towns carried with them such a respect for the methods of the Hunters that they became responsible for the founding of similar medical schools. Thus the College at Philadelphia had been founded, the New York Hospital, and the Medical Faculty in Pennsylvania. In Great Britain, Manchester, Edinburgh, Glasgow, and Leeds became centres of training in the same way.

What was it that had so influenced the Hunters' pupils, and made the Hunters such pre-eminent teachers? Teaching by example rather than precept seemed to have been their guiding principle: throughout their lives both Hunters continually urged that practising surgeons should also teach. John Hunter particularly impressed on his pupils the importance of observation and experiment.

John Hunter himself had practically no formal education at school—what we would now call "general education." This made one ponder on the effects of trying to force people into a common mould. Indeed, the heart attack which caused Hunter's death was brought on by his vigorous protests about the advisability of his teaching two would-be pupils whose education fell short of official requirements. At the present time educational standards were governed by examination, and that had resulted in competition between the universities and other licensing bodies. The time seemed opportune for a reconsideration of John Hunter's contribution to medical education. In the lectures attributed to him he seemed to present his students with a fully integrated subject. With the growth of natural science, subjects now tended to be presented independently of each other. It was for the universities to restore their integration.

THE NEWCASTLE FLYING SQUAD

TWENTY-FIRST BIRTHDAY CELEBRATION

The Newcastle Flying Squad—or more correctly the Newcastle Obstetric Emergency Service—celebrated its twenty-first birthday by a party on February 21. A pioneer of such services in Britain, the squad answered its first call in October, 1935. Since then it has responded to 1,377 urgent calls, the peak being in 1955, when 146 calls were received. The party, given by the Governors of the United Newcastle-upon-Tyne Hospitals, was held at the Princess Mary Maternity Hospital, the squad's base. The opportunity was taken to honour Professor E. FARQUHAR MURRAY, formerly professor of midwifery and gynaecology at Newcastle and now professor emeritus, the prime mover in establishing the

squad. His portrait was presented to him by VISCOUNTESS RIDLEY, chairman of the Princess Mary Maternity Hospital's management committee. Those at the party included senior members of the medical and nursing staffs of the Royal Victoria Infirmary, the Princess Mary Maternity Hospital, and the Newcastle General Hospital; representatives of the Board of Governors, the Regional Hospital Board, the Regional Blood Transfusion Service, and the College of General Practitioners; and the Medical Officers of Health of Newcastle, Northumberland, and Durham.

Organization of the Squad

Telephone calls for the squad are switched direct to the labour room at the Princess Mary, where a senior sister is always available. The words "Flying Squad" give priority. The sister then informs the antenatal sister on duty and calls the obstetrician and the anaesthetist. Great care is taken to record accurately the name and full address of the patient, the nature of the emergency, and the ABO and Rh blood-group of the patient. The caller is told to station at an agreed point near the house a guide, armed during darkness with a white towel or large handkerchief for identification.

The squad's equipment is in the care of the antenatal sister, and she always accompanies the squad when it goes out. Her intimate knowledge of the equipment and her wide experience in converting the most unpromising environment into an adequate labour room are of great value to the service. Owing to the considerable distances to be covered by the squad (up to 60 miles—96 km.), it has been found quicker for the consultants to collect the sister and the equipment at the hospital. To avoid any possible delay, the anaesthetist travels in his own car. This arrangement works well, as all the consultants concerned live within a short distance of the hospital, and it is extremely rare for the patient to be moved to hospital. The equipment is comprehensive and quite adequate for whatever treatment may be needed—even caesarean section, although this has been performed only in exceptionally urgent circumstances where the squad was called to a small remote maternity unit. Some squads operating in very restricted areas advocate simple resuscitation and rapid transfer to hospital by ambulance, but at Newcastle this has never been regarded as the service's proper role. Treatment is carried out on the spot.

The teaching and research undertaken last year at the London School of Hygiene and Tropical Medicine is described in its recently issued annual report. All the school's main courses of instruction were filled to capacity. The dean, Professor A. BRADFORD HILL, F.R.S., mentions that the new course for the academic diploma in applied parasitology and entomology seems likely to attract medical, veterinary, and zoological graduates of high quality. The investigation of the protein value of tropical dietaries and supplementary foodstuffs by the department of human nutrition has been greatly helped by a grant of £17,000 by the Rockefeller Foundation. The department of statistics and epidemiology has many subjects under review, in addition to the well-known continuing investigation by Dr. Doll and Professor Bradford Hill of the mortality of doctors whose smoking habits were recorded five years ago. Poliomyelitis, whooping-cough, and B.C.G. vaccines are being assessed, the epidemiology of cardio-respiratory disease is being investigated, and general practitioners have collaborated in the study of otitis media. A survey is being made of the incidence of tuberculous illness among pathologists, post-mortem room attendants, and young technicians. The department of applied physiology has looked into the problem of ventilating lecture-rooms, and in the section devoted to the work of the department of public health there is an informative account of "The Natural History of Study Groups," based on experience gained during the courses for the D.P.H.

Preparations and Appliances

MODIFIED BRONCHOSCOPIC FORCEPS

Mr. KEITH D. ROBERTS, F.R.C.S., of the Children's Hospital, Birmingham, writes: Foreign bodies in the adult's and child's bronchial tree may be dealt with adequately using the present range of biopsy and grasping forceps. However, in neonates and infants the size of the bronchoscope introduced (3 or 4 mm. diameter) precludes the use of a normal-sized forceps, as the view obtained with the forceps down the bronchoscope is extremely poor, and in addition the airway is almost completely obstructed.

A boy of 21 months was admitted to hospital having inhaled a widely open safety-pin; this was lying with the point directed up the trachea, the remainder of the pin being in the left main bronchus. A 3-mm bronchoscope was introduced through the larynx, which was extremely small, but the pin could not be grasped with the available forceps owing to the poor view; a tracheotomy was done and a 4-mm. bronchoscope inserted through this. Again the pin could not be extracted, and a bronchotomy had to be done in order to remove it. Unfortunately the child became anoxic and cardiac arrest occurred before the endotracheal tube had been passed. Although the child's heart-beat was restored by endotracheal insufflation with oxygen and cardiac massage, irreversible cerebral damage had resulted and he died 20 hours later.

In view of this tragedy two biopsy forceps of 2-mm. and 3-mm. diameter, of Chevalier Jackson type, were specially made and have recently been used successfully in several children under 2 years of age.

A boy of 2 years had a post-anaesthetic aspiration of vomit in another hospital following an operation for strangulated inguinal hernia. A tracheotomy was done there in order to clear the airway by suction, as the hospital had no small endoscopic forceps available. A radiograph showed atelectasis of the right upper and middle lobe with obstructive emphysema of the lower lobe, suggesting the presence of a foreign body in the right main bronchus. He was transferred to the Children's Hospital, Birmingham, where a 4-mm. bronchoscope was introduced through the tracheotomy. A nut was seen in the right main bronchus, and was easily extracted under direct vision using the 3-mm. biopsy forceps.

It was felt that the best pattern of forceps to be constructed was the biopsy type, as metallic foreign bodies can be grasped with these, while vegetable matter, such as nuts, are more easily held than with the ordinary type of grasping forceps.

Details of these forceps are as follows: (a) Biopsy forceps, 2 mm. diameter cup jaws; inserting length 35 cm., with 2 mm. shaft; stainless-steel handle; suitable for use through Chevalier Jackson and Negus type newborn infants' bronchoscopes having an internal diameter of 2.5 mm. or more over the light-carrier. (b) Biopsy forceps, 3 mm. diameter cup jaw; inserting length 35 cm., with 2.4 mm. shaft; stainless-steel handle; suitable for use through Chevalier Jackson and Negus type infants' bronchoscopes having an internal diameter of 3.5 mm. or more over the light-carrier. Both forceps are of the usual tubular type—that is, the action of the handle forces a slender tube over the stylet which carries the jaws.

I am indebted to Mr. J. Blair, of Messrs. Philip Harris, Ltd., Birmingham, 3, for his help in the construction of these forceps.

Reports of Societies

**PSYCHIATRIC INDICATIONS FOR
TERMINATING PREGNANCY**

The Section of Psychiatry of the Royal Society of Medicine met on February 12, with the President, Dr. WILLIAM SARGANT, in the chair, to discuss "The Psychiatric Indications for the Termination of Pregnancy." Members of the General Practice Section were specially invited to attend. The meeting was distinguished by the complete lack of agreement on what constituted grounds for advising termination in women suffering from mental illness.

Quot Homines, Tot Sententiae

Dr. J. D. W. PEARCE (St. Mary's Hospital, London) opened the discussion by reminding the audience that in Britain abortion was a felony punishable by life imprisonment. It could be condoned only when the life of the mother or her mental or physical health was at stake. The psychiatrist must ask two questions—what psychiatric conditions were likely to be aggravated by pregnancy, and how serious must these be to warrant termination? A review of the literature revealed distressingly little uniformity of opinion: in general, termination was recommended for organic psychoses, severe depression, and suicidal tendencies, but there were those who said it was rarely needed even in the most severe cases. Very often mental disorders arising early in pregnancy improved with time, while those appearing later persisted after the puerperium and were not influenced by termination. It was therefore wise to wait until quickening rather than advise premature hysterectomy. There was more agreement, however, on when not to terminate: psychoneurosis, for example, was never an indication, and psychopaths benefited from pregnancy. There was a very real danger that abortion would produce a guilt complex in the mother.

Dr. Pearce found a similar lack of common ground when he analysed questionnaires sent to 45 psychiatrists and one general practitioner. The majority agreed that there must be a clear causal relationship—for example, a previous breakdown during pregnancy—between the psychiatric illness and pregnancy, and that severity was a useful criterion. There was a deplorable lack of precise knowledge of the effects of pregnancy and abortion on the course of mental illness. What was needed was a group of specialists, including the general practitioner, to study each patient on her merits, preferably in hospital. With adequate medical care in the fullest sense probably very few women would be advised to seek termination. So often those in a position to offer advice were influenced by emotional, ethical, moral, and religious views rather than by objective criteria based on scientific evidence.

Experience at Manchester

Professor E. W. ANDERSON (Manchester Royal Infirmary) also stressed the paucity of the material and the difficulty of scientific investigation in a field which by its nature precluded accurate assessment. There had been remarkably few attempts to systematize what knowledge there was. Up to 1933 in England the weight of evidence was against the increasing tendency to terminate pregnancy. Since then experience in countries like Switzerland and Sweden, where abortion laws had been relaxed, suggested that, while a majority of women expressed satisfaction with termination, a definite proportion continued to have mental symptoms. He had analysed the records of 52 patients with psychiatric illness who had been referred for termination and/or sterilization. Half of these had threatened suicide; diagnoses were mixed, but there were no certain schizophrenics in the series. Only one of the twelve patients whose pregnancies had been

terminated showed definite improvement, and half of those who were allowed to proceed to term had had no further trouble. On the other hand one of the very definite risks of refusing termination was that the patient herself would attempt abortion. The resilience of women in the face of stress was often underestimated, and there seemed very little medical justification for termination of pregnancy on psychiatric grounds. But if the State insisted on continuation of pregnancy, said Professor Anderson, then it must provide adequate social services to protect the mentally ill or unstable mother.

Winchester Abortion Panel

Professor W. C. W. Nixon (University College Hospital, London) made an impassioned plea for the gynaecologist, on whom fell the onus of performing the operation "in good faith." It was very difficult for him to assess the risk to the patient, especially where there were threats of suicide, but if there was a likelihood of injury to health then abortion was justified. Antagonism must never be allowed to develop between the psychiatrist and the gynaecologist, though this was likely to happen if the latter felt that he was being used merely as a technician. There was a great need for an "abortion panel" on the lines of that started at Winchester ten years ago by Mr. Philip Mitchell. This consisted of six members of the hospital staff elected annually, and proceeded as informally as possible. The patient was referred by the general practitioner in the usual way for an opinion from the gynaecologist and the appropriate specialist. The whole case was then reviewed by the panel. The patient and her husband and the general practitioner were invited to attend. For such a scheme to work successfully it was vital that both the clinician and the gynaecologist should abide by the majority opinion of the panel, even if it was contrary to their personal view. Equally important in the whole problem of termination was the fullest possible follow-up, and particularly adequate contraceptive advice. In one Swedish series no less than 20% of the patients had unintentionally become pregnant again in the 12 months following termination in spite of such advice. This should not be allowed to happen.

A review of just over 500 patients whose pregnancies had been terminated in the last 18 years at University College Hospital showed that 39% had had psychiatric disorders, and these headed the list of indications. On the other hand mental symptoms would yield to early and sympathetic care, particularly in hospital. No gynaecologist should be asked to terminate a pregnancy at a stage later than the 14th week. The hazards of therapeutic abortion in the second trimester were very real: long-term effects such as sterility, habitual abortion, and endocrine shock were as important as the operative risks involved; in addition there was the overwhelming sense of detestation in those who had to carry out what amounted to no less than a caesarean section in miniature.

Discussion

In the discussion which followed Dr. ALECK BOURNE said that termination was useless in established psychoses. Dr. E. TYLDEN quoted case histories to show that it was virtually impossible to predict the effect of a particular course of action in the individual patient, except possibly in puerperal psychosis, where prodromal symptoms might be recognized early enough to make termination of value. Dr. BRIAN ACKNER hoped that psychiatrists would not prejudice the decision of the gynaecologist by what they said to the patient about termination. Dr. E. STENGEL assured the audience that in spite of the frequency of threats of suicide the incidence in pregnancy of the act itself was extremely low. Other speakers confirmed the general impression that it was quite impossible to lay down definite criteria for termination, and that there was a pressing need for study by groups of interested persons. The tone of the meeting was summed up by a general practitioner, who said that he was becoming increasingly convinced that termination for mental illness was not the right answer.

Levene and Michaels," you have misquoted as a case of Hodgkin's disease: in fact there was not more than a superficial resemblance histologically to Hodgkin's disease; the case was a difficult and complex one, but there is no justification for interpreting it as Hodgkin's disease. Well-proved cases of Hodgkin's disease in which torulosis developed as a terminal infection have now been recorded often enough for the fact of this association to merit acceptance. In view of the evidence, does your annotation not err too far on the side of caution in describing the association as between torulosis and a lymphadenopathy closely resembling Hodgkin's disease? Cannot the words which I have put in italics be left out?

If you will allow me the space, Sir, may I mention what seems to be a bibliographical anomaly in the annotation? Your reference to Busse and Buschke suggests a joint communication. In fact Busse and Buschke never collaborated in print, although each published a number of contributions based on the same case. The journal reference which you printed is to a summary of the proceedings of a session of the *Greifswalder medizinischer Verein* on July 7, 1894: the various papers are clearly numbered as separate abstracts: the first two, which relate to the case in question, are attributed respectively to Buschke and Busse, and should surely be listed independently in a bibliography.^{10, 11} In any event, priority in print must be conceded to Busse, whose lecture to the Greifswald meeting was published in full¹² before the abstract appeared, although Buschke seems to have had the first word at the meeting itself.

In conclusion, then, it may be said that the great majority of cases of Hodgkin's disease remain free from torulosis, and that most cases of torulosis occur without any evident predisposing cause. It is impossible to say how frequently the two diseases are associated: Zimmerman and Rappaport³ found the association 11 times among their 60 cases of torulosis, and the 60 cases were filed at the A.F.I.P. during about the same period as "over 1,000" cases of Hodgkin's disease. This suggests an incidence of one case of torulosis among about a hundred cases of Hodgkin's disease, and there are obvious reasons for taking this figure as only the roughest guide to the real incidence. A search for predisposing factors in patients with torulosis, and a complementary study of immunological behaviour in patients with Hodgkin's disease and the like, are potentially useful lines of research. Meanwhile, it is worth remembering that recurring headaches in a patient with Hodgkin's disease can signify the clinical onset of torulosis of the brain or meninges and should not too readily be attributed to radiation malaise or other passing cause.—I am, etc.,

Northwood, Middx.

Antibiotic Cover for Dental Extractions

SIR.—The thought-provoking article by Drs. F. G. Hobson and B. E. Juel-Jensen (*Journal*, December 29, 1956, p. 1501) contains statements leading to far-reaching therapeutic conclusions that cannot be accepted uncritically. Cases of subacute bacterial endocarditis are classed in two groups as due to *Str. viridans* or other organisms; in 42% of the former, however, blood cultures were negative, bacteriological diagnosis resting thus on clinical grounds, which are hardly ever conclusive. Nevertheless, the essential difference between patients with positive and negative haemocultures is amply revealed by the fact that only 18% of the

former, but 39% of the latter, died in course of active treatment. Due consideration for the more serious prognosis of abacteraemic subacute bacterial endocarditis as already demonstrated by us¹ on over 1,000 cases observed during 1945–51 in Hungary—would have guarded the authors against the statement contradicting most literary data that immediate mortality is unaffected by the intensity of antibiotic therapy. As a matter of fact, they had almost identical numbers of deaths in 1946–50 with low, and in 1951–5 with higher, penicillin doses; the different composition of both groups, however, should not be disregarded, as negative blood cultures totalled a third of the first, but one-half of the second. Within this prognostically unfavourable fraction, 4 out of 7 died during 1946–50, and 4 out of 14 during 1950–5, increased dosage of the antibiotic producing thus a 50% reduction of mortality, quite in accordance with our own findings. In the light of the authors' own data, the view that the organism concerned and the antibiotic used will largely determine the final success or failure seems justified and the search for some other explanation less imperative.

No experienced physician will underrate the importance of infected teeth and incautious dental surgery in the pathogenesis of subacute bacterial endocarditis. The authors' observation that no case of viridans-caused or abacteraemic endocarditis ever occurred in an edentulous individual is very interesting and calls for confirmation on greater material (the high frequency of completely toothless persons in the control group—40% in the fifth and 62% in the sixth decade of life—somewhat surprises me, but may be accounted for by local and national differences). While fully agreeing with the authors concerning the necessity of removing infected teeth under adequate "cover," I hardly see my way to live up to their postulate of extracting all intact teeth too as an essential item of the therapeutic attack upon subacute bacterial endocarditis. I am almost sure the majority of physicians will abstain from extracting prophylactically all the excellent teeth of a patient in symptomless remission (Case 4) as long as there is little more standing for it than the statistically rather insignificant fact that, of seven patients stripped of all teeth, none relapsed, although 1.4 relapse should have been observed according to the computed rate of expectation.—I am, etc.,

Budapest, Hungary.

Long-acting Antibiotics

SIR.—While pharmaceutical manufacturers are searching the earth for new antibiotics they have neglected one aspect of research which would be of greater benefit to patients in general practice. I am writing this letter as a plea to drug houses to provide us with the newer antibiotics in a form that can be injected at infrequent intervals. In hospital a drug can be administered six-hourly by a stroke of the pen, but outside we are all familiar with the patient who has a few capsules remaining a week after we have prescribed a five-day course, and with little Willy "who was much better after he had a dose of Johnny's medicine." Many of our patients, given careful instructions, can be trusted with oral antibiotics, but others cannot, and for these we need the newer antibiotics in forms similar to procaine and benethamine penicillin.—I am, etc.,

South Shields.

R. W. NEWMARK.

Toxic Psychosis Caused by "Preludin"

SIR.—Dr. M. F. Bethell (*Journal*, January 5, p. 30) and Dr. Lewis Clein (*Journal*, February 2, p. 282) reported the cases of two female psychopaths who developed abnormal mental states after taking excessive doses of Preludin for several months. The history of a patient recently admitted to this hospital shows several features closely resembling in particular those of Dr. Clein's patient.

A male neurotic alcoholic, aged 35 years, had in the past taken amphetamine, dexamphetamine, and, to counteract their effects,

pentobarbitone at night-time to excess. In August, 1956, he stopped drinking, and, anxious to reduce his overweight, he began to take Preludin. He soon found that by increasing the dosage he experienced a "kick" similar to that obtained from alcohol and a feeling of exhilaration and well-being, three or four Preludin tablets having an effect on him comparable to that of one amphetamine or dexamphetamine tablet. However, gradually Preludin took "a worse grip" on him than alcohol had before. He needed more and more tablets to achieve the same effect, and, as he could not acquire nearly enough Preludin on prescription to satisfy his craving for it, he began to buy it from chemists in different districts of the town. For the first two weeks the pleasant effects of five to eight tablets lasted two to three hours and were then followed by feelings of depression and irritation, headache, and difficulty in concentrating and insomnia. To dispel this "hangover" he regularly took three butobarbitone tablets at night-time. By December the doses of Preludin had gradually increased to 20 tablets in the morning and 50 in the evening, followed later by eight butobarbitone tablets taken as an "antidote." The effect of 50 Preludin tablets lasted about six hours, during which time he was excited, over-confident, and garrulous. When the effect of Preludin began to wear off he felt that people were staring at him and looking at his eyes.

During the whole of this period he had been off alcohol, except on one occasion when he had no sleeping tablets in stock after having taken 40 Preludin tablets. He therefore took 4 pints (2.3 l.) of cider in the evening, but these did not prevent a severe hangover next morning. He then consumed 20 more Preludin tablets and a double gin, afterwards feeling confused, walking unsteadily, and thinking that a policeman was watching him. According to the patient's own estimate his average daily Preludin dose over the four months had been about 50 tablets. At the end of this period he was—according to his wife's account—in an excitable and irritable state; he avoided going to public places, as he felt people were looking at him, and he complained that people were insulting him. He had lost 3 stone (19 kg.) in weight in the four months. Both the craving, and especially the hangover, were described by the patient as stronger with Preludin than in the case of alcohol. It was only when the Preludin effect was wearing off that he felt depressed and had other disagreeable symptoms. When the supply of butobarbitone tablets was stopped by his doctor early in December the fear of the unpleasant Preludin withdrawal symptoms apparently proved greater than his craving for the exhilarating effect of Preludin, and he then took Preludin tablets at the same time as butobarbitone. In the next few days he felt restless, "vague mentally," depressed, and he could not sleep at night. Four days afterwards he suffered an epileptiform convulsion (? barbiturate withdrawal) and was taken to hospital. An E.E.G. there is said to have been normal. He reverted to excess drinking a fortnight after stopping Preludin.

As in the case of Dr. Clein's patient, the history reported here shows some of the features described as characteristic of drug addiction¹—i.e., craving, a tendency to increase the dose, and a (psychological) dependence on the effects of the drug. These cases also bear out the opinion of the W.H.O. Expert Committee that "any substance which . . . will adequately replace the drug which has produced the addiction" (in this case alcohol and amphetamines) "must be considered as also capable of producing an addiction." Like the amphetamines, Preludin seems to belong to that group of drugs "whose pharmacological action is intermediate" between habit-forming and addiction-producing drugs, so that addiction to this drug can develop in certain unstable individuals.—I am, etc.,

Apartheid in Blood Transfusion

SIR.—Since you have not yet closed the correspondence on this pathetic topic, I should like to comment on Dr. P. G. Preston's letter (*Journal*, December 22, 1956, p. 1487), which has just reached here. A major reason for our presence in Africa has been the impulse to eradicate harmful superstitions by education, and this process should eventually solve Dr. Preston's problems of tribal incompatibility. Unfortunately, there appears to be little secular machinery to combat the racial myths still current among literate people, while the laudable work of certain religious organizations is slow and at present of only limited appeal. Surely those international bodies which are so generous with grants for technical study could be persuaded to support a scheme in which, for example, some of our colleagues from South Africa or the southern U.S.A. could visit an area like Trinidad where many races are living in harmony. I believe that they would return with a vastly different approach to the problem of race relations and that they could do much to curb their more fanatical countrymen. Meanwhile I can assure them that it is not difficult for a hospital with staff and patients of many African, European, and Asian origins, with a variety of religious beliefs, to run with efficiency and harmony. Our blood bank is organized on a scientific, not a superstitious, basis, without harm to patients or donors.—I am, etc.,

Trinidad.

B. SYMONDS.

Mass X-ray of Refugees

SIR.—It seems that the arrival of 11,000 aliens recently in this country without any preliminary screening is quite likely to swell the tuberculous "infector pool" which we are all so concerned to empty. From every authoritative source come exhortations to weed out the old chronic infectious case, while at the same time considerable numbers of far more mobile persons are admitted to the country without any question of a systematic x-ray check on arrival. Apparently any amount of money is forthcoming to treat those aliens who fall ill with tuberculosis—after they have been allowed to infect those with whom they live and work—and it seems there is no lack of money for treating those whom they infect. Neither money, nor forethought, nor any national policy is apparently available for steps which would help to prevent such a state of affairs.

In 1950 my unit visited a Polish hostel for displaced persons, finding no fewer than 9 cases of extensive tuberculosis among 300 persons examined—a case rate of over 27 per thousand. Two weeks ago we visited a transit camp for Hungarians and found 2 sputum-positive cases among 240 young persons, and 8 other persons requiring further supervision. In addition, two persons with extensive disease had already been admitted to hospital before we arrived. The camp had thus a case rate of 16 per thousand, as compared with the 6 persons per thousand in the general population estimated by Cochrane¹ (Rhondda Fach survey) to have active disease. These experiences have been frequently paralleled and reported by colleagues in the mass radiography service examining groups of foreign workers in this country, yet over 7 years this seems to have caused little or no concern to our authorities, and the admission of aliens without any systematic check proceeds exactly as before.

However sympathetic we may feel towards the unfortunate Hungarians or other refugees, our first consideration is for the health of our own people, especially school-leavers and young people who may come in contact with them at work, and it seems urgently necessary that all those admitted so far should be x-rayed before they are placed in employment, or before they go to live or work in families with young children. Unfortunately about half the refugees have already started work, and are now scattered far and wide throughout the country. The only way they could be reached would be through the Ministry of Labour, their employers, the police, or through general practitioners with

whom they may register. May I urge the latter to arrange for a routine chest film for any new foreigner who comes on to their list? Canada, Australia, and the United States require a clear chest x-ray as a condition of entry for every intending emigrant. Must this country gradually accumulate the unfit or those rejected by our own Dominions? We certainly cannot afford to have 7,000 persons die a year from tuberculosis any more than they can.

It would be interesting to know whether arrangements are being made to x-ray the next influx of refugees from the Austrian camps, and to ask why several mass radiography units were not immediately detached at the beginning of the emergency to deal with refugees at their first holding units. As a taxpayer, and as a doctor who has spent several years endeavouring to empty the pool of potential tuberculosis infectors in the community, one takes grave exception to the lack of any firm policy in this country about allowing the uncontrolled admission of aliens who may have communicable tuberculosis. It seems quite disgraceful that no steps are being taken to stop feeding the infector pool from outside sources. It costs the country over £1,000 to keep and treat a man in a sanatorium for a year and provide for his dependants, and it is still apparently not fully recognized that mass radiography justifies itself economically if a single unit can find only a small number of cases a year at a sufficiently early stage to obviate or reduce the necessity for costly hospital treatment. If we cannot afford any extension of mass radiography facilities, surely deployment of certain units to check foreigners entering this country would be more than justified.—I am, etc.,

Cambridge.

Treatment of the Cord in the Newborn

SIR,—Reading, as unfortunately frequently seems to occur, back numbers of medical journals, I have come across Dr. Victoria Smallpeice's note on treatment of the cord in the newborn (*Journal*, July 14, 1956, p. 104) in which she refers to Dr. A. B. Murray's memorandum (*Journal*, June 30, p. 1530) which I had already seen, and more recently there has been another reference by Mr. A. L. Deacon (*Journal*, December 1, p. 1299). The method used here in the Hadassah Hospital has proved thoroughly satisfactory in over 8,000 deliveries for which I have been responsible during the last five years. I learnt the method here and would certainly not be tempted to revert to any other treatment. At birth in all babies known to be Rh-positive the cord is clamped by Kocher's forceps as close as possible to the umbilicus. About three hours later the cord is cut with a scalpel close to the closed Kocher's. The stump is painted with iodine tincture and the forceps are removed. Bismuth subgallate powder is then applied on a sterile gauze swab which is attached by a binder for 24 hours. The dressing is inspected after half an hour, and thereafter whenever the babies have their napkins changed. Only about four cases of slight haemorrhage have occurred and were easily controlled by a suture. If any cases of infection occurred they must have been very mild, as none returned, and we are the only hospital available. The umbilicus is dry and clean from the beginning, which is a particular advantage here where the patients are discharged from hospital three or four days after delivery. The method needs a little courage on the part of the obstetrician and nursing staff for the first half-dozen cases, but conviction quickly follows.—I am, etc.,

Beersheba, Israel.

DORIS SELBY.

Varicose Ulcers

SIR,—I am replying to Dr. Peter Darby's letter on varicose ulcers (*Journal*, February 2, p. 287), because I have met in the literature an astonishing amount of dogma on this subject that does not agree with my findings when I was working in ulcer clinics at the London Hospital. Perhaps the difficulty in treatment stems from the varied pathology which

can be found in this "lower leg syndrome," even when thrombosis has apparently been excluded. Nevertheless, Foote² asserts that all varicose ulcers can be cured, but I agree with Naide,³ who says that some cases appear to be incurable.

Nobody will dispute that the application of some salve⁴ and some kind of support may suffice. Brodie⁵ described supportive treatment in 1846, although I had heard a rumour that a German peasant brought the idea over during the last war. The addition of a "venous heart" (a rubber sponge which contracts as the patients walks) may promote healing. I agree with Foote and your correspondent that good, even bandaging is very important. Indeed, many patients insist that experienced bandagers gave them most relief. But it is untrue to say that one simple treatment is a panacea, and this bears out my belief that there is a varied pathology, either locally, or in the venous drainage of the limb, or in the arterial supply. To this are added the personal idiosyncrasies of the patient. The only series I have found claiming 100% success is MacAuley and Carey's⁶ series of popliteal vein resections, followed by grafting in some cases.—I am, etc.,

Dublin.

T. HEATON WILLIAMS.

Neostigmine-resistant Curarization

SIR,—I am surprised to find that in a discussion of cases of neostigmine-resistant curarization the dose of the offending drug is often omitted, and therefore places under some doubt the conclusions drawn. Dr. A. R. Hunter (*Journal*, October 20, 1956, p. 919) does not mention the dosage of suxamethonium, D-tubocurarine, or gallamine in any of his six cases. There seems to be, among anaesthetists, a wide variation in the doses of relaxants considered necessary for the production of satisfactory operative conditions. For endotracheal intubation, in the induction phase, 15 mg. D-tubocurarine is regarded as adequate by one anaesthetist, while another would not regard 30 mg. as being unduly high. Drs. W. E. B. Scott and J. C. Clarke (*Journal*, November 17, p. 1174) gave to a "small, wizened lady of 67, weighing 64 st. (41 kg.)," with a small-bowel obstruction, as an initial dose 80 mg. of gallamine, whereas from the information given others may regard 40 mg. as being more suitable for the occasion. Dr. P. A. Foster (*Journal*, December 22, p. 1485) used 35 mg. of D-tubocurarine and 40 mg. of gallamine, which also appears to be a large dose, although admittedly we are not told the weight of the patient or the duration of operation.

And what of the criteria for administering further increments? They may be given when abdominal muscle tone is about to delay the surgeon's rate of progress or to maintain "finger-tip" controlled respirations by suppressing the first flicker of spontaneous respiration. The total relaxant given, therefore, during an operation is subject to wide variation because of the individuality of the anaesthetist, quite apart from the individuality of the patient. A record of the dosage of the relaxants, age and weight of the patient, and operative duration would, I think, provide some useful data for discussion with regard to the optimum management of these cases.

I hope that the advice of Dr. C. Langton Hower (*Journal*, January 5, p. 45) and many others against the use of both types of relaxant in the one case will not pass unheeded. Unless the combination of relaxants is proved to have no adverse effect the luxury of intubation under suxamethonium should be forgone, thus eliminating one unnecessary complicating factor. In view of the fact that D-tubocurarine may depress cholinesterase activity and that suxamethonium produces marked depletion of muscle potassium, their combined use on a moribund patient would appear unwise.

I feel that overdosage of relaxant may account for many of these cases. This may occur (1) when a justifiable anxiety over vomiting makes a rapid, trouble-free intubation highly desirable and leads to a too liberal administration in the induction phase, and (2) at the point where we have to decide whether the surgeon's difficulties are due to abdominal distension or to inadequate relaxation.

Perhaps I have been fortunate not to have met neostigmine-resistant curarization using an orthodox technique of thiopentone, D-tubocurarine, nitrous oxide/oxygen, with controlled respiration, avoiding pethidine and using the thiopentone for the induction only. I have found that controlled respiration can often be maintained for an hour or so using only 15 mg. of D-tubocurarine. It is a method in which I still have every confidence.—I am, etc.,

Liverpool.

ITHEL LL. FRANCIS.

SIR,—It was with great interest that I read Dr. A. R. Hunter's article (*Journal*, October 20, 1956, p. 919) and the additional reports and comments (*Journal*, November 10, p. 1113; November 17, p. 1174; November 24, p. 1240). It may well be that the cases reported can be divided into two groups.

The first group is characterized by a circulatory failure which does not respond to intravenous fluids or vasopressors for more than a short time. The accompanying general muscular weakness with its associated respiratory insufficiency seems to me to be related to the same primary cause as the circulatory disturbance. Patients of this group are old or debilitated and have a considerable upset of nutrition, with or without accompanying sepsis. This clinical picture suggests a diagnosis of acute suprarenal cortical insufficiency provoked by surgical stress, anaesthesia, or anoxaemia in a severely ill patient. These patients die, as Dr. Hunter described, of "circulatory degeneration and peripheral vascular failure . . . in spite of adequate artificial respiration." It seems to me possible that these patients could be saved by the rapid infusion of hydrocortisone, and there is probably no connexion between this complication and the use of relaxant drugs or neostigmine.

On the other hand, there is a second group characterized by profound derangement of the central respiratory modulation with muscular weakness or paralysis, but there is in them no circulatory failure, provided adequate artificial or assisted respiration is maintained. Curiously enough, these patients are sometimes able to move their limbs, though weakly, but are unable to breathe. There is a relationship between this complication and the use of fully controlled respiration, particularly in patients with emphysema. In my experience this complication occurs as often after the administration of D-tubocurarine as after an infusion of suxamethonium, and always when complete apnoea with artificial ventilation has been maintained for some time. So far I have never heard of a similar case when partial muscular relaxation with assisted respiration and small doses of relaxants have been used. Hence there is, in addition to the use of local analgesia, a possible way of avoiding this complication. If it appears in a patient, one must consider whether unnecessarily high doses of the relaxant drug have been given, or whether artificial respiration in excess of the needs of the patient has been continued for too long a time. The prognosis is not bad if the anaesthetist is patient enough to assist respiration carefully and manually until it becomes adequate again—a process which may take as long as four hours after the operation.—I am, etc.,

Basle.

W. HÜGIN.

Noradrenaline in Shock Due to Visceral Perforation

SIR,—I wish Dr. D. D. Davies had given more information on the anaesthetic technique used in his report of three cases of post-operative circulatory collapse treated successfully with noradrenaline (*Journal*, February 2, p. 261). Each case showed an initial rise of blood pressure before the fall. This and other features suggest that the effects of carbon-dioxide retention were being added to those produced by the surgical

condition. Was the respiration assisted or controlled? What type of breathing system and gas flows were used?

Trichlorethylene is an interesting agent to choose for abdominal surgery. When positive-pressure ventilation is used without carbon-dioxide absorption a non-breathing system is required to avoid respiratory acidosis. This can be achieved with devices such as the Cardiff inflating piston-type valve,¹ or a flap rubber non-return valve. The Magill semi-closed attachment will eliminate rebreathing when the patient is breathing spontaneously and when the gas flow is at least equal to the patient's minute volume.^{2,3} As soon as the reservoir bag is compressed by hand, the conditions change. The expiratory valve lifts during the last part of the inspiratory phase, discharging relatively fresh gases into the room. The expired mixture is pushed back into the lungs first. Luckily a variable amount of longitudinal mixing takes place, and a healthy subject is able to withstand this not uncommon practice for a short time, but the poor risk is poorer.

Dr. Davies also questions the safety of long-acting muscle relaxants in these shocked patients. Many anaesthetists would consider D-tubocurarine to be safer than the mixed neuromuscular block produced by the suxamethonium-gallamine-suxamethonium sequence used in the three cases described.—I am, etc.,

London, E.14.

Glycyrrhetic Acid

SIR,—In view of the conflicting reports of the therapeutic effectiveness of glycyrrhetic acid preparations and the suggestion by Dr. E. Colin-Jones that some isomers are active and others inactive (*Journal*, January 19, p. 161), I am carrying out a series of planned experiments in animals to investigate the anti-inflammatory actions of glycyrrhetic acid. I am finding that some fractions of glycyrrhetic acid are definitely active against certain types of induced inflammation, details of which will be published shortly. In reply to the letter by Drs. J. W. Cornforth and D. A. Long (*Journal*, February 9, p. 340), I have in one experiment tested an active fraction of glycyrrhetic acid by the method described by Long and Miles,¹ and found it to actively depress the sensitivity to tuberculin in B.C.G.-infected guinea-pigs in a manner similar to cortisone. Further tests are in progress.—I am, etc.,

London, W.C.1.

"Pacatal"

SIR,—We were interested in the article by Drs. P. H. Mitchell, P. Sykes, and A. King on effects of "pacatal" on symptoms (*Journal*, January 26, p. 204). Pacatal has been in constant use in Prestwich Hospital for the past 12 months, during which time 300 patients were treated for periods of from 2 to 6 months. Their ages ranged from 20 to 80 years, and the period of hospitalization from 7 weeks to over 20 years. Our routine dosage has been as follows: During the first week, 150 mg. daily, increased, if necessary, after the seventh day to 300 mg. daily. In a few cases the maximum dose was 600 mg. daily. The average duration of a course was about 8 weeks, but in some cases as long as 24 weeks. A full blood count was carried out before commencing treatment, the white cells being estimated at weekly intervals during the first month of treatment and thereafter at fortnightly intervals during the remainder of the course.

The symptoms described in the *Journal*—noisiness, incontinence, and aggressive behaviour—were, generally speaking, well controlled by pacatal. We have experienced no serious side-effects with the drug. We have seen hypotonia, the symptoms of which disappear completely on cessation of the drug, but the minor side-effects, such as

dryness of the mouth, do not necessitate discontinuation of the treatment. The more serious side-effects, such as jaundice and agranulocytosis, have not been encountered in our cases, and no patient undergoing treatment by this drug has suffered any ill effects or died. We feel it is only fair to say, therefore, that we have had at least 12 months' experience with this drug on a fairly extensive scale, and consider that its use is justified. In many cases it is preferable to chlorpromazine, and certainly sensitivity reactions, such as dermatitis, have not been encountered with pacatal. —We are, etc.,

Prestwich, Lancs.

M. KRZANOWSKI.
M. ROGERS.

SIR,—We were interested in the article by Dr. P. H. Mitchell, Dr. P. Sykes, and Dr. A. King on "pacatal" (*Journal*, January 26, p. 204). We cannot give figures, but we have used it with some enthusiasm in place of chlorpromazine, since it seemed to have, and still seems to have, a qualitatively and quantitatively better action on the patient's mental state and behaviour. We now find, however, that it is the side-effects which are troublesome, and sufficiently so for us to revert to chlorpromazine not infrequently. Disturbances of accommodation are not very troublesome in the chronic psychotic, but constipation is, and is sometimes difficult to detect early. Dryness of the mouth is also common and troublesome, frequently causing appearances like those of vitamin B deficiency, and in two of our cases there was a sudden acute parotitis. We have seen mild hypotensive and ataxic symptoms but no leucopenia or jaundice (we have, however, had only one case of jaundice from chlorpromazine in the hospital in spite of extensive use of the drug).—We are, etc.,

Norwich.

E. A. BURKITT.
P. E. RIXON.

SIR,—I should like to comment on the article on "pacatal" by Drs. P. H. Mitchell, P. Sykes, and A. King which appeared in the *Journal* of January 26 (p. 204).

I have recently completed an investigation with pacatal on 50 (25 male and 25 female) chronic psychotic patients, the results of which have not yet been published, and found very little in the way of toxic complications. Although two deaths occurred in the course of the trial, they were not unexpected and were not due to pacatal, but it was considered that the effects of the drug as a contributory factor could not be entirely excluded. One, a woman aged 68, had been on 150 mg. of pacatal daily for six weeks when she developed a temperature and was found to have a *Bact. coli* urinary infection. The drug was stopped and the pyelitis responded to antibiotics, but she died 17 days after pacatal was stopped. The cause of death, ascertained by necropsy, was (1) acute congestive heart failure, (2) myocardial degeneration, (3) coronary atherosclerosis. Eight days after stopping pacatal she developed an adenitis of the submandibular salivary glands which may well have been connected with the decreased salivation produced by the drug. The other death was in a male, aged 48, a mental defective with superimposed schizophrenia in poor physical condition at the onset of treatment who required every nursing attention. He received pacatal 150 mg. daily for six weeks, pacatal 75 mg. and chlorpromazine 75 mg. for four weeks, chlorpromazine 150 mg. daily for five weeks, and finally pacatal 300 mg. daily for eight days. His physical condition continued to deteriorate slowly during the investigation, and all drugs were eventually stopped. The physical deterioration continued, and he died 19 days after pacatal was stopped. The cause of death, ascertained by necropsy, was (1) acute congestive heart failure, (2) myocardial degeneration, (3) schizophrenia.

The average age in my series was 46.3 years as against 59.5 years in the group of Dr. Mitchell and his colleagues, and the average stay in hospital 12 years against 21 years. No case of jaundice occurred. In their cases, 10 patients developed hypotonia. Seven of my patients (2 male and 5 female) showed unsteadiness and loss of balance, and two

of these had other features suggestive of incipient Parkinsonism. However, in my series this toxic feature appeared in all but one case on 300 mg. of pacatal daily and soon disappeared on reducing the dose. Only in one male patient did the loss of balance persist with the reduced dosage, and this necessitated stopping the treatment. When this investigation was begun the danger of agranulocytosis had not been reported, but a careful clinical check was kept on all patients, although routine white counts were not done. There was no suspicion of this complication in any of the 50 cases. Our consultant pathologist, who conducted the necropsies on the two patients who died, reported that there were no findings suggestive of agranulocytosis. There were two instances of recurrent vomiting, but again only on the higher dosage.

Dr. Mitchell and his colleagues quote the report of Kline and Jacob,¹ who also recorded serious toxic effects. However, Kline² has since written that his material, supplied from Germany, was probably either contaminated or inadequately prepared. He has used the product manufactured in the U.S. for nine months, and, although this has side-effects (as does any effective medicament, including those in the psychiatric field), there is evidence that there was something wrong with the batch on which they did their original examination. Bowes³ reports that constipation occurred in 10% of a series of 250 cases, and if this was overlooked the patients became quite toxic and started vomiting. In my investigation a laxative was given as a routine twice weekly, and this might well account for the relatively few serious toxic side-effects that I found. In Bowes's 250 cases there was no evidence of liver or kidney damage and no cases of agranulocytosis, although he did have two instances of leucopenia, in one of which the white count gradually returned to normal in spite of persisting with the drug.

From reports, which my findings confirm, pacatal would seem to be a valuable tranquillizing agent which is worthy of further investigation. However, a careful physical check must be kept on patients to whom it is administered, and I fully agree with Dr. Mitchell and his colleagues that it should not at present be used in out-patient practice.—I am, etc.,

Fareham, Hants.

R. WALLACE SIMPSON.

Vaginitis

SIR,—In your annotation (*Journal*, January 19, p. 155) you rightly stress the increase in the incidence of non-bacterial vaginitis in recent years and the numerous chemicals which have been advocated for treatment. There is no doubt that, if reinfection is avoided, most patients get cured by one or other method of treatment in a shorter or longer time. The patient, however, wants treatment to be as short as possible, and for this to be achieved it is essential that (1) the partner be examined and treated if necessary; (2) the chemical used by the patient (whether in the form of tablets or vaginal pessaries, etc.) must be applied accurately, and this means after individual instruction—furthermore, the medicament must be used in the first instance every day between two menstrual periods and then continued for a week after each period until at least four months have elapsed since treatment was begun; (3) a reminder should be given that while under treatment the use of contraceptive jellies and creams should be avoided—this is because it is essential that the pH of vaginal secretions should remain reasonably constant and not be affected by the addition of substances used for contraception to those prescribed for the treatment of *Trichomonas vaginalis* and allied infections.—I am, etc.,

London, W.1.

G. M. SANDES.

SIR,—We have been very interested to read the letter of Dr. R. D. Catterall *et al.* (*Journal*, February 2, p. 287) regarding the treatment of trichomonas vaginitis, also that

due to *Candida albicans*, with oral trichomonocides such as aminitrazole. Their findings have been confirmed in all our cases thus treated; also in three cases of urethritis in the male due to the *Trichomonas vaginalis* in which there has also been no response whatever. We have come to the conclusion that these preparations are therapeutically valueless in the treatment of these conditions.—We are, etc.,

NEVILLE MASCALL.
J. CHESNEY.F. G. MACDONALD.
R. BAKER.

London, W.C.2.

SIR,—We would like to support the opinion expressed in the letter from Drs. R. D. Catterall, E. M. C. Dunlop, and Eva Gallagher (*Journal*, February 2, p. 287) concerning the use of "an oral trichomonocide such as aminitrazole." In our clinic we have treated a small series of female patients suffering from trichomonas vaginitis with combined aminitrazole by mouth and local vaginal treatment as recommended. The *T. vaginalis* reappeared in the vaginal secretions after the completion of treatment in every case where follow-up was possible. These patients denied further sex contact after treatment, so that reinfection was unlikely as a cause of the reappearance of the *T. vaginalis*.—We are, etc.,

London, E.C.1.

CLAUDE NICOL.
AIDAN REDMOND.

Weight Trends During Pregnancy

SIR,—An important and not very uncommon cause of weight gain during pregnancy, not mentioned by Dr. A. M. Thomson and Mr. W. Z. Billewicz in their article (*Journal*, February 2, p. 243), is depression. Some mothers who are upset by an unwanted pregnancy react by over-eating and put on weight, the pathogenesis here being identical with that of simple obesity. The excess weight may persist after the birth unless the depression is dealt with. In such women the mother-child relationship is likely to be disturbed.—I am, etc.,

London, W.1.

D. F. O'NEILL.

Sign of Wind in Infants

SIR,—I was interested to read the letter by Dr. Jean McEwen (*Journal*, January 26, p. 229) regarding facial pallor and wind in infants. I recently saw two infants exhibiting facial pallor, which disappeared after eructation. One infant developed a typical attack of "three months' colic," with high-pitched scream, drawing-up of legs, and red congested facies. Approximately five minutes after the attack began I noticed a definite circumoral pallor, more marked over the upper lip, and thought it may have been due to vasoconstriction caused purely by mechanical stretching of the skin over the gums.

On observing another attack, also with pallor, I gently applied pressure to the cheeks, so releasing the tension on the circumoral skin, with resultant return of colour to the pallid area.—I am, etc.,

Llantwit Major, Glam.

MALCOLM J. PHILLIPS.

SIR,—In view of the interesting observation made by Dr. Jean McEwen (*Journal*, January 26, p. 229), I should like to record a personal observation in connexion with the diagnosis of "wind" in infants. The sign is a purely mechanical one and is comparable to the Hippocratic succussion splash which may be elicited in a case of hydropneumothorax.

To elicit the sign after a milk feed the baby is sat up on the observer's right knee facing his left. The baby is held upright between the observer's right hand, which is placed over the back of the baby's chest, and his left hand, which is placed over the lower part of the front of the baby's chest. The infant is now gently rocked towards and away from the observer. If there is "wind" to be brought up a sound not unlike that obtained when a glass of champagne is being poured will be easily audible. At times the sound produced is not dissimilar to the sound of waves lapping up against a boat. In the smaller infant who is unable

to hold his head erect he can be made more comfortable during the manoeuvre by supporting the chin between the thumb and index finger of the left hand.

The gastric succussion splash (as I have called it) is, of course, due to the splashing movement back and forth of fluid gastric contents made possible by the presence of the stomach gas bubble. Once eructation has occurred the sign cannot be elicited, and the absence of the succussion splash excludes the presence of "wind" in any significant amount. The sign should be elicited cautiously in the infant who tends to regurgitate more than the average amount with eructation.

The prime importance of the sign is in the prevention of "three-month colic," where it is essential to know whether there is any "wind" left before the baby is put down to sleep.—I am, etc.,

Brighton.

RONALD J. CANTWELL.

Bowel Obstruction

SIR,—Mr. R. J. Williams in his letter on bowel obstruction (*Journal*, February 2, p. 285) states that brussels sprouts have not been cited before as a cause of such obstructions. This brings to mind a case of lower small-bowel obstruction I saw about three years ago. On laparotomy and subsequent enterotomy the cause was found to be a brussels sprout more or less undigested. It may be of interest to note that this patient had previously had a partial gastrectomy of a full-width stoma type of operation performed.—I am, etc.,

Bradford.

B. N. COLABAWALLA.

Rupture of Hind-waters and Haemorrhage

SIR,—I see that two cases of infant death are discussed by Drs. J. K. Russell, D. F. Smith, and R. Yule (*Journal*, December 15, 1956, p. 1414), both being due to trauma of the placenta by a Drew Smythe catheter used to rupture the hind-waters. After the recording of the two cases the authors went on to elaborate on a test that may be done to differentiate between foetal and maternal blood. This seems a completely unnecessary elaboration of what should be a straightforward procedure. Would it not be more simple to suggest that the Drew Smythe catheters be withdrawn from service and rupture of the fore-waters be substituted when surgical induction of labour is contemplated? In the hospital with which I am associated 112,000 babies have been delivered in the past thirty years without a recorded loss of infant life due to such an accident—the point being that no Drew Smythe catheters are used.—I am, etc.,

Montreal.

THOMAS PRIMROSE.

Rheumatic Carditis

SIR,—Everyone who has been interested in the institutional care of children with rheumatic carditis will be interested in Professor N. B. Capon's article on the subject (*Journal*, February 9, p. 335).

What is missing from any article that I have read on this subject is the results of any organized follow-up of these important cases into later life. Such centres as London and Liverpool must surely have unique facilities for inquiring into the subsequent life histories of these patients.—I am, etc.,

Broadstairs.

MARTIN O. RAVEN.

Cricket

SIR,—The B.M.A. v. Law Society cricket match this year will take place at Hurlingham on Sunday, May 26. In order that the B.M.A. XI should be truly representative I would be very grateful if members interested in cricket would write to me, recommending the names of fellow-members whom they consider ought to play in this side. There are, I know, many doctors playing first-class club cricket who do not like to put themselves forward because they are too modest but who would be only too pleased to play if invited.—I am, etc.,

91, Warren Road,
Worthing, Sussex.

P. C. RUSHTON.

Obituary

Sir PERCIVAL HARTLEY, C.B.E., M.C., D.Sc., F.R.S.

Sir Percival Hartley, formerly director of biological standards at the National Institute for Medical Research, died at a London nursing-home on February 16. He was 75 years of age.

Percival Hartley was born on May 28, 1881, the son of Mr. W. T. Hartley, of Calverley, Yorkshire, and was educated at the Bradford Technical College and at Leeds University, where he graduated B.Sc. in 1905. With a Grocers Company Research Scholarship he then went to the Lister Institute of Preventive Medicine, where he

was from 1906 to 1908. In 1909 he obtained the London D.Sc., and in the same year went to India to join the staff of the Imperial Bacteriological Laboratory at Muktesar, in the United Provinces. He returned to the Lister Institute from India in 1913, but left during the first world war to serve as a captain in the R.A.M.C. from 1915 to 1919, being awarded the Military Cross in 1917. After demobilization he spent two years at the Wellcome Physiological Research Laboratories and then, in 1922, joined the staff of the National Institute for Medical Research. There his work gained him the William Julius Mickle Fellowship of the University of London in 1927. His achievements there were further recognized when, in 1936, he was appointed C.B.E., and by his election the next year to the Fellowship of the Royal Society. In 1944, two years before he left the National Institute, he was created a knight for his work in connexion with the development of penicillin for medical use. While at the National Institute he was appointed to the responsible post of director of biological standards. He continued his research work as a Wandsworth Fellow at the London School of Hygiene and Tropical Medicine from 1946 to 1948; at the Sir William Dunn School of Pathology, Oxford, in 1948-9; and at the Lister Institute again from 1949 to 1953. He was a member of the British Pharmacopoeia Commission from 1933 to 1948 and of the Medical Research Council from 1949 to 1953. In 1948 the University of Leeds conferred on him the honorary degree of D.Sc. He married Miss Olga Parnell in 1920. Lady Hartley died in 1950, and he is survived by the two daughters of the marriage.

Professor A. A. MILES, Director of the Lister Institute of Preventive Medicine, writes:

Percival Hartley's outstanding qualities are perhaps best appreciated against a background of biological standards, because they fitted him admirably for work in the important field that he made peculiarly his own. To it he brought enthusiasm, devotion, extreme care in bench work, and a determination to fight for principles. The many immunological standards that Hartley made, and the methods he devised for doing so, have been models for

the rest of the world and the principles of standardization on which he worked a part of the canon. He never tired of preaching these and became impatient only when he thought they were wilfully ignored. I remember a conference on the standardization of a drug at which a visiting expert defended certification of all batches without test on the recommendation of a committee, and, while Hartley chafed, detailed the qualifications of each eminent committee member. Hartley, leaping up, exploded with, "I don't care if you have Matthew, Mark, Luke, and John on it, what they are doing isn't standardization." He had little respect for mere authority and would protest to anyone he thought was violating either scientific principles or his own firm principles of decent behaviour. A diffident man, he would worry for some time about what form his protests should take, but he never hesitated to make them.

Hartley was an admirable teacher of his own subject, and no one ever acquired a shoddy technique from him. He was modest about his researches, but justifiably realized their value, especially his work on diphtheria immunity and on the effect of species differences, or refining techniques on the protective and sensitizing action of antibody. He was wont, a little slyly and perhaps a little wryly, to say that he was chiefly known for "Hartley's broth." But he will be remembered for much else in the science of immunology and for his integrity and charm—and remembered with the affection that can be inspired only by a kindly and devoted man.

Dr. D. A. LONG writes:

Sir Percival's standing as man and scientist will be acknowledged by those of his contemporaries all over the world who shared with him in the real achievements of the League of Nations and later the World Health Organization. More than anyone else he was responsible for the introduction of the international biological standards, and he never tired of describing the contributions, direct and indirect, that they have made to research. The scientific world will mourn the passing of a Fellow of the Royal Society. The medical practitioner will remember the man who fought long and effectively to eradicate diphtheria. Lady Hartley shared in his research in this field, and Sir Percival used to boast that his wife taught him all he knew in this branch of immunology.

The things of which he would boast were few—his family, the achievements of his country in international medicine, the National Institute for Medical Research, his assistants, his pride at being an Englishman. He never boasted of his own achievements. One story will suffice to show his selflessness and humility. As a young man he had accepted a major chair at an English university, but as the time of his appointment approached he asked for it to be given to another; his reason was that he felt that he could not fill it adequately. This was the only instance in which I knew his judgment to be false. He could unite a group of temperamental, even disagreeable, individuals into a team by the affection they felt for him. His enthusiasm for his subject was intense. He taught well and with great simplicity. He loathed shoddy technique, and one of his favourite sayings was, "A man is as good as his methods." No man could have been more kind to his juniors, and as the number of people who had served under him mounted with the years so the respect and affection in which he was held also increased.

Possibly the most remarkable thing about Sir Percival was his courage. He was a very sensitive man. Sometimes his simplicity and youthful enthusiasm—for he remained a young man all his life—led him to be the victim of the cynical and sophisticated scientist. On such occasions he was easily and deeply wounded. In spite of all his honours he was unconscious of his own ability, and worried a great deal even if he had to give a lecture to students. A shy port. Though he survived his wife for some years, he never fully recovered from her death. Those of us whom he taught will remember him in the techniques we use each

day at the laboratory bench. I shall always think of him when I read in *King Henry VIII* the King's tribute to Cranmer: "This good man—few of you deserve that title."

Mr. HARRY COOPER

It is with much regret that we record the death on February 14 of Mr. Harry Cooper, official reporter to the *British Medical Journal*. Mr. Cooper was 76 years old, and had been in ill-health for the past five years. Harry Cooper left school at the age of 15 and entered the office of a coal merchant and cornchandler in Boston, Lincolnshire. He taught himself in his spare time, among other things learning shorthand. At the age of 20 he went to London and was employed by the Amalgamated Press. He joined the Camera Club and

began to report for the Röntgen Society, now the British Institute of Radiology, thus beginning a connexion with the medical profession that grew as the years went by and earned him the gratitude and respect of a large number of medical men both within the British Medical Association and in the numerous medical societies that sought Cooper's help. In 1907 he reported the Section of Radiology at the Annual Meeting of the Association in Exeter, and in the then editor of the *Journal*, Dr. (later Sir) Dawson Williams, quickly appreciated Cooper's qualities. Cooper helped in the reporting of the meeting of the Association in Sheffield in 1908, and in 1909 accepted the position as reporter to the *British Medical Journal*, a position he held until his death.

For nearly 50 years Mr. Harry Cooper has been responsible for reporting the Annual Representative Meeting of the B.M.A., the proceedings of the Council and of its committees, and some of the scientific sections of the Annual Meeting and of the Royal Society of Medicine. He had an amazing capacity for concentrating his whole attention on the work he was doing, and this absorption in his task made him in time as familiar with medical terminology as were the speakers he reported. Cooper's "copy" was so excellent that it could go straight to the printer without much more attention than a few straight "cuts" to adjust it to the limitations of space. No pains were too great for him to achieve accuracy and conciseness, and no call for help in reporting was ever too late in the day. Over the years he acquired a remarkable knowledge of the medical profession and its personalities, and for all his modesty and self-effacement he was not slow in measuring a man's worth. Three editors of this *Journal* learned just how valuable were these qualities of mind and of character, and as time went on Cooper's developing ability as a journalist found increasing application in the writing of memoirs of the eminent, of leading articles on general topics, of concise summaries of voluminous official reports. His writing was lucid and direct and free from the cliché and the overworked phrase. Although, as one became aware, the *Journal* was first in his affections, Cooper's activities as a re-

porter and journalist spread far beyond it. Before the war, for example, he used to report matters coming before the annual assemblies of the League of Nations and the International Court at The Hague. His working day must have been as full as that of the busiest general practitioner.

Harry Cooper was a deeply religious man whose modesty was as much a part of himself as was his natural courtesy of manner. His finely tempered mind enabled him to outstrip the handicaps of his early education, and he looked upon his work as as much a contribution to something he valued as a way of earning a living. He was a most unusual man, and nothing would have surprised him more than to be told this.

Medical Notes in Parliament

Chronic Rheumatism

The MINISTER OF HEALTH was asked by Mr. P. COLLUCK (Birkenhead, Lab.) what was the estimated number of people in Britain suffering from rheumatism, arthritis, and kindred diseases, and what was the proportion of the population. He stated on February 13 that precise figures were not available, but surveys in particular areas and other evidence suggested that the rate of incidence of the chronic rheumatic diseases might be between 2 and 4% of the population per annum.

Prescriptions for Skin Complaints

Mr. PHILIPS PRICE (Gloucestershire, West, Lab.) asked the Minister of Health whether he was aware that in dermatological clinics the average prescription requiring more than one preparation was higher than any other type of clinic; and whether, in view of the heavy burden that this put on patients suffering from skin trouble in comparison with other types of cases, he would abolish making a charge of 1s. on all items in excess of a certain figure. Mr. D. VOSPER, replying on February 12, said his information was that there was some tendency for the average number of items for these prescriptions to be higher than the general average; but he was not satisfied that any special action was needed in addition to the existing arrangements to give assistance when it was required.

Poliomyelitis Vaccinations

Mr. B. JANNER (Leicester, North-west, Lab.) asked the Minister of Health on February 14 how many children had now been vaccinated against poliomyelitis since this method was put into effect; what report on the new batch of vaccine he had received from the Medical Research Council; and what reasons had they given in support of their views. Mr. VOSPER said the number was approximately 178,000. The report on the first batch of vaccine expected this year stated that it had passed all tests for freedom from active poliomyelitis virus and for potency, but that it failed to reach the required standards of purity. Tests on a second batch were still in progress.

Multi-racial Hospitals

Mrs. LENA JEGGER (Holborn and St. Pancras, South, Lab.) asked the Secretary of State for the Colonies how far it was his policy to encourage hospital development in the colonies on a multi-racial basis. Mr. A. LENNOX-BOYD stated on February 13 that the development of "group" or multi-racial hospitals in the territories was encouraged so far as religious beliefs and social customs permitted, but the basic aim was to produce an efficient hospital service acceptable to the inhabitants.

Composite Packs

Mr. NESS EDWARDS (Caerphilly, Lab.) asked the Minister of Health on February 18 what were the composite

packages now issued on one prescription, and whether any further composite packages had been proposed by the British Medical Association. Mr. VOSPER informed him that the following sets of apparatus or dressings, each of which included two or more articles, might be ordered as one prescription: atomizer, colostomy apparatus, douche, hypodermic syringe, smog mask, multiple pack dressing, perfusion fittings, suprapubic belt, Higginson's enema syringe, urine sugar analysis set, vaporizer. He said he was still awaiting the views of the Association on further packs.

Radiation Dangers

Mrs. E. HILL (Manchester, Wythenshawe, Con.) asked whether the Minister of Health could make a statement on the technical and administrative steps taken to reduce the amount of radiation from hospital and other radiology units; and, in view of the increased evidence of the danger of leukaemia and of general hazard to health arising from radiation, what steps were being taken to ensure that patients received strictly limited and not indiscriminate or repeated exposure when undergoing x-ray examination. Mr. VOSPER stated that radiologists and other members of the medical profession were well aware of these hazards, and he could not accept the implication that patients were exposed indiscriminately or unnecessarily to radiation. The whole question was, however, under review by a committee under the chairmanship of Lord Adrian, and any further action must await its report.

Increased Contributions to N.H.S.

In a statement on February 19 Mr. PETER THORNEYCROFT, Chancellor of the Exchequer, spoke of the savings in civil expenses to be concurrent with the expected saving in defence. The price of welfare milk is to be increased to 4d. a pint and the charge for school meals by 2d. to 1s. When the National Health Service was first introduced it was expected to cost £175m. a year. In 1957-8 the total cost of the Service would be £690m. Towards this a sum of £40m. would come from the contributions from the National Insurance fund (which collected 10d. from an adult man every week), £100m. from other receipts, including charges to patients, and the balance of £550m. from general taxation. It was proposed to increase National Insurance contributions by 10d. for an adult man and proportionate sums for women and juveniles. The employer would pay the same proportionate share as he did now. The purpose was to establish a separate National Health Service contribution towards the cost of the Service, and the results of the increase would be that the contributory element next year would rise from one-seventeenth to one-ninth of the total cost of the Service. It would provide an additional £40m. for the Chancellor in a full year.

Welfare of the Handicapped.—The Minister of Health is to reconstitute the Advisory Council for the Welfare of Handicapped Persons on April 1 as an advisory committee to advise him on questions relating to the health as well as the welfare of the handicapped. It is hoped to hold the first meeting of the new committee in April.

Medico-Legal

POLICE EVIDENCE PREFERRED

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

On February 11 Robert King, a Stranraer general dealer, was prosecuted before the Ayr Sheriff Court for driving a car while under the influence of drink to such an extent as to be incapable of having proper control over it, and for careless driving and failure to stop after an accident.

King, who had bought the car for £8 and later sold it for scrap for £5, said that on the evening in question he

Scotsman, February 13, 1957.

was driving in search of his wife, who had left him. He had had one drink of beer in an Ayr public house. The evidence for the prosecution was that his car had swerved and caused a van to mount the verge of the road; had gone round two corners on its wrong side; had collided with a taxi; had ignored diversion signs and gone down a road under repair; had zigzagged down a street, making people run to safety; and had reversed into a cul-de-sac and crashed into a hedge and railings.

King was arrested, and was examined by the police doctor, Dr. R. L. Leask. Dr. Leask, who was medical officer of health for Ayr and had 20 years' experience as police doctor, certified that, though King smelt of alcohol and at one point during the examination staggered slightly, he was not unfit to drive. In spite of this the sheriff-substitute, Mr. James Frame, convicted him after hearing the facts about his driving and the opinions of a police inspector, two sergeants, and two constables as to his condition. The depute procurator-fiscal observed that in spite of Dr. Leask's "failure" to certify King as unfit to drive he had the evidence of policemen of experience who would not let him leave the police station, and "no policeman would be likely to detain a man, knowing the rights of the subject in this country."

The sheriff-substitute relied on the "expert" evidence of the five policemen in preference to the view of Dr. Leask, who had said after a full examination that in his opinion it was not even a borderline case. Some short time must have elapsed between King's arrest and the doctor's examination, so the police had the advantage of him there, and no doubt the driving described in the prosecution evidence required explanation. But, as the agent who appeared for the defence said with some force, there seems to be little purpose in asking accused persons to undergo a test by the police doctor if, when the result is favourable to the accused, the prosecution can disregard it and ask the court to convict on the visual evidence of laymen.

King was sent to prison for 30 days and fined £20 for careless driving and failing to stop, and was disqualified from driving for three years.

Universities and Colleges

UNIVERSITY OF OXFORD

In Congregation on December 15, 1956, the following degrees were conferred:

B.M.—G. H. Fowler, D. C. S. Hutchison, A. J. Pemberton, M. S. Whitehouse, H. G. Nicol, W. D. Stone, E. D. A. Hay, Y. E. Hsia, S. R. Richardson, E. W. Sturton, J. B. Dawson, B. A. Roper, E. M. Swannie, T. Osborn, F. P. Greenwell, R. D. Last, R. C. Poynting-Wright, J. B. Sayer, T. P. Snell, G. C. Rivett, M. W. B. Bradbury, R. L. Buchanan, D. N. Cousins, P. F. Binnion, P. S. H. Browne, C. B. Clay, R. W. Griffith, J. R. Cousins, D. R. Laney, Joyce I. A. Little, Rosemary E. Troughton.

Dr. R. G. Eager has been appointed representative of the University on the governing body of Burford Grammar School, in place of Mr. H. A. Smith, until September 1, 1958.

Dr. W. H. Taylor has been elected to an Official Fellowship at St. Peter's Hall, as Tutor in Natural Science from October 1, 1957.

UNIVERSITY OF CAMBRIDGE

In Congregation on January 26 the following degrees were conferred:

M.D.—J. B. Lyon, N. B. Malleon.
M.B., B.Ch.—G. Screech, *C. Cohen, *E. W. Lord, *F. B. Grossmark, P. H. W. Sheard, *S. J. M. Fernando, St. J. Dowling, *M. K. T. Valentine, *P. G. C. Beney, F. K. Amarquaye, D. B. Hill.
M.B.—R. J. Rushton, D. H. Hull, *A. E. H. Mence, G. A. Irving, *B. H. Gooch, W. E. Ince, *H. M. Melville, *Patsy J. M. Lachelin, *Gillian A. Watson, *Marguerite A. M. von Bergen.

Dr. J. D. Lever has been elected into a Fellowship of Trinity College, on appointment as College Lecturer in Anatomy.
*By proxy.

UNIVERSITY OF LONDON

The following degrees were awarded by the Senate on December 19, 1956:

M.D.—R. Goulding, H. R. C. Riches
M.S.—S. M. Chris, E. M. Elmhirst.

The degree of M.D. was awarded by the Senate on January 30 to P. H. Connell and J. G. P. Hutchison.

Professor J. M. Mackintosh has been appointed a representative of the University on the governing body of the London School of Economics and Political Science.

Professor R. W. Scarff has been appointed the representative of the Board of Studies in Pathology on the Board of the Faculty of Medicine for 1957.

The following have been recognized as teachers of the University in the subjects indicated in parentheses: *Postgraduate Medical School of London*, Dr. B. E. Heard and Dr. A. G. E. Pearce (Pathology). *Institute of Ophthalmology*, Mr. S. J. H. Miller (Ophthalmology). *Institute of Diseases of the Chest*, Dr. F. J. Prime (Medicine). *Charling Cross Hospital Medical School*, Mr. N. C. Tanner (Surgery) and Dr. J. F. D. Frazer (Physiology). *St. Mary's Hospital Medical School*, Dr. Victor Wynn (Chemical Pathology) and Dr. R. F. Mottram (Physiology).

UNIVERSITY OF WALES

At a Degree Congregation held at Cardiff on January 12 the following degrees were conferred:

M.B., B.Ch.—D. J. W. Anderson, D. Davies, A. E. Dudley, E. G. H. Edmunds, Gwenda Harcombe, I. H. Horn, C. D. Jones, H. V. R. Jones, Margaret Jones, Thelma Lancaster, B. R. Lewis, D. N. D. Lewis, H. B. Lewis, Olwen G. M. Rees, J. H. Thomas.

UNIVERSITY OF LIVERPOOL

The following candidates have been approved at the examination indicated:

DIPLOMA IN TROPICAL MEDICINE AND HYGIENE.—J. A. Attard, F. P. Brown, J. J. Y. Ch'Uai, B. Das, G. S. Dhalwal, Nishat Fahmy, K. N. Ghose, Mehar Q. Hasan, H. Hollis, T. J. G. Howie, A. Lanzo, Yvonne G. R. Mahabir, M. Masuduzzaman, P. N. Mehrotra, G. A. Parsons, F. Rahim, A. Z. Rizavi, S. Sen, A. K. Shakir, O. P. Sharma, P. N. Sharma, Premila Singh, S. Sukondhamana, C. R. W. Turner.

In Congregation on December 14, 1956, the following degrees were conferred:

M.D.—J. Ainsworth, N. Coulshed, J. A. Donnellan, J. F. Foulkes, D. Heibert, E. S. Watkins.
M.Ch.Orth.—R. M. Bhansali, J. C. N. Joshipura, A. H. McKenzie, R. B. J. Peiris, A. E. Pritchard, S. K. Roy, W. A. L. Thompson.
M.B., Ch.B.—Stella R. Alsop, J. L. Bowmer, P. G. Bullough, G. G. Copeland, H. W. C. Davies, H. J. P. Digory, H. Gordon, H. G. P. Jones, Zoë Kenyon, W. W. Littler, Eileen M. Millward, Mary W. Pritchard, F. Richards, N. G. Roberts, P. F. Teebay, A. J. Williams, Margaret V. Wilson.

The following candidates have been approved at the examinations indicated:

M.B., Ch.B.—Passed in separate subjects: W. G. Clayton (Medicine and Surgery).

DIPLOMA IN PUBLIC HEALTH.—Part I: Frances Allan, G. W. Danger, L. H. Dutchie, P. H. Grace, T. L. Hobday, P. G. Holt, Marie T. Hyde, Brenda Jones, A. L. Kirkland, Margaret M. Lewis, Dora Marren, J. E. O'Malley, D. C. Pattison, D. P. W. Roberts, W. G. Timmis, Mary P. K. Williams. Part II: W. A. Jones, B. J. Kelly, N. T. W. Pover.

QUEEN'S UNIVERSITY OF BELFAST

At a graduation ceremony on December 21, 1956, the following degrees were conferred:

PH.D.—In the Faculty of Medicine: John Bowden.
M.B., B.Ch., B.A.O.—S. W. Agnew, W. A. Beck, J. P. Bradley, S. S. Brown, G. J. Cole, M. D. L. Eakin, E. T. T. Hu, H. R. McGaughey, R. M. H. Malone, J. Noble, J. P. Savage, Y. E. Shirazi.

UNIVERSITY OF BRISTOL

The dissertations submitted by the following candidates for the degrees indicated have been approved:

M.D.—D. R. Coles, C. H. Gurd, Lisa E. Hill, R. Hill.
PH.D.—In the Faculty of Medicine: S. M. A. Zaidi.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND

The following were admitted to Membership of the College on February 1:

Elizabeth A. A. Awoliji, W. D. Linehan, R. J. P. Skelly.

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

At the meeting of the Council of the College held on January 26, with the President, Sir Charles Read, in the chair, the following were elected to Membership of the College:

D. C. Aird, G. B. Batchelor, R. A. T. Boland, G. D. D. Cable, M. I. Cassimjee, J. S. W. Chambers, P. K. Choudhuri, C. A. B. Clementson, K. I. Digwood, A. Freier, W. J. Garrett, W. Gault, W. Gavin, I. Goldman, C. J. Goosen, B. Kirsch, Margaret A. Lakeman, E. W. Lillie, H. H. C. J. Marks, A. E. B. Matthews, T. T. E. Michael, A. B. McCrosbie, J. G. Marks, A. E. B. Matthews, T. T. E. Michael, A. B. Miller, A. K. Mitra, Jessie M. B. Muirhead, A. G. Muttuthamby, A. B. L. Peake, A. C. C. Pinaon, L. J. Rice, R. Richards, T. J. Ryan, G. J. W. Stamp, S. M. Thanevala, K. F. G. Wilson, R. Yule.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS

At a meeting of the Faculty held on January 7, with Professor Stanley Alstead, President, in the chair, the following were admitted Fellows of Faculty: N. K. Barber and G. C. Robin.

Vital Statistics

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases (deaths for influenza) of certain diseases notified weekly in England and Wales (great towns for influenza). Highest and lowest figures reported in each week during the years 1948-56 (influenza, 1952-6) are shown thus ———, the figures for 1957 thus ———. Except for the curves showing notifications in 1957, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

In England and Wales during the week ending February 2 a rise in the number of notifications of most infectious diseases was recorded. The largest rises were 3,481 for measles, from 9,527 to 13,008, 462 for dysentery, from 635 to 1,097, 89 for acute pneumonia, from 572 to 661, 69 for whooping-cough, from 3,233 to 3,302, and 36 for scarlet fever, from 829 to 865.

The largest increases in the incidence of measles were 633 in Lancashire, from 2,304 to 2,937, 310 in Essex, from 803 to 1,113, 289 in London, from 682 to 971, 278 in Durham, from 810 to 1,088, 277 in Middlesex, from 224 to 501, 271 in Yorkshire West Riding, from 484 to 755, 223 in Cheshire, from 259 to 482, 171 in Staffordshire, from 215 to 386, 144 in Kent, from 104 to 248, 128 in Oxfordshire, from 87 to 215, and 121 in Surrey, from 404 to 525; the only large fall was 121 in Lincolnshire, from 264 to 143. The largest fluctuations in the returns of whooping-cough were an increase of 42 in Kent, from 208 to 250, and a fall of 46 in Suffolk, from 99 to 53. The only large variations in the number of notifications of scarlet fever were a rise of 30 in London, from 47 to 77, and a fall of 44 in Shropshire, from 47 to 3. 5 cases of diphtheria were notified, 4 more than in the preceding week, and 2 of these cases were notified in Birmingham C.B.

37 cases of acute poliomyelitis were notified, and these were 7 more for paralytic and 3 more for non-paralytic cases than in the preceding week. The largest returns were Lancashire 5 (Liverpool C.B. 2), London 4 (Islington 2), Southampton 4.

A rise in the incidence of dysentery was general throughout the country. The largest local increase was 127 in Accrington M.B., from 4 to 131. The largest returns, during the week, were Lancashire 299 (Accrington M.B. 131, Stretford M.B. 85, Liverpool C.B. 14), Warwickshire 121 (Coventry C.B. 66, Birmingham C.B. 40), Yorkshire West Riding 96 (Sheffield C.B. 21, Bradford C.B. 20, Worsborough U.D. 15, Leeds C.B. 13), London 80 (Islington 14, Lewisham 11), Nottinghamshire 72 (Arnold U.D. 47, Nottingham C.B. 19), Yorkshire East Riding 52 (Kingston-upon-Hull C.B. 41), Durham 41 (Gateshead C.B. 14), Northumberland 32 (Blyth M.B. 13, Alnwick U.D. 12), Middlesex 29 (Tottenham M.B. 9), Oxfordshire 25 (Oxford C.B. 24), Leicestershire 22 (Hinckley U.D. 14), Essex 21 (Thurrock U.D. 11), Carmarthenshire 21 (Kidwelly M.B. 21).

Week Ending February 9

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 869, whooping-cough 3,148, diphtheria 9, measles 16,752, acute pneumonia 720, acute poliomyelitis 34, dysentery 1,290, paratyphoid fever 5, and typhoid fever 6.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending February 2 (No. 5) and corresponding week 1956.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

† Includes primary and influenza pneumonia.
‡ Includes puerperal pyrexia.

LATE PARLIAMENTARY NEWS

After the printing of the JOURNAL had begun we received the following Parliamentary report:

The PRIME MINISTER announced on February 20 that the whole question of medical remuneration is to be referred to a Royal Commission. He said that the claim for a 24% increase in the remuneration of doctors in the Health Service would mean an extra cost to the country of about £20m. a year, and in present circumstances the Government did not feel able to admit that claim. "This does not mean that the Government has reached any conclusion as to the merits of the claim." They decided that the time "was opportune for a full review of medical remuneration from an independent inquiry, which would look into the remuneration of the medical profession in relation to other professional classes in the community and would suggest how the matter could be kept under review. I have accordingly recommended to the Queen, and Her Majesty has approved, that a Royal Commission be appointed for this purpose." He added that within the last few days a similar claim had been received on behalf of the dental profession, and that the dental profession would be included in the review. The question whether the remuneration of doctors and dentists employed by local authorities should be included was under consideration. The names of the members and terms of reference of the Royal Commission would be announced later.

Mr. H. GAITSKELL, Leader of the Opposition, immediately asked how long this review was expected to take, if it was to be in the nature of an arbitration tribunal on the claim. Would the terms of reference include specialists as well as general practitioners, and would it have the power to recommend back-dating the award if there was one? Mr. MACMILLAN said the Commission would be able to recommend that any award and proposals should be retrospective. The review would include specialists. But as regards the character of the Commission, he thought that would be best set out in detail when he could announce the names and terms of reference. He thought it was generally agreed that it would be a good thing if the relations of this profession with other professions could be established and if some satisfactory system could be adopted by which reviews could be carried out from time to time.

Mr. HERBERT MORRISON (Lewisham, South, Lab.) described this as a very doubtful way of seeking to settle the remuneration claim. He recalled that the Spens Committee in similar circumstances landed the country into expenditure and repercussions which had been embarrassing. Mr. MACMILLAN said this was a difficult problem, and he felt that the work of the Royal Commission on the Civil Service—similar but not exactly parallel—had been to advantage, and if some equally good results could follow from this Royal Commission he thought it would be generally acceptable.

Mr. G. NABARRO (Kidderminster, Con.) asked the Prime Minister to make it clear that a primary purpose of the review should be to eliminate all the legal and other uncertainties that had arisen from the Spens Report and Danckwerts award. Mr. MACMILLAN said one purpose of the Commission would be to clear up this situation and lay down a system which through the years would be more workable and more acceptable.

Dr. EDITH SUMMERSKILL (Warrington, Lab.) said this was virtually a repudiation of the Spens Reports and asked what the reaction of the professional organizations was to this suggestion. Mr. MACMILLAN said that the discussion between representatives of the profession and the Minister of Health was one matter. To-day he had confined himself to the announcement of the appointment of the Commission. Detailed questions had better be left to the Minister responsible.

MEETINGS TO BE CALLED

Immediately after receiving the above report the Negotiating Committee met at B.M.A. House. It was decided to

summon at once meetings of the constituent bodies of the Committee. The Council of the B.M.A. is to meet next week. The Negotiating Committee authorized the dispatch to the Prime Minister of a personal letter signed by Sir Russell Brain and Dr. A. Talbot Rogers, joint chairmen of the Committee.

Medical News

Hunterian Society.—The annual dinner to commemorate John Hunter's birth was held in London on February 14, with the president of the Society, Dr. CECIL COYLE, in the chair. It was the 229th anniversary. The dinner was also a double jubilee. It was fifty years ago that a Lord Mayor of London first attended the commemoration dinner, and the presence at the High Table of this year's Lord Mayor, Sir CULLUM WELCH, with the LADY MAYORESS and the Serjeant-at-Arms, Commander JOHN POLAND, attested to the Society's traditional links with the City. The other jubilee was of the first admittance of ladies. Indeed, at this year's dinner, so fast have times altered and prejudices softened, there seemed more women than men in the large gathering. To mark the day—it was St. Valentine's too—the last speech of the evening was entrusted to a lady, Miss ROSE HEILBRON, Q.C., Recorder of Birmingham. After the Loyal Toasts and the "immortal memory" had been honoured, LORD LUKE, proposing the health of the Society, neatly epitomized the reason for John Hunter's continuing influence: "His life," he said, "was a challenge to worn-out theories." Dr. COYLE in his reply spoke of the Society's tradition of "informal but serious thought" which enlivened their clinical meetings. Two honorary fellows had been elected this year, he said—Sir Robert Young and Sir John Weir. "The Lord Mayor and the Corporation of the City of London" was proposed in a speech of quicksilver wit by Dr. MACDONALD CRITCHLEY, himself the Master of a City Company (the Apothecaries), as the Lord Mayor was quick to note in his reply. The Hunterian Society, said Sir CULLUM WELCH, had been born and bred in the City. It was renowned for its addiction to meeting in the taverns there. Replying to Mr. IAN ROBIN'S toast of "The Guests and Kindred Societies," Miss HEILBRON expressed her special pleasure at being at the dinner, not only on account of the close and usually most happy relationship that existed between Medicine and the Law, but also for personal reasons as the wife of a doctor. She complimented the Society—and the medical profession generally—on their forward-looking attitude to women. "Even at this dinner," she said, "the ladies have the last word."

Leverhulme Associates of R.S.M.—The council of the Royal Society of Medicine invites applications for the one hundred Leverhulme associateships which are available each year thanks to the generosity of the Trustees of the Leverhulme Trust Fund. The associates enjoy nearly all the privileges of the Society's fellows but without paying any subscription. The scheme started a year ago, and is intended for the holders of full-time clinical or non-clinical teaching or research appointments in medical, dental, or veterinary departments of British universities whose total income from academic or professional sources does not exceed £1,500 a year. Awards are made for one year in the first instance but may be extended annually up to a maximum of three years. Most vacancies are filled in the last week of March, for the year beginning April 1, so candidates are advised to apply between March 1 and 15, though applications may be made at any time. Application forms may be obtained from the deans of medical schools or the secretary of the Royal Society of Medicine, 1, Wimpole Street, London, W.1.

Mentally Handicapped in Scotland.—Local authorities have been asked by the Department of Health to ascertain the number of mentally handicapped in their areas needing care and guidance. This is recommended in a circular on the welfare of the mentally handicapped. The circular also

draws attention to the need to encourage voluntary effort in this field and for the provision of occupation centres, aftercare hostels, and clubs. So far out of the fifty-five local health authorities in Scotland only two have provided occupation centres suitable for both school-age and adult mental defectives.

Royal College of Surgeons.—The College council, at a meeting on February 14, agreed to the holding of a primary fellowship examination at Colombo in January, 1958. This had been requested by Ceylon University. The council also appointed Sir HARRY PLATT, president of the College, visitor to the first primary fellowship examination of the College of Physicians and Surgeons of South Africa. The College's honorary medal was presented to Lady WEBB-JOHNSON.

COMING EVENTS

Harveian Society.—Sir RUSSELL BRAIN, P.R.C.P., will deliver the Harveian Lecture on March 27 at 8.15 p.m. at 11, Chandos Street, London, W.1. His subject will be "Some Disorders of the Cerebral Circulation." The lecture is open to any member of the medical profession.

Twelfth International Congress on Occupational Health.—Helsinki, July 1-6. Registration before April 1. Details from the organizing committee, Työterveyslaitos, Haartmaninkatu 1, Helsinki-Töölö, Finland.

"Child and Family Psychiatry."—Refresher course for medical practitioners (including postgraduate students), April 8-12, at the Ipswich and East Suffolk Hospital. Details from Dr. H. G. HOWELLS, Department of Child Psychiatry, 11, Fore Street, Ipswich. No fee.

National Association for Mental Health.—Annual conference will be held at Church House, Westminster, London, S.W.1, April 11 and 12. The theme will be "The Maladjusted Child: The Underwood Report and After." Details from the Association, 39, Queen Anne Street, London, W.1.

British Tuberculosis Association.—Provincial meeting in Oxford, April 12 and 13. Details from the hon. secretary, 59, Portland Place, London, W.1.

NEW ISSUES

Abstracts of World Medicine.—Issued in the first week of each month, this journal contains abstracts of important papers selected from the current medical literature of the world. Annual subscription £4 4s., single copy 8s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

British Journal of Ophthalmology.—The new issue (Vol. 41, No. 2) is now available. The contents include:

ACTION OF DIAMOX AND AMMONIUM CHLORIDE ON FORMATION OF AQUEOUS HUMOUR. MAURICE E. Lankham and Patience M. Lee.
DISTENSIBILITY OF THE EYE. E. S. Perkins and J. Gloster.
EXTENSIBILITY OF STRIPS OF SCLERA AND CORNEA. J. Gloster, E. S. Perkins, and Marie-Louise Pommer.
SUMMERSKILL'S DACTYLOSCOPIC RHINOSTOMY. R. W. B. Holland.
AIR IN THE EYE. A. Lister.
CONGENITAL IRIS LESION. W. J. Levy.
LEUCOBIOTE OF THE CORNEA. M. Gilkes.
CORRESPONDENCE.
BOOK REVIEW.
NOTES.
OBITUARY.

Issued monthly; annual subscription £4 4s.; single copy 8s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, February 25

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Professor M. L. Rosenheim: Pyelonephritis.
ROYAL INSTITUTE OF CHEMISTRY: THAMES VALLEY SECTION.—At Physical Chemistry Laboratory, South Parks Road, Oxford, 8.15 p.m., joint meeting with Alembic Club. Professor W. C. Fernelius (Pennsylvania): Polonium.
UNIVERSITY COLLEGE LONDON: DEPARTMENT OF PHARMACOLOGY.—At Physiology Theatre, Gower Street, W.C., 5.30 p.m., Dr. T. S. Work: Biochemical Approach to the Problems of Protein Synthesis.

Tuesday, February 26

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Professor J. B. Duruid: Arterial Occlusion.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Mr. B. E. D. Cooke: Disorders of Buccal Mucosa.
ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Professor W. Melville Arnott: Physiological Features of Emphysema.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Professor D. F. E. Nash: Congenital Spinal Palsy—The Management of Incontinence.
ROYAL STATISTICAL SOCIETY: MEDICAL SECTION.—At Keene Lecture Theatre, Westminster Medical School, S.W., 5.30 p.m., Mr. D. J. Newell and Dr. A. T. Elder: Provision of Hospital Beds.
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Institute Theatre, 5 p.m., Dr. P. M. F. Bishop: Problems of Intercerebral Vascular Disease.
WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Dr. J. N. Milnes: neurological demonstration.

Wednesday, February 27

BIRMINGHAM MEDICAL INSTITUTE: SECTION OF PSYCHIATRY.—8 p.m., Dr. Stephen J. L. Taylor: Psychiatry and Politics.
COUNCIL OF SCIENTIFIC MANAGEMENT IN THE HOME: WOMEN'S GROUP ON PUBLIC WELFARE.—At British Institute of Management, 8, Hill Street, W., 3.30 p.m., public lecture by Dr. C. A. Boucher: Planning for Safety in the Home.
HARVEIAN SOCIETY OF LONDON.—At 11, Chandos Street, W., 8.15 p.m., clinico-pathological meeting.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Miss Phyllis Wade: Radiation Treatment of Skin Cancer (Part II).
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Mr. Vernon C. Thompson: Surgery of Mitral Stenosis.
INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Mr. A. R. C. Higham: Neoplasms of the Kidney.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Dr. J. H. Humphrey: Biochemical Mechanisms Underlying Hypersensitivity Reactions (2).
ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE: EDINBURGH BRANCH.—At West Medical Theatre, Edinburgh Royal Infirmary, 5 p.m., Lieutenant-Colonel John Morison, I.M.S. (ret.): How the Problem of Plague Was Solved.

Thursday, February 28

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Professor H. Grunberger, F.R.S.: Localization of Inherited Diseases in the Body.
GLASGOW UNIVERSITY MEDICO-CHIRURGICAL SOCIETY.—7.30 p.m., joint meeting with Dialectic and Law Societies: "Royal Commission" on Homosexuality.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. H. Haber: Cutaneous Manifestations of Syphilis.
LIVERPOOL MEDICAL INSTITUTION.—8 p.m., Symposium: Poliomyelitis. Speakers, Dr. A. B. Christie; Professor A. W. Downie, Mr. G. E. Thomas, and Dr. J. R. Esplen.
NORTHFIELD ORTHOPAEDIC CENTRE.—At Wingfield-Morris Orthopaedic Hospital, 8.30 p.m., Mr. O. J. Vaughan-Jackson: Some Surgical Aspects of the Rheumatoid Hand.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.30 p.m., Otolaryngology Lecture by Dr. D. B. Fry: Speech and Language.
ROYAL NORTHERN HOSPITAL.—2.45 p.m., Mr. R. S. Murley: Carcinoma of the Breast and its Treatment.
ROYAL SOCIETY OF HEALTH.—At the Town Hall, West Bromwich, 10 a.m., Dr. J. F. Skone: The Coloured Worker.

Friday, March 1

BRITISH TUBERCULOSIS ASSOCIATION.—At 26, Portland Place, W., 4.30 p.m., Subject: Acute Emergencies in Chest Medicine. Speakers, Dr. Thomas Simpson, Mr. N. R. Barrett, and Mr. T. Holmes Sellers.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. E. J. Moynahan: clinical demonstration.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. R. W. Riddell: clinical demonstration.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—10 a.m., Mr. A. Dickson Wright: Intestinal Obstruction. 4 p.m., Dr. J. N. Morris: Epidemiology of Coronary Heart Disease.
ROYAL MEDICAL SOCIETY, EDINBURGH.—8 p.m., dissertation by Mr. D. Fleinley: Bronchitis.
ROYAL MEDICO-CHIRURGICAL SOCIETY OF GLASGOW.—At Royal Faculty of Physicians and Surgeons of Glasgow, 8.30 p.m., Dr. A. T. Dore: Prevention of Industrial Diseases.
ST. MARY ABBOTS HOSPITAL.—At Lecture Room, School of Nursing, 6 p.m., Third Annual James Yearsley Memorial Lecture by Mr. I. Simpson Hall: Mobilization Operation in the Treatment of Otosclerosis.
WHIPPS CROSS HOSPITAL MEDICAL SOCIETY.—At Occupational Therapy Department, 8.30 p.m., lecture and demonstration by Dr. B. E. Brooks: Occupational Therapy as a Factor in Treatment.

Sunday, March 3

UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL.—10.15 a.m., clinical demonstration for general practitioners. Dr. G. I. M. Swyer: Use of Hormones in General Practice.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Bush.—On February 13, 1957, at Edgware General Hospital, Middlesex, to Lois and Dr. Richard Bush, of New Zealand, a sister for Tony Woods.—On February 9, 1957, at the Jesson Hospital for Women, Sheffield, to Gilbert and Sheila Woods (formerly Costello), a daughter.

DEATHS

Gluscepi.—On January 19, 1957, in a hospital, London, Paul Eugène Hedwige Gluscepi, M.B., C.M., aged 88.
May.—On January 26, 1957, at Woodleigh, Ware, Herts, George Ernest May, M.R.C.S., I.R.C.P., aged 89.
Robinson.—On January 26, 1957, at 36, Mayfield Avenue, Orpington, Kent, Harold Joseph Robinson, M.B., B.Ch., formerly of Kirkoswald, Cumberland.
Sinnette.—On January 22, 1957, Margaret Mitchell Sinnette, M.B., Ch.B., of "Wayside," Barkend Road, Bradford, Yorks.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Weight Gain in Pregnancy

Q.—(1) What are the principal factors contributing to the gain in weight during pregnancy? (2) What is the normal range of the gain, and does the mother's starting weight, age, or parity affect this? (3) How should an excessive weight gain be managed?

A.—Gain in weight during pregnancy is determined by: an increase in the volume of the blood; an increase in tissue fluids; the foetus; the liquor amnii; the placenta; the increase in size of the breasts; the growth of the uterus; and a deposition of fat in subcutaneous and other tissues. An excessive overall gain in weight during pregnancy may be determined by any of these factors, but the ones which matter most are the foetus (multiple pregnancy, for example), the liquor amnii (hydramnios), tissue fluids (oedema), and deposition of fat. The last is usually the most common. An excessive gain occurring suddenly or during a short period generally denotes abnormal fluid retention, but can also be accounted for by acute hydramnios.

The average weight gain during the whole of normal pregnancy, in which no attempt has been made by dieting to increase or decrease the rate of gain, is of the order of 28 lb. (12.7 kg.). Of this only about 2 or 3 lb. (0.90 or 1.36 kg.) are usually gained during the first trimester. When the nausea and vomiting of early pregnancy has ceased it is probably normal for patients to have a hearty appetite and to gain weight at the rate of about 1½ lb. (0.68 kg.) weekly until about the end of the fifth month. During the second half of pregnancy an average weekly gain of about 1 lb. (0.45 kg.)—within limits of ¾ to 1½ lb. (0.34 to 0.57 kg.)—appears to be consistent with the greatest chances of a satisfactory outcome. The rate of gain usually decreases during the last few weeks, and a slight loss of weight may occur after term. Total weight gains ranging from over 50 lb. (22.7 kg.) to practically nothing may be associated with a satisfactory outcome, but towards both extremes the chances of abnormality are relatively high. Starting weight, age, and parity seem to exert relatively little influence upon the rate at which weight is gained, but many obese women gain less than the average during pregnancy.

A high but steady rate of weight gain seems in most cases to be due to deposition of fat and other tissues, and does not affect adversely the outcome of pregnancy. But a high rate of gain, and particularly a sudden increase in the rate, may foreshadow the onset of pre-eclampsia; careful examination for rising blood pressure, albuminuria, and oedema is therefore indicated. Before oedema appears clinically the patient may report that her ankles swell at night or that her rings have become tight. It must be remembered that high rates of weight gain may also be associated with recovery from vomiting or an infection, or, as stated above, with hydramnios or twin pregnancy. There is strong evidence that control of weight gain by dietary restriction does help to reduce the incidence of eclampsia and severe pre-eclampsia, at least in primigravidae.

While the dangers associated with excessive gains of weight are well known, it is less commonly appreciated that unduly low gains, especially in undersized women, are often associated with premature labour or the birth of an underweight baby at term; there is, however, little evidence so far that the incidence of prematurity can be reduced by encouraging such patients to eat more and so to put on more weight. Loss of weight may be useful in assessing the severity of vomiting or infection during pregnancy, and in late pregnancy or after term may precede intrauterine death.

Allergy to Mascara

Q.—A patient is allergic to all the varieties of mascara she has tried. What is the responsible ingredient, and are any makes of mascara suitable for allergic subjects?

A.—Mascara is a generic term applied to all forms of colouring material applied to the eyelids. A very large number of bases and tinting materials are used commercially. Universal allergy is most unlikely. Carbon black, for example, is quite inert. Possibly the patient is upset by the vehicle—e.g., soap. A number of quite inactive and non-sensitizing formulae can be found in *Modern Cosmetology*.¹

Luminous Dials

Q.—In the light of recent knowledge about the hazards of ionizing radiations, what advice should be given to patients who inquire about the safety of objects such as clocks, watches, etc., where luminous paint is used for the numerals?

A.—This point is covered in the Medical Research Council's recent report, *The Hazards to Man of Nuclear and Allied Radiations* (Cmd. 9780, H.M.S.O., 1956). The contribution of radiation from the estimated four million watches and ten million clocks with luminous dials in Britain is small but real (equivalent to about 1% of natural background). The main hazard is to workers in the luminizing industry, but the risk from the widespread use of such instruments is not entirely negligible. While there are circumstances which require and justify the use of instruments with self-luminous dials, for most people there is no such necessity and their wider use constitutes an avoidable, if small, genetical risk as regards the population as a whole, which could be minimized for all concerned if the amount of radioactive material in these instruments were reduced to the lowest possible level.

To this may be added the comment that, as regards the individual, possessors of luminous wrist-watches, and especially children, should be discouraged from taking these articles into bed with them. If at any time the watch-glass is broken, the timepiece should not be used at all until adequate repairs have been effected.

Treatment of Otosclerosis

Q.—Are hearing-aids of value in otosclerosis? If so, what kind of aid is required, and how much benefit may be expected? What are the indications for operative treatment in this condition?

A.—Deafness in otosclerosis is typically of the conductive type and results from fixation of the stapes in the oval window by the disease process, thus impeding the passage of sound waves to the cochlea. In this type of deafness practically all of the hearing loss is regained by hearing-aids of the valve amplifier type.¹ The Medresco hearing-aid, which is obtained and serviced without cost to the patient under the National Health Service, may be used with great benefit. If commercial hearing-aids are preferred, information about reliable firms who supply these may be obtained through the National Institute for the Deaf, 105, Gower Street, London, W.C.1.

Operative treatment in otosclerosis is directed towards breaking through the bony barrier that prevents sounds from reaching the cochlea. Various methods of achieving this have been described.² The most successful has been the so-called fenestration operation in which a window is drilled above the oval window opening into the vestibule and adjacent ampulla of the lateral semicircular canal. A second method which has lately given promising results is that of mobilization of the stapes.³ Such operations are unlikely to be successful unless undertaken by a surgeon with special

experience of the technique, and are usually performed in a magnified field using a binocular dissecting microscope.

If the nerve of hearing is affected to any great extent, surgical treatment will not help. Indications of such nervous involvement include voice changes, intolerance of amplification, disappearance of paracusis, and, very often, loss of acuity for bone-conducted sounds. On an average there will be an improvement of 25 decibels for the critical speech frequencies (512, 1024, 2048 c.p.s.). For patients with a much greater initial hearing loss than 50 decibels, the benefit they are likely to experience from operation will be limited.

Transmission of Toxoplasmosis

Q.—Can you give me some information on the mode of transmission of toxoplasmosis? I have come across a case in which a mother transmitted it to her child in utero. Is there a likelihood of its being transmitted to another baby if she should conceive again?

A.—Toxoplasmosis can be congenital or acquired. It is thought that congenital infection arises when the mother undergoes her initial infection with toxoplasms during pregnancy, the accompanying parasitaemia promoting transplacental spread of the infection. It is most unlikely, therefore, that more than one infant of the same mother could suffer from congenital toxoplasmosis. Clinical congenital toxoplasmosis must be distinguished from positive serological tests in the infant due to antibodies passively transferred from the maternal circulation.

In acquired toxoplasmosis, where our knowledge is incomplete, the reservoir of infection appears to be domestic animals and food products from them, such as meat, which have been insufficiently cooked to kill the contained toxoplasms. Further details about the animal reservoirs will be found in a report of a recent meeting of the Royal Society of Tropical Medicine and Hygiene.¹ There is also some evidence to suggest a direct spread from human to human by contact or droplet infection.

Chinese Liver Fluke

Q.—What treatment is advised for infection with the Chinese liver fluke (*Clonorchis sinensis*)? Here in south-west Korea chloroquine is popular but successful in only about half the patients treated. What is known of the pathology of the condition?

A.—The treatment of *Clonorchis sinensis* infection is unfortunately unsatisfactory. In addition to the use of chloroquine, which is generally regarded as being of very limited if any value, sodium antimony tartrate and gentian violet are commonly used. Sodium antimony tartrate is given in a 0.5% solution in sterile isotonic glucose or sodium chloride solution. The solution may be boiled for five minutes in order to sterilize it, but it should not be autoclaved. The first dose consists of 0.5 gr. (32 mg.), and this may be increased by amounts of 0.5 gr. (32 mg.) until doses of 2–2.5 gr. (130–160 mg.) are being given. These should be administered intravenously at 24- or 48-hour intervals, the solution being injected slowly over a period of 15 minutes. The total course consists of 25–35 gr. (1.65–2.3 g.). Patients usually complain of nausea while having the larger doses in this treatment. Gentian violet is administered in enteric-coated capsules containing 1–2.5 gr. (65–160 mg.) thrice daily; the course of treatment should be continued for two to four weeks.

A recent comprehensive study of the pathology of the condition has been made by P. C. Hou.¹

Management after Intra-articular Hydrocortisone

Q.—What is the best treatment after an injection of hydrocortisone into (a) a joint, and (b) a tendon sheath, e.g., in tennis elbow? Should the joint be moved or rested, and what form of physiotherapy is recommended?

A.—Injection of hydrocortisone into a joint after aspiration of excess synovial fluid is performed with the object of exerting an anti-inflammatory effect. Therefore it is wise to rest the joint for a period afterwards—usually about 48 hours. Following this the muscles around the joint should be built up to provide as strong a support as possible. This can best be done by means of exercises. Preliminary faradism may be used to show the patient how the muscles can be contracted if they are weak.

On the other hand, when hydrocortisone is given into the soft tissues for lesions such as tennis elbow, the object of treatment is to free any adhesions between the muscles. Therefore the structures should be moved actively after a short time.

Threadworms

Q.—What order of number of threadworms may be present in the intestine of a heavily infected child? Where do they principally congregate, and can they interfere with the child's nutrition by reason either of their bulk alone or of their own metabolic demands?

A.—There may be hundreds or only a few. No one has taken the trouble to count the number in one individual, although over 40% of the children in this country are infected with threadworms.

The worms normally inhabit the caecum, but may occasionally be found in the ileum or appendix, and rarely in the stomach, oesophagus, or nose. In a few instances they have migrated into the peritoneum and Fallopian tubes. Unlike the males, which remain in the caecum, the gravid females migrate via the rectum to the perianal region where they normally lay their eggs. Sometimes they also enter the vagina. The movements of the worms on the anal folds cause intense itching.

Heavily infected children may show some anaemia with loss of appetite and malnutrition. This cannot be due to the "bulk" of the worms, as the latter are very small. More probably it is attributable to catarrhal inflammation resulting from mechanical irritation of the intestinal mucosa. The possibly toxic effects, if any, of the worms' metabolic products have not been investigated. But the nervous symptoms shown by heavily infected children and occasionally by adults are due, partly, to the psychological effects of the movements of the gravid worms on the perianal surface. The "metabolic demand" of the worms is, of itself, unlikely to interfere with the patient's nutrition.

Books of "Any Questions?" and Refresher Course Articles

The following books are available through booksellers or from the Publishing Manager, B.M.A. House. Prices include postage. *Any Questions?*, Volumes 2 and 3 (8s. each); *Refresher Course for General Practitioners*, Volumes 2 and 3 (26s. 6d. each inland, 26s. overseas); *Clinical Pathology in General Practice* (22s. 3d. inland, 21s. 9d. overseas).

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 4499. TELEGRAMS: *Any Questions?*, London. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Director, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.) TELEPHONE: EUSTON 4499. TELEGRAMS: *Britmedad*, Westcent, London.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association, TELEPHONE: EUSTON 4499. TELEGRAMS: *Medisecra*, Westcent, London.

B.M.A. SCOTTISH OFFICE: 7, Drumshugh Gardens, Edinburgh.

The graph above is of an experiment to measure the effect of Transvasin on skin temperature on a subject. The red line plots the skin temperature before and at intervals after a single application of one inch of cream (0.924 grams) from a tube of Transvasin. The black line gives similar information with regard to the application of a plain vanishing cream used as a control. Skin temperatures were measured with an electro-thermo couple every five minutes for two hours. Photographs show the affected area before application; three minutes and thirty minutes later.

It is generally agreed that cases of soft-tissue rheumatism and of many types of arthritis benefit by hyperaemia of the affected tissues. Transvasin, which contains two quick-acting esters of nicotinic acid, induces such a deep and prolonged hyperaemia at the same time as it produces superficial erythema.

In addition to the esters of nicotinic acid, Transvasin contains the fat- and water-soluble esters of salicylic and p-aminobenzoic acids. Both these well-tried analgesic drugs are readily conveyed through the skin in therapeutic quantities and enable an effective concentration to be built up where they are needed.

Transvasin is now being widely prescribed, with successful clinical results. Since a very small quantity is sufficient for each application, the cost of treatment is extremely low.

Transvasin is available in 1 oz. tubes, basic N.H.S. price 2/6 plus P.T., and is not advertised to the public. Samples and literature will be gladly sent on application.

LLOYD-HAMOL LTD.

11 Waterloo Place, London, S.W.1. Whitehall 8654/5/6.

COMPOSITION OF TRANSVASIN

Salicylic acid tetrahydrofurfuryl-ester	14%
Nicotinic acid ethyl-ester	2%
Nicotinic acid n-hexyl-ester	2%
p-Aminobenzoic acid ethyl-ester	2%
Water-miscible base ad	100%

counting the cost...of living

It is estimated that over 50 per cent of the average practitioner's patients show some degree of anxiety neurosis. Such is the price exacted by the tempo of today. In this type of case MILTOWN meprobamate has far-reaching applications. MILTOWN is superior to other conventional sedatives and is remarkably free from side reactions. It acts safely and selectively to ease emotional and muscular tension without autonomic effects. MILTOWN helps to 'unwind' the patient relieving his worry, agitation and anxiety. It induces true sedation by day and natural sleep without narcosis at night.

MULTIPLE SCLEROSIS

A PLEA FOR A FRESH OUTLOOK*

BY

DOUGLAS McALPINE, M.D., F.R.C.P.

From the Institute of Clinical Research, Middlesex Hospital

Despite its importance the subject of multiple sclerosis tends to be obscured by an aura of defeatism and even apathy for which there appear to be four main causes: (1) the apparent lack of progress in discovering the cause; (2) the generally accepted view that diagnosis is seldom possible in the early stages and cannot be made unless certain signs are present; (3) the belief that, variable though the course may be, sooner or later increasing disability is inevitable, leading to premature death; and (4) the lack of any therapeutic measure which can be relied upon to influence the disease.

I propose to deal with these points in some detail.

Aetiology—The Allergic Theory

Until quite recently the belief that multiple sclerosis was due to a single cause has dominated thought on this problem. This is well exemplified by the infective theory, which postulates that multiple sclerosis may be caused by a particular form of bacterium or virus. The negative results of earlier experimental work, particularly on the virus theory, are not entirely trustworthy because of limitations in technique. However, Lumsden (1955) has described a tissue-culture method for the detection of virus in plaques. His failure to confirm the presence of virus in a small series of plaques should not discourage others from repeating his experiments. It should be recalled that Dawson (1916), as a result of intensive histological study, concluded that multiple sclerosis might be caused by a soluble toxin conveyed to the nervous tissues, probably by the blood stream. It may well be that this concept, if viewed broadly and translated into terms of immuno-chemistry, may yet prove to be near the truth.

The so-called allergic theory, to which increasing attention has been paid in recent years, carries with it the implication of a multifactorial causation. The idea that a hypersensitivity reaction to an infection might cause disease of the nervous system was probably first put forward by Glanzmann (1927) in connexion with the neurological complications of chicken-pox, smallpox, and vaccination. In 1932 van Bogaert postulated that a similar mechanism might be at work in multiple sclerosis. In 1942 Pette further developed the theory of neuro-allergy when considering the acute forms of demyelinating disease. Ferraro (1944), on the basis of histological studies, suggested neuro-allergy as a common basis in all the demyelinating diseases, including multiple sclerosis.

*Based on the Annual Address given to the Newcastle upon Tyne and Northern Counties Medical Society on December 6, 1956.

Clinical support for this viewpoint came from studies of the natural history of the disease (McAlpine, 1946; McAlpine and Compston, 1952). The possibility that multiple sclerosis may be due to an antigen-antibody reaction within the nervous system is at present based on deduction from a number of widely different observations.

Familial Tendency

In England (Pratt, Compston, and McAlpine, 1951) and Northern Ireland (Millar and Allison, 1954) the familial incidence lies between 6 and 7%. In Northern Scotland, Sutherland (1956) obtained the high figure of 11%. Siblings are more frequently attacked than other relatives. Examples of the disease in three generations are exceedingly rare. Studies by Thums (1951) in twins has shown that the disease does not necessarily occur in identical twins. These facts suggest that, when present, the genetic influence is usually weak and must be reinforced by constitutional and environmental factors before the nervous system is attacked, and, furthermore, that the disease may develop in the absence of any obvious genetic influence.

Occurrence of Allergy in Multiple-sclerosis Subjects

In a study of 250 cases of multiple sclerosis and of 250 controls from a hospital population we did not find any difference in the incidence of allergy in the two groups, but just before and after the onset of symptoms of multiple sclerosis a history of some form of allergy was obtained in 9% of this series as compared with 2.5% of the control series (McAlpine and Compston, 1952). In multiple-sclerosis patients the occasional reaction in the nervous system to organic arsenical preparations and to vaccines suggests a similar mechanism.

Precipitating Factors

Although the first symptom of the disease may appear in an apparently healthy individual without any recent incidents in the general health that can be related to the onset, more usually one of the following closely precedes it:

Fatigue.—Long recognized as a factor which may precipitate or aggravate the disease, excessive tiredness, with or without physical or mental cause, is not unusual in the history of these patients. Just as signs of paralysis may be hastened in the laboratory animal, previously injected with brain emulsion, by causing it to run about the cage, so in multiple sclerosis physical exertion may bring the disease to light or cause a relapse.

Infection.—Roughly 10% of patients give a history of an infection, usually in the form of a "cold" or "sore throat" or an attack of influenza preceding the onset. The Table illustrates this point. "Whenever I get a cold,

Infection Preceding Onset (From McAlpine, Compston, and Lumdsen, 1955)

Author	%	No. of Cases
Bramwell (1917)	14.0	200
Hoesslin (1934)	10.5	109*
Kolb <i>et al.</i> (1942)	2.0	199
McAlpine (1946)	5.0	142
Adams <i>et al.</i> (1950)	14.0	389†
McAlpine and Compston (1952)	10.0	250

* Acute. † Within six months of onset.

it goes to my legs" is an expression sometimes used by these patients; it illustrates the part which an intercurrent infection may play in causing either a temporary exacerbation of symptoms or a true relapse.

Trauma.—Since the end of the last century references may be found in medical literature, especially German, to the relation between trauma and multiple sclerosis. In Hoesslin's study of 516 cases trauma (including operation) precipitated the onset in 11.4% of cases. In our series of 250 cases we obtained a history of trauma, including dental extraction but not surgical operations, in 14% as compared with 5.2% in the control series. In a recent series Abb and Schaltenbrand (1956) estimated a figure of 10%. Hoesslin first suggested that there may be a relationship between the site of the trauma and the level of the lesion in the central nervous system, a finding which we confirmed in certain of our cases and which has a parallel in acute poliomyelitis.

Emotional Stress.—Although statistical evidence that an emotional upset can be regarded as a valid precipitating factor is lacking (Pratt, 1951), in individual cases it can be so regarded. Of its importance during the course of the disease, particularly as a cause of temporary exacerbations of symptoms, there can be no doubt.

Mode of Onset and Course of Disease

An abrupt onset and a natural tendency for symptoms to remit and later recur are features which have long been recognized as likely to provide a clue to the underlying cause of multiple sclerosis. Particularly in the middle-aged, there may be a slow progression of symptoms from the onset (the progressive spinal form of the disease). It would seem likely, as in certain other diseases, notably rheumatoid arthritis, that age may be a factor in modifying the individual's reaction to the morbid process.

Changes in Cerebrospinal Fluid

In roughly 70% of cases the C.S.F. is abnormal at some stage of the disease, as shown by a mild pleocytosis, an increase of protein, or an abnormal Lange colloidal gold curve. It is known that any one of these abnormalities may occur as an isolated finding. At the present stage of our knowledge it is impossible to estimate the significance of these changes in relation to the course of the disease. Recent electrophoretic studies have shown that the gamma-globulin fraction in the C.S.F. is usually increased, while that of the serum is not significantly raised. Furthermore, it is known that a change in the colloidal gold curve is closely linked with the gamma-globulin content of the fluid. Press (1956) has reported the presence of a protein in the C.S.F., component "S," which she isolated from the gamma-globulin fraction; this substance has the effect of inhibiting the colloidal gold reaction. In multiple sclerosis the proportion of component "S" tends to be decreased as compared with the amount in normal C.S.F.

Since antibodies migrate mostly with the gamma-globulin fraction of the serum it is reasonable to suppose that this component of the C.S.F. performs the same function. From the above findings it seems permissible to make two tentative deductions: first, that the changes in the C.S.F. are the result of an immunological reaction, and, secondly, that this reaction may be in the nervous tissues rather than due to an increased selective permeability of the blood/C.S.F. barrier.

Experimental Evidence

The experimental pathologist now has at his command an established technique by which he can produce a demyelinating disease (encephalomyelitis) in animals by injecting them with homologous or heterologous brain tissue. This injection has a greatly increased effect if it is given with an adjuvant, such as heat-killed tubercle bacilli. Neither the injection of an emulsion of other organs nor that of the adjuvant alone produces this effect. Brain antibodies have been demonstrated by complement-fixation tests, but they are not capable of passive transfer. All grades of encephalomyelitis, ranging from acute to chronic, can be produced by varying either the number of injections or the amount of brain tissue injected. When a chronic form is produced in the monkey, cerebellar and pyramidal signs are prominent, partial remissions may occur, and at post-mortem examination plaques of demyelination may be found in the optic nerve and brain stem that, superficially at least, bear a striking similarity to the plaques of multiple sclerosis. The literature on the subject, the reasons for supposing that this reaction may represent an immunological mechanism, and the light which these experiments may throw on the cause of multiple sclerosis have been discussed by Lumdsen (1949, 1951, 1956) and by Wolf (1952).

Until more is known about the nature of the hypothetical antigen in brain tissue, the significance of experimental encephalomyelitis in relation to multiple sclerosis must remain *sub judice*. However, grounds for the belief that a form of allergy may be operative in both of these diseases have been strengthened by the marked similarity that exists between the type of polyneuritis which can be produced in rabbits by injecting them intradermally with rabbit sciatic nerve or spinal ganglia and the clinical picture of the Guillain-Barré syndrome or acute toxic polyneuritis (Waksman and Adams 1955).

Comment

It is clear that none of the clinical facts which I have briefly mentioned are in any way conclusive with regard to the allergic theory of multiple sclerosis. However, when viewed collectively the occasional familial incidence, the nature of the precipitating factors, the occurrence in some patients of a known form of allergy or a hypersensitivity to drugs, the abrupt onset and fluctuating course, and the change in the C.S.F. are all compatible with this theory.

Until disproved, the allergic theory of multiple sclerosis should be used as a basis for further research, particularly in the direction of determining the nature of the hypothetical antigen or antigens. By analogy with the results of experimental encephalomyelitis it would seem likely that, if an antigen-antibody reaction is concerned in the genesis of multiple sclerosis, part of the antigen is derived from a chemical component of the central nervous system; in other words, multiple sclerosis could in part be explained by auto-sensitization (Kabat, Wolf, and Bezer, 1947; Wolf, 1952; Lumdsen, 1956). In addition to an *intrinsic* component of the antigen it is necessary to postulate an *extrinsic* one. Theoretically this could be a specific chemical agent derived from one or more sources.

The work of Colover (1956) on the chemistry of the tubercle bacillus may point the way to the type of chemical agent that might be expected to serve as the source of extrinsic antigen in multiple sclerosis; he has shown that the residue in the tubercle bacillus, which is active in producing encephalomyelitis, is largely protein in character with

glutamic acid and alanine as predominant amino-acids. From clinical observations, it would seem necessary first to consider as possible sources of allergen the breakdown products of the common pathogens. From the foregoing remarks it is obvious that for the elucidation of this fascinating problem we must rely on the immuno-chemist and experimental pathologist, but there remains a place in research not only for the epidemiologist but also for the clinician who is prepared to view the problem broadly.

Early Diagnosis

A diagnosis of multiple sclerosis is usually not made until at least the fourth or fifth year of the disease. There are two main reasons for this delay. (1) The patient fails to report to his or her general practitioner early symptoms—for example, an episode of tingling or of numbness or of tiredness in a limb. Only by making the public aware of the existence of the disease and its early manifestations could this difficulty be overcome. Until the medical profession adopts a less defeatist attitude towards treatment it is doubtful whether such a step is at present justified, although as an indirect result of the activities of lay societies knowledge of the disease is slowly spreading. (2) The fallibility of us all, consultant and general practitioner alike, when confronted with a minor disturbance of function of any part of the body, more especially of the nervous system. Instead of dismissing an apparently trivial complaint regarding vision, sensation, or use of a limb, sometimes with labels as "eye-strain" or "neuritis," we must train ourselves to think of multiple sclerosis as a possible cause, even though on examination of the patient we can find little or no evidence to suggest organic disease.

There are certain features of the clinical picture which individually or collectively may lead to a correct diagnosis.

History.—This is of major importance, since it often raises suspicion of the disease, especially if after careful probing of the past one or more episodes come to light, often trivial and almost forgotten, suggesting a previous lesion in the central nervous system.

Family History.—In a suspected case of multiple sclerosis discreet inquiries should always be made for any neurological disorder in a near relative. Occasionally a positive history of multiple sclerosis in another member, or of paralysis occurring in youth or early middle age, which hospital records may confirm as due to multiple sclerosis, will heighten the suspicion of the same disease in the patient.

Prodromata.—Lassitude, easily induced fatigue, headache, irritability, difficulty in concentrating, and vague pains in the limbs are among the symptoms which may occasionally precede or accompany the onset and which may indicate a constitutional phase of the disease.

Behaviour of Early Symptoms.—Of major importance in diagnosis is the tendency for early symptoms to clear up, entirely or partially. Often, however, this important feature of multiple sclerosis, instead of arousing suspicion, has the opposite effect, and the reassurance given to the patient may seem well founded when perhaps months or even a few years pass by without any recurrence. The word "transitory" as applied to early symptoms is usually interpreted as meaning days or even weeks. However, quite commonly when taking the history one comes across episodes of disturbed vision, giddiness, or of tingling or numbness that lasted only hours or even minutes. Just because these early symptoms may be very short-lived they should not be dismissed as insignificant.

Evidence of Multiple Lesions.—It is often held that a diagnosis of multiple sclerosis cannot be entertained unless there is evidence of multiple lesions. It is quite true that such evidence—for example, the association of double or blurred vision and of paraesthesiae or weakness in a limb—is extremely helpful. However, a monosymptomatic type of onset is relatively common. In a recent analysis of 309 cases admitted to the Middlesex Hospital over a five-year period, in no less than 63% a history of a single symptom

was obtained at the onset: retrobulbar neuritis (21%) headed the list, followed by paraesthesiae (17%), motor weakness (14%), double vision (7%), and vertigo or vomiting (5%) (McAlpine, 1955).

Distribution of Symptoms.—Highly characteristic of multiple sclerosis is the irregular distribution of plaques in the central nervous system; consequently symptoms tend to be asymmetrically distributed. However, it is important to realize that they may occasionally show a remarkable degree of symmetry; for example, an attack of blurred vision in both eyes or paraesthesiae appearing symmetrically in the upper or lower limbs. If this feature of the disease is not recognized, difficulties in diagnosis may arise, especially when symmetrical paraesthesiae are present, thus imitating the distribution seen in acute polyneuritis.

Tendency for Local Spread of Early Plaques.—While it is quite common for a symptom to remain localized, not uncommonly there is a tendency towards spread. For example, a patient may describe how she first noticed a blurring in the centre of the field of vision which rapidly spread to involve the whole field. Or, again, numbness may spread locally; for example, from the little and ring fingers to the remaining fingers and rest of the hand, or widely from the upper limb to the trunk and lower limb on the same side, or in the reverse direction. This type of spread does not occur haphazardly, but is determined by the anatomical arrangement of fibres in the neighbourhood of the plaque. For example, paraesthesiae such as tingling and numbness are usually caused by a plaque in the posterior column, and if they spread widely it is sometimes possible to correlate the mode of spread with the arrangement of the proprioceptive fibres. The rapid manner in which spread may occur in multiple sclerosis is of diagnostic importance.

Physical Signs.—It is still widely held that a diagnosis of multiple sclerosis cannot be made unless certain signs are present, notably nystagmus and an extensor plantar response. It is of course true that the presence of these and other signs, particularly temporal pallor of a disk, are of the utmost value; nevertheless their relative or complete absence should not allay suspicion if the history is suggestive.

Cerebrospinal Fluid Findings.—A mistaken idea that lumbar puncture may be harmful in cases of multiple sclerosis may be one reason why this important diagnostic procedure is not used more often. Replacement of the fluid by 5 ml. of sterile normal saline solution reduces the risk of headache.

Some Remarks on Early Symptoms

Retrobulbar Neuritis

The clinical picture of an acute retrobulbar neuritis and its close association with multiple sclerosis is well known. I wish to draw attention to certain atypical features of this condition, some of which, so far as I can judge, are not well recognized. The first concerns short-lived attacks of blurred vision in both eyes, a history of which may sometimes be obtained in a patient who presents with a frank retrobulbar neuritis or with other evidence of the disease. Frequently, but not invariably, these attacks are brought on by exertion, fatigue, bright light, or reading. Multiple sclerosis is, of course, not the only condition in which temporary attacks of blurred vision occur; it may, for example, be caused by cerebral anoxia, or by posterior fossa tumours (Shepherd and Wadia, 1956). In multiple sclerosis this symptom has a significance, not only for early diagnosis, and as a probable explanation of temporal pallor of a disk in the absence of a positive history of a frank attack of retrobulbar neuritis, but also in relation to the physiopathology of the early plaque.

The next point concerns field defects. Although usually centrally placed, a scotoma may vary not only in density but also in its position in the visual field. Whatever the site of the original defect, there is a tendency for the scotoma to spread. Retrobulbar neuritis may be painless; on the other hand, pain in or behind the eye, especially on upward or

inward movement, is not uncommon. Of particular interest is the fact that pain in this situation may precede any subjective alteration in vision by a week or even longer. I have seen patients with retrobulbar neuritis who have had one or more attacks of pain in the eye without any visual failure. Pain preceding retrobulbar neuritis may be referred sometimes to the same frontal region or more widely over the whole of the side of the head. Where is the site of the pain in such cases? Ophthalmologists usually localize pain in and around the eye to the attachment of the superior and internal recti in the sheath of the optic nerve. This explanation does not adequately account for the occasional widespread pain met with in retrobulbar neuritis. Obviously this is a subject much in need of study, since if we knew what structures were involved we might have a valuable clue to the site of the early lesion.

Paraesthesiae

When a young or middle-aged patient presents with a disturbance of sensation as a solitary symptom the possibility of disease of the central nervous system does not readily come to mind. However, before explaining such symptoms as tingling, pins-and-needles, numbness, or deadness on the basis of a disturbance of the peripheral nervous system, the distribution, mode of onset, and duration of paraesthesiae should be carefully noted. If they are referred to the periphery of one limb confusion with a mononeuritis may readily occur; if, however, pins-and-needles or numbness is referred to the proximal half of a limb or to the trunk, then a root or cord lesion must be considered. I have already drawn attention to the symmetry sometimes shown by the paraesthesiae of multiple sclerosis and their striking resemblance to those occurring in some forms of polyneuritis (including the opening phase of subacute combined degeneration of the cord). Rapidity of onset and of spread characterize the paraesthesiae of multiple sclerosis. A spreading tingling going on to numbness and clumsiness of the affected part, with diminution or loss of two-point discrimination and vibration and postural senses, are well-recognized features of a plaque in the posterior column. A feeling of warmth or of coldness or dampness in a lower limb or inability to appreciate the warmth of a hot bath, coming on abruptly, should arouse suspicion of a plaque in the contralateral spinothalamic tract. The issue as between a peripheral and a central cause of paraesthesiae may be clarified first by the results of clinical examination and secondly by the clearing up of symptoms. Symmetrical or four-limb paraesthesiae when due to a peripheral neuritis tend to progress, while depression of the deep reflexes is followed by their disappearance.

Pain is not at all uncommon in the opening phase of multiple sclerosis. It is usually described as an ache referred to the back or the upper or lower limbs. Occasionally it may be sharp, though it is not aggravated by coughing or straining. A recent history of pain should not automatically exclude multiple sclerosis as a possible cause of an episode of paraesthesiae.

Motor Weakness

Here again it is the minor degree of disability, disguised as a "tiredness," a "heaviness," or a "stiffness" in one or both limbs, especially after walking, that is often misinterpreted. In some cases pyramidal signs are evident; in others a careful examination is required to bring out fatigability or depression of the abdominal reflexes, a slight inequality in knee- and ankle-jerks, and an equivocal plantar response. When the first plaque or plaques giving rise to symptoms are situated in the optic nerve or the dorsal half of the brain stem or posterior columns, pyramidal signs may be absent.

Sphincter Disturbance

Sphincter disturbance is uncommon as an early symptom unless there is evidence of a myelitis due to the disease. Occasionally, however, frequency and urgency of micturition

or, rarely, incontinence are presenting symptoms, and I have met with a few cases of this type in which pyramidal signs were indefinite or even absent. If the urologist's report is negative, then the possibility of multiple sclerosis should be considered and lumbar puncture performed.

Progressive Spinal Form of Multiple Sclerosis

In approximately 10% of all cases of multiple sclerosis the onset is insidious and the course progressive. This form is more common in the middle-aged than in the young. Differentiation from other causes of paraplegia in the middle-aged may be extremely difficult. Two conditions are apt to be confused with it: cervical spondylosis and spinal cord compression. Some progressive cases of multiple sclerosis have relapses superimposed on their progression, and this fact may be helpful in diagnosis. More important may be the detection of an extraspinal lesion, either from the history or from the clinical findings. Among the latter, nystagmus, other than purely horizontal, temporal pallor of a disk, dysarthria, or intention tremor in an upper limb should be looked for. A positive Lange colloidal gold curve in the C.S.F. may decide the issue. Lastly, radiological proof of a cervical spondylosis does not necessarily mean that associated cord signs are due to it; multiple sclerosis and cervical spondylosis may coexist. Myelography is necessary to establish this fact, as well as exclude the possibility of spinal-cord tumour.

Brain-stem Signs

An early case of multiple sclerosis may present signs which clearly indicate the presence of plaques in both brain stem and spinal cord. However, when signs are confined to the brain stem the diagnosis may not be clear. There are three ways in which multiple sclerosis of the brain stem may present.

(1) *As an Acute or Subacute Encephalitis.* An abrupt onset of drowsiness, paresis of one or more cranial nerves, especially the third or sixth, with the appearance of motor, sensory, and cerebellar signs in the limbs, may closely simulate a virus encephalitis, particularly that due to poliomyelitis virus, and it is understandable that such cases should sometimes be admitted to infectious-fever hospitals. The absence of fever and neck stiffness, a positive Lange colloidal gold curve in the spinal fluid, a tendency for fresh symptoms to develop in the second or third week of the illness, and the persistence of sensory disturbance are some of the features which would suggest acute multiple sclerosis. Euphoria is occasionally met with in both these types of acute encephalitis, but is relatively more common in multiple sclerosis.

(2) The second group of cases are characterized by focal signs, sometimes suggesting a unilateral lesion, for example, of the pons, but more usually a paresis of a single cranial nerve. *Double vision* occurs at the onset of multiple sclerosis in roughly 15% of cases, in half this percentage as an isolated symptom. The sixth nerve is more commonly affected than the third. Multiple sclerosis is a common cause of a transitory diplopia in a young adult, and here again lumbar puncture may be of the greatest value. *Numbness in the face* may occur either as part of a unilateral pontine picture or as an isolated symptom. If, after extraction of a tooth, numbness persists for a few days it should not be attributed to the effect of a procaine injection. *Bell's palsy* may on rare occasions be the first symptom. Although an absence of pain and of loss of taste with rapid recovery may be noted as unusual features, its possible relationship to multiple sclerosis is usually not considered until later, when the patient presents with undoubted signs of the disease.

(3) *Vertigo* in varying degrees of severity is a relatively common symptom during the course of multiple sclerosis and occasionally it may be the presenting symptom. Vomiting may accompany or precede giddiness. The resemblance to Ménière's syndrome may be close, particularly when a degree of deafness is present. As a rule, however, in multiple sclerosis hearing appears to be normal though audiometry

may show some degree of nerve deafness on one or both sides. Although "epidemic vertigo" and "vestibular neuronitis" are better-recognized causes of an acute vestibular upset with normal hearing, multiple sclerosis should not be forgotten as a possible cause, more especially when nystagmus persists after vertigo has disappeared or other signs are present. *Cerebellar signs* may be prominent at the onset, as shown by dysarthria and a reeling or drunken gait without vertigo; as a rule other evidence of the disease can be found.

Course of the Disease

Most textbook descriptions of multiple sclerosis imply that, although its course is extremely variable, sooner or later a severe degree of disability is inevitable. Although this statement is unfortunately true of the majority of cases, it fails to take into account the possibility of a high resistance to the disease. For example, in the Middlesex Hospital series of 586 cases, 13% of those followed for 15 years showed no disability (McAlpine and Compston, 1952). The preliminary results of a fresh follow-up on which I am at present engaged would appear to confirm the existence of a *benign form* of the disease, characterized in the main by a good recovery from the initial attack and a tendency for relapses to be mild and infrequent or cease altogether. It has long been recognized that after an attack of retrobulbar neuritis the disease may remain quiescent for many years; for this reason such cases are often excluded from a follow-up of this type, and accordingly I have adopted this practice unless on one or more occasions there have been other signs of the disease or changes in the cerebrospinal fluid. However, the emphasis on retrobulbar neuritis in relation to long latency of the disease has tended to obscure the fact that other isolated symptoms such as diplopia or an episode of paraesthesiae may be followed by an equally long latent interval.

Earlier I mentioned certain factors that might influence not only the onset but also the course of the disease. These in order of importance are (1) intercurrent infection, (2) fatigue, (3) emotional upset, and (4) trauma. From work on the effects of pregnancy (Müller, 1949; Tillman, 1950; McAlpine and Compston, 1952) it is clear that its role has in the past been exaggerated. The risk of relapse can be further minimized by discouraging pregnancy until the disease has been stabilized for at least two years, by an extra period of rest after confinement, and by the provision of adequate help in the house so as to reduce fatigue, consequent upon the care of a young baby.

Treatment

The lack of a realistic approach to the problem of multiple sclerosis is chiefly responsible for the negative attitude towards its treatment. The knowledge that no drug is available that can be relied upon to prevent relapses and thus modify the course of the disease is not a valid reason for neglecting general principles in treatment. In a case of rheumatoid arthritis or of chronic asthma the physician is not content to focus his attention on joint or chest but realizes that success or failure may depend on the extent to which he can improve his patient's physical and mental health.

Likewise in treating an early case of multiple sclerosis our attention should be fixed on the constitutional and environmental background of the patient rather than on the nervous system. If arrest of the disease may occasionally occur spontaneously, this fact should encourage us to do our utmost for the early case. Failing an effective remedy, I suggest that the greatest contribution that we can make towards early treatment is to adopt the same attitude of mind as that taken towards the tuberculous patient. If this were done I feel convinced that, in a worth-while proportion of cases, the disastrous results which we see all too often would be avoided or at least mitigated. Therefore every effort should be made to establish the diagnosis at the earliest possible moment.

Turning to general principles, there are two that should be in the forefront of our minds when confronted by an early case. (1) To ensure the maximum degree of recovery from the initial attack and early relapses. This is best attained by an adequate period of rest in bed during the active phase of the disease, followed by prolonged convalescence, varying from two to six months. (2) To adopt all measures which may reduce the risk of relapses. In practice this means careful attention to general health and mode of life. When the diagnosis of multiple sclerosis is suspected admission to hospital should be arranged, preferably under the care of a neurologist, for a fourfold purpose: (a) to confirm the diagnosis from clinical and cerebrospinal fluid findings; (b) to ensure proper rest in bed; (c) to afford an opportunity of correcting any abnormalities in the general health suggested by the history—in particular, possible foci of infection (for example, sinuses, tonsils, teeth, and urinary tract), and to discuss frankly the cause of any anxiety symptoms; and (d) to carry out any therapeutic measure that may increase resistance.

The variety of remedies at present advocated scarcely suggests that any will eventually prove to be of value. They include isoniazid, vasodilators, a low-fat diet (Swank, 1955), Evers's uncooked food diet, and lastly vaccines and serums. Of those preparations used in Great Britain liver and vitamin B₁₂ are the most popular; multiple sclerosis is not a deficiency disease, therefore their use does not extend beyond the possible effect on general health. Theoretically a claim could be made out for trace elements, in particular copper and cobalt, but in practice they have not so far proved effective. Judged by reports in the literature, the results from the use of corticotrophin and cortisone have been disappointing. If the allergic origin of the disease be used as a working hypothesis some method of stimulating the defence mechanism of the body would seem worth a further trial. In the meantime we must rely on an old-established remedy—namely, arsenic. I have used this for many years in the form of intravenous neoarsphenamine, four courses yearly, with Fowler's solution in between the courses. Although this treatment, if begun early in the disease and kept up for five years or more, does not necessarily prevent relapses, I believe that in some patients it may modify their frequency and severity and so delay or even prevent the stage of progression. In those patients whose resistance is low a downward course occurs despite this or any other form of treatment. An antihistamine drug is indicated when there is an associated allergic disorder or in those patients who can tolerate arsenic only in the form of Fowler's solution.

Many of those who advocate a particular line of treatment in multiple sclerosis are inclined to quote individual cases in which a cure seems to have been produced. They should bear in mind that in at least one patient in every ten resistance is high and there may be no disability after 15 years. In order to prove the efficacy of any method of treatment it would have to be shown that in a series of cases relapses were prevented, and that disability was negligible in more than 20% of a series of cases followed up for a similar period.

Under what circumstances should a patient with multiple sclerosis be informed of the diagnosis? Neurological opinion, in this country, would, on the whole, appear to be in favour of withholding this knowledge until the disease is well established. However, a positive attitude towards the management of the early case demands the intelligent co-operation of the patient, and therefore in responsible adults an explanation of the nature of their illness is essential. A comparison with the known allergic disorders is useful as it affords an opportunity of referring to relapses, to the circumstances which may lead up to them and which therefore must so far as is possible be avoided, and to the importance of complete rest should a relapse occur. A decision to recommend long-term treatment, for example with arsenic, is usually accepted by the patient if the advice is given with a degree of conviction. If tactfully conducted, this method of approach nearly always leads to a quick

adjustment and a readiness to co-operate to the full during the first crucial years of the disease. Above all, the impression must not be left on the patient's mind that he or she is suffering from a mysterious disease about which nothing is known and for which there is no treatment.

Summary

An air of defeatism tends to surround the subject of multiple sclerosis. The reasons for this attitude are examined in some detail.

Aetiology is discussed with especial reference to the allergic theory.

A diagnosis of multiple sclerosis is usually not made until the fourth or fifth year of the disease. The causes of this delay are discussed and early symptomatology is reviewed.

The traditional belief that multiple sclerosis inevitably leads to increasing disability and premature death requires modification in the light of recent studies. A brief reference is made to the concept of varying degrees of resistance and to a benign form of the disease.

A plea is made for a more positive attitude towards treatment. In an early case more attention should be paid to the constitutional and environmental background of the patient. Stress is laid on the importance of rest during active phases of the disease, followed by prolonged convalescence. In responsible adults an explanation of the nature of their illness is essential in order to obtain intelligent co-operation in treatment.

A new British Standard (2805:1957) specifies a range of straight artery (haemostatic) forceps of the Spencer Wells pattern having a screw joint and made of stainless steel. Provision is made for the 5 in., 6 in., 7 in., 8 in., and 9 in. (12.7–22.8 cm.) sizes. The preparation of this Standard was recommended by the Ministry of Health and authorized by the Surgical Instruments and Medical Appliances Industry Standards Committee of the British Standards Institution. British Standard 2805 may be obtained through the Sales Branch of the British Standards Institution, 2, Park Street, London, W.1, price 3s. 6d.

POLYRADICULITIS (LANDRY-GUILLAIN-BARRÉ SYNDROME)

TREATMENT WITH CORTISONE AND CORTICOTROPHIN

BY

R. HUGH JACKSON, M.C., B.M., M.R.C.P.

Senior Registrar

HENRY MILLER, M.D., F.R.C.P.

Physician in Neurology

AND

KURT SCHAPIRA, M.B.

Research Fellow in Neurology

The Royal Victoria Infirmary, Newcastle upon Tyne

The clinical and pathological identity of Landry's ascending paralysis and the Guillain-Barré syndrome (polyradiculoneuritis; acute infectious, toxic, or febrile polyneuritis; or infectious neuronitis, polyneuritis cranialis, etc.) was fully established by the important review of Haymaker and Kernohan (1949). Since then the non-specific nature of the syndrome and its relation to other acute inflammatory diseases of the nervous system, and possibly to allergy, have been noted (Stanton *et al.*, 1953), while the results of treatment with corticotrophin and cortisone have been described by Clarke *et al.* (1954) and others.

In the past three years we have treated five deteriorating cases of this condition with corticotrophin or cortisone, and in this paper we present these cases, review the available literature on the subject, and endeavour to draw some general conclusions.

Case 1

On November 6, 1953, three weeks after a brief attack of acute febrile bronchitis, a 28-year-old docker developed an illness initially regarded as influenzal, characterized by fever, backache, and headache. Twenty-four hours later he developed tingling in the tip and dorsum of the tongue, and, after a similar interval, ascending paraesthesiae and weakness in both lower limbs. By November 9 he could progress round the room only by holding on to the furniture. Weakness of the legs increased further, and on November 13 he noticed paraesthesiae in both hands. His speech became slurred, and food stuck in his throat; there was slight dysuria and some constipation. At this stage he came under medical observation, and over the course of the next few days all deep reflexes disappeared, asymmetrically bilateral facial weakness developed, and loss of superficial sensibility became evident over the whole of both lower limbs, the forearms, and a band round the trunk between nipples and umbilicus. The legs were much weaker than the arms, and when he was admitted to our care on November 18 he was unable to stand. Weakness and muscle tenderness were generalized, but were most marked in the proximal limb muscles. Blood examination, E.S.R., E.C.G., and x-ray films of the chest and spine showed nothing abnormal. The only abnormality in the spinal fluid was a protein content of 240 mg. per 100 ml., rising subsequently to 480 mg.

In view of continuing deterioration, and especially pharyngeal pooling of mucus owing to bulbar weakness, oral administration of cortisone was begun at once. He was initially given 300 mg. daily, but this was reduced gradually to 100 mg. daily by the fifth day, and the smaller amount administered daily for a further five days.

Within 18 hours of first receiving cortisone (225 mg.) the patient claimed to feel much better and that his voice was stronger, but examination failed to substantiate his claim of improvement, which was attributed to pharmacologically induced euphoria. Within 36 hours of instituting treatment, however, the facial diplegia showed unequivocal improvement and he could whistle feebly. His voice appeared to be somewhat stronger, but his own claims of improvement in swallowing and improved power in the limbs were unsupported by objective evidence, which showed no change in power, reflexes, or sensation.

Reassessment at the end of 10 days' treatment suggested that the condition had ceased to progress. Facial weakness was greatly improved, the voice stronger, and swallowing normal. Sensory loss was less extensive on limbs and trunk, while pain and muscle tenderness had disappeared. Motor weakness in upper and lower limbs, however, was as severe as on admission, while there was no return of reflex activity.

Subsequent improvement was slow but steady, and five months later his sole disability was some weakness of the left leg. By August, 1954, there was no residual disability and all deep reflexes had recovered.

Comment.—In this severe case of polyradiculitis the administration of cortisone was followed by unequivocal clinical improvement within 36 hours, and at the end of 10 days' treatment this improvement was striking. From this point onwards, however, further improvement was slow, and it was eight months before recovery was complete.

Case 2

A 33-year-old housewife was admitted to hospital under the care of Dr. H. A. Dewar on November 16, 1955, with an eight-weeks history of tingling of the fingers and hands, followed by slight loss of grip. Five weeks before admission she had developed weakness of her ankles and legs and had been put to bed for one week, following which she got up again, but was able to get about the house only with the aid of sticks. The weakness increased and two days before admission she was unable to walk. Constipation had been troublesome throughout the illness.

On examination she appeared to be in good health. The cranial nerves were normal, but there was some loss of power in the forearms and marked loss of power in both legs, with severe bilateral foot-drop. All deep reflexes were absent, and muscle pains and tenderness were conspicuous. There was loss of superficial and deep sensibility in both feet. The spinal fluid contained 800 mg. of protein per 100 ml. Other ancillary investigations were negative.

During an initial period of two days' observation there was no improvement in her condition, and after this time cortisone was administered. She was given 200 mg. daily for three days, 100 mg. daily for 18 days, the drug being then gradually withdrawn over the course of a week. Within 48 hours subjective and objective improvement was evident: her grip was improved and toe movements had returned. Within eight days she could move the legs weakly, and improvement of power in the hands permitted knitting. There was improvement in sensibility in the legs, and the deep reflexes had returned weakly in the arms.

From this time progress was slower. Within three weeks, however, she was able to walk with assistance, and was discharged from hospital on December 31—six weeks after admission.

When the case was reviewed six months later, progress had been continuous but slow, and the patient was able to walk without the use of sticks. Her only complaint was that she put her feet down rather heavily when walking. All limbs showed absence of deep reflexes, but power was good apart from slight weakness of dorsiflexion of the feet; sensation was normal.

Comment.—This patient, an example of mild polyradiculitis, showed what appeared to be a satisfactory initial

response to treatment with cortisone, followed by slow improvement indistinguishable from that seen in untreated cases which recovered.

Case 3

A 40-year-old driver was well until a month before admission to hospital, when he noticed some tingling in his fingers and toes. A week later he developed stiffness and pain in the neck and shoulders, and four days after this sharp cramping pain occurred in the muscles of the left thigh. During the next two weeks muscle pains became severe and generalized; he developed a moderate fever, a right facial palsy of peripheral type, mistiness of vision, and slurred speech.

On his admission to hospital on December 30, 1955, examination revealed slurring dysarthria, neck stiffness, bilateral facial palsies more evident on the right, loss of power in the limbs which was more marked peripherally in the lower and proximally in the upper limbs, general hypotonia, and loss of reflexes with widespread muscle tenderness, especially marked in the calves. There was no sensory loss, but the soles were hyperaesthetic. The left plantar response was flexor, the right variably extensor. Ancillary investigations were normal, but spinal fluid examination yielded as the only abnormality a protein content of 290 mg. per 100 ml., a figure which was almost doubled on subsequent examination.

Clinical deterioration continued, and, as the patient developed slight difficulty in swallowing, 200 mg. of cortisone was administered at once, followed by 100 mg. thrice daily. Some improvement was evident within 18 hours of the first dose and was quite marked in 48 hours, by which time the facial palsies were much less conspicuous (the severe right-sided paralysis showing the more striking response), he was able to whistle a little, and speech was distinctly clearer. The dose of cortisone was gradually reduced to 200 mg. and then to 100 mg. daily, and its administration was stopped on the seventh day. At this time, in addition to the improvement already noted, there was increased power in the lower limbs; he was able to dorsiflex both feet, while both plantar responses had become clearly flexor.

Twenty-four hours after the last dose of cortisone the patient, a phlegmatic individual, complained of suddenly feeling very ill with intense pain in the limbs, particularly the legs. These symptoms cleared up within half an hour, but by this time a marked deterioration in physical signs was evident. His right facial weakness was again much more pronounced, vision in the left eye was blurred (without objective findings), his legs were weaker, and the plantar responses were unobtainable. By the next day this deterioration was more evident. His speech had once more become slurred, and he was having some difficulty in passing water.

In view of these developments he was given a further course of cortisone, beginning five days after the end of the previous treatment. On this occasion no dramatic response was obtained. He claimed to feel better, and there was certainly no further deterioration, but on re-examination after 10 days on cortisone his objective improvement was negligible.

From this time the slow but progressive improvement in function which occurred was similar to that with which we are familiar in a severe case of the untreated disease. It was four months before he was able to stand, and even in September, 1956, walking was still much impaired, while the deep reflexes had not yet reappeared.

Comment.—This patient showed unequivocal improvement within 24 hours of the administration of cortisone, but a relapse which occurred when the drug was withdrawn showed little response to a further course of treatment given within four days of the onset of deterioration. On this second occasion the drug relieved pain but produced no improvement in physical signs.

Case 4

A 5-year-old girl was admitted to the Sunderland Children's Hospital under the care of Dr. J. B. Heycock on February 7, 1956. Six weeks before admission she developed tonsillitis, and after this had subsided she remained unwell in herself for a week, during which time she was kept in bed. At the end of this period she developed spontaneous pains and painful cramps in the legs and was observed to limp. These symptoms became more pronounced during the fortnight preceding admission, and she was noticed to lie down a good deal with knees flexed in order to obtain relief.

On admission she was unwell and miserable, with flaccid weakness of all limbs, especially in the legs, and with total disappearance of deep reflexes. The muscles were tender, but no loss of sensation was demonstrable. The spinal fluid protein was 100 mg. per 100 ml., and all other ancillary investigations were negative.

Over a period of 48 hours' observation there was unequivocal deterioration with increasing weakness and at the end of this period (February 17) cortisone was started by mouth, 100 mg. daily being given in four doses for five days, and then 200 mg. daily for seven days, after which time the drug was gradually withdrawn over the course of four days.

The response was not dramatic. What had previously been a steadily deteriorating course ceased to progress, and pain disappeared within 24 hours and the child's general condition also appeared to be improved. There was, however, no convincing change in the neurological findings, except for the disappearance of the muscle tenderness, until seven days after the end of treatment, when the condition began to show unequivocal improvement with increase in power in the legs which was rapidly progressive. Within a month there was a marked degree of improvement in the power of all limb groups, though the deep reflexes remained absent.

She was discharged from hospital on April 4, and continued with exercises and physiotherapy for a further month, when she was again reviewed. Re-examination showed steady but slow improvement; there still being some weakness of the arms and legs, most pronounced in the quadriceps. The deep reflexes were still absent.

Comment.—Except for disappearance of pain and muscle tenderness, this child showed no evident improvement on cortisone, the administration of which coincided, however, with the arrest of progressive deterioration in her condition. Objective improvement in physical signs was not evident until after treatment was withdrawn, following which the course of the illness was characteristic.

Case 5

A 40-year-old stone-mason presented on August 24, 1956, with a story of four days' numbness and weakness spreading up the arms and legs. His weakness rapidly became so profound that the condition was at first thought to be hysterical, but he was seen by a physician, who discovered absence of reflexes, muscle tenderness, and peripheral sensory loss. The condition remained fairly static for three weeks and then quite rapidly became worse, with ascending intercostal parestheses, facial diplegia, and bulbar weakness with pooling of mucus in the pharynx. At this stage spinal puncture showed 800 mg. of protein per 100 ml. In view of increasing difficulty in breathing, the patient, who was now under the care of Professor G. A. Smart, was given intermittent assisted respiration and 40 units of corticotrophin twice daily. Improvement was dramatic. Within 24 hours he was able to whistle, there was a surprising improvement in the power of the left arm, and his cough was stronger. Six days later breathing was normal, both arms were stronger, there was some return of power in the legs, and sensory change was beginning to shrink. Within a month of beginning treatment the only disability was partial bilateral foot-drop, rapidly improving, though knee- and ankle-jerks remained

absent. As a safeguard against possible relapse, 5 mg. of prednisone was given three times daily for three weeks after the completion of 10 days' treatment with corticotrophin.

Comment.—An apparently dramatic response to corticotrophin in a severe and advancing case of polyradiculitis was followed by unusually rapid recovery.

Review of Literature

Since Stillman and Ganong (1952) first reported a case of Landry-Guillain-Barré syndrome treated with corticotrophin, there have been 34 papers in which the treatment of 68 cases has been described. Review of these shows that in 50 there has been some response and in 18 the response has been negligible. In one case the disease developed during cortisone therapy (Grant and Leopold, 1954), but in no other case was deterioration reported during treatment.

In evaluating the treatment of the Landry-Guillain-Barré syndrome with corticotrophin and cortisone, it would be desirable theoretically to have a sufficiently large series of cases under the care of one observer, so that variations in the amount, duration, and route of treatment could be standardized, allowance made for the wide variation in clinical picture, and a control series of non-treated cases arranged. Practically, however, this is impossible, and we would emphasize that we have been able to draw only a few general conclusions; the wide variations in the degree of detail of these reports have made it impossible to study the exact clinical pictures. In general, cases in which there has been a gratifying response have been reported in greater detail than those in which the response has been less dramatic, and it must be borne in mind also that there is always a tendency to report successfully treated cases while the unsuccessful ones remain in obscurity.

One further difficulty in analysing the literature of such a pleomorphic condition as Landry-Guillain-Barré syndrome is to know whether in fact the cases reported are examples of this condition. There is no easy solution to this problem, for it is difficult to draw up a list of criteria which have to be fulfilled before a particular case can be accepted as Landry-Guillain-Barré syndrome, and we have therefore included in our survey all cases so described.

In analysing the literature note has been made of the following points: sex, age, association with any other disease (such as infective hepatitis, periarteritis nodosa, etc.), severity of the disease, protein level of the spinal fluid, length of history prior to admission to hospital, duration of observation before treatment, dosage and mode of administration of the drug, and duration of treatment. These have been assessed to see if they have any bearing on the response to treatment. The severity of the disease has been arbitrarily defined as "severe" if there have been bulbar or cranial nerve involvement, phenomena such as sudden circulatory collapse sufficient to endanger life seriously, and extensive and profound limb involvement. "Moderate" is used to describe cases in which there has been no bulbar involvement but in which the limb paralysis has proceeded as far as a complete paralysis or tetraplegia. "Mild" means limb weakness only, without complete paralysis, even if widespread. It is felt that some such classification as this is useful in relating severity of disease to response to treatment.

As mentioned above, 18 cases failed to respond, but 12 were unsuitable for analysis as no details are given, and it is felt that the six cases in which details are available do not constitute a large enough group to make an analysis valid. It is not possible, therefore, to compare a group of cases which respond to treatment with a group which failed to respond. Consequently we have no means of predicting which cases are likely to respond.

The 50 cases showing response seem to fall naturally into three types: type 1, in which there is an immediate and sustained response to treatment, and in which recovery is complete within one month of starting treatment (21 cases);

type 2, in which there is a brisk initial response with early partial improvement, but in which final recovery does not occur so rapidly and the tempo of the initial improvement is not sustained (full and final recovery is usual—this type comprises 23 cases and also Cases 1 to 3 described above); and type 3 (6 cases), a miscellaneous group in which the type of response is not readily classified under the other two headings. Examples of types 1 and 2 are as follows:

Type 1.—A 17-year-old girl (Seltzer *et al.*, 1952) developed symptoms of Landry-Guillain-Barré syndrome 10 days before admission to hospital. During the next 10 days she continued to deteriorate and required tracheotomy. On the twentieth day of the illness—that is, 10 days after admission—treatment with 25 mg. of corticotrophin eight-hourly for five days was started, with effect within 24 hours. Improvement was maintained and she progressed so satisfactorily that the tracheotomy was closed nine days after the commencement of treatment, walking was possible seven days later, and 28 days after admission the patient was well enough to be discharged; a fortnight later she returned to school.

Type 2.—A boy aged 15 (Hay, 1955) was admitted to hospital with a five-weeks history of difficulty in walking, paraesthesia for a fortnight, and complete inability to walk for two days before admission. Examination showed generalized lower-limb weakness associated with loss of deep tendon reflexes. Steady deterioration, manifested by increasing weakness in both arms associated with loss of tendon reflexes, was noted during the initial period of nine days' observation, at the end of which time a course of cortisone was started. Subjective and objective improvement in both hands was noted within 24 hours. The patient was able to sit up on the fifth day, and by the 26th day was able to walk, although some weakness persisted until five months later, when full recovery of muscle power had taken place (at that time, loss of tendon reflexes in both legs was still evident).

The dramatic and possibly life-saving effect of corticotrophin or cortisone as typified in the type 1 case made us examine the cases further to decide if there were any indications of the type of case which would produce this response. However, there is no obvious difference between types 1 and 2 in sex, age, severity, spinal fluid protein, or in the dosage or route of administration of the drug employed. Cases in which treatment was started within one month of the onset show a slightly increased tendency to show a sudden and sustained response, though the difference is not statistically significant.

In fact, although the occasional dramatic response to cortisone is at least suggestive, statistical proof of its value is lacking. No control trial has been reported in the literature, and information on the natural history of the disease is curiously lacking in terms of concrete figures which can be used for comparison. Brain (1951) states that in the most favourable cases the patient may not be convalescent until from three to six months. Bradford *et al.* (1919) state: "In cases of a severe type it would seem that a period of about two months elapses between the onset of the palsy and a degree of recovery that renders evacuation feasible, and that a period as long as six months may be necessary for the patient to regain his usual health." Holmes (1917), in a series of 12 cases, noted "steady and rapid improvement which usually sets in within two or three weeks of onset. The pains and hyperaesthesia diminish quickly after the first fortnight or so, and somewhat later the power of the paretic muscles begins to return gradually." However, in none of his cases was recovery complete. Gilpin *et al.* (1936) state that the entire duration of the illness in 20 cases varied from 10 weeks to 2½ years, the average being about 6½ months. The fact that 21 cases out of 68 treated with cortisone recovered completely within one month does at least suggest that the rate of recovery is hastened as a result of the treatment.

Reported death rates vary considerably. Guillain *et al.* (1916), in their original paper, laid down complete recovery as one of the criteria for diagnosis, and Guillain (1936) much later affirmed that none of his patients died. Other authors (see Table) give a mortality rate varying from 8.7% to 42% in cases not treated with cortisone.

Of reported cases treated with cortisone or corticotrophin, only two patients have died. In one (Guiang and Leones-Guiang, 1954) the patient, a boy aged 2, was removed from hospital by his mother when he appeared to be responding to treatment. He relapsed and died at home. In the second

Mortality Rate of Landry-Guillain-Barré Syndrome

Author	No. of Cases	Deaths
Holmes (1917)	12	2 (16.6%)
Bradford <i>et al.</i> (1919)	30	8 (26.4%)
Gilpin <i>et al.</i> (1936)	20	4 (20%)
Roseman and Aring (1941)	16	3 (18.8%)
Forster <i>et al.</i> (1941)	26	11 (42%)
Von Hagen and Baker (1953)	23	2 (8.7%)

(Fazlullah, 1956) the patient died of acute pulmonary oedema associated with adrenal failure following a complex and bizarre illness with some features suggesting polyarteritis nodosa.

Discussion

The general features of the condition are familiar—a rapidly or insidiously ascending flaccid paralysis, sensory impairment often being inconspicuous or absent, with muscle tenderness, loss of deep reflexes, and, in classical though not in all cases, cytoalbuminological dissociation in the spinal fluid. A considerable number of these cases show meningism, while an occasional transient extensor plantar response bespeaks extension of the lesion into the spinal cord. Frank myelitic or encephalitic concomitants are rare, but such mixed forms undoubtedly occur.

Aetiology is multiple. The condition occurs as an occasional complication, much less frequent than encephalitis or myelitis, of many specific infections, among which measles, varicella, rubella, and mumps are conspicuous examples, while its occurrence in infectious mononucleosis and infective hepatitis has recently attracted attention. Significantly, its occurrence is not limited to such infections, and it is seen also as a complication of serum sickness and of many sterile prophylactic inoculations such as T.A.B. or rabies vaccine, diphtheria toxoid, etc. (Miller and Stanton, 1954). Most cases, however, arise "spontaneously," though in many such patients there is a recent history of banal infection.

According to Von Hagen and Baker (1953), Bergamasco and Bottigioni have claimed evidence of a neurotropic virus, but Aring and Sabin (1942) found that culture and transmission experiments were unsuccessful (quoted by Chusid and Marquardt, 1945).

Histopathological changes are maximal in the spinal nerve roots; Scheinker (1949) found that the axis cylinders in the nerve roots were enlarged owing to oedema, and that fragmentation and "corkscrew" formation were also present. Changes in the myelin sheaths—beading and irregular swelling—were also found in some cases. In the cord itself there was some swelling of the anterior horn cells and the axis cylinders, and the white matter showed marked swelling. Inflammatory reaction was conspicuous by its absence. These findings agree largely with those of Gilpin *et al.* (1936) and of Roseman and Aring (1941), and are similar to those described in polyradiculitis complicating frankly allergic disorders such as serum sickness.

An explanation of the clinical picture and the cytoalbuminological dissociation is put forward by Scheinker (1949) and by Reitman and Rothschild (1950), who suggest that the oedema of the nerve roots and trunks produces compression within the firm perineural sheaths. Hassin (1948) claims that about one-fifth of the spinal fluid is absorbed through the perineural spaces in the spinal canal, and Aring (1945) showed that in cases of Landry-Guillain-Barré syndrome the spinal fluid protein level in the lumbar theca was much higher than that in fluid obtained by

cisternal puncture. Boshes and Sherman (1953) point out also that if spinal fluid is allowed to drain off during a lumbar puncture the fluid collected in the first tube and therefore coming from low down in the spinal canal has a higher protein content than fluid collected in subsequent tubes coming from higher up. As Reitman and Rothschild (1950) point out, it is possible that the oedema of the nerve roots prevents the passage of the larger protein molecules, but allows selective absorption of the fluid, and this leads to the high protein level that Guillain regards as the *sine qua non* of the diagnosis of the Landry-Guillain-Barré syndrome.

It appears probable that oedema and nerve-root compression may give rise to the clinical features of the syndrome by an immediate loss of function of the nerve, which may be temporary and quickly reversible if the oedema subsides rapidly. If, however, pressure from the oedema persists or is unduly severe, permanent damage is produced with demyelination, recovery from which can take place only by regrowth of axons down the nerve. This view is in agreement with Seddon's (1948) concept of peripheral nerve injury.

Recovery from the Landry-Guillain-Barré syndrome therefore might be expected to take place in two stages: first, an immediate recovery resulting from the regression of the oedema, and, secondly, a more gradual recovery of some months' duration, while the axons are growing down the nerve. This "two-stage" recovery is precisely what appears to happen during treatment with corticotrophin or cortisone; the degree of recovery may be rapid and complete if the lesion is due to oedema only (this corresponds to type 1 cases noted in our analysis of the literature), or a partial recovery may be followed by a longer period of disability during regeneration of the demyelinated axon (type 2).

This perhaps rather speculative interpretation of the histological changes observed in the disease provides at any rate a plausible explanation for the two main types of response to cortisone which we have noted above.

Stanton *et al.* (1953) have pointed out that Landry-Guillain-Barré syndrome can be related closely to other acute "inflammatory" diseases of the C.S.N., and possibly to allergy, and since all these syndromes, whether mixed or pure, arise on a similarly non-specific aetiological basis it seems possible that to regard them as varying manifestations of an "allergic neuraxitis" may be something more than merely a facile oversimplification.

In this context a case seen by one of us (H.M.) is of interest:

A physician aged 49 was given 1,500 units of antitetanic serum into the left upper arm, and six days later developed signs and symptoms of serum sickness, with joint pains, high fever, and sweating. On the second day he developed a headache with neck stiffness and photophobia, and became mentally confused. Within six hours of the onset of the headache he was given cortisone and salicylates, a therapeutic response occurring within six hours. Next morning he was so much better that the cortisone was stopped after 50 mg. had been given. The same evening he developed severe pains and paraesthesiae in all limbs, and 48 hours later marked weakness of the right arm, loss of both ankle-jerks and of the left knee-jerk, and impaired vibration sense in the toes. A diagnosis of polyradiculitis complicating serum sickness was made but no lumbar puncture was done. He was given cortisone again as he appeared to be deteriorating, and again dramatic clinical improvement occurred within 12 hours, power recovering and paraesthesiae and pain completely disappearing. Within three days the deep reflexes had also recovered completely.

The Landry-Guillain-Barré syndrome appears, then, to belong to a spectrum of diseases of the nervous system which are secondary to a wide variety of aetiological agents but which have in common a probable basis of allergy. The effect of cortisone is unpredictable, inconstant, and difficult to analyse statistically, but, as in other allergic disorders, its use is justified on theoretical grounds as well as in practice.

Summary

Five cases are described of the Landry-Guillain-Barré syndrome treated with cortisone or corticotrophin.

The literature recording similar cases is reviewed.

The response to the drugs is unpredictable and inconstant, and the material available is not suitable for statistical analysis. However, in 21 out of 68 recorded cases complete recovery occurred within a month. This is unusual in untreated cases. Twenty-three other patients showed a rapid initial response followed by slower subsequent recovery. Arrest of deterioration is usual, and the mortality in this admittedly heterogeneous collection of treated cases was much lower than in previously recorded series.

The aetiology and pathology of the disease are discussed. It is considered that the clinical features, pathology, and response to treatment are compatible with an allergic pathogenesis.

We thank our medical colleagues in the Royal Victoria Infirmary and in the No. 1 Area, especially Dr. H. A. Dewar, Dr. J. B. Heycock, and Professor G. A. Smart, for kindly referring their cases.

PULMONARY FUNCTION BEFORE AND AFTER SEGMENTAL RESECTION AND AFTER "IDEAL" PNEUMOTHORAX TREATMENT*

BY

H. A. FLEMING, M.D., M.R.C.P.

Senior Registrar in Thoracic Medicine, Sully Hospital, Glamorgan

Before the advent of antituberculous drug therapy, pulmonary tuberculosis remained a serious disease and the available methods of treatment were limited. In that era the success of treatment was justifiably chiefly assessed by such simple criteria as survival of the patient over a number of years (Foster-Carter, Myers, Goddard, Young, and Benjamin, 1952). With modern advances, which so greatly increase the effectiveness and types of treatment, the patient almost invariably survives and the merits of the various forms of treatment must be assessed on more exacting grounds. These will include freedom from relapse, persistently negative sputum, and return to full activity without any symptoms. In fulfilling this last criterion the pulmonary function of the patient is very important, and as the years of survival approach the normal span this importance will increase. Defects of function that cause little trouble in early life may well produce symptoms in later years, when irreversible changes have continued over a long period and been added to the normal degenerative effects. It is thus now desirable that in the assessment of any form of treatment for tuberculosis it should be considered not only from the point of view of its success against the disease process but also the success with which it preserves, or at least does not further interfere with, normal lung function.

Pneumothorax played a most important part in the preservation of life and health in the days before antituberculous drug therapy and resectional surgery. Recent studies (Scadding, Nicholson, and Hoyle, 1951; Foster-Carter *et al.*, 1952) leave no doubt about this aspect of the matter. However, the complication rate has been high, and, as Savage and Fleming (1955) have mentioned, complications may have ruined the health of the patient and caused marked loss of pulmonary function and chest-wall deformity. The use of antituberculous drug therapy in conjunction with pneumothorax (Birath, 1953; Scadding, 1955) will undoubtedly reduce the number of these tragedies, but the functional results of no such series have yet been reported, and with the loss of popularity of pneumothorax as a form of treatment it will be some time before enough cases can be collected.

Fleming and West (1954) have confirmed Pinner, Leiner, and Zavod's (1942) observation that even trouble-free pneumothoraces may cause gross reduction in function which can only certainly be known by measuring the differential lung function. Functional loss is apt to be much greater where there has been an effusion, even though it has appeared to clear very satisfactorily. Any such loss of function is an unfortunate accompaniment of successful treatment of the disease process, particularly if the original lesion might have been adequately treated by other methods.

*The substance of this paper was communicated to the meeting of the Thoracic Society of Great Britain in London in February, 1956.

Resection has been increasingly used in the treatment of pulmonary tuberculosis, and in recent years has been extended particularly into the field of localized lesions which can be removed by resection of the one or two segments in which they lie. Many series reported (including Overholt, Woods, and Wilson, 1953; Thompson, Savage, and Rosser, 1954; Eerland and Seghers, 1955; Douglass, Bosworth, Judd, and Chang, 1955) demonstrate that in good hands the mortality and the morbidity rates are very low.

In the present study pulmonary function has been assessed before and after thoracotomy for segmental resection, and the results are compared with those obtained in cases of uncomplicated pneumothorax treatment. Few of the pneumothorax cases had the benefit of effective modern antibacterial treatment.

Pneumothorax

At Sully Hospital routine pneumothorax maintenance treatment is not carried out and cases available for study were therefore patients in whom the pneumothorax had either failed to control the disease satisfactorily or who had developed contralateral activation and had then been admitted for further treatment. A total of 62 cases of old pneumothorax have been studied from the point of view of pulmonary function, and from these were chosen all those which had had unilateral collapse for localized disease and which at no time in the course of treatment had developed any detectable fluid or other complication. It is thought that these ideal cases should closely resemble cases of pneumothorax which have the added benefit of anti-tuberculous drug therapy.

Sixteen such cases (about 25% of the total) fulfilled these criteria. In 10 of these (62%) there was localized contralateral disease, the presence of which would tend, because of the method of expressing differential lung function results by the percentage of total function, to minimize the apparent functional loss on the pneumothorax side.

In these 16 cases the extent of the parenchymal disease under the pneumothorax was of the same order as that in the segmental resection series, and the losses of function due to the disease process would be similar.

Segmental Resection

Cases were chosen in which, after full assessment, it was decided that segmental resection was indicated and that the removal of one or two segments or less would be sufficient. In most cases this procedure would remove all known disease. The 27 cases formed a consecutive series, and all cases had had prolonged antituberculous drug therapy and showed cavity closure and radiological stability, and were sputum-negative repeatedly. These patients had the purpose of the study explained to them. It was made clear that their co-operation would be entirely voluntary and that the investigations would be of no particular value to their individual case. It was also explained that the necessary information would be obtained only on repetition of the tests after operation. Following on previous studies (Fleming and West, 1954) showing that there were no adverse effects and that the investigation was no great ordeal to the patient, it was thought justifiable to use these methods for purely research purposes. The series of cases studied by bronchospirrometry with the Carlen's catheter at this hospital now stands at over 400, and the complete absence of complications reported in the first 125 of this series is fully substantiated.

Methods

The chest was examined with particular attention to movements and breath sounds, and diaphragmatic movement was studied fluoroscopically. Investigation of the maximum breathing capacity and differential function was carried out by previously described methods (Fleming and West, 1954).

Segmental resection was in all cases performed at Sully Hospital in the latter part of 1954 and early 1955, using the methods described by Thompson *et al.* (1954). The investigations were repeated as late as possible after operation. This was often little more than six weeks, as at that stage most of the patients were transferred to widely scattered institutions for graded convalescence. The average time after operation was 8.7 weeks (range 6 to 20 weeks) and the grade of activity of the patients was much the same as before operation.

The number of segments removed in each case averaged 1.3, with a range of 0.5 to 3 (only one case had an upper lobectomy, because of a caseous node adherent to the upper lobe bronchus). The segments were all in the upper lobe or the apex of the lower lobe, with one exception when a lateral basal segment was removed.

Results in "Ideal" Pneumothorax Cases

The group consisted of 16 patients (5 women, 11 men) with an average age of 30 years and a range of 21 to 49 years. The average value of the maximum breathing capacity was 106.6 litres a minute (range 55 to 150).

The average duration of the pneumothorax was 3.09 years (range 1 to 4.5 years) and the average time that had elapsed since the lung expanded was 3.2 years (range, 2 months to 13 years). Five pneumothoraces were on the right side and 11 on the left.

From bronchspirometric studies the departure of the function on the pneumothorax side from the average normal values (right side = 55%; left side = 45%) (Baldwin, Courmand, and Richards, 1948) was as shown in Table I.

TABLE I.—Departure of Function on Pneumothorax Side From Average Normal Value. Standard Deviations are Given in Parentheses

Oxygen uptake	..	-10.86% (6.2); range -20 to -1
Minute-ventilation	..	-7.46% (5.9); .. -23 .. +5
Vital capacity	..	-8.3% (5.45); .. -16 .. -4

It should be remembered that over 60% of these cases had contralateral disease, which would cause a small loss of function in the "more normal" lung and tend to diminish the apparent loss on the pneumothorax side when the results are expressed in this way.

Results in Segmental Cases

The average age of the 27 patients in this group was 27 years (range, 15 to 54 years), and there were 9 women and 18 men. The age and sex distributions are thus very similar to those in the pneumothorax group. In 17 the disease was on the right side and in 10 on the left.

Bronchspirometric studies before operation showed the functional loss as compared with the normal (R.L. = 55%; L.L. = 45%) as shown in Table II. This loss is entirely due to the disease process. The average number of segments found to be diseased at operation was 1.3 (range 0.5 to 3). From a consideration of the detailed operation reports and the pathological findings on the resected material Table III is composed. In 26 cases (96%) caseous material

TABLE II.—Departure of Function on Side With Segmental Disease from Average Normal Value. Standard Deviations are Given in Parentheses

Oxygen uptake	..	-4.98% (4.9); range -16 to +5
Minute-ventilation	..	-3.42% (5.7); .. -13 .. +6
Vital capacity	..	-2.8% (4.73); .. -10 .. +5

TABLE III.—State of Expansion of Diseased Segments

Predominantly well aerated	..	17 (63%)
" collapsed and fibrosed	..	10 (37%)

was found in the resected segment, but it is evident that in most cases this segment was by no means entirely destroyed and functionless. This is fully confirmed by the bronchographic appearances, which in the 17 cases with an aerated segment showed either no abnormality or minor changes in the subsegmental bronchi, while in the 10 cases of collapsed segment there was invariably bronchiectasis of the segmental bronchus. There was a close relationship

between the appearances in the bronchogram and the state of aeration of the segment.

In these cases, taken as a group, there is thus only a small amount of destruction of lung tissue, and in only 37% of them was the involved segment largely destroyed.

Other changes that might adversely affect function were also looked for, but none were found. Localized adhesions over the lesion, present in 48%, had no apparent effect on function.

Findings After Segmental Resection

Chest movement and breath sounds were in all cases normal before operation. After operation, at the time of the repeated function studies, the findings were normal in 89%. In all cases with less than normal chest movement (11%) there was considerable improvement in the ensuing months.

Diaphragmatic Movement.—Before operation this was normal in all except two cases in which the phrenic nerve had been crushed two years previously. The early results after operation are shown in Table IV. In the following

TABLE IV.—Diaphragmatic Movement in Early Post-operative Period

Normal full range	..	11 (41%)
50-80% of normal	..	10 (37%)
25% of normal	..	3 (11%)
Fixed but no paradox (2 previous phrenic crushes)	..	3 (11%)

months all cases with 50% or more of normal function improved until the diaphragm movement appeared entirely normal, though in a few cases this took nearly a year to be achieved. In the cases with less than 50% of normal movement the range of excursion increased steadily, usually to the region of 60%, though the cases with previous phrenic interruption showed no such change. There was no obvious relationship between this impairment of diaphragmatic function and the immediate post-operative course or the functional results, though under conditions of stress it is likely that there must have been considerable effect on function.

Maximum breathing capacity had fallen by an average of 4.8% (S.D. = 11.4; range -47 to +24) of the pre-operative value. This is surprisingly good considering that the patients had not only lost some functioning lung tissue but were only two months removed from a thoracotomy and still on a very modest grade of activity. The average maximum breathing capacity was 120 litres a minute in 27 cases. This is somewhat higher than in the pneumothorax group.

Bronchspirometric Studies

In 27 cases the loss from the normal value (R.L. = 55%; L.L. = 45%) on the affected side is as shown in Table V, which does not take into account the change from the actually observed pre-operative figure which is discussed below. The losses presented here arise from the disease plus the operation. Table VI shows the loss of function

TABLE V.—Average Departure of Function on the Operated Side from the Normal Figure in 27 Cases. Average Number of Segments Removed = 1.3 Per Case. Standard Deviations are Given in Parentheses

Oxygen uptake	..	-8.1% (4.7); range -18 to +5
Minute-ventilation	..	-5.6% (5.75); .. -20 .. +5
Vital capacity	..	-8.75% (5.5); .. -19 .. +7

TABLE VI.—Reduction of Function of Operated Lung Following Resection. Standard Deviations are Given in Parentheses

Oxygen uptake	..	-3.2% (3.66); range -9 to +3
Minute-ventilation	..	-2.2% (6.4); .. -11 .. +6
Vital capacity	..	-5.2% (4.7); .. -12 .. +5

on the operated side following resection. The figure is obtained by working out the percentage of the total function contributed by that lung in each case and subtracting the post-operative from the pre-operative result. These losses represent those due to the operation alone.

Loss of Function

The methods already used in presenting the results in this paper are those usually employed in the expression of

results and changes of function measured by bronchspirometry. However, such methods refer only to the fraction of the total function being performed by the lung under consideration and give no accurate picture of the amount of function lost by that individual lung due to any procedure to which it has been subjected. In the present study the figures already recorded are a useful index for comparison with the pneumothorax series and with other series in the literature where other methods of treatment have been used. We are now chiefly interested in the actual loss of function in the operated lung due to the segmental resection and compared with the measured pre-operative function.

In working out the percentage function of, for instance, the left lung in the ordinary way, the following simple fraction is used:

$$\% \text{ function contributed by the left lung} = \frac{L}{L+R} \times 100,$$

where L is the function of the left lung in absolute values and R is the function of the right lung in absolute values.

On repeating such function studies the state of the patient is rarely the same as in the first examination, and even in the normal and unchanging lung the recorded absolute measurements of function have changed. It is for this very reason that the results of such tests are usually expressed as a percentage of the total function.

In the cases in this series post-operative control was good, and there was no reason to suspect that any change in the function of the healthy lung had occurred between the pre-operative and the post-operative studies. Presuming this to be so, it is possible by simple proportion to obtain a "corrected" value for the absolute figure of the function recorded on the operated side. This is then directly comparable with the absolute figure obtained before operation, as they are both with reference to the same figure—that is, the initial absolute figure for the unoperated side.

In the case of the left lung

$$\text{"Corrected" } L_2 = \frac{L_2}{R_2} \times R_1,$$

where R₁ is the pre-operative absolute value for the right lung, R₂ is the post-operative absolute value for the right lung, and L₂ is the post-operative absolute value for the left lung.

This calculation is carried out separately for the oxygen uptake, the minute-ventilation, and the vital capacity.

The percentage loss of function of the left lung is then

$$\frac{L_1 - \text{"Corrected" } L_2}{L_1} \times 100,$$

the result giving an easily recognizable estimate of the amount of function that the individual lung has lost from the procedure.

I am not aware of results being previously reported in this way, but it has obvious advantages, and, further, allows the loss per segment removed to be calculated.

Table VII shows the loss of function per segment removed. This is expressed as a percentage of the pre-operative function of the operated lung (100%). For the compilation of Table VII the total percentage loss of function in the lung is divided by the number of segments removed. For these purposes anything less than a segment was counted as 0.5, the apical lower as 1.5, and the left apico-posterior as one segment. In the intact lung this gives 10.5 segments on the right and 9.5 on the left, so that each segment is contributing

approximately 10% of the function of one lung. The results given in Table VII are thus very satisfactory, as the loss of oxygen uptake is much less than that figure and the ventilation only slightly more. The loss of vital capacity is somewhat greater, but this may be largely accounted for by the early stage in the post-operative period at which the tests were done, and the already-mentioned improvement in diaphragmatic movement in many cases in the ensuing months would suggest that the vital capacity would improve with time.

TABLE VII.—Percentage Loss of Lung Function Per Segment Removed. Standard Deviations are Given in Parentheses

Oxygen uptake	..	-7.13% (17.3); range -26 to +14
Minute-ventilation	..	-10.8% (27.2); .. -40 .. +10
Vital capacity	..	-17.5% (20.0); .. -35 .. +22

It should be remembered that the actual disease in the segment had caused a small loss of function from the average normal figure, and this would tend to reduce the loss demonstrated after removal of that portion of the lung.

The higher standard deviations in Table VII are largely due to the fact that the length of the scale in use has been doubled as compared with previous tables (previous tables 0-50%, this table 0-100%).

This method of presenting the results throws markedly into prominence losses that are not at all conspicuous in the standard method of presentation.

An average good result is illustrated by the following case.

A woman aged 26 had cavitated disease in the apical segment of the right lower lobe. Bronchography showed bronchiectasis of the segmental bronchus, and at thoracotomy the segment was found to be collapsed and fibrosed, with a caseous lesion. Fig. 1 shows the traces taken at bronchspirometry and the results obtained.

These figures show a moderate pre-operative decrease in function (6-9%) due to the destruction of the segment. This is followed by an increase in the maximum breathing capacity and a very small further loss of function (1-2%) when expressed in the usual way. For this single and functionless segment (counting as 1.5) the percentages of loss of the functions of the right lung were 4.3, 4.0, and 2.7 respectively.

FIG. 1.—Example of average good functional result after segmental resection. Bronchspirometry traces and results before and after segmental resection.

Discussion

The pneumothorax cases are not the most satisfactory series as a basis for comparison, but this is a difficulty commonly met with. As Gaensler, Watson, and Patton (1953) point out, the really successful cases of re-expanded pneumothorax are not hospitalized and are unlikely to be accessible for study, while most of the cases still connected with hospitals are in some way complicated. It should be clearly realized that the cases in this group are ideal pneumothoraces and by no means represent the average result in the past. They are intended to give only an indication of the loss of function that may be expected from a pneumothorax induced at the present time with the advantages of antituberculous drug therapy, and they do not give any indication of the state of affairs to date. Gaensler *et al.* (1953) found that in 62 patients who had at one time had a therapeutic pneumothorax the re-expanded lung contributed on the average only 30% of the total oxygen uptake. They also found, as encountered in the 62 cases in this study, that many of these cases were complicated in various ways and the average was produced from a great variety of results. The 16 cases were selected to avoid this difficulty as much as possible. The comparison of them with the resection cases is admittedly open to criticism, but it is suggested they do provide some yardstick on which to judge the functional results following surgery.

TABLE VIII.—Percentage Loss of Function Below Normal Values. Mean Values. Standard Deviations are Given in Parentheses

	M.B.C. (l./min.)	Oxygen Uptake	Ventilation	Vital Capacity
Ideal pneumothorax (16 cases)	106.6	-10.86 (6.2)	-7.46 (5.9)	-8.3 (5.45)
Segmental lesion (27 cases)	—	-4.98 (4.9)	-3.42 (5.7)	-2.8 (4.73)
Segmental resection (27 cases)	120	-8.1 (4.7)	-5.6 (5.75)	-8.75 (5.5)

Table VIII gathers together the results shown in Tables I, II, and V for ease of comparison. These results are diagrammatically presented in Fig. 2, where the average normal value is taken as 50%. The numbers on top of the columns state the loss from this value.

The maximum breathing capacity is somewhat lower in the pneumothorax group than in the segmental resection group, though these groups are well matched with respect

FIG. 2.—Percentage of total function compared with average normal figures. The second and third blocks refer to the segmental series. The distance separating the tops of the columns from the average normal line represents the reduction in function. The loss following operation is very small.

to age and sex. In the pneumothorax group the slightly greater loss of oxygen uptake than ventilation and vital capacity suggests that pleural factors are of importance even in this group without definite pleural complications. It can be seen that the deviation of the function from the average normal value is slightly less in the cases subjected to segmental resection than in the pneumothorax cases. Thus, from the point of view of function segmental resection is rather preferable to the best that has been offered with pneumothorax treatment. This is emphasized when it is remembered that the loss of function due to contralateral disease is concealing some of the loss due to the pneumothorax. It is not intended to discuss at any length the more general aspects of the merits of these treatments, but it is relevant to mention that in 96% of the cases in this series of resections actual caseous disease was still present after many months of antituberculous drug therapy. Such caseation must remain a constant menace to the health of the patient and is surely better removed if this can be done with safety.

Really prolonged drug treatment appears to reduce the number of such cases in which tubercle bacilli can be cultured from the residual caseous lesions, and if these findings are further substantiated the attitude to resection will obviously need modification.

In assessing cases before surgery, when radiological stability has been achieved after some months of antituberculous drug therapy, it has been possible, using all previous radiographs, two-plane tomography, and bronchography, to come to an accurate estimate of the extent of the disease. In the present cases the assessment made at thoracotomy was identical with that made before operation. This experience is, with very few exceptions, borne out by large numbers of patients at Sully Hospital and is contrary to the findings of Logan (1955), who reported that the correlation was good in only slightly more than 50% and fair or poor in the rest. In our cases bronchography procedure, and in many hundreds of cases there have been none of the unfortunate experiences of the type recorded by Perry (1955) with oily media. In this series the cases present have invariably had a contracted and fibrosed segment with little or no function. In those cases where the bronchi were either normal or the changes were limited to the subsegmental level, the segment was predominantly well aerated, of approximately normal volume, and there was little loss of function. Our experience is thus, in general, in agreement with that of Shaw, Collins, and MacNamara (1954) on the value of bronchography in the segmental localization of tuberculous disease.

In the series as a whole, before operation (Table II and Fig. 2) there were small losses of function due to the disease. In these the oxygen uptake was slightly more affected than the ventilation and vital capacity, a fact which would suggest a slight pleural factor but is more likely to be due to the small amount of bronchiectasis. This is confirmed by the observation that in the individual cases with segmental collapse there was a tendency for the oxygen uptake to be more affected than usual.

The studies following segmental resection could with profit have been postponed to a later date, but for the administrative reasons mentioned this was not possible. At the stage of eight weeks after thoracotomy it is unlikely that the chest wall has returned to its maximum mobility, and the observations made on the movements of the diaphragm show that at this stage it is impaired to some degree in nearly 60% of cases, but that in all it improves over a period of months and in 78% it returns to the normal excursion. This impairment of function probably accounts for the small drop (-4.8%) in the maximum breathing capacity and for much of the loss of vital capacity on the operated side.

The results of the differential function studies following resection recorded in Tables V and VI and Fig. 2 show a small loss of function which is similar to that recorded for

small numbers of segments by Taylor, Petter, and Whittenberger (1955), using the same methods of presentation.

These losses are somewhat less than those described by Gaensler *et al.* (1953) after resection of one or two segments. They also fail to show any striking excess of loss of oxygen uptake over ventilation, a finding which the work of Gaensler *et al.* (1953) prompted them to suggest that much of the loss of function following segmental resection was due not so much to decrease of functioning lung tissue as to post-operative haemothorax, parietal pleural fixation, and eventual fibrothorax. The figures presented here do not support this contention, and suggest that the great part of the loss of function is due to removal of lung tissue. It is felt that the careful technique (Thompson *et al.*, 1954) aimed at the early and complete re-expansion of the lung and the avoidance of the accumulation of any fluid in the chest is of the greatest importance in achieving this result.

It is apparent that the usual method of presenting the function of one lung as a percentage of the total function, while being useful in isolated studies, has in follow-up studies the disadvantage of obscuring changes that have taken place in the only lung which has been subjected to procedures likely to change the function. It is surprising that the method described here has not been used in previous reports on function following surgery. While the mathematics involved in bronchspirometry results are of the simplest, they are not always so regarded by those not familiar with them, and one is therefore reluctant to introduce a different method of presentation. However, the calculation of the change in function of the actual lung under consideration is not only a more useful but also a simpler and more easily understood concept. This enables (Table VII) the actual percentage loss of the lung per segment removed to be calculated. The results so obtained have been shown to be of a very reasonable order, particularly as in 63% of the cases the lung tissue was predominantly aerated and functioning.

The losses from segmental resection are similar to those reported for extrapleural pneumothorax (Gaensler and Strieder, 1950) and for five-rib thoracoplasty (Lindahl, 1954).

In this study the rather wide scatter of the results as indicated by the high standard deviation and range is a matter of some concern. Other reports do not include estimations of the standard deviation, but Taylor *et al.* (1955) give their range of values, and these appear to be much the same as those observed in the present study. Such scatter would appear to be inevitable in this type of biometric work.

Summary

From 62 cases of old pneumothorax studied, 16 (about 25%) were chosen as being "ideal" and the functional results analysed; 10 of these also had contralateral disease.

Twenty-seven cases with localized tuberculosis were studied before and after segmental resection. Physical signs, fluoroscopy, maximum breathing capacity, and differential lung function were investigated in the early post-operative period (8.7 weeks average).

In the "ideal" pneumothorax series the average loss of function was a little greater than that due to segmental resection.

In the segmental series the loss of function due to the disease was small, and in 63% of cases the segment was predominantly well aerated. The bronchographic appearances were closely related to these findings.

After operation there was often limitation of the movement of the diaphragm, but this almost invariably improved in later months.

The loss of function after resection was small. A method of expressing this as a percentage of the initial function of the operated lung is described and the per-

centage loss per segment is calculated. This demonstrates that the loss is of the order to be expected from the removal of the lung tissue alone.

The extent of the disease can almost invariably be accurately assessed by study of all previous radiographs, two-plane tomography, and bronchography.

Thanks are due to the patients whose willing co-operation has made this study possible and to the consultant staff of Sully Hospital for permission to investigate patients under their care. I thank Dr. L. R. West, who constructed the excellent equipment used and whose practical assistance has been invaluable.

TOTAL COLECTOMY AND ILEO-RECTAL ANASTOMOSIS IN DIFFUSE ULCERATIVE COLITIS

BY

STANLEY AYLETT, M.B., B.Sc., F.R.C.S.

Surgeon to the Westminster Hospital Teaching Group (Gordon Hospital) and the Metropolitan Hospital

In view of the increasing incidence of surgery in the treatment of ulcerative colitis it seems an appropriate time to record the results achieved by total excision of the colon and restoration of continuity by ileo-rectal anastomosis. The results reported in this paper are those of a consecutive series of 47 cases of the diffuse disease involving the colon and the rectum treated by this method since 1951. Before operation every patient had been under experienced medical treatment, and surgery was undertaken only because this had failed to arrest the progress of the disease. On some desperately ill patients operation was performed as an emergency life-saving measure.

The concept of the preservation of the rectum in all except the very rare case, so that a normal route of evacuation may be established, has been referred to previously (Aylett, 1954, 1955). It can only be justified if it can be shown that: (a) the procedure can be carried out with low mortality and low post-operative morbidity; (b) the large majority of the patients return to full health and full economic ability and that the number of bowel actions, increased as a result of the excision of the colon, interferes little if at all with their lives; (c) the inflammatory changes in the rectum resolve in most cases; and (d) should the disease persist or recur in the remaining rectum to an extent sufficient to endanger health an ileostomy can be established and the rectum removed without risk.

It is proposed that each of these questions shall be answered by reference to the series under review, because if they can be replied to satisfactorily the suggested method of treatment must surely be regarded as preferable to the routine total ablation of the whole of the large intestine and the formation of a permanent ileostomy without any attempt to restore the continuity of the intestinal tract. However great the improvement in modern ileostomy-bag design, such a stoma is a very real handicap to inflict upon a patient often entering the threshold of his or her full adult life, and, moreover, it is one that is not infrequently the source of both major and minor surgical complications.

Can Total Colectomy and Ileo-rectal Anastomosis be Carried Out with Low Mortality and Morbidity?

On setting out upon this procedure it seemed that a direct anastomosis of ileum to rectum after removal of the colon would be fraught with the danger of failure of union

FIG. 1.—Line drawing showing the "safety-valve" temporary ileostomy made in continuity a few inches from the end-to-end anastomosis of ileum and rectum.

or at least of leakage, with consequent pelvic cellulitis and fistula formation. The end of the rectum is friable, inflamed, and oedematous, so that if the anastomosis was to be subjected to any increased intraluminal pressure, such as might readily occur in the immediate post-operative period as a result of the development of a minor degree of ileus, the possibility of disruption of an uncertain suture line appeared to constitute a very real risk.

FIG. 2.—Photograph showing the position of the temporary ileostomy with a disposable ileostomy bag in position.

It was thought that this risk would be eliminated if a side-to-side anastomosis of ileum to rectum was carried out and if, after mobilization of the rectum by division of the upper thirds of its lateral ligaments and of its posterior attachments, its upper end was to be exteriorized on the anterior abdominal wall, preferably through the lower-most part of the

paramedian incision. A "safety-valve" would thus be formed through which gaseous and intestinal content would discharge if the intraluminal pressure became raised. Thereby the anastomotic line would be protected from the effects of any distension.

This method was therefore adopted, and in no case in which it was employed did any leakage occur from the line of anastomosis. The only case of leakage in the series was in a patient with lesser inflammatory changes in the rectum in whom, misguidedly, anastomosis without this safety-valve was considered safe. In spite of drainage down to the anastomotic site the patient developed a pelvic abscess and a faecal fistula. Although final recovery resulted, the fistula required full exploration and weeks of drainage to effect its ultimate closure.

More recently we have carried out an end-to-end anastomosis of the ileum to the rectum decompressing the line of suture by means of a temporary ileostomy made in continuity and established through a separate stab incision in the left iliac fossa (Figs. 1 and 2). It is, of course, essential in such cases to obliterate the gap existing between the ileostomy and the lateral abdominal wall to prevent the possibility of post-operative obstruction resulting from the insinuation of coils of small intestine into this hiatus. This method was adopted because the closure of the proctostomy had at times proved difficult, and in some cases several operations were required to effect a final closure. The temporary ileostomy, sited as it is some distance away from the anastomosis, is readily closed, and it seems that as this method protects the anastomotic line equally well it will be the operation of choice.

The second way of achieving operative safety is, in the severely or desperately ill case, to carry out the procedure in two stages. We believe that in such cases the essential requirement is the excision of the colon, and we consider that the formation of an ileostomy alone has no place in the emergency surgery of ulcerative colitis. Haemorrhage and grave toxæmia can continue, and disruption of the

colon proceed, in spite of the presence of a defunctioning ileostomy. The excision of the colon, therefore, must be undertaken, but owing to the grave condition of these patients further operative time must not be expended in attempting an immediate restoration of continuity. Thus, as a routine in these cases, following the colectomy, the upper end of the rectum is exteriorized through the lower end of the paramedian incision and the terminal ileum through the same wound at a slightly higher level (Fig. 3). The union of the two exteriorized ends, which does not involve the opening of the general peritoneal cavity, is undertaken when the patient has recovered from the effects of his or her colitis.

With these techniques and with the closest attention to post-operative care the mortality has been well under 5%. 2 of the 47 patients having died. In one the cause of death was obstruction following secondary suture of a burst abdomen. The second patient died from anuria. He was admitted with acute ulcerative colitis and an associated complete prostatic obstruction and uræmia. Whilst the bladder was being decompressed and the colitis treated with

FIG. 3.—Photograph showing completion of first stage of two-stage procedure. Ileum and upper end of rectum have been exteriorized through lower end of paramedian incision.

cortisone perforation occurred. Emergency colectomy was undertaken, but anuria subsequently developed.

Post-operative morbidity has not been excessive. One patient had three episodes of obstruction—two due to adhesions and one to the volvulus of the small intestine—in the first post-operative month. Two patients developed intestinal obstruction two years after their operation, the result of band formation. Five operations were therefore undertaken for obstruction and all three patients recovered. In another patient secondary haemorrhage into the pelvis 10 days after operation necessitated reopening the abdomen for its control.

One patient who had had a side-to-side anastomosis of ileum and rectum, with the formation of a safety-valve proctostomy, developed a fulminating staphylococcal enteritis with associated heavy infection and disruption of the abdominal wall. As it seemed likely that the anastomosis might break down it was undone and the end of the ileum brought out through a separate incision in the left iliac fossa. The patient recovered with antibiotic therapy, and restoration of continuity will be undertaken subsequently.

In seven patients closure of the safety-valve proctostomy was not effected at the first attempt, and in one patient five operations were required for its final closure. The method of eliminating this difficulty has been referred to. A further patient referred to above, in whom a safety-valve was not included in the operation, developed a faecal fistula.

Mild perianal excoriation has been present in four cases, one of which was complicated by a minor fistula-in-ano, which after operation healed completely. All these cases have responded to local applications of ointment.

With the exception of one case in which a transient arthritis of the knee-joint occurred six months after operation and which could have been attributable to other causes apart from the colitis, no systemic complications have resulted.

Do the Majority of Patients Return to Good Health Without an Excessive Number of Bowel Actions?

In the assessment of this question in respect of the 45 live patients in this series, five have been excluded, as the final stages of their treatment have not yet been completed. Forty patients therefore remain for consideration. These have been divided into four categories as follows:

1. Those whose health has returned completely, who have regained or in some cases exceeded their normal weight, who are engaged fully in their former occupations, who enjoy a normal social life, and whose number of bowel actions do not exceed six in 24 hours. Many, as will be seen from the table, have a smaller number of evacuations.

Number of Bowel Actions Experienced by Patients in Category 1

No. of bowel actions in 24 hours	1	2	3	4	5	6
No. of patients	1	1	2	7	10	8

IsoGel, and in some cases the occasional codeine tablet, is all that is required to control their bowels. Twenty-nine, or approximately 70%, of the cases in this series fall into this category (Fig. 4).

2. Those who are in good health, who have gained weight, who are back to work, but whose number of bowel actions, varying between 7 and 10 in 24 hours, limits slightly their full return to a normal life. Nevertheless in this category is included an engine-driver, a long-distance lorry-driver, and a foreman builder. Our experience has been that after about 12 months some in this category join those in category 1. At present there are six patients in this group, or 15% of the total.

3. Those who have returned to good general health but whose number of bowel actions is over 10. There are two female patients in this group, and both have weak sphincters. Each is 67 years of age. One suffered from complete prolapse of the rectum in addition to her colitis and prior to operation had not been outside her house for two years. The excessive number of bowel actions in this small group would undoubtedly seem to be associated with laxity of the sphincters, and the urgency with which the frequency is associated also suggests this. In the older female patient with patulous sphincters a permanent ileostomy may be preferable, but neither of the patients in this group would consider this step, as in spite of their disability they appear to manage reasonably well.

4. Those who at present have a residual proctitis producing symptoms. In this category are three patients, or approximately 8% of the series. Although two of these patients have been back to full work and the third, a girl, has been attending school with few absences, periodic anaemia has had to be treated. The two adult patients are now under treatment with intrarectal ultra-violet light, and the degree of subsidence of the inflammation in the rectal mucosa has so far been most pronounced.

Do the Inflammatory Changes in the Remaining Rectum Resolve in Most Cases?

We had noted, before undertaking ileo-rectal anastomosis, that in certain cases treated successfully by a medical regime the gross ulcerative changes visible on sigmoidoscopy subsided with apparent re-epithelization of the ulcerated areas. In such cases the resolution appeared to follow the control of the toxæmia associated with the disease and the return of the patient to normal health.

Biopsies from the rectum taken before and after a successful end to medical treatment confirmed our visual impression that the wall of the bowel had in fact become re-covered with epithelium. It was indeed true that the normal regimented pattern of mucosal glandular structure was not re-formed, but nevertheless the underlying partially fibrosed rectal wall did become covered with epithelium.

As a result of this observation it seemed reasonable to suppose that if in those cases

FIG. 4.—Pre- and post-operative photographs of a patient treated by the method described. Her bowel is opened once in each 24 hours. Pre-operative weight 5 st. 11 lb. (36.7 kg.), post-operative weight six months later 8 st. 9 lb. (54.9 kg.).

FIG. 5.—Pre-operative (a) and post-operative (b) rectal biopsies.

which were not responding to medical treatment the colon containing the vast bulk of the disease was to be excised, then the cause of the gross toxæmia would be removed and with the consequent return of the patient to good health the inflammatory changes in the residual rectum might well resolve.

If the toxæmia was to be overcome it seemed essential that the whole of the colon, including the pelvic colon, should be excised, as clinical and pathological examination of many specimens of the disease had shown that the distal regions were often the most heavily affected. Should a lesser excision be undertaken it appeared likely that ill-health associated with the presence of a segment of the pelvic colon might well continue in a considerable proportion of the cases, so that resolution of the inflammation would not take place. The whole of the colon was therefore excised in the cases in this series and ileo-rectal anastomosis carried out, and we believe that the resolution of the inflammation in the remaining rectum that has taken place in all but three of the patients is dependent upon this total excision.

All patients have been repeatedly examined in the follow-up department and have been examined by a narrow-bore proctoscope. The mucosa appears to have regenerated in all except the three cases referred to. As a result of fibrosis the rectum will not distend as will a normal rectum, which is the reason for the use of a proctoscope with a smaller lumen. The mucosa, too, appears fixed to the underlying structures and has not the mobility of the normal rectal lining.

To record this resolution of the inflammatory change we have in many of the cases taken a rectal biopsy before and after operation, and the healing suggested by macroscopic examination has been confirmed to have taken place by the pathological examination of these specimens (Fig. 5).

It is therefore established that, following total colectomy and ileo-rectal anastomosis, resolution of the residual inflam-

mation in the rectum can occur, but, as will be seen from the sections, the normal pattern of palisaded glandular formation is only partially regained.

Should the Disease Persist or Recur in the Remaining Rectum can the Latter be Removed and an Ileostomy Established Without Risk?

No case has been converted to a permanent ileostomy, as the indications for this have not arisen in the present series. It would seem, however, that the conversion would not present any great surgical problem.

Summary

A series of 47 cases of diffuse ulcerative colitis treated by total colectomy and ileo-rectal anastomosis is analysed.

It is concluded that the operation can be carried out with a low mortality rate and low post-operative morbidity, and that 70% of the patients return to a normal economic and social life and a further 15% have only minor limitations, the result of some frequency of bowel action.

It is suggested that the procedure described should be the primary method of choice in the surgery of diffuse ulcerative colitis.

[Since the completion of this article several months ago the residual rectal ulceration in the two cases treated by intracavitary ultra-violet light has resolved. These patients could now be included in the first category.]

SIMPLIFIED RADIOACTIVE IODINE THERAPY

BY

ALASTAIR G. MACGREGOR, M.D., M.R.C.P.
M.R.C.P.Ed.

Senior Lecturer in Therapeutics, University of Edinburgh;
Associate Physician, Royal Infirmary, Edinburgh

The treatment of thyrotoxicosis with radioactive iodine (^{131}I) is now an established procedure for the management of selected patients.

The long-term experience of one of the pioneer groups of American workers has been reported (Chapman and Maloof, 1955), and Myant (1956) has reviewed the results achieved throughout the world from 1942 to 1954. In this country the most extensive reported experience has been that of Blomfield, Jones, Macgregor, Miller, Wayne, and Weetch (1955), who reviewed results in the first 140 patients treated in Sheffield.

Varying techniques have been used to obtain consistent and satisfactory results. Some workers attempt to simulate partial thyroidectomy by achieving remission in as many patients as possible by a single treatment with the isotope (Blomfield, Jones, Macgregor, Miller, and Wayne, 1951; Freedberg, Kurland, Chamovitz, and Ureles, 1952; Fraser, Abbott, and Stewart, 1954; Chapman and Maloof, 1955). Others give small and repeated doses of the isotope, preferring to treat the patient gradually and slowly, hoping thereby to minimize the likelihood of producing myxoedema (Williams, Towery, Jaffe, Rogers, and Taggon, 1949).

Whatever technique is adopted, however, the prime consideration is that when the dose is prescribed for an individual patient the need for an early remission of symptoms is balanced against the likelihood of producing eventual myxoedema (Myant and Pochin, 1955).

Any technique which attempts to cure the patient quickly and effectively by a single treatment with ^{131}I involves the selection of a dose thought to be optimal in terms of ^{131}I concentration in the thyroid gland (Chapman and Maloof, 1955; Fraser *et al.*, 1954) or of radiation dosage in rads delivered to the thyroid (Blomfield *et al.*, 1951; Freedberg *et al.*, 1952). The calculations necessary to determine these doses are complicated (Myant and Pochin, 1955), and depend upon a number of assumptions that are not always valid.

This paper is a preliminary account of the experience of one observer who endeavoured to employ a precise and quantitative technique for a number of years (Blomfield *et al.*, 1955) and then, as a result of the experience gained, followed thereafter a different and, by previously accepted standards, completely heretical technique. The results are reported on the first 150 consecutive cases so treated after a minimum observation period of one year.

Principles Involved in Dosage Prediction

Any attempt to use a predetermined dosage of radiation in terms of rads or of ^{131}I concentration makes a number of assumptions the validity of which is doubtful.

(1) It is assumed that the dose of radiation is delivered uniformly throughout the gland. It has, however, been shown (Kelsey, Haines, and Keating, 1949) that there is an uneven distribution of ^{131}I in the thyroid gland. Oddie (1951) has moreover calculated that, even where a uniform concentration throughout the gland is assumed, there could theoretically be a hundredfold difference between the highest and lowest dosage received within any one gland. So, at best, any prediction of dose concentration is no more than an inaccurate mean value.

(2) The variable factors required to calculate the radiation dosage are the peak percentage uptake of the isotope by the gland, the effective half-life of the isotope in the gland, and the mass of the gland itself. For the calculated dosage to have any meaning these preliminary measurements must be exact, and although uptake and half-life can be defined accurately there is no sure method of assessing thyroid gland mass. Soley, Miller, and Foreman (1949) accepted that the mass, as judged by inspection and palpation, might be inaccurate by as much as 30 to 40%. Many attempts have been made to devise objective techniques, such as that of Blomfield *et al.* (1953), by which gland volume may be calculated. Measurements can be made in two planes with a collimated Geiger or scintillation counter, but even such techniques cannot be dissociated from a possible subjective bias by the observer. Kelly (1954) found that there might be very large errors inherent in similar and even more refined methods. Gland size is undoubtedly the most important factor in dose determination, and its accurate calculation is essential if doses are to be expressed either in rads or in microcuries per gramme of thyroid tissue. If a figure is applied to an estimate of gland mass it may acquire undue significance, and on subsequent review it is easy to forget the fictitious accuracy of the original estimate. The false precision of many of the calculations previously performed in relation to isotope therapy has often deluded the protagonists of such calculations that they have a value in excess of their real worth.

(3) Predetermined dosage techniques require that the metabolism of the ^{131}I be similar following both the tracer investigation and the therapeutic dose. Uptake measurements are usually in reasonable agreement, but Blomfield *et al.* (1951, 1953) and Freedberg *et al.* (1952) found

occasional alterations in effective half-life. The biological elimination of the isotope from the gland was often shorter after treatment, presumably owing to an early release of hormone as a result of radiation damage. Table I demon-

TABLE I.—Comparison of Predicted and Measured Radiation Doses (rep)

Case No.	Predicted from Tracer Measurements	Measured after Therapy
1	8,000	8,600
2	10,800	13,500
3	7,900	7,500
4	8,700	8,300
5	9,000	5,600
6	8,000	7,300
7	11,000	11,800
8	6,200	6,200
9	8,500	11,300
10	8,000	7,300

strates the sort of variation in dosage that may ensue, and the calculated radiation dose delivered is thus significantly different from that originally planned. In this series of 10 cases, originally discussed by Blomfield *et al.* (1953), the actual dose delivered in Cases 2, 5, and 9 is appreciably different from that envisaged. The same gland size was used in the estimation of both doses, and the variations in these cases were chiefly due to differing effective half-lives. Miller and Sheline (1951) also found a very wide range of values for the actual dose delivered to the patient. When they "pre-selected" a dose of 6,000 reps (roentgen-equivalent physical) the doses actually delivered varied from 2,000 to 20,000 reps.

(4) The use of a predetermined dose schedule assumes that the biological response to a given dose of radiation or concentration of ^{131}I is constant and predictable. This is certainly not the case. The radiosensitivity of different glands is a biological variable. This results in some patients

Relationship of rad dosage delivered to the thyroid gland to the clinical result, after the first treatment with radioactive iodine (from Blomfield *et al.*, 1955).

between clinical result and the actual dosage of radiation delivered was shown by Miller and Sheline (1951). Myant (1956) has fully discussed the factors which may be partly responsible for these results, but, making all possible allowances, it is apparent that such a degree of biological variability renders dose prediction impracticable.

Alternative Therapeutic Techniques

It is apparent that precise calculation of ^{131}I concentration in the gland demands an accurate knowledge of gland mass, and this is not easy to ascertain. The technique involving dosage fractionation by means of the repeated administration of small doses of ^{131}I involves numerous measurements of thyroid function. These may be of prognostic value (Myant, 1953), but the inevitable time-lag before treatment is complete makes the method unsatisfactory and inconvenient for patient and physician.

Alternatively, the disease can be treated more simply by adjusting the dose in millicuries to that most likely to effect a rapid clinical cure while avoiding as far as possible the development of myxoedema. An attempt has therefore been made to treat patients on these lines, without considering the details of uptake measurements and without attempting to assign a figure in grammes to the size of any given thyroid gland.

Method Used

Patients judged suitable for ^{131}I therapy by criteria defined previously (Blomfield *et al.*, 1955) were given a preliminary tracer dose of ^{131}I . This confirmed the diagnosis and ensured that the thyroid gland was able to absorb a high proportion of the administered dose. The criteria of toxicity were those of Goodwin, Macgregor, Miller, Wayne (1951) and Fraser, Hobson, Arnott, and Emery (1953).

Patients who lived within a reasonable distance from hospital were treated as out-patients, and comparatively few required to be admitted. ^{131}I was then given, the size of the dose being judged on the simple principle of a small dose for a patient with a small gland and a large dose for a patient with a large gland. Past experience had shown that myxoedema was seldom produced by doses as low as 5 millicuries even where gland enlargement was minimal. Chapman and Maloof (1955) have since shown that among 520 patients the smallest single dose to produce myxoedema was 6 millicuries. Our practice was to give 4 millicuries to patients in whom the thyroid was palpable, 5 or 6 millicuries for minimally enlarged glands, and increasing doses up to the highest single dose of 15 millicuries, which was given to a patient with a large nodular gland. Other factors besides that of gland mass also influenced the size of dose prescribed: for example, larger doses were given to patients with significant cardiac failure, if the gland was nodular, or if the need to obtain a rapid remission of symptoms was greater than the risk of the production of hypothyroidism.

A few of the most thyrotoxic patients received a course of carbimazole before ^{131}I , but normally no preliminary treatment of this nature was prescribed. In such cases, however, the principles governing the prescription of the dose remained unaltered, and the ^{131}I was given after the administration of the antithyroid drug had been stopped for at least four days and after the tracer-dose investigation had been completed. If it was thought advisable to diminish the patient's toxicity before the effect of the ^{131}I therapy had had time to develop, a course of potassium iodide, 60 mg. daily, was given, starting not earlier than one week after the ^{131}I had been given, and continuing for not longer than three weeks. On general principles it was felt undesirable to give antithyroid drugs after ^{131}I therapy, but this was in fact done on a few occasions as a preliminary to further isotope treatment.

Patients were normally seen six weeks after treatment, and thereafter at successively longer intervals. If, however, there was no clinical improvement after six to ten weeks, it was our custom to arrange for a further tracer-dose investigation and for the administration of additional ^{131}I . The same principles governed the size of dose prescribed. Many patients who have been inadequately treated experience appreciable shrinkage of the thyroid gland, and this may determine that a smaller dose should be used on a subsequent occasion.

Results

We are here concerned only in reporting these initial results so that this technique may be compared with the more elaborate methods previously employed. It is not intended to detail the sequence of recovery and complications which ensues after ^{131}I therapy, as this has been fully discussed elsewhere (Blomfield *et al.*, 1955; Myant, 1956).

Between January 1, 1953, and October 31, 1956, 267 patients were treated by this technique. Table II summarizes the results in the first 150 consecutive patients followed for a minimum period of one year after they were first treated.

TABLE II.—Clinical Results of Radioactive Iodine Therapy (Minimum Follow-up, One Year)

	Result of First Treatment				Clinical State after 12-46 Months	
	Patients		Dose (mc.)		Patients	
	No.	%	Mean	Range	No.	%
<i>Present Series (150 Patients)</i>						
Euthyroid	89	59	8.0	4-15	130 (3 dead)	87
Still toxic	48	32	8.4	6-12	3 (2 dead)	2
Hypothyroid	13	9	7.9	4-10	17 (1 dead)	11
<i>Blomfield <i>et al.</i> (1955) (140 Patients)</i>						
Euthyroid	—	62	9.6	2.4-22.4	—	84
Still toxic	—	27	12.2	4.0-31.6	—	4
Hypothyroid	—	11	9.2	5.2-15.9	—	12

At the time of follow up 87% of the patients had been rendered euthyroid; 11% had become hypothyroid and were receiving thyroxine maintenance treatment; and 2% (3 patients) had either died while still thyrotoxic or required further treatment. Fifty-nine per cent. of the patients were rendered euthyroid, and 9% became myxoedematous after their first dose of the isotope.

Of the 48 patients (32%) who required more than one treatment, 41 later became euthyroid; of these, 28 required two, 11 required three, and 2 required four therapeutic doses. Four of these 48 patients became myxoedematous after their second treatment. Of these four, two were made hypothyroid intentionally because of associated intractable cardiac failure.

Two patients died within a year of receiving ^{131}I . One died as a result of long-standing portal hypertension, but, although improved, she was still thyrotoxic at the time of death despite having been treated on three occasions. The other was a woman aged 70 who died a few days after her second treatment. She fell heavily while in hospital and fractured the neck of her femur; fatal hypostatic pneumonia ensued. A third patient was still toxic after one year, but became euthyroid following further treatment.

Apart from the two patients who died while still thyrotoxic, four others had succumbed by the time the review was made (November 1, 1956). Three were elderly men who had been rendered euthyroid and who later had myocardial infarctions. The fourth was a patient with advanced diabetic nephropathy who died in uraemia two and a half years after severe hyperthyroidism had been adequately controlled.

Table II also includes for comparison the corresponding percentage figures for the 140 patients reported by Blomfield *et al.* (1955), who had been treated by a method of dose selection involving an elaborate and quantitative technique. It can be seen that the results in Edinburgh were essentially similar and the differences between the two groups are insignificant. The range of doses in millicuries employed in both centres is roughly comparable, but the mean figures are slightly lower in Edinburgh.

Discussion

The results achieved with this simple clinical technique are in no way different from those previously obtained when the prescription of the dose was governed by more meticulous and elaborate methods. Furthermore, they are essentially the same as have been reported by other centres. The four patients who became myxoedematous after a second therapeutic dose were all among the first 60 who received treatment. The production of hypothyroidism in this way can usually be avoided if sufficient patience is exercised and the physician is prepared to wait for the late remission that sometimes occurs. Nevertheless, our experience coincides with that of Myant (1956), who found that if no improvement has occurred after 10 weeks further therapy is almost invariably necessary.

If it is confirmed that similar or better results can be obtained by the use of this technique, ^{131}I therapy could be

greatly extended. The principles are essentially so simple that there is no reason why other physicians should not achieve the same results even if they have not previously had the advantage of experience with more meticulous methods. It is important that tracer-dose investigations should always precede ^{131}I therapy, because they confirm the diagnosis, and ensure that the uptake of ^{131}I by the thyroid gland is high. Failing such tests it is inevitable that mistakes in diagnosis and management will occur.

The majority of patients who receive ^{131}I therapy would in the absence of the isotope be treated by partial thyroidectomy. This operation, including the pre-operative preparation and recovery, usually involves at least three weeks in hospital, with all the expense to the National Health Service that such an admission entails. Thereafter a shorter or longer period of convalescence is necessary before the resumption of ordinary activities. When patients are treated with ^{131}I in hospital they need not remain for longer than three or four days unless their general condition warrants it. Treatment of out-patients, on the other hand, involves no expense except that of the isotope itself. This is trivial in comparison with the costs of the hospital admission. Including transport charges, an average dose of 8 millicuries costs less than £2. The economies effected by isotope therapy are therefore considerable.

The elaborate methods previously used in an attempt to determine precisely the dose to be prescribed are expensive. The detailed measurements necessary, particularly when gland size is estimated by scanning techniques, involve physicists and technicians in an expenditure of time and effort probably unjustified by any advantage which accrues.

From the long-term point of view it is important that some centres with adequate facilities, and a sufficient staff of physicists and technicians, should continue to make quantitative observations upon the amount of radiation delivered in isotope therapy. Only then can further knowledge be obtained about the factors responsible for the variation in response. Effective and safe treatment, however, can be carried out at any centre with a minimum of equipment and technical personnel. The cases here reported have been treated by one physician with the assistance of a single technician. It therefore should not be thought that the application of radioactive iodine in the treatment of thyrotoxicosis is necessarily a complex procedure.

Summary

A series of 150 consecutive cases of thyrotoxicosis have been treated with radioactive iodine. A simple clinical dosage technique has been used, based primarily upon an approximate estimate, by inspection and palpation, of thyroid gland mass, although certain other clinical factors were also taken into consideration.

On review after a minimum period of one year, 87% of patients had become euthyroid, 11% were myxoedematous, and 2% had been inadequately treated. Fifty-nine per cent. of the patients were satisfactorily treated with a single dose of the isotope.

The results achieved did not differ appreciably from those previously reported in which a method had been employed for dose selection involving an elaborate and quantitative technique.

The prescription of an entirely accurate radiation dose is impracticable, chiefly because of the errors inherent in the techniques for the estimation of gland mass, and because of the biological variability in the radiosensitivity of different glands. Elaborate techniques are unnecessary for the safe and effective treatment of thyrotoxic patients.

I am grateful to Professor D. M. Dunlop for his interest in this work, and to Professor R. McWhirter for his co-operation. I

am indebted to the Secretary of State for Scotland, through the Advisory Committee on Medical Research, for a grant towards expenses.

DANGEROUS BLEEDING ASSOCIATED WITH CARCINOMA OF PROSTATE

BY

H. T. SWAN, M.B., M.R.C.P., D.C.H.

Department of Haematology, the Royal Infirmary, Sheffield

K. F. WOOD, M.D., F.R.C.S.

AND

OWEN DANIEL, M.B., F.R.C.S.

University Department of Surgery and the Royal Infirmary, Sheffield

Excessive bleeding sometimes develops in patients with metastatic carcinoma of the prostate. The bleeding may occur either spontaneously or in association with surgical procedures, especially those directly involving the malignant prostate. Bleeding of varying degree may arise from any site, particularly the urinary tract and the nose, and in the skin as ecchymoses. If surgery is performed dangerous bleeding may take place into the traumatized area. Scott (1956) reports the loss of 1.5 litres of blood into the scrotum following orchidectomy in such a case. The haemorrhage may be severe enough to cause death if properly directed treatment is not given.

The relationship between bleeding and carcinoma of the prostate has not been fully explained. Recent studies of abnormal clotting have shown, however, that in certain cases of metastatic carcinoma of the prostate the phenomenon of fibrinolysis develops and that this is associated at times with a drop in the level of plasma fibrinogen (Tagnon *et al.*, 1953a, 1953b). Such fibrinolysis is thought to be due to proteolytic enzymes which dissolve away blood clot by digesting fibrin (fibrinolysis), in some cases also lysing fibrinogen (fibrinogenolysis) and other clotting factors such as prothrombin and factor V. Tagnon *et al.* (1953b) have demonstrated an abnormal fibrinolysin in the blood of 12% of their patients with metastatic carcinoma of the prostate, and

they have shown that this proteolytic enzyme is produced by the carcinomatous tissue itself.

In the following two cases of metastatic carcinoma of the prostate profuse bleeding occurred, sufficient to endanger life.

Case 1

First Admission

A 60-year-old man was admitted to hospital on December 27, 1953, with acute urinary retention and one month's history of urinary frequency, urgency, dribbling, and haematuria. Examination revealed a bladder distended to the umbilicus and enlarged nodes in the left groin. The left lobe of the prostate was enlarged, hard, and irregular, and a clinical diagnosis of carcinoma of the prostate was made. The patient was catheterized and 2 pints (1,140 ml.) of clear urine was obtained. A few hours after this procedure he started to bleed from the nose, rectum, and bladder. The bleeding was of moderate degree and did not require blood transfusion, but it lasted for four days.

Investigations.—Hb, 86% (12.7 g. per 100 ml.); W.B.C., 8,800 per c.mm.; platelets (Lempert), 77,000 per c.mm.; blood urea, 46 mg. per 100 ml.; serum acid phosphatase, 35 Gutman units; serum alkaline phosphatase, 29 K.A. units; plasma albumin, 3.1 g. per 100 ml., globulin, 2.9 g. per 100 ml., fibrinogen "practically zero." The patient's recalcified plasma formed a tiny pellicle of fibrin which disappeared during overnight incubation at 37° C. This test was not carried out aseptically, but even without proof of sterility the evidence was very suggestive of abnormal fibrinolysis.

On December 31, while he was still bleeding, he began treatment with stilboestrol, 10 mg. t.d.s., and this dose was increased to 15 mg. t.d.s. five days later. This therapy coincided with, or was responsible for, the cessation of all bleeding. Moreover, his platelet count, which had remained between 50,000 and 70,000 per c.mm. while he was bleeding, rose steadily to 230,000 per c.mm. over the succeeding five days and remained at that level. Subsequently his urological symptoms improved so much that there was no further need to consider transurethral prostatectomy.

Second Admission

Seven months later, while still receiving stilboestrol, 15 mg. t.d.s., the patient was admitted again with acute urinary retention. On this occasion he looked pale, and his chest, abdomen, and right wrist were covered with petechiae. Urine obtained by catheter was clear.

Investigations.—Hb, 60% (8.9 g. per 100 ml.); W.B.C., 7,900 per c.mm.; platelets, 86,000 per c.mm.; blood urea, 52 mg. per 100 ml.; serum acid phosphatase, 68 Gutman units; serum alkaline phosphatase, 33 K.A. units. Radiographs of the pelvis revealed secondary deposits in the bones, but the chest films showed no abnormality.

On the day after his readmission the patient suddenly collapsed, complaining of pain in the right shoulder and scapular region. He began to bleed round his indwelling catheter, and blood began to ooze from a venepuncture wound of the previous day. His nose started to bleed, and further showers of petechiae appeared on his arms and trunk. He became very shocked, and his clinical condition was not improved by the transfusion of three bottles of stored and one of fresh blood. Eight hours after the onset of bleeding he died from shock due to exsanguination from massive bowel haemorrhage.

A post-mortem examination confirmed the presence of a poorly differentiated adenocarcinoma of the prostate penetrating the capsule. There were metastases in the lungs, ribs, vertebrae, and pelvis. Petechiae were seen on the serosal surface of the gall-bladder, on the submucosal surface of the renal pelvis, and in the mucosa of the bladder as well as the skin, and there were haemorrhages into the wall of the pharynx, liver, and bowel. No local lesion was found to account for the large amount of blood in the alimentary tract.

Comment

At this time (1954) the condition of hypofibrinogenaemia associated with fibrinolysis in cases of carcinoma of the prostate was not recognized by us. It is possible, however, that fibrinogen depletion and fibrinolysis caused the haemorrhagic tendency which ultimately proved fatal to the patient even though this diagnosis is substantiated by relatively few haematological investigations.

Case 2

On February 13, 1956, a man aged 71 presented with haematuria which had developed over the previous week. He gave a history of six months of unremitting backache and of scalding and frequency of micturition. The liver was palpable 1½ in. (3.8 cm.) below the costal margin. He had a large fixed prostate gland which was thought to be probably malignant. By the time of his admission to hospital on March 6 the haematuria had stopped spontaneously.

Investigations

Hb, 97% (14.4 g. per 100 ml.); total serum acid phosphatase, 220 Gutman units; serum alkaline phosphatase, 30 K.A. units; serum bilirubin 1.1 mg. per 100 ml.; thymol turbidity, 1 unit; total serum proteins, 6.5 g. per 100 ml. Radiographs of the pelvis did not show any evidence of bony metastases, but an intravenous pyelogram revealed a moderately severe left hydronephrosis and a lobulated filling defect on the bladder base.

As an initial therapeutic procedure bilateral orchidectomy was performed, and a perineal biopsy of the prostate was also taken. This ultimately confirmed the presence of an anaplastic carcinoma of the prostate. After the biopsy had been taken all the traumatized tissue began to bleed freely, and the patient developed peripheral circulatory failure. Post-operatively the perineal wound continued to bleed, and his condition deteriorated. No improvement was observed as a result of the emergency transfusion of three bottles of stored blood over four hours; indeed, he began to develop spontaneous subcutaneous bruising around the shoulder-girdle and arms. At this stage it was reported that the original specimen of venous blood removed for the emergency cross-matching had still failed to clot. The syndrome was fully investigated by the following laboratory tests.

1. **Failure of Blood to Clot.**—The specimen of blood removed immediately after the operation had not been in contact with an anticoagulant, and yet it appeared to remain completely fluid apart from a very minute clot which comprised little more than a few fibrin strands lying loose within the specimen. This tiny clot did not increase in size thereafter. Indeed, it became less visible during the succeeding five hours.

This single observation, which was made in the blood bank, was enough to suggest the diagnosis of fibrinogen depletion in such a patient. The following emergency test confirmed the presumptive diagnosis.

2. **Thrombin Plus Whole Blood.**—Since thrombin acts directly on fibrinogen and by-passes all the earlier clotting factors, it is, in the absence of inhibitors, a specific indicator of the presence of fibrinogen. 0.2 ml. of commercial thrombin (Maw, 50 N.I.H. of oxalated whole blood (Scott, 1955). When assessed some 60 seconds later a very poor clot had formed. It was small in size, occupied a mere fraction of the total volume, and was ineffective in enmeshing red cells. By contrast, normal blood produced a large firm clot occupying the whole volume and enmeshing almost all the red cells.

When the original specimen which had been sent for cross-matching without an anticoagulant was then used in place of the oxalated specimen, and thrombin was added, no clot at all was formed. This showed the complete absence of fibrinogen. One presumes that such fibrinogen as had been present originally had all gone to form the few strands of fibrin described above.

This simple thrombin test demonstrated hypofibrinogenaemia, and this was enough to be the basis of specific emergency therapy. It did not supply information about the presence or absence of fibrinolysis such as affects formed clots. Perhaps the simplest demonstration of abnormal fibrinolysis occurs when sterile clotted blood liquefies spontaneously within 24 hours, but in this case lack of fibrinogen precluded the test in that form.

Treatment of the Bleeding.—Dried fibrinogen kept in readiness by the Sheffield Regional Blood Transfusion Service for such an occasion as this was used. This had been fractionated from pooled human plasma. About 4 g. was dissolved in 200 ml. of pyrogen-free distilled water and given to the patient intravenously over 20 minutes. At that time he was dangerously shocked, with blood running freely from the wound, and had a weak pulse of 130 a minute. All serious bleeding ceased within half an hour, and within one hour of the fibrinogen transfusion all oozing had stopped, with dramatic clinical improvement. No further fibrinogen therapy ever became necessary. The wound subsequently healed well.

Subsequent Investigations

The time interval between operation and removal of blood for the test described is given in parentheses.

1. **Platelet count** (Lempert) (12 hours), 150,000 per c.mm.
2. **Whole-blood Clotting-time** (Lee and White).—(12 hours):—A clot formed at about 20 minutes. This was still not a whole-volume clot, and it shrank considerably, until two hours later it was scarcely apparent amongst the red cells.

3. **Thrombin Plus Whole Blood.**—(12 hours):—Repetition of this test for the presence of fibrinogen (see above) showed a moderate-sized but nevertheless incomplete clot when examined at 60 seconds. The clot was much larger than it had been the previous night. (60 hours):—Identical with the control.

4. **Serial Plasma Dilution with Added Thrombin** (0, 12, 60 hours).—This is a simple emergency method for fibrinogen assay as advocated by Wolf (1954). The principle of the test is evident from the Table.

Serial Plasma Dilutions

Dilution in Saline:	1:10	1:20	1:40	1:80	1:160	1:320
Patient's plasma:						
Before fibrinogen therapy (0 hrs.)	+	+	—	—	—	—
After fibrinogen therapy (12 hrs.)	+	+	+	+	—	—
After fibrinogen therapy (60 hrs.)	++	++	+	+	+	+
Normal plasma as control (0, 12, and 60 hrs.)	++	++	+	+	+	+

+ = large clot, ++ = small or very small clot. Formed by the addition of thrombin to all tubes.

It will be appreciated that the clot formed by the addition of thrombin to a dilution of normal plasma of 1:320 is very minute and, to be seen, requires close scrutiny in a good light. From the Table the fibrinogen level in the patient's plasma can be calculated on the basis of a dilution factor of $\times 2$ between each tube. Thus, if one assumes the control fibrinogen level to be 200–400 mg. per 100 ml., then the pre-fibrinogen therapy specimen of the patient would be 12.5–25 mg. per 100 ml. and the post-therapy specimen would be 50–80 mg. per 100 ml. An estimate of fibrinogen by the Kjeldahl method later showed this second specimen to have in fact a fibrinogen content of 80 mg. per 100 ml. It thus confirmed the approximate range as given by this emergency method. The latter, however, took only 20–30 minutes to perform and read, as compared with hours by the Kjeldahl method.

5. **Estimation of Plasma Fibrinogen by Kjeldahl Method.**—At 12 hours, 80 mg. per 100 ml.; at 60 hours, 390 mg. per 100 ml.

6. **Quantitative Test for Fibrinolysis** (Biggs and Macfarlane, 1953a).—(12 hours):—Serial estimations showed no evidence of commencing fibrinolysis up to four hours. The blood was not kept chilled before the test. (60 hours):—A minimal increase of lysis was found after 19 hours when compared with the control, but the difference was not regarded as significant.

7. **Examination for Lysis of Normal Clot by Patient's Plasma.**—(12 hours):—No lysis was visible to the naked eye following the immersion of a washed fibrin clot (formed by

the addition of thrombin to normal plasma) into undiluted patient's plasma, followed by incubation at 37° C. for 24 hours.

8. **Quick's One-stage "Prothrombin" Time.**—(12 hours):—Control 15", patient 25", prothrombin index 60%, prothrombin arbitrary efficiency 18%. A prolongation of the "prothrombin" time may be expected in the presence of a low fibrinogen level, but this does not exclude the possibility of other defects (see below).

9. **Two-stage Prothrombin Time** (Biggs and Douglas, 1953a).—(36 hours):—True prothrombin was 77% of normal. This level is within our normal range allowed by the method.

10. **Qualitative Test for Deficiency of Factor V or of Factor VII** (Biggs and Macfarlane, 1953b).—(12 hours):—No deficiency of factor V or of factor VII.

11. **Thromboplastin Generation Test** (Biggs and Douglas, 1953b).—(36 hours):—No abnormality demonstrated by this test in the patient's plasma, serum, or platelets.

Discussion

In Case 2 it was demonstrated that a dangerous fall occurred in the plasma fibrinogen level during a minor operative procedure on a malignant prostate gland followed by bilateral orchidectomy. Furthermore, the plasma fibrinogen rose to an adequate haemostatic level after a single intravenous infusion of 4 g. of human fibrinogen. The plasma fibrinogen was only 80 mg. per 100 ml., however, some hours after all bleeding had ceased, and this level is lower than that which is commonly believed to be haemostatic. The plasma fibrinogen then continued to increase, apparently spontaneously, until it reached normality on the third day. This recovery may have been assisted by the orchidectomy. The bleeding in Case 1 appeared to develop in the absence of any surgical trauma to the prostate gland, unless catheterization can be described as such.

Fibrinolytic activity was probably present in Case 1, as shown by the complete lysis of the clot left overnight. In Case 2 it is unfortunate that the first specimen examined specifically for fibrinolysis was taken from the patient 12 hours after bleeding had stopped as the result of treatment. By then there was no satisfactory evidence of fibrinolysis by the method used. Possibly a modification of the cold method advocated by Fearnley and Lackner (1955) might have given more information. Hypofibrinogenaemia therefore remains the unequivocal feature of these two patients. Fibrinolysis remains a probability in Case 1 but an unproved factor in Case 2.

Tagnon *et al.* (1953b) have shown in cases of metastatic carcinoma of the prostate with fibrinolysis that, while the platelet count is often depressed, it may remain normal despite the fibrinolysis. In Case 1 the platelet count was abnormally low at the time of the bleeding and recovered subsequently during oestrogen therapy. The exact significance of this is not clear.

An unusual feature present in Case 2 was the apparently isolated fall in plasma fibrinogen. There was no obvious fibrinolytic activity to which proteolytic digestion of fibrinogen could be attributed. Nor do we know of any evidence to suggest that the mechanism is the same as that found in premature separation of the placenta (Stevenson *et al.*, 1953) and perhaps in certain lung operations (Chalnot *et al.*, 1952), where it seems that intravascular clotting may take place with consequent depletion of fibrinogen, as a result of the release into the circulation of excessive thromboplastin from the organ involved. The fibrinolytic factor, when it is present, is more easily understood, since tissue juices from a prostatic carcinoma have been shown *in vitro* to cause clot lysis and also to digest fibrinogen, factor V (ac-globulin), and probably prothrombin (Tagnon *et al.*, 1953a, 1953b).

Therapy is directed to controlling fibrinolysis and correcting hypofibrinogenaemia. In practice these two may perforce have to be treated together. Oestrogen therapy has an important place in controlling the lytic factor when present

(Tagnon *et al.*, 1953a) and this is substantiated by Case 1. The position in Case 2 is less certain. Also it seems that removal of the source of testosterone by orchidectomy has an experimental justification over and above the mere need to make the female hormone preponderant over the male hormone, since it was shown by Tagnon *et al.* (1953a) that the addition of testosterone to a maintenance dose of oestrogen made the latter ineffective in their patient. Corticotrophin has also been claimed to diminish the lysis, thereby helping to control the bleeding manifestations in these patients, and Stefanini *et al.* (1953) claimed that response to this treatment was more rapid than with oestrogens. Therapy of the hypofibrinogenaemia is extremely important, and must be as specific as possible. It will be appreciated that whole blood is relatively useless for this purpose, since it supplies so little fibrinogen in each bottle. Fractionated fibrinogen or triple-strength reconstituted dried plasma is the only type of emergency therapy. If whole blood must be given to replace blood loss, fibrinogen infusion should be given first, or at least simultaneously. About 4 g. of fibrinogen should be given intravenously in the first place, and subsequent additions to this should depend on the patient's recovery and on laboratory findings. As Case 2 has shown, one injection alone may be sufficient.

In conclusion, therefore, we suggest that the association of abnormal bleeding and carcinoma of the prostate is not infrequent, and, when suspected, should be confirmed by the more simple tests described in Case 2. The control of hypofibrinogenaemic bleeding depends on its recognition and the immediate availability of human fibrinogen.

Summary

Two cases are described in which the patients suffered from metastatic carcinoma of the prostate and developed a generalized haemorrhagic state. During these episodes the blood of both patients was incoagulable owing to a deficiency of plasma fibrinogen. In the first patient, who died as a result of the bleeding, this loss was probably associated with a fibrinolytic mechanism. The second patient recovered dramatically on receiving 4 g. of human fibrinogen intravenously.

Simple methods are described for the emergency laboratory diagnosis of hypofibrinogenaemia, using commercial bovine thrombin.

Whole blood is almost valueless as a specific therapy for hypofibrinogenaemia, and should be used only for its bulk, its cellular constituents, and its other clotting factors. Hypofibrinogenaemia should be treated by fractionated fibrinogen intravenously or by triple-strength reconstituted dried plasma.

The treatment of fibrinolysis is discussed.

We thank Professor R. P. Jepson for permission to describe these patients, who were under his care; Dr. H. Lempert, of the Royal Infirmary, Manchester, for allowing us to use the results of his haematological investigations in the first patient; and Dr. E. K. Blackburn for his help. We are indebted to Miss Pauline Hall for technical assistance, and to the Endowment Fund of the Board of Governors of the United Sheffield Hospitals for a grant towards the cost of laboratory expenses.

PROPHYLACTIC VALUE OF TETANUS ANTITOXIN IN MICE PREVIOUSLY INJECTED WITH HORSE SERUM

BY

LEON S. KIND, Ph.D.

From the Department of Microbiology, Medical College of South Carolina, Charleston, S.C.*

Littlewood, Mant, and Payling Wright (1954) reported a case in which a patient died of tetanus despite the fact that he was given the generally accepted prophylactic dose of tetanus antitoxin (1,500 units) shortly after injury. The patient was shown to be allergic to tetanus antitoxin (via a positive skin test), and his case history revealed that he had been given a prophylactic dose of tetanus antitoxin after an injury six months previously. Littlewood *et al.* suggested that the therapeutic ineffectiveness of the tetanus antitoxin was due to the state of hypersensitivity to the antitoxin which resulted in its accelerated removal from the circulation. They cited data from investigations of Glenny and Hopkins (1924). Talmage *et al.* (1951), and others which clearly indicate that previous experience with an antigen results in an accelerated removal of that antigen from the circulation upon its subsequent injection. The following experiment tests the hypothesis of Littlewood *et al.* by noting the duration of the prophylactic effectiveness of tetanus antitoxin in normal mice and in mice previously injected with horse serum.

Methods

Female 22–30 g. Carworth Farms CF strain of mice were divided into three groups. Group I was injected intraperitoneally with 0.1 ml. of *Haemophilus pertussis* vaccine† and 0.5 ml. of undiluted horse serum. Groups II and III received only 0.1 ml. of pertussis vaccine. Normal horse serum rather than horse-serum antitoxin was used to sensitize mice to a subsequent injection of antitoxin, since preliminary experiments indicated the superiority of normal horse serum as a sensitizing antigen. This result was not surprising in view of the fact that the antitoxin employed (Lederle) was of the type that is treated with proteolytic enzymes to modify its allergenic properties. Pertussis vaccine was administered along with the horse serum since it has been shown by Malkiel and Hargis (1952), Kind (1953), and Munoz *et al.* (1954) that this vaccine increases the sensitivity of mice to anaphylactic shock. Eleven days later the mice in groups I and II were inoculated intraperitoneally with 0.2 ml. (300 units) of tetanus antitoxin.

Of 62 mice sensitized with horse serum and injected with the antitoxin, 2 died and 4 others showed symptoms of severe anaphylaxis but recovered. On the third, seventh, fifteenth, nineteenth, and twenty-fourth day after receiving antitoxin, 12 mice from group I and 12 mice from group II were challenged intraperitoneally with approximately 1 M.L.D. of tetanus toxin. On each of these days 12 mice from group III (previously injected with only pertussis vaccine) were similarly challenged with tetanus toxin. The tetanus toxin employed in this experiment was obtained from Lederle Laboratories (lot No. 1872M). The fluid toxin had been stored at refrigerator temperatures for two years, but possessed considerable potency; 0.1 ml. of a 1:200 dilution injected intraperitoneally was approximately 1 M.L.D. Toxin dilution was made in nutrient broth, and deaths were noted for four days after injection.

*This investigation was supported by research grant (E372C2) from the National Microbiological Institute, National Institutes of Health, Public Health Service, Department of Health, Education, and Welfare.

†48.8 billion organisms per ml.

Results

The data in the Table and the Chart indicate that up to the fifteenth day after the administration of tetanus antitoxin all mice possessed sufficient antitoxin to neutralize the

Effect of Previous Administration of Horse Serum on Duration of Protective Ability of Tetanus Antitoxin

‡The difference in the percentage of survivors in these two groups is statistically significant ($P < 0.01$).

Duration of prophylactic effectiveness of tetanus antitoxin in mice inoculated with horse serum and in mice not so inoculated.

challenge dose of toxin. Of the mice challenged on the fifteenth day, two deaths occurred among the animals of group I which had been inoculated with horse serum 11 days prior to antitoxin. No deaths occurred among the animals which had no previous experience with horse serum (group II). Of the mice challenged on the nineteenth day after the administration of antitoxin, only 4 of 13 (30%) of the animals inoculated with horse serum survived the challenge dose of tetanus toxin, as compared with 11 of 12 (91%) of the mice which had not previously received horse serum. The difference between the percentage of survivors in the two groups is a significant one ($P < 0.01$). In a second experiment conducted in a similar manner, comparable results were obtained. Of 23 mice inoculated with horse serum and challenged with tetanus toxin on the seventeenth day after the administration of tetanus antitoxin, only 7 survived. In contrast, of 24 mice with no previous experience with horse serum, 22 survived challenge doses of toxin administered on the seventeenth day after injections of antitoxin. The difference between the percentage of survivors in the two groups is a significant one ($P < 0.01$).

Discussion

The data presented here support the contention of Littlewood *et al.* that previous experience with horse serum may

result in failure of antitoxin to protect. However, we agree with Beeson (1955–6) that an alternative explanation of the fatal case of tetanus cited by the aforementioned authors may be that the conventional prophylactic dose of tetanus antitoxin (1,500 units) was insufficient to neutralize the toxin present. Beeson cites other cases of prophylactic failure of 1,500 units of tetanus antitoxin and suggests that 10,000 units should be used for adequate passive immunization.

An increase in the prophylactic doses of tetanus antitoxin from 1,500 to 10,000 units would thus seem to be advantageous for two reasons. Ten thousand units would offer better protection in cases in which unusually large amounts of toxin were being produced. Ten thousand units of tetanus antitoxin might also be more effective in cases in which the antitoxin was being rapidly eliminated because of the patient's previous experience with horse serum.

A SIMPLE QUICK TEST FOR GLUCOSE IN URINE

REPORT ON USE OF CLINISTIX

BY

GEORGE LUNTZ, M.R.C.P.

Consultant Chest Physician, Birmingham Chest Clinic;
 Consultant Physician with Charge of Tuberculosis
 Diabetic Service, Birmingham Regional
 Hospital Board

Two extremely simple enzyme tests have been developed which are highly specific for glucose in urine. These are "tes-tape" and "clinistix," but the present paper is concerned only with the latter. The method consists in dipping a specially treated thick paper stick approximately the size of a book-match, the last half-inch of which is impregnated with reagents containing an enzyme system, into a specimen of urine. The stick turns blue in the presence of glucose, and the blue colour should have developed in one minute. If the stick remains colourless there is no significant glucose in the specimen.

Application of the Test

This paper reports on a field trial in which clinistix was used for detecting glucose in urine and the effectiveness of the test compared with "clinitest" reagent tablets as standard. The trial was limited to patients over the age of 11 years attending the Birmingham Chest Clinic for the first time. Nursing staff were responsible for obtaining a specimen of urine from all new patients in the specified group. This was normally done in the interval between the taking of the chest radiograph and the clinical examination, so that the tests were completed before the patient was seen by the physician. Nurses performed the actual tests after being trained in the technique, and recorded the results. The technique is simple, no special apparatus or boiling is required, and specificity is beyond doubt. Hunt, Gray, and Thorogood (1956) have already stressed that the test is essentially an ultra-micro-method in the strictest sense and requires all the standards of chemical cleanliness such methods demand.

In the small number of patients whose specimens gave a positive result, blood-sugar estimations were carried

out in the pathological laboratory within 10 minutes of the positive finding. The details of the further management of patients with positive findings in the urine depended on whether any pulmonary abnormality was present in addition or not. All cases of glycosuria, however, were fully investigated either as out-patients, if their lungs were normal, or as in-patients if pulmonary disease was present.

Results

During a period of five months, from June 1, 1956, to October 31, 1956, 942 patients (593 males and 349 females) attended for examination. Positive findings on clinitest or clinistix, or both, were found in only 26 (2.76%). These are set out in Table I. Of the 26 with positive findings on urine examination, 20 were males and 6 were females, and these are discussed below.

TABLE I.—Results of Tests in 26 Cases with Positive Findings

Six were known diabetics referred with chest symptoms and found to have active tuberculosis (Cases 7, 9, 14, 16, 21, and 25). Clinitest and clinistix were positive in five, but in one (Case 25) clinistix only was positive. Blood-sugar levels were 260, 270, 340, 220, 270, and 190 mg. per 100 ml. respectively.

In five cases diabetes was diagnosed without the patients being aware of their diabetic symptoms (Nos. 1, 3, 8, 10, and 23); three of these had tuberculosis and the other two had carcinoma of the lung. Clinitest and clinistix were both positive in the first four but clinitest only in the fifth, whilst blood-sugar estimations at the time of the positive findings were 280, 300, 290, 170, and 183 mg. per 100 ml. respectively.

In eight cases renal glycosuria was present (Nos 5, 6, 12, 15, 18, 19, 22, and 24). Clinitest and clinistix were both positive in all but three (Cases 6, 18, and 24), in which clinistix only was positive. The blood-sugar levels in these eight cases were 75, 100, 120, 90, 130, 125, 104, and 90 mg. per 100 ml. respectively. Oral glucose-tolerance tests confirmed the presence of a low renal threshold for glucose in the eight cases. The lowest threshold was 75 mg. per 100 ml. (Case 5).

In the six non-diabetics clinitest gave a positive result owing to the presence of reducing substances, but clinistix gave a negative result, indicating that there was no glucose present (Cases 2, 4, 11, 13, 17, and 20). The blood-sugar levels were 100, 85, 124, 110, 100, and 100 mg. per 100 ml. respectively, and the reducing substances giving a "trace" reaction with clinitest in these six cases were accounted for by the drugs being taken by the patients at the time.

In one patient clinitest was negative and clinistix positive, with a blood-sugar level of 210 mg. per 100 ml. (Case 26). This patient, a non-diabetic, was found to have a post-gastrectomy hyperglycaemia.

Discussion

Clinistix was used specifically for detection purposes, and is extremely accurate and reliable. It is more specific than clinitest for detecting glucose in that there are fewer false positives, and from the point of view of detecting diabetics clinistix is more dependable than clinitest. In 930 out of 942 cases the results of the two tests were identical (Table II)—916

TABLE II.—Results of Urine Tests in 942 Cases

Clinitest	Positive	Negative	Total
Positive	14	7	21
Negative	5	916	921
Total	19	923	942

being negative and 14 positive. In seven instances clinitest was positive and clinistix negative. Further investigation showed that in all these cases the positive result was due to reducing substances other than glucose. It is worth emphasizing that there have been only a few false positives, although the tests have been carried out by nurses outside the laboratory. In five cases clinistix was positive and the clinitest negative (Cases 6, 18, 24, 25, and 26): these included three renal glycosurics, one diabetic, and one patient with a post-gastrectomy hyperglycaemia. In all these the trace of glucose present was detected by clinistix but failed to be seen on clinitest.

A number of factors such as variations in the temperature and pH of the specimen of urine, and also variations in the amount of ascorbic acid present, affect the sensitivity of the enzyme test and the intensity of the colours, thus making the test unreliable for quantitative use. Warnings about the unreliability of the enzyme test as a quantitative test have already been given by Hunt *et al.* (1956), and Tunbridge, Paley, and Coulson (1956).

The test is, however, of great value in detecting glycosuria and may be used for screening purposes in any busy clinic, such as a chest clinic, medical, surgical, and ophthalmological out-patient departments, and antenatal and post-natal clinics. It should prove invaluable to the general practitioner both in his surgery and during domiciliary consultations. The test has little place in the day-to-day management of diabetic patients having insulin.

Conclusion

This study has shown the reliability of clinistix in detecting glucose. The simplicity of applying and interpreting the test has been substantiated during the course of this trial.

I thank the Ames Company (London) Limited for supplies of clinitest reagent tablets and clinistix reagent strips; Dr. Victor Springett for helpful criticism and permission to carry out the field trial; the consultant staff of the Birmingham Chest Clinic for permission to study patients under their care; Sister M. Hamilton and her staff for carrying out a large number of urine tests; and Miss F. L. Tomkins for assistance with the estimation of blood-sugar levels.

The University of London has authorized the expenditure of the total amount of money necessary for completing the School of Pharmacy in Brunswick Square, Professor W. H. Linnell, Dean of the School, told the council of the Pharmaceutical Society recently. In 1935 the cost was put at £350,000. To-day it would be £1,300,000. Although the official date for the completion of the new building was next December, teaching, he said, would begin in October.

A QUICK AND EASY METHOD FOR BLOOD-SUGAR ESTIMATION

BY

MARY H. DAVIES, M.B., Ch.B.

Senior House Officer

AND

RONALD G. PALEY, M.D., Ph.D.

Research Fellow

WITH THE ASSISTANCE OF

I. HILL and B. STANNARD

Department of Medicine, University of Leeds

The need for a speedy and easy method of blood-sugar estimation has long been recognized, especially in the prompt diagnosis and correct treatment of certain medical emergencies, and particularly those associated with diabetes mellitus. Most of the standard methods of blood-sugar estimations require apparatus and techniques rendering them unsuitable for use outside the laboratory.

Hall (1950) and Lee (1954) respectively modified Haslewood and Strookman's (1939) method and Sumner and Graham's original work using dinitro-salicylic acid (Sumner and Graham, 1921; Sumner, 1924-5, 1925). The final methods are quick but still require a number of manipulations and the external application of heat.

The method presented here is extremely easy, apparatus is compact, no external heat is required, and it is very quick.

Method

Reagents.—(1) Tablet A: salicylsulphonic acid is the protein-precipitating agent. (2) Tablet B, for determining the reducing sugars, consists of copper sulphate, sodium hydroxide, sodium bicarbonate, and citric acid (Patent Nos. 2, 387, 244).

Procedure.—In a small test-tube provided with the kit,* water is added to mark 2, and tablet A is then placed in this water. The solution thus formed precipitates proteins; blood is then added to mark 3 on this test-tube. In the present study blood was actually delivered to the deproteinizing fluid by means of a 1-ml. shellback pipette. A rubber bung is placed in the mouth of the test-tube, which is vigorously shaken. A very fine precipitate ensues. A filter cone provided is placed in the top of a second, identical test-tube. The brown mixture is filtered into the second tube and the clear filtrate collected up to mark 1. One tablet B is added to the filtered solution. The fluid boils without external heat being applied, and when this stops the test-tube is shaken three or four times; after a wait of 30 seconds the colour is compared with the scale provided in the kit: blue=100 mg./100 ml., green=150 mg./100 ml., and orange=200 mg./100 ml.

Selection of Patients and Experimental Design.—The blood samples were obtained by venepuncture from patients during visits to the Diabetic Clinic, General Infirmary at Leeds. The blood was placed in a special oxalated tube. At the close of each clinic, estimations were done on these samples by an independent worker using the new method under constant and ideal conditions, while routine Hagedorn-Jensen estimations (Hagedorn, Halstrom, and Jensen, 1935) were also made on the same specimens, with only 1-2% error, and these were done in a different laboratory. This eliminated any unconscious bias in either estimation. Three workers with varying laboratory experience used the new method. Workers X and Y did the estimations with the new

*Kindly supplied by Ames Co. (London) Ltd.

blood-sugar kit (B.S.K.) under standard conditions with respect to light, time, and continuity. Worker Z was not allowed such constant conditions.

Results

The results obtained by the Hagedorn-Jensen method showed that none of the groups estimated by three workers was biased by an excess of either high or low blood-sugar levels.

Worker X did 105 estimations with the B.S.K., and these were graded blue, green, and orange according to the chart. The division between blue and green was arbitrarily taken at 125 mg./100 ml. and between green and orange at 175 mg./100 ml. Thus individual results were given not only a grading according to colour but also an estimate of blood sugar in mg./100 ml. For example, a greenish-yellow colour resulting from the B.S.K. was estimated as 170 mg./100 ml., whilst the standard Hagedorn-Jensen method for blood-sugar estimation revealed 184 mg./100 ml. When all the

Comparison of blood-sugar determinations by the Hagedorn-Jensen method with the new blood-sugar kit.

B.S.K. estimations done by worker X are compared with the independent Hagedorn-Jensen estimations there is a remarkable agreement (see Chart). The correlation coefficient r is + 0.9. When the 88 results from worker Y are analysed there is not such close agreement, and the correlation coefficient $r = + 0.78$. The 106 results from worker Z gave a correlation coefficient of + 0.85.

Discussion

It will be seen from the Chart that no patient given an "orange" rating by B.S.K. had a true blood sugar as revealed by the Hagedorn-Jensen method below 160 mg./100 ml. Conversely, only one patient given a "blue" rating by the B.S.K. had a blood sugar level over 125 mg./

100 ml. when estimated by the Hagedorn-Jensen method. In over 300 estimations, only once was there a widely differing result which could have caused an error in treatment. The B.S.K. revealed 110 mg./100 ml. whilst the Hagedorn-Jensen method showed 212 mg./100 ml. The worker questioned the blue-grey colour of the B.S.K. reaction, and this estimation should have been repeated.

The accuracy of results depends on the appreciation of a range of colours. In a few estimations this was difficult, particularly when a muddy or grey tinge appeared in the final sample. Worker X was able to distinguish a muddy blue from an orange grey with reasonable accuracy in all shades, whilst workers Y and Z had difficulty. This problem was resolved by repeating all estimations when an unreliable colour was obtained. Usually a pure colour was finally produced. No explanation has been found for this "muddy" colour, and it occurred 22 times out of 300 estimations.

There is no doubt that ideal conditions and laboratory experience improve the accuracy of this method. Nevertheless, with a little practice, proficiency is attained whereby blood-sugar estimations can be done that are of inestimable value in the correct treatment of emergency medical patients.

It was felt that further refinement of the test was not essential since the B.S.K. was not designed to usurp the established blood-sugar methods. In emergency practice the question is usually not the actual level of blood sugar but whether the level is low or whether it is high. The B.S.K. would appear to be capable of giving this information speedily and accurately enough for clinical purposes. A further extensive trial is under way to test these laboratory findings under emergency conditions.

Summary

A new simple and quick blood-sugar estimation is described. Results when compared with the Hagedorn-Jensen method are in remarkable agreement. Varying conditions and experience of the workers are shown to influence the results. The new blood-sugar method would appear to be helpful in medical emergencies.

We thank all the patients for their kind co-operation in this study; Professor R. E. Tunbridge for permission to study his patients and helpful criticism of the MS.; and Mr. J. Bunce, Director, Ames Company (London) Ltd., for the supply of B.S.K. and his help at all times.

The John Horniman Home is a home for children with severe physical handicaps such as cerebral palsy, muscular dystrophies, paralysis due to poliomyelitis, or severe heart disease. The home, situated in Worthing, is run by the Invalid Children's Aid Association, and can accommodate 24 children. It takes both boys and girls between the ages of 7 and 16. They are usually admitted for periods of two to eight weeks, either as a holiday to give their parents a respite or for convalescence after illness. The first object of the home is to help families in carrying the burden of a severely handicapped child. In special cases a long stay with education can be arranged. A serious difficulty in running the home, which has now been open for nearly three years, is that there is a peak demand during the summer holidays but vacancies at other times of year. With the skilled staff needed for such work this makes for uneconomic operation, and a more even flow of admissions, especially during the winter months, is wanted. Full details may be obtained from the Invalid Children's Aid Association, 4, Palace Gate, London, W.8.

A RAPID METHOD FOR THE ESTIMATION OF BLOOD SUGAR

BY

R. A. OSBORN, M.B., B.S., B.Sc.

Resident Pathologist, Derbyshire Royal Infirmary; Late House-Physician, the Middlesex Hospital

A number of rapid and simple methods for the estimation of the blood sugar have been described (Hall, 1950; Lee, 1954). Although the results obtained by these methods agree with those in routine laboratories, they are not really suitable for performance by a busy house-physician at the bedside or in a ward side-room. A very simple procedure involving the use of tablets has recently been developed, and its use has been studied in the wards and the Diabetic Clinic of the Middlesex Hospital.

Method

The equipment is contained in a small box and consists of two test-tubes each with three graduations (at 1, 2, and 3 ml.), a test-tube stand, a dropper, a box of filter cones, and two bottles of tablets (A and B). Tablet A is dissolved in 2 ml. of water in one of the tubes and blood is added to the 3-ml. mark. The proteins are rapidly precipitated and the mixture is allowed to filter through one of the filter cones into the second tube until 1 ml. of filtrate has collected. Tablet B is then added, and after the contents of the tube have boiled the froth is shaken down and 30 seconds later the colour is compared with that on a chart provided: blue or blue-green = 100 mg./100 ml. or less, green = 150 mg./100 ml., and orange = 200 mg./100 ml. or more.

Blood samples were obtained by venepuncture and a fluoride-oxalate anticoagulant mixture was used. If for any reason the estimation could not be performed immediately the specimen was stored, but not frozen, in a refrigerator. In practice it was found preferable to measure the volumes of blood and water with an ordinary 2-ml. insulin syringe. If the result was more than 200 mg./100 ml. the estimation was repeated, using 2.5 ml. of water with tablet A and adding 0.5 ml. of blood. If this still gave maximum reduction the test was repeated, using 2.75 ml. of water and 0.25 ml. of blood. For higher dilutions the blood was diluted with water first. No attempt has been made to perform the estimations under set conditions of lighting; so far as possible, the method has been studied as it would be used in practice—artificial or daylight being used as circumstances required.

Duplicate samples of each specimen were sent to the Courtauld Institute of Biochemistry at the Middlesex Hospital, where blood sugars were estimated by the method of Kingsley and Reinhold (1949), using sodium tungstate and sulphuric acid as protein precipitant. The error of this method is ± 6 mg./100 ml.

Results

The results obtained by the tablet method and the Kingsley-Reinhold method are compared in the Chart. The

Comparison of blood-sugar determinations by the method of Kingsley and Reinhold with the new blood-sugar kit.

correlation coefficient is 0.84, but there is a slight overall tendency for the tablets to give a high reading. In practice it was found that the mid-point between 100 and 150 mg./100 ml. gave a colour that could be recognized quite satisfactorily, and some readings of 125 mg./100 ml. are therefore shown. The mid-point 150-200 mg./100 ml. proved less easy to detect. Occasionally an impure colour was obtained and it was found necessary to repeat the test.

Discussion

A rapid and simple method for the performance of blood-sugar estimations in the out-patient clinic, consulting-room, or ward side-room would help the control of treatment of diabetes and in the management of diabetic emergencies.

This method cannot be recommended even as a screening procedure for the diagnosis or exclusion of diabetes. Definite diagnosis of this condition is of great significance to the patient and only methods of proved accuracy should be used. The tablet method is not really suitable for control of treatment in hospital diabetic clinics, where arrangements can usually be made for blood-sugar estimations by routine methods. It may be helpful for practitioners supervising the treatment of diabetics in their surgeries, an occasional check on the blood being desirable in all cases.

The method has proved very useful in the management of diabetic emergencies in hospital. In post-operative patients, in cases of ketosis, and in cases of suspected hypoglycaemia a rapid guide to treatment has been obtained. At night and at week-ends its use has often made it unnecessary to call on the services of the resident biochemist. In hospitals without a 24-hour biochemistry service this equipment would be very valuable.

I am indebted to the staff of the routine laboratories of the Courtauld Institute of Biochemistry of the Middlesex Hospital, where the control estimations of the blood sugar were made. I thank Dr. J. D. N. Nabarro, under whose guidance this paper was written, for allowing me to perform these tests on his patients, and the Ames Company (London) Ltd. for the provision of the blood-sugar kit.

Medical Memoranda

Treatment of Ammoniacal Dermatitis with Folic Acid and Soya-bean Milk

The oral administration of either folic acid or soya-bean flour encourages the growth of lactobacilli and possibly inhibits the growth of ammonia-producing organisms in the stools. It would seem rational to try to cure ammoniacal dermatitis in infants by the oral administration of these substances.

The following report concerning the treatment of chronic napkin rash by the administration of (a) folic acid and (b) soya-bean milk may prove of value to others faced with a similar problem.

Five infants aged between 3 and 16 months, who had suffered from severe ammoniacal dermatitis in which there was desquamation and exudation for periods ranging from 1 to 12 months, and who failed to respond to routine methods of treatment, were given folic acid by mouth. The dosage was 10 mg. daily as an elixir. Routine treatment to napkins and buttocks continued unchanged, while in each case the infant's diet remained similar to that in use immediately before the start of folic acid therapy. After a month three patients showed slight improvement, but the other two were no better. In view of this unsatisfactory response to treatment folic acid was withheld and soya-bean

milk was given. The milk consisted of 1½ oz. (42 g.) of soya-bean flour added to a pint (570 ml.) of water. This was used to replace half the quantity of cow's milk normally taken daily, so that patients consumed 10 to 20 oz. (285 to 570 ml.) of soya-bean milk each day. The routine treatment of the napkins and buttocks continued as before and the infants' diets were not altered. Within five days of starting the treatment all the patients had shown some improvement in the condition of the buttocks, while four of them had become more contented. Within two weeks the appearance of the skin was normal in all cases. During the third and fourth weeks of treatment there was no deterioration, though very transitory erythema of the skin in the napkin area was sometimes noted.

In view of these findings further observations on the effect of treatment with soya-bean milk in cases of ammoniacal dermatitis would be useful, and it should be given a trial in all resistant cases of this condition. Soya-bean flour can be obtained from Soya Foods, Ltd., London, E.C.3, and possibly from grocers. Its food value compares favourably with cow's milk, so that it is possible to rear infants from birth on this food. The cost of soya-bean milk is approximately twopence a pint. It is possible that treatment with larger doses of folic acid than were used in these few cases might prove more satisfactory, and it may be that cases resistant to soya-bean therapy might respond to large doses of folic acid.

R. A. MILLER, M.D., Ph.D., F.R.C.P.Ed.,
Consultant Paediatrician, Royal Hospital for Sick Children, Edinburgh.

Pregnancy in Addison's Disease

Adrenocortical insufficiency is not necessarily incompatible with fertility. In earlier days the hazards of pregnancy in such circumstances were well known and were such as to make conception inadvisable or therapeutic abortion necessary. Now with modern complete substitution therapy the prognosis of pregnancy in Addisonian patients is much better. Approximately 60 such cases are on record, and in 14 of these pregnancy has occurred in the past five years when potent adrenocortical hormones have been available (Hendon and Melick, 1955). Only 7 cases appear to have been reported since cortisone has been used for maintenance. Below is a further case in which pregnancy occurring during treatment of Addison's disease was brought to a successful conclusion.

CASE REPORT

A nulliparous 23-year-old woman who had been married for four years presented with generalized weakness, tiredness, loss of weight, oligomenorrhoea, and skin pigmentation. There was no gastro-intestinal upset and no past history of tuberculosis. She was dehydrated, the skin was inelastic, the tongue dry, and the oral mucous membrane pigmented. Her blood pressure was 70/50 mm. Hg. Serum electrolyte values were compatible with Addison's disease: sodium 130, potassium 5.7, chlorides 69 mEq. per litre. Blood urea 93 mg. per 100 ml.; haemoglobin 85% (Haldane). Urinary 17-ketosteroid excretion 2.9 mg. in 24 hours. Radiographs of chest and abdomen normal. On a standard water load a diuresis of only 50% was recorded in the first four hours.

Initial therapy consisted of deoxycortone acetate (D.C.A.) 10 mg. daily by injection, together with 6 g. of salt a day and an adequate fluid intake. Her general condition improved on this treatment; the blood pressure rose to 110/70 mm. Hg, the electrolytes returned to normal values, and she gained 10 lb. (4.54 kg.) in weight, thus confirming the diagnosis of Addison's disease. A month later it was decided to institute maintenance therapy consisting of an implant of 200 mg. D.C.A. and 3 g. of salt a day. After about six months additional salt was given to overcome increased weakness and lethargy. Her blood pressure and serum electrolytes continued normal. It was decided to

give a further implant of D.C.A., 200 mg., and to continue 3 g. of salt a day.

Two months later she was found to be eight weeks pregnant. She complained of morning sickness, weakness, and lassitude at the end of the third month of pregnancy in spite of continued maintenance therapy. She was admitted to hospital, and improved on bed rest, adequate fluid intake, and dimanhydrinate ("dramamine") to a total of 100 mg. daily. As previous maintenance therapy had been inadequate this was changed to cortisone, 25 mg. daily by mouth, with trimethyl deoxycorticosterone, 60 mg. intramuscularly monthly, and salt, 3 g. a day. The pregnancy progressed satisfactorily on this regimen.

Four weeks before term the patient was again admitted to hospital, and, in addition to the maintenance therapy of 3 g. of salt and 25 mg. of cortisone a day, was now given daily injections of 10-15 mg. of D.C.A., her general condition, blood pressure, and electrolyte levels being the main guide. It was considered inadvisable to give her a longer-acting steroid at this stage. When labour started she was given 100 mg. of cortisone. The second stage was prolonged over eight hours and low forceps under pudendal block analgesia were applied. She was delivered of a living female child of 9 lb. (4.082 kg.). Next day she was given 100 mg. of cortisone, 10 mg. D.C.A., and 3 g. of salt, and the day after a return was made to the previous level of cortisone 25 mg., D.C.A. 10 mg., and salt 3 g. daily.

She had a mild puerperal infection which responded adequately to chemotherapy. Two weeks later she had oedema of the ankles and a blood pressure of 160/110 mm., together with serum electrolyte values of sodium 148, potassium 3, and chlorides 108 mEq. per litre. D.C.A. and salt were therefore stopped but cortisone continued. Within a week the blood pressure was normal and the oedema had subsided. Smaller doses of D.C.A. with a varying salt supplement were started again, and a week later D.C.A. was replaced by trimethyl deoxycorticosterone. The skin pigmentation, which decreased with the initial treatment, increased again near term, but had become less marked by the end of the puerperium. Lactation was successful to start with, but because of cracked nipples it was artificially suppressed after the second week by ethinylloestradiol.

COMMENT

Before 1949 the maternal mortality among patients with Addison's disease who became pregnant was 35-45% (Brent, 1950), but since the introduction of replacement therapy with adrenocortical hormones and cortisone the prognosis is much better. Cases of successful pregnancy in Addison's disease have been recorded by Simpson (1946), Knowlton *et al.* (1949), Brent (1950), Richards (1952), Rolland *et al.* (1953), Lutwyche (1953), Hunt and McConahey (1953), Hendon and Melick (1955), and De Gennes *et al.* (1956). In cases reported so far in which maintenance has been by cortisone in addition to D.C.A. and salt there has been no maternal mortality and the incidence of associated complications has been much lower.

In the case now described Addison's disease was diagnosed and treatment started ten months before pregnancy occurred. The rapidity with which conception followed therapy suggests that the treatment was an important factor in the patient's fertility.

In the first trimester of pregnancy nausea, vomiting, and other gastro-intestinal disorders are more likely to occur, leading to electrolyte disturbance and thus precipitating an adrenal crisis (Brent; Hunt and McConahey; De Gennes *et al.*). In the present case there was only a slight upset at this stage, which was easily corrected. It was thought advisable to start cortisone at this point. In the second half of pregnancy in Addisonian patients there may be an increase in the remaining adrenal function which may ameliorate the adrenal insufficiency state, and substitution therapy may have to be reduced accordingly (Knowlton *et al.*; Hunt and McConahey; De Gennes *et al.*).

Before the introduction of cortisone 25-50% of patients being treated for Addison's disease had hypoglycaemic episodes (Soffer, 1946). In the present case there were no symptoms to suggest this, nor did blood sugar determination, which was carried out monthly throughout the pregnancy, give abnormal results at any time. During labour the added stress of physical exertion, haemorrhage, pain, surgical intervention, and anaesthesia may be too great, and in the early puerperium the physiological diuresis with excretion of sodium, and the removal of adrenal hormones provided by the foetal adrenals, may lead to development of an Addisonian crisis (Knowlton *et al.*; Brent; De Gennes *et al.*). Immediately before delivery, therefore, the patient should be treated as for an impending crisis and every measure taken to avoid undue stress. In this case the dosage of cortisone was increased before delivery and the second stage of labour curtailed by the application of low forceps under regional block analgesia with minimal sedation.

Before the advent of cortisone lactation rarely occurred in these cases, and it has been suggested (Rowntree and Snell, 1931) that this might be due to atrophy of the mammary glands. Breast-feeding used to be forbidden, as it acted as an additional stress on the already deficient metabolism of the mother. There are earlier reports of lactation being artificially suppressed, but with adequate replacement therapy successful lactation is possible without great risk to the mother (Lutwyche, 1953). In the present case lactation was successful, and was artificially suppressed only because of technical difficulties.

Hypertension, cardiac failure, oedema, or potassium deficiency may occur from overdosage with D.C.A., and such symptoms arising in the latter half of pregnancy might lead to confusion with pregnancy toxemia (Brent). Alterations in blood chemistry and disappearance of symptoms on withholding steroid therapy for a few days will assist the differential diagnosis. Hence it is preferable at this stage to give short-term daily injections of D.C.A. rather than such long-term therapy as pellet implantation or trimethyl deoxycorticosterone injections. Theoretically less D.C.A. should be needed in the second and third trimesters because of the adrenal hormones supplied by the foetal adrenals and the high level of circulating sex hormones, which also have a salt-retaining effect (Soffer, 1946; Samuels *et al.*, 1943; Knowlton *et al.*, 1950). However, in the present case an increased dosage of D.C.A. was necessary during this period.

Signs of steroid overdosage appeared two weeks after the puerperium, but responded well to withdrawal of treatment for a week, after which a maintenance dose of D.C.A. and salt was easily achieved. Three weeks later the patient was discharged from hospital. Mother and child are both doing well.

I am grateful to Dr. I. Gilbert, consultant physician, and Dr. R. Crawford, consultant obstetrician, under whose supervision the patient was treated, for their permission to report this case.

M. M. SINGH, M.R.C.P.,
St. Andrew's Hospital, Billericay, Essex.

Reviews

BRITISH SURGERY

Operative Surgery. Under the general editorship of Charles Rob, M.C., M.Chir., F.R.C.S., and Rodney Smith, M.S., F.R.C.S. (Volume I—Introductory, Surgery of Trauma, Abdomen (Part); Volume II—Abdomen (Completion). £5 10s. per volume. Index to all eight volumes £2.) London: Butterworth and Co. (Publishers) Ltd. 1956.

In the introduction to this work the editors wisely state that the best way to learn how to operate is to act as assistant to a master of the craft. Failing that, the next best way is to learn from a well-illustrated account of the various operations. In such an account the emphasis may be greater either on the written description or on the pictorial representation. In these superb volumes, which are but the advance-guard of a monumental series, the emphasis is purposely laid on the illustrations, which are very numerous. The descriptive part is just sufficient to give a connected account of the operative procedures. When complete this will be the most elaborate and ambitious work of its kind ever published in Great Britain.

The general editorship has been undertaken by two distinguished surgeons, who have as associate editors men whose names are a guarantee of good judgment. The contributors have been selected because of their special skill or interest in a particular subject; they form a representative cross-section of the younger school of surgeons throughout Britain. An interesting editorial problem is mentioned in the introduction. Each contributor was asked to describe those methods which he had found most efficient; on certain occasions the two chief editors felt "a certain disapproval," but left the matter to the expert. As to which particular methods their remark applies to they discreetly keep silence.

The first volume, after an introductory section dealing with technique and about 100 pages given to the surgery of trauma, is chiefly devoted to gastric surgery; Norman Tanner deals with partial gastrectomy and with gastrectomy for cancer, while Professor Rob describes the operation of vagotomy. Volume II deals with the surgery of the small and large intestines, the pancreas, spleen, liver, and bile passages. As might be expected, Rodney Smith contributes the section dealing with pancreatotomy, and we note that he received a personal communication from that master of technique, Cattell.

In a short review there is no space for a detailed survey of all the contributions. Suffice it to say that the illustrations, which come from many artists, reach a high standard, and the whole production provides a welcome testimony to the authoritative place which British surgery has attained. We look forward to the succeeding volumes with great expectation.

ZACHARY COPE.

ANAESTHETIC ACCIDENTS

Anaesthetic Accidents. By V. Keating, M.B., B.Ch., D.A., F.F.A.R.C.S. (Pp. 261+vi; illustrated. 25s.) London: Lloyd-Luke (Medical Books) Ltd. 1956.

The reports on anaesthetic deaths recently published under the auspices of the Association of Anaesthetists have pointed in no uncertain manner the way in which these and other less serious preventable accidents occur. Not only anaesthetists but also medical practitioners in general, and both nursing and lay administrators, are taking a very close interest in this matter. Any book on this subject is therefore topical and will be read widely with critical eyes.

Keating's book is a scholarly and up-to-date account of anaesthetic accidents, in what might be called the classical manner. Thus pride of place is given to the circulatory and respiratory accidents, and these are discussed fully from the pharmacological and physiological aspects. Pulmonary and neurological complications and those due to intravenous and spinal anaesthesia follow and are all treated at length.

Further chapters deal with endotracheal anaesthesia, posture, and the relaxants, while a few remarks are included on explosions, safety precautions in general, and medico-legal considerations. The emphasis, however, might have been different. Inhalation of vomit, for example, is more important as a preventable cause of death and morbidity than primary cardiac arrest: a future edition should include vomiting in the index. The more traditional arrangement of the text used here is an orderly one, and is helpful in what is essentially a book for those studying for examinations and for those who seek for references to the literature on the complications of anaesthesia. Illustrations are not a strong point, there being only 13 simple line drawings, though these are very helpful as far as they go.

For anyone who really wants to get to practical grips with the problem of anaesthetic accidents and deaths the reports of the Association of Anaesthetists should be a first choice. For more leisurely study of the complications from an academic point of view Keating's book is invaluable and its place on the library shelf assured.

W. W. MUSHIN.

PRACTICAL UROLOGY

Practical Urology. Case-Comments and Late Results. By Alex. E. Roche, M.A., M.D., M.Ch., F.R.C.S. (Pp. 258+xii; illustrated. 35s.) London: H. K. Lewis and Co. Ltd. 1956.

This short, very readable volume describes the clinical and radiological aspects of 51 urological cases, some of them typical. The symptoms in each are presented first, and are followed by the clinical and pathological details, also the after-history and the late result when it is known. The work is entirely from the experience of the author, with no references to the literature. A commentary is usually given in which the writer emphasizes various principles of urological diagnosis which the case illustrates, with details of the pathology of the condition or variations which may occur in the symptoms and physical signs, often flavoured with his well-known humour or adorned with classic quotation. Among the cases described are a number of renal, ureteric, and vesical calculi, in their many clinical variations. Several cases of renal tumour, renal tuberculosis, and hydro-nephrosis of special interest, congenital lesions of the upper urinary tract, and a few rarities such as aneurysms of the renal artery, are also included. Only about one-fifth of the reports relate to diseases of the bladder, prostate, and urethra, so that the emphasis is on diseases of the upper urinary tract, in which radiographic diagnostic aids are so valuable. There is no pretence at over-elaboration in the method of investigation by techniques such as aortography, but a simple, straightforward, over-all picture in each instance is given. The reports contain much surgical wisdom presented in a way easy to remember.

The book is a valuable and interesting ancillary to the standard textbooks of urology. In addition to being of use to the urologist, the radiologist, and the general surgeon, it should be of help to senior students and to general practitioners. It is well produced, and the illustrations in general are good.

L. N. PYRAH.

FREUDIAN PSYCHOLOGY

A Primer of Freudian Psychology. By Calvin S. Hall. (Pp. 137+xii. 13s. 6d.) London: George Allen and Unwin Ltd. 1956.

The author of this primer, who is a professor of psychology in Ohio, has grasped the fact that the importance of Freudian psychology lies in its formulation of a theory of mind which is relevant to normal as well as to abnormal psychology. It has seemed to him, therefore, a good idea to extract from Freud's writings such passages as deal with normal mental function, to paraphrase them so far as possible in non-technical language, and so to build up an outline of normal psychology suitable at the same time for university students and for the general reader. The risks of this procedure, of which the author is well aware, are that in the work of

collation, paraphrase, and exposition the substance of the original texts may be distorted by faulty definition, lack of precise understanding, and defects in the balance of presentation. In his preface Professor Hall expresses the hope that he has been able to escape such errors of commission or omission; and up to a point—as where he quotes directly from Freud or holds closely to the original texts—he has achieved some measure of success. This is offset, however, by a considerable number of theoretical misprisions; also by the fact that his illustrations are drawn largely from the field of preconscious rather than that of unconscious psychology—a labour-saving but often misleading device. It would be invidious in a short notice to single out and argue particular examples of misunderstanding of Freudian definitions; and perhaps it is sufficient to say that, while the primer may serve the purposes of the university student, who needs no more than a smattering of psycho-analysis, it would not do for any accredited student of the subject. The general reader would in any case do better to study some of Freud's own hornbooks, even if these are concerned with abnormal as well as normal psychology.

EDWARD GLOVER.

CURRENT CONCEPTS OF PSYCHOTHERAPY

Contemporary Psychotherapists Examine Themselves. By Werner Wolff, Ph.D. (Pp. 299+xvii. 51s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1956.

The author states in his preface: "The present study is a consideration of the status of psychotherapy as viewed by the adherents of various schools. The tremendous growth of psychotherapy in our time has resulted in a need for clear information on the basic differences, goals, and successes of the various schools of therapy." The method employed was a "guided interview" based upon the answers given to an elaborate questionnaire. Of the 50 psychotherapists approached 43 responded, the majority it would seem with alacrity. Specimen interviews fill the major part of the book.

The author concludes that "the present survey seems to indicate that contemporary psychotherapists recognize that psychotherapy is in a state of fermentation and development." Put more bluntly, they disagreed on most of the wide issues put before them. It is, however, interesting to note among "major trends": (1) The desirable length of treatment on the average was held to be one to two years with two or three sessions a week. (2) Directive and didactic as opposed to a more passive approach was becoming more common. (3) "The average rate of cure was: full cure in 15-20% of patients, improvement in 20-50%, and failure in 15-20%." (4) Psychotherapists found they got their best results with neuroses and hysterias, were less effective with phobias, psychopaths, and delinquents, and least effective with psychotics, obsessionals, and homosexuals. (5) "Very few definite statements concerning the permanency of cures were made. The reason was a lack of systematic follow-up studies. Only 10% of our interviewees made a systematic follow-up of their cases; 34% made an occasional follow-up of their patients; 34% stated that they left the initiative to their patients; and 22% did not care for a follow-up." The reply given by Dr. Joseph Wortis to the question: "Which type of psychotherapy do you think is best and why?" illustrates the difficulties and may commend itself to many:

"Before answering this question, it would be well to define our terms. Psychotherapy, according to my dictionary, is 'treatment of disease, especially nervous disorders, by psychological means.' Unfortunately, however, we do not all agree on what disease and treatment mean. I would like to say at the outset that I cannot accept a definition of nervous and mental disease that includes practically every kind of disorder or discontent and involves almost all humanity.

"I also think it would be better if we did not use a concept of treatment that includes every kind of real

and sensible advice, insight, and help that can be held out to troubled people. I should prefer, from a practical point of view, to limit the concept of disease to the relatively few kinds of disorders that draw on the specific technical equipment of physicians. Unfortunately, however, so large a section of our educated population has been persuaded that the way to achieve personal happiness is through psychotherapy that all private practising psychiatrists, including myself, are called upon to 'treat' people who for one or another reason are very unhappy but by no means diseased. From this point of view, psychiatry has nowadays spread itself out too far and taken on a bigger piece of human discontent than it can ever handle. To say nothing of eliminate. Unless psychiatrists make a distinction between the common or garden variety of unhappiness encountered in our society and bona-fide psychiatric disease, they will be contributing to the current confusion."

DESMOND CURRAN.

The publishers of *Blakiston's New Gould Medical Dictionary* say that 12,000 new terms have been added and 8,000 changes made for the second edition of this 1,463-page dictionary. Some of these are of surprisingly recent introduction for a work of this kind, which includes, for example, meprobamate, prednisone, and penicillin V. The proprietary names of many drugs are also included, though whether a dictionary is the place for them seems questionable. The spelling is American, so that "hematology," for instance, is only to be found so spelt. But the range of words and proper names is commendably international; even the names of living Englishmen appear—among them Geoffrey Hadfield, Sir Leonard Rogers, and F. Parkes Ltd. for 86s. 6d.

About 500 tables in *Handbook of Biological Data* list the measurable attributes of a very wide range of plants and animals, including man. The data include such variables as nutrient requirements, biochemical changes, composition of tissues, chromosome numbers, environmental effects on living creatures, and taxonomic classifications. It is edited by W. D. Spector for the American National Academy of Sciences-National Research Council, and published by W. B. Saunders for 52s. 6d.

The third edition of *List of Films on Human and Comparative Parasitology* has now been compiled under the aegis of the International Scientific Film Association and published by its Netherlands branch. The catalogue includes all the known films on the subject. The third edition has an index according to the general classification of parasites, simplified for the purpose of the list. The information is given under countries; the films available from each country are listed, together with a short description of the subject matter, type of photography, running time, and address from which it is obtainable. Nineteen countries are represented. The catalogue is obtainable from the Hon. Treasurer, Netherland Scientific Film Association, Catharijnesingel 59, ingang Sterrenbos, Utrecht, Holland, price 10s.

In their *Textbook of Physiology and Biochemistry* Professors G. H. Bell, J. N. Davidson, and H. Scarborough give students the conjoined experience of a physiologist, a biochemist, and a clinician. First issued in 1950, the book has gone through a second edition, been twice reprinted, and now reached a third edition. The demand for it is thus evident, and so that it may continue to be adequately satisfied the authors have made considerable alterations to keep the book abreast of recent developments. Text and illustrations remain admirably clear. This fine standard work is published by E. and S. Livingstone Ltd. for 60s.

Professor Alan Moncrieff's booklet *Infant Feeding* was described in these columns as "a clear and practical account, based on much experience," when it first appeared in 1940. Since then it has been reprinted eight times and has now been revised by the author for a second edition. He briefly describes the principles and practice of breast-feeding, artificial feeding, and feeding the premature infant, combining a useful array of detailed instructions with the injunction set out in the preface "to regard each baby as an individual with his or her own ideas about feeding times and quantities." Young doctors, whether in hospital or general practice, will find much worth learning in this booklet. Edward Arnold Ltd. publish it for 2s.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY MARCH 2 1957

THROUGH THE LOOKING-GLASS

In a leading article which went to press before the profession's negotiators on Wednesday last week met the Minister of Health, Mr. D. F. Vosper, we said that if the Government refused, through him, to admit the validity of the Spens recommendations "relations between it and the profession will be at breaking point." The breaking point has been reached. The Government has repudiated the Spens reports, reports drawn up to decide the basis of remuneration of consultants and specialists and of general practitioners in a publicly organized medical service, reports accepted by both Government and profession, the terms of which satisfied doctors that, in a National Health Service they for the most part disliked, their status would be preserved and their remuneration adjusted to the changing value of money. Once doctors were safely inside the Health Service Ministers of Health have tried to avoid honouring their obligation to a nationalized profession. Their efforts were rudely shaken when an independent adjudicator, Mr. Justice Danckwerts, made an award to general practitioners in 1952 based on the Spens formula. Just a year ago the then Minister of Health, Mr. R. H. Turton, was informed that a further claim would be made during 1956, and the profession's negotiators, under the combined chairmanship of Sir Russell Brain for the consultants and Dr. A. Talbot Rogers for the general practitioners, presented their claim in June. They took expert economic and statistical advice before arriving at a betterment factor of 24%. As the Minister denied that the Government had a contractual obligation to honour the terms of the Spens reports our negotiators sought the legal advice of Sir James Millard Tucker on this point. His careful analysis of the situation was presented to the Minister of Health in a cogent document of some 6,000 words. The reply to this was a curt rebuttal in a letter of 94 words from Sir John Hawton, the Permanent Secretary of the Ministry of Health, which in effect said: "We don't agree with you. Test it in the courts." The reply was unmannerly in its curtness. In the Government reshuffle under Mr. Macmillan Mr. Turton was replaced by Mr. Vosper, and

last week the Prime Minister took the matter out of Mr. Vosper's hands by recommending the Queen to set up a Royal Commission to inquire into doctors' pay. The *Manchester Guardian* describes this "as quite the wrong instrument for this task." If Mr. Macmillan had given a small advance without prejudice to the major claim and had proposed a Royal Commission on the working and structure of the Health Service generally he would have stood on firm ground, the *Guardian* states, concluding thus: "Now we face a quagmire." It is all a very sad story of evasion and subterfuge, of political expediency, and of double dealing. At any one time during the past years any one of many Ministers of Health could have said: "We don't think the Spens formula and the methods of applying it are really satisfactory. Let's have a look at it together to see if anything more suitable and more practicable can be worked out." But such a straightforward and simple approach seems uncongenial to the political mind and not complicated enough for the civil servant. All they could do was to repeat the White Queen's dictum: "The rule is, jam to-morrow and jam yesterday—but never jam to-day." As we go to press we learn that Mr. Macmillan, in a letter to the Negotiating Committee's chairmen, says that a Royal Commission "does not preclude some interim adjustment." As Alice observed: "It *must* come sometimes to jam to-day."

The White Queen might have been bluffing, but the Chairman of Council, Dr. S. Wand, in an admirably firm reply to the Editor of *Truth* in a broadcast last week made it plain that the medical profession is not, in its present attitude to the Government's attitude. Dr. Wand repeated what he told the General Medical Services Committee last Thursday: the Minister of Health had admitted to the negotiators that "No one can dispute that there is justice in an increase for the doctors." And at the same meeting of the G.M.S. Committee Dr. Wand recalled that in the course of the negotiations with the Ministry of Health in 1950 the Minister of Health had admitted the validity of the Spens formula. The actual words used by the Secretary of the Ministry, in a letter to the B.M.A., were as follows (May 2, 1950): "*The Minister agrees that the Spens Report remains the basis of the remuneration of general medical practitioners until such time as after the usual consultations some other basis is substituted.*" (Our italics.) The Prime Minister's decision to set up a Royal Commission—"some other basis"—has been reached without any consultation. Therefore the Spens report remains the basis of the remuneration of general practitioners, and surely, too, of consultants and specialists, and of hospital staff. The affinity of the

Ministers and the Ministry to the White Queen in *Through the Looking-Glass* is remarkably close.

"It is a poor sort of memory that only works backwards," the Queen remarked.

"What sort of things do you remember best?" Alice ventured to ask.

"Oh, things that happened the week after next," the Queen replied in a careless tone.

What is going to happen the week after next?—a Royal Commission, which is to consider the pay of doctors and dentists and possibly of medical auxiliaries, and "the position of the medical profession in relation to other professional classes in the community." The terms of reference of the Royal Commission have not been announced, nor its composition, but the terms will presumably include what the Prime Minister said would be opportune for an inquiry to embrace: an inquiry wide enough to last two or three years. In the meanwhile, our negotiators were informed last week that the Government are willing to instruct the management side of Whitley Committee B to agree to an interim increase to junior medical staff and dental staff in hospitals. And presumably the management side will be instructed that the increase will be determined "by all relevant factors" and not by the terms of the consultant Spens report. The farce of negotiation with the staff side will be duly conducted but with one side acting on instructions from which it will not dare to budge: it will be conducted "Through the Looking-Glass."

ACTION AND REACTION

The reaction of the G.M.S. Committee to the action of the Minister of Health and the Prime Minister was the same as that of those negotiating for both consultants and general practitioners—anger and distrust. As our report in this week's *Supplement* shows, the G.M.S. Committee seized upon the one essential point in this grave crisis: it is nothing more nor less than the fate of an ancient and learned profession which, trusting in a Government's word, allowed itself to become nationalized in a State-provided medical service. It is not a question of this per cent. or that per cent. in the doctors' pay. The Chairman of Council made this plain in his broadcast last week when he said, to quote *The Times* report, "that if an adjudicator, who ought to be a judge, produced a fair figure in response to the doctors' pay claim, the doctors would accept it." The G.M.S. Committee had no doubt at all that the Spens reports, accepted by the Governments of 1946 and 1948 and by the Minister of Health in 1950, gave the profession a charter of rights in the hazardous experiment of a National Health Service. Without such a charter it would have been folly to

enter the Service. Without such a charter it will be folly to continue in it. That is why the G.M.S. Committee is recommending to a special conference of local medical committees that, "unless the Government agrees to an immediate and satisfactory settlement of the profession's claim or to arbitration, general practitioners throughout the country will be advised to send in their resignations from the Service." The Public Health Committee of the B.M.A. last week resolved to back up their colleagues in the present struggle. The Joint Consultants Committee met on Thursday this week and the Council of the B.M.A. had a special meeting on the same day. Sir Russell Brain informed *The Times* last week that the work of the hospitals will not be interrupted, and that the Committee of which he is chairman "will consider what other action they can most usefully take in support of the claim." General practitioners will, of course, also continue to look after their patients, but if this has to be done outside the present N.H.S. it will be according to a scheme the details of which will be made public at the appropriate time. Hospital staffs cannot provide an alternative scheme, because they have to work in hospitals owned by the State. *The Times* of February 23 gave reports from different parts of the country which showed, for example, that doctors in Wales and Scotland, Birmingham, Manchester, Liverpool, Plymouth, Leicester, were behind the B.M.A. in this crisis: "The doctors' trust in the Government has been badly shaken . . . feelings were running very high among Manchester doctors. . . . There seemed little doubt yesterday that very few Scottish areas would fail to respond to the B.M.A. lead—even Edinburgh, a traditionally conservative city in every way, being highly dissatisfied, according to local opinion, with the Government's attitude to the salary claim," *The Times* reports. The same story is told over and over again in the provincial press.

The medical profession to-day is 24% worse off than it was in 1951, and insists upon some readjustment of pay according to the Spens formula. It insists upon sticking to a principle. The Government rejects the principle and seeks for an expedient. This has brought to a head present discontents with many aspects of Britain's National Health Service. Young men are finding it difficult to enter general practice; the frustrated and overworked general practitioner unloads some—and at times much—of his clinical burden on to hospitals; senior registrars are frozen in their jobs and see little prospect of advancing to more responsible positions. Many have emigrated and many are considering this course. All are deeply disturbed at the way Medicine has got mixed up in politics, and long to see it freed from this unnatural

embrace. Dr. Wand gave expression to this when he said to the G.M.S. Committee last week:

"I am going to ask you, and this is a very serious question, that we have to consider very carefully, not merely whether we can go on working for such an employer now, but whether we can go on working for such an employer in the more distant future. The whole basis on which doctors enter service of this kind depends on trust. Can we any longer trust the Government? If we cannot trust the Government it is not a matter of resigning now, it is a matter of saying we will have nothing to do with any service which is run by any Government; that is, as I see it, the issue before us. The issue is no longer one only of remuneration for the immediate future. . . ."

Before it is too late, as many correspondents suggest, a Health Service might be moulded into a structure within which doctors could work contentedly and so be able to give of their best to the community they live in and care for. There is far more to be settled than the present claim for the fulfilment of the Spens recommendations. That must be settled first. But after that has been done, many consider that the N.H.S. must be overhauled if Medicine is to continue to be a calling and a profession which will attract men and women able to make a valuable contribution to the art and science of Medicine in practice and research.

ANAEMIA IN RHEUMATOID ARTHRITIS

Anaemia is a frequent accompaniment of many chronic diseases not primarily or obviously affecting the haemopoietic system. Thus, chronic renal and hepatic disease, disseminated cancer, and chronic infections are all usually associated with secondary anaemia. Secondary anaemia is also found in rheumatoid arthritis, particularly in patients with active disease, but despite its frequency the exact mechanism of its production is uncertain. Its pathogenesis is undoubtedly complex—which is also true of other secondary anaemias—for not only is the production of red cells impaired but their life-span is shortened. In addition, some patients appear to suffer from genuine iron deficiency. The relevant literature is summarized in three recent papers.¹⁻³

The typical anaemia of rheumatoid arthritis differs significantly from that of true iron deficiency, although there are some similarities. The red cells are normocytic rather than microcytic,⁴⁻⁷ and there is less anisopoikilocytosis than in iron deficiency; similarly, the haemoglobin concentration is reduced,^{4-6,7} but not to the same extent as in iron deficiency; the same is true of the serum-iron level.⁷ The total iron-binding capacity of the serum (siderophyllin content) is normal in rheumatoid arthritis,⁷ but typically increased in

iron deficiency. The free erythrocyte protoporphyrin is usually increased.⁸ These findings, and the unusually rapid clearance from the plasma of iron injected intravenously,⁹ are similar to those found in anaemia associated with infection, in which an increased demand for iron by the tissues has been postulated.⁸ J. J. R. Duthie and his colleagues¹ suggest that extensive tissue damage may be the common factor. The low levels of serum iron cannot be accounted for by impaired absorption.¹ That simple iron deficiency—due to failure of absorption or loss of blood—is not an important aetiological factor is shown by the fact that the haemoglobin levels of only a minority of patients can be improved by oral iron; it is possible that genuine iron deficiency plays a part in causing the anaemia in such patients. Intravenous iron therapy with saccharated iron oxide is a more successful treatment^{5,10,11}; nevertheless, the blood picture seldom returns to normal in patients with active rheumatic disease. The reason for the superiority of intravenous over oral therapy is unknown.

The haemolytic aspect of the anaemia has received attention from several groups of workers.^{2,9,12,13} The classical signs of haemolysis are usually lacking; that is, the concentration of serum bilirubin is not raised, and the excretion of urobilinogen in the faeces is not often demonstrably increased,^{6,7} while the reticulocyte count is usually less than 2%. These apparent anomalies are due in part to the fact that destruction of red cells is only slightly to moderately increased in rate, as a rule not more than three to four times the normal. The greatest increase in destruction of red cells is found in patients whose rheumatoid arthritis is active and progressive. Even so, the degree of excess destruction would not lead to anaemia unless the function of the marrow was impaired; W. H. Crosby and J. H. Akeroyd¹⁴ calculated that healthy bone marrow was capable of a sixfold increase in haemopoiesis and haemoglobin formation. The cause of the shortened life of the red cells is obscure. There is no evidence of an immune mechanism for the haemolysis; the direct antiglobulin test is typically negative.

¹⁴ McCrea, P. C., quoted by Mollison, P. L., *Blood Transfusion in Clinical Medicine*, 2nd ed., 1956, p. 168, Oxford.

The evidence for a defect in the function of the bone marrow in cases of rheumatoid arthritis has recently been summarized.³ Microscopical studies on the marrow revealed no striking abnormalities. Iron, detected by the Prussian blue reaction or other chemical means, was present in the majority of marrows (69% of 61 samples) despite the hypochromia of the red cells in the peripheral blood. The cellularity of the marrow was generally normal, with the normoblast count ranging from 10.0 to 46.8%. In only 16 of the 61 marrow samples did the percentage of normoblasts exceed the normal range; this observation is in accord with the peripheral reticulocyte count being normal or only slightly raised. The only other abnormality was a slight excess of plasma cells in 35% of the cases. This could be correlated directly with the concentration of serum globulins. Duthie and his colleagues conclude,³ in agreement with E. J. Freireich and co-workers,⁹ that the anaemia cannot be explained by a deficiency of iron or by haemolysis. It is caused rather by the inability of the marrow to increase the rate of erythropoiesis above the normal level. This in some mysterious way is brought about by the patient's underlying disease.

QUINQUAGENARY OF THE M.I.A.

During the coming week the Medical Insurance Agency, which has its headquarters in B.M.A. House, is celebrating its fiftieth anniversary. Its genesis was a conversation during lunch between the editors of the *British Medical Journal* and of the *Lancet*, Dr. (later Sir) Dawson Williams and Dr. (later Sir) Squire Sprigge. They took notice of the size of the commission paid by an insurance office to the agent through whom a medical man had taken out a large life assurance policy. If such commissions could go to an agency which would arrange policies with most suitable terms for doctors, and if the insured could receive rebates and medical charities the surpluses left over, the benefits of such an enterprise would be kept within the medical profession: this was the idea Dawson Williams and Squire Sprigge had. Early in 1907 Dawson Williams accordingly persuaded the Journal and Finance Committee of the B.M.A. to consider a scheme which would enable doctors to insure against their risks under the Workmen's Compensation Act of 1906. The first meeting of the Insurance Committee met on March 7, 1907, and the minutes of this meeting were headed British Medical Association Medical Insurance Committee, with the first three words scored through with red ink. It was decided, in fact, that the Committee should be independent of the B.M.A., but the Council of the Association promised to assist in any way it

could "the proposed scheme for an Insurance Agency." In November, 1913, the Committee changed its name to the Medical Insurance Agency, so that it should not be confounded with the committees under the National Insurance Act. For many years now it has been known familiarly to thousands of medical men simply as "The M.I.A."

Some idea of its growth and of its great donations to medical charities may be gathered from the following figures. The premiums collected by the agency in 1907 amounted to £1,400; in 1921 to £31,000; in 1936 to £280,000; and in 1956 to more than £2,000,000. In 1909 the Agency gave £47 to medical charities; in 1946, £4,980; and the annual donations since 1951 have been between £23,000 and £25,000. These remarkable results illustrate the growth of confidence of the medical profession in the M.I.A., and *pari passu* with this the increased efficiency of a management whose expertness in the field of insurance has been matched with great integrity in the conduct of business. Many distinguished medical men have acted as chairmen of the M.I.A., but it would not be invidious here to mention the impetus given to its development when Dr. Henry Robinson became Honorary Secretary of the M.I.A. in 1938—as he still is. He made it his first job to secure for the M.I.A. the services of a properly trained expert in insurance, and Mr. A. N. Dixon, now the general manager, was appointed in this capacity. The remarkable expansion of the business of the M.I.A., with its benefits to doctors and medical charities, owes much to these two men. From a single office in the B.M.A.'s premises in the Strand the agency has grown to departmental dimensions in B.M.A. House with branches in many English cities, in Scotland, Wales, and Eire. The two men from whose minds the idea of the M.I.A. sprang are commemorated by a Dawson Williams Scholarship for boys at Epsom College and a Squire Sprigge Fund for orphan girls, both established and endowed by the M.I.A. The M.I.A. to-day is a magnificent monument to the practical wisdom of two medical editors.

CONGENITAL INDIFFERENCE TO PAIN

An otherwise normal person may have a congenital indifference to pain. The condition may pass unrecognized for many years, parents simply congratulating themselves on an unusually stoical child. In other cases some accident which ought to cause pain may occur early in life and the child's behaviour be so unexpected as to lead to the diagnosis. Tests to a full range of painful stimuli will then reveal that they are not appreciated as painful. In some cases some slight element of pain may be experienced, as E. C. O. Jewesbury¹ and others have found, but appreciation is so slight as to be in striking

contrast to that of a normal individual. In equally great contrast is the almost normal appreciation of sharp and blunt and hot and cold sensations—the primary elements of classical "spinothalamic" sensation. Once the condition is recognized, there is usually plenty of confirmatory evidence that it has been present for some time. Thus many and extensive scars, old fractures, often ununited and malunited, or traumatic arthropathies, even to the extent of a fully developed Charcot joint, may be present. In the majority of such cases other modes of sensation are entirely normal, and intelligence is well preserved. Behaviour is altered only in so far as reaction to pain is concerned.

There is another and larger group of individuals who also show indifference to pain. The condition is here part of a more general mental defect, and will fairly commonly be found if looked for in mental deficiency hospitals. The disadvantages and slight advantages of the condition are well illustrated in this setting. The diagnosis of severe disease can be made much more difficult by the absence of reaction to pain, and the onset of major catastrophes may pass unnoticed. On the other hand, the patient bears without apprehension a course of treatment entailing frequent painful injections. In this group the unusual reaction to pain is rightly regarded as dependent on the known structural abnormalities of the central nervous system which accompany mental defect. But in the first group, for which the term congenital indifference to pain should be reserved, the problem of what neurological deficit exists is a fascinating and unsolved one. What evidence there is does not suggest any peripheral abnormality.

At the central end of the pain mechanism two conditions have some similarities to this. The lesion of frontal leucotomy is sometimes used to produce an indifference to pain when it is severe and caused by irremediable disease such as carcinomatosis. But here the picture differs in an important respect. After leucotomy the apprehension of pain to come—so important a part of the suffering in chronic recurrent pain—is abolished and the clinical benefit may be enormous. Yet the immediate reaction to pain may not be reduced; indeed, it may sometimes be enhanced by the uninhibited behaviour that follows this operation. The other condition which may provide a clue is one described by P. Schilder and E. Stengel² as "asymbolia for pain." In this a condition of indifference to pain occurs in adult life, probably as a result of lesions in the posterior parietal region of the dominant hemisphere, and is commonly associated with dysphasic difficulties. A congenital defect in the same cortical area could account for the cases with an innate indifference. This argument is strengthened by the occasional report of other agnosias in association with congenital indifference to pain. For the time being this is perhaps the most satisfactory explanation, and we may tentatively regard the condition as one form of limited congenital agnosia. This is to some extent simply cloaking our ignorance in fine language, since the detailed cerebral abnormalities

(anatomical and physiological) in all these conditions are largely unknown. While they remain a matter for further investigation, the removal of all pain experience from an individual's life suggests interesting avenues of speculation. In the words of Macdonald Critchley, who with his flair for the neurological borderland has several times discussed this condition,³⁻⁵ "the subject may well prove to be richer and still more rewarding to the psychologist and also to the philosopher."

DANGERS OF CHICKEN-POX

Chicken-pox is one of the most benign diseases. It seldom provides interest for the clinician or the epidemiologist, nor stimulus to the specialist in preventive medicine. Children are expected to contract the infection before or during their schooldays, and generally there seems little reason to prevent this from happening. Complications are uncommon, often taking the form of skin sepsis or respiratory infections as a result of secondary invasion by staphylococci or streptococci, but they are seldom serious. Neurological lesions such as encephalitis, myelitis, and polyneuritis are rarely encountered but carry a mortality of 10%, coma and convulsions being the two signs of most serious omen.¹

Primary chicken-pox pneumonia has been described on few occasions, but is fully discussed in two recent papers,^{2,3} one of which gives details of 16 cases seen in Boston, Massachusetts. The condition is an interesting one and could easily be overlooked or ascribed to secondary pneumonia. In nearly all cases the rash is widespread if not actually confluent, and many vesicles are present in the mouth and pharynx. Within five days of the appearance of the rash the patient, usually an adult, develops a distressing cough productive of a little blood-streaked sputum, and may be critically ill. The temperature, which is high at the onset, settles by lysis after one or two weeks. Antibiotics do not influence the course of the disease but probably help to prevent secondary infection. The radiological changes in the lungs are remarkably typical. There are widespread nodular shadows, rather larger than those seen in miliary tuberculosis, superimposed on increased lung markings. Rapid changes can be followed in serial radiographs, some lesions resolving while new ones appear. There is no lobular consolidation or collapse. Resolution in most cases is complete within two weeks. In general the patients with the severest skin lesions develop the most marked radiological changes, but even then the physical signs in the lungs are few. There were no deaths in the Boston series, but the authors refer to reports of four fatal cases in which the histological appearances were in keeping with a virus infection. Similar lung changes associated with widespread visceral lesions have also been found in newborn infants when the infection has started *in utero*.⁴

There has recently been evidence, also from Boston,

that varicella may become a diffuse fulminating infection in a patient who is receiving cortisone.⁵ After seeing two such cases in two years R. J. Haggerty and R. C. Eley suspected something more than a coincidence and sought further information. Inquiries directed to sixty-five physicians in the United States, Canada, and England brought to light ten similar fatalities. The ages of children affected ranged from eleven months to eight years, and they had received cortisone for periods of a few days to two months. Other patients receiving cortisone had severe skin lesions, or an atypical rash making early diagnosis difficult. Although varicella sometimes takes an uneventful course in spite of the administration of cortisone the Americans now advise the rapid withdrawal of such treatment from susceptible children who have been exposed to the infection. These observations may be difficult to explain but should be widely known, for the use of cortisone is increasing and chicken-pox is ubiquitous.

PYROGENS AND FEVER

The process by which fever is produced has puzzled clinicians since the earliest days of medicine. With the advent of the bacteriological era it soon became apparent that fever was usually the result of microbial infection. But the frequency with which a febrile response is associated with infarction, internal haemorrhage, and trauma, even when uncomplicated by microbial infection, emphasizes that infection is by no means the whole story. The parenteral introduction into the body of warm-blooded animals not only of bacteria, dead or alive, but of almost any foreign protein is nearly always followed by a rise in body temperature. A single explanation of these diverse observations postulates that the ultimate stimulus to the heat-regulating centres in the hypothalamus is an endogenous substance resulting from cellular or tissue injury.

V. Menkin, who has done so much to formulate a dynamic concept of inflammation, has isolated from sterile inflammatory exudates a series of substances capable of eliciting more or less separately the various components of the inflammatory reaction, including the development of fever.¹ To the substance so isolated, which causes a distinct rise of temperature when injected into experimental animals, he has given the name pyrexin. More recently two non-protein substances of bacterial origin have been widely used in the study of experimentally induced fever. These are the polysaccharide from *Serratia marcescens*² and a lipopolysaccharide from *S. abortus equi*.³ The relationship between these substances and pyrexin is therefore of considerable interest, and Menkin himself has done much to clarify it.⁴ Not only is the intravenous injection of one of these substances followed within an hour or so by a rise in temperature of 2-3°F. (1-2°C.), but the serum of the recipient simultaneously acquires the

property of inducing a similar febrile response when injected into another animal. The serum of animals injected with pyrexin, however, does not acquire this capacity to induce a further febrile response in another recipient. Menkin has therefore suggested, on the basis of further experiments, that these pyrogens of bacterial origin do not themselves directly influence the thermoregulating centres but that an interaction in some way with the euglobulin of the plasma results in the formation of a pyrexin-like material. It is then this material in the blood stream that directly influences the regulating centres of the animal itself and can in addition similarly affect those centres in another animal when passively transferred. Much the same conclusion was reached by E. Atkins and W. B. Wood⁵ as a result of their work on the pathogenesis of the fever produced in rabbits by the injection of typhoid vaccine. Their results strongly support the view that the bacterial pyrogen excites in some way the formation of an endogenous pyrogen. Thus, if blood is withdrawn from rabbits 5 minutes and 120 minutes after the injection of the vaccine and injected into other rabbits, then the febrile response to the 120-minute sample is significantly quicker than the response to the 5-minute sample. Presumably the increased latent period with the earlier sample represents the time required for the formation of the endogenous agent.

While Menkin regards the pyrogen in sterile inflammatory exudates as arising in some way, possibly by proteolysis, from plasma euglobulin, I. L. Bennett and P. B. Beeson⁶ have produced considerable evidence that in rabbits a main source is the polymorphonuclear leucocyte. Of the many types of cell extract studied by them only extracts of these leucocytes were active. The properties of this pyrogen differ in many ways from those of pyrexin, which they suggest might well be nothing more than the result of bacterial contamination of Menkin's preparations. This contention has been convincingly rebutted in Menkin's most recent paper.⁴

Some at least of the considerable differences of opinion held by workers in this field might be due to the different methods of assessing a febrile response. Individual responses to a fixed dose of pyrogen vary not only in the height of the fever attained but in its duration. In a well-controlled experiment to determine the best method of assessing these responses F. Wendt and colleagues⁷ found no correlation between the quantity of pyrogen and the duration of the subsequent fever, but a definite correlation with the maximum height of the fever. A still better correlation was found between the dose and the area under the time-temperature response curve. This curve is simply obtained by plotting the temperature at regular intervals after the injection of the pyrogen. The coefficient of correlation between the dose and this area is 0.817, which is significantly better than the figure of 0.501 obtained for the relationship between dose and maximum height of fever. A further point of great interest in the work of Wendt and his colleagues is that it is carried out entirely on human subjects. From the experimentalist's point of view it is most gratifying to find how similar are the responses of man and animals.

UNDERWRITING SUBSTANDARD LIVES

MODERN LIFE ASSURANCE PRACTICE

The revision of underwriting standards necessitated by medical progress was the theme of Dr. K. SHIRLEY SMITH'S presidential address to the Assurance Medical Society on February 6. Speaking as a cardiologist, he dealt particularly with the creation of "substandard pools" as a means of extending life cover to those with certain well-defined types of disability, such as diabetes, hypertension, and coronary disease, without at the same time financially penalizing the "first-class life." Of all proposals for life assurance, he said, about 90% were accepted at ordinary rates, 3-4% rejected outright or postponed, and 6-7% accepted as substandard lives. In Britain in 1951 assurances on substandard lives totalled £230m.—a substantial volume of business.

How should an impaired life be translated into terms for a policy? There were many answers. In Britain the usual practice was to assess each proposer individually and to express the extra risk in terms of years added to his age: rating up by five years, for instance, corresponded to an extra mortality of about 9% when the age of entry was 30 and to about 34% when it was 50. But, unless the extra mortality due to the proposer's disability ran exactly parallel with the general mortality curve, this method of rating was unsatisfactory. Another way was to accept substandard lives in large groups or pools. There was nothing new about this. The first of the big substandard pools—for diabetics—was started in 1949 by the Mercantile and General Reinsurance Company. Since then a pool had been formed for hypertensives, which had been going for about four years, and now a coronary pool had just been begun. The premiums for those in these substandard pools were weighted so as to discount the effect of their inclusion on the with-profit policies of first-class lives.

The Coronary Pool

Into the coronary pool were accepted those with angina insufficiently severe to prevent their working, and those who had had a single coronary thrombosis. Any additional impairment excluded them.

Coronary disease was becoming a particularly acute problem for assurance companies. An increasing number of men in their sixties and seventies were seeking life cover, and often for substantial sums—in itself a factor known from mortality statistics to be associated with a higher than average mortality. A further difficulty was the importance of the history—and therefore of the proposer's frankness—in assessing a coronary case. Estimates of the long-term prognosis in angina had become increasingly optimistic during the past three decades. Last year P. D. White and his colleagues¹ in Boston had published the results of a 25-year follow-up of patients with angina, finding an average survival from onset of nearly 10 years. In those who survived longest hypertension, cardiac infarction, cardiac enlargement, and abnormal electrocardiograms were infrequent findings. During the period of follow-up the excess annual mortality of this anginal group—7% for the men and 5.3% for the women—had remained constant, and there was no difference between a younger and an older group of patients in this respect.

The Boston team had also completed a similar follow-up of 200 patients with cardiac infarction.² Thirty-eight had died within four weeks of the initial attack. Of the remaining 162 about one-half had survived for five years and one-third for 10 years; only 14% lived on for 15 years and 5% for 20 years. The best index for long-term prognosis was the degree of clinical recovery from the attack: when this was complete 56% were alive after 10 years—nearly double

¹ Richards, D. W., Bland, E. F., and White, P. D., *J. chron. Dis.*, 1956, 4, 423.

² *ibid.*, 1956, 4, 415.

³ Cole, D. R., Singian, E. B., and Katz, L. N., *Circulation*, 1954, 9, 321.

the average survival. In another important follow-up of 461 cases of cardiac infarction³ two-thirds had survived for more than five years and nearly half for more than 10 years. It was on these findings that the coronary pool was based. The other principle on which the pool was founded was the recently established fact that the long-term prognosis depended on the severity of the initial attack. Another study from Boston, of 100 patients under 40 years of age with cardiac infarction, had shown that 37 of their fathers had died from coronary attacks compared with only 18 in a matched control group, and that a heavy muscular build rather than obesity was predisposing. More notice, therefore, said Dr. Shirley Smith, should be taken of family history and build, and probably also of heavy smoking.

Outlook in Other Disabilities

Surveys in both Britain and America had revealed a striking fall in the incidence of rheumatic fever: first attacks were now only one-third as frequent as twenty years ago. There had been a corresponding drop in the mortality of children from rheumatic heart disease, but the rate for adults had not fallen. The view was now that if acute rheumatism was going to cause heart disease definite physical signs would become apparent within five years in almost every instance.

Cancer was an increasing menace. In his own recent review of 735 claims cancer had accounted for between 11 and 12%; and as a cause of claims within the first two or three years of life assurance malignant disease had been said to rank second only to road accidents. No relaxation of underwriting standards was possible here, and care was still needed if precancerous lesions such as duct papilloma of the breast or polyposis of the colon were found.

On the other side of the picture, the decline in mortality from respiratory tuberculosis was one of the most arresting developments in public health. It was not so very long ago that any personal history of the disease automatically disqualified a proposer from life assurance. Nowadays many medical officers would advise acceptance if the proposer had been symptom-free and the disease clinically inactive for five years—provided it had never been extensive. A history of pleurisy with effusion within the past five years, however, still called for a most careful appraisal.

The general relaxation of underwriting standards in many cases of peptic ulceration reflected the improvements in treatment of both the disease itself and its main complication, gastro-duodenal haemorrhage. However, gastric ulcer was still a difficult disease to assess, as freedom from symptoms did not necessarily mean cure. In spite of the increasing tendency to treat peptic ulceration surgically, the Society of Actuaries' "impairment study" in 1951 had shown a significantly lower mortality in the medically treated cases. No doubt this was due to a higher proportion of the more severe cases being included among those coming to surgery.

The widening scope of life assurance, and especially the group systems, Dr. Shirley Smith said in conclusion, not only represented a great advantage to the community but also brought the life assurance offices increasing credit.

The Common Cold Research Unit at Harvard Hospital, Salisbury, has received over 900 inquiries from prospective volunteers as a result of its appeal in January. Of the total, 844 were from people living in England, 323 of these being from London and the Home Counties. Outside this area, the largest number of inquiries, 55, came from Yorkshire. Scotland produced 35 people who showed interest, Wales 23, and Ireland only 3—one fewer, in fact, than India, from which four letters were received. One person wrote from France. Those volunteers who go to the hospital have their fares paid up to a maximum of £3, and 3s. a day pocket money for the 10 days they spend at the Unit. Not more than half the volunteers are likely to catch cold during their visit.

MEDICINE BY THE PERSIAN GULF

NEW HOSPITAL IN QATAR

On February 5 the Shaikh of Qatar, His Excellency SHAIKH ALI BIN ABDULLA THANI, opened what one experienced British observer describes as perhaps the most luxurious hospital to be found in any country. The hospital is the General Hospital at Doha, the capital of the Shaikhdom. Qatar is an oil-bearing peninsula projecting into the Persian Gulf, about 8,000 square miles (20,700 square km.) in extent, with a population of about 30,000. The oil is worked by a British company under a concession granted by the Shaikh.

Luxurious Design

The hospital, whose design was the subject of an R.I.B.A. competition some years ago, cost about £3m. to build. It has 130 beds, 44 of which are in single-bed wards. The remainder are in two-, four-, and six-bed wards. Each single-bed ward has a large verandah with a bathroom and lavatory; altogether there are 128 lavatories in the hospital. There is an isolation block, an orthopaedic wing, and a paediatric unit. The five operating theatres are equipped with the most modern fittings and surgical instruments. They are supplied with filtered dust-free sterile air from a special heating, cooling, and humidifying plant, which is controlled electronically from a switchboard in the theatre, and there is piped oxygen and nitrous oxide to the wards and theatres. First-class diagnostic and therapeutic x-ray equipment has been installed. The physiotherapy department is lavishly equipped. The pathological department comprises laboratories for biochemistry, haematology, serology, and histology. The pharmacy is equipped with electric mixers and machines for making ampoules and tablets. A small Arabic and English press prints hospital literature. There is a signalling system for summoning doctors and staff. The kitchen and laundry are exceedingly well provided, and there is even a piped supply of chilled water running everywhere in the building. The main A.C. plant to the wards is claimed to be the largest in the Middle East.

At the opening ceremony the B.M.A. was represented by Dr. IAN GRANT, who was visiting Qatar as a guest of the Government. Distinguished medical representatives had also come from Saudi Arabia; the medical faculties of Bagdad, Cairo, and Damascus; from the American University at Beirut; from Kuwait, Bahrain, and the Lebanon. And there were also the medical officers of the local oil companies.

Health in a Desert Community

The Shaikh of Qatar deems himself the Father of his People, and regards it as his duty to promote a very high standard of health in his country. Already almost 100% of the population have been vaccinated. All the children have had B.C.G. vaccination, and mass miniature radiography of the whole population is being done; so far over 6,000 persons have been x-rayed. The incidence of tuberculosis in this sample was 12 per 1,000. At present all active cases of tuberculosis amongst the native population are sent to a sanatorium in the Lebanon, but plans are afoot to build a 60-bed sanatorium in Doha. If foreign nationals develop the disease they are given 100 rupees and a free passage to their own homes. In all this preventive work, and much else, the head of the State medical department, Colonel A. E. KINGSTON, has played an outstanding part. In addition, during the last five years he has not only supervised the building of the new hospital but has undertaken the administrative and much of the routine medical and surgical work at the old hospital it replaces. At the new hospital there are at present a consultant physician (Dr. C. ELGOOD) and a consultant surgeon (Mr. R. D. EWING). Additional staff is required, however, and there will be vacancies for well-qualified specialists in ophthalmology, anaesthetics, pathology, E.N.T., radiology, and gynaecology.

RADIATION HAZARD FROM DIAGNOSTIC RADIOLOGY

U.N. COMMITTEE SEEKS FACTS

The United Nations' scientific committee on the effects of atomic radiation has issued a statement headed "The Responsibilities of the Medical Profession in the Use of X-Rays and Other Ionizing Radiations." In it the committee asks for information from the profession in each country on how the medical hazards might be minimized, and for an estimate of the total radiation to the gonads received by the population before and during the reproductive age. Where estimates have been made, states the committee, diagnostic radiology appears to account for "the greatest gonad irradiation of the population." The committee, which was established by the General Assembly in December, 1955, consists of scientific delegates from fifteen nations, including the United Kingdom, Australia, Canada, India, the United States, and Russia.

Limiting the Gonad Dose

Discussing permissible levels of irradiation for the whole population, the committee states: "It is considered prudent to limit the average dose to germinal tissues from artificial sources to the order of magnitude of that received from all natural sources." In estimating this dose, the relevant dose is defined as the "mean gonad irradiation among the population as a whole up to the end of the average reproductive period." In Sweden and the United States, says the committee, genetic irradiation from diagnostic radiology is known to be at least equal to that from natural sources, while in Britain a minimum figure of 22% has been given. It is clear, therefore, even without more exact data, continues the statement, that this type of exposure can be substantial in countries with extensive medical facilities.

The committee accordingly asks radiologists to suggest ways of reducing such exposure. In particular the committee would like to know the extent to which attention to the following points might be expected to reduce irradiation of the gonads: (a) Better design or shielding of equipment; (b) fuller training of those carrying out radiography and fluoroscopy; (c) local shielding of the gonads; (d) the use of radiography rather than fluoroscopy when the information given would be equally satisfactory; (e) avoidance, by better administrative arrangements, of unnecessary repetition of the same examination; (f) studies of various medical conditions such as peptic ulcer to define the exact circumstances in which a radiological examination really assists in treatment or prognosis. In Britain the committee recently appointed under Lord Adrian's chairmanship to review radiological practice (see *Journal*, February 16, p. 413) is expected shortly to be sending a questionnaire on these and kindred matters to departments of radiology and radiotherapy and to others concerned. This body will receive evidence from British radiologists. Its secretariat is at the Ministry of Health, Savile Row, London, W.1.

Monthly meetings are held at the Royal Northern Hospital, London, between the hospital staff and family doctors. Many day-to-day medical difficulties have been discussed, but recently there was a more general debate on "The Medical Out-patient Service and the Family Doctor's Problems." Most of those present emphasized the importance of the exchange of careful and adequate letters between general practitioner and consultant. The former could sometimes provide more information about the home situation, previous investigations, and drugs given, while those from hospitals were often delayed in arrival and on occasion a trifle inhuman or obscure. Follow-up letters, both from the family doctors and from hospital, were to be encouraged, and the value to the G.P. of negative findings at hospital was also stressed.

Reports of Societies

CORONARY THROMBOSIS

PET THEORIES AND AWKWARD FACTS

The reason for the present high mortality in Britain from coronary disease is still obscure. Speaking as an epidemiologist before the Manchester Medical Society recently, Dr. J. N. MORRIS could find no proof of the view that fats are the main cause; and he was at some pains to point out that neither the incidence nor necessarily the aetiology of coronary atheroma runs parallel to those of ischaemic heart disease. Dr. Morris is director of the Medical Research Council's social medicine research unit. In Britain before the first world war coronary atheroma was apparently rife but ischaemic heart disease less common than now, he said. An increase of massive thrombosis in atheromatous coronary arteries seemed to be one element in the modern transformation. Moreover, it was possible to distinguish occlusive from merely mural coronary artery disease—thus in deaths from peptic ulcer, in contrast with what happened in hypertension, there seemed to be a selective increase of occlusive disease—and this might provide another approach in the search for environmental factors.

A nation-wide survey of necropsies in middle-aged males, in which 200 departments of pathology had co-operated, had shown an excess of ischaemic myocardial fibrosis in those with light occupations dying of cancer, injuries, etc. This excess was most noticeable in the case of solitary scars of large healed infarcts, a finding which might link up with the previous observation of an excess of "sudden deaths" and other rapidly fatal ischaemic heart disease in sedentary workers such as bus drivers and clerks.

Doubts about Dietary Fats

Discussing the main social pathology now postulated—that Western man was eating himself into the disease—Dr. Morris regretted that he could do no more than share his own confusions. What might be called the "appeal to epidemiology" was persistently refusing to confirm hypotheses of a single or simple dietary aetiology for ischaemic heart disease. In the present climate of opinion he found such a negative role exceedingly uncomfortable. But it was impossible to match in any logical way what was known about mortality from coronary heart disease with the known trends in fat consumption. Thus, the marked variations in mortality among Western countries with similar high fat-intakes disposed of any story that total fat consumption was the critical factor. Changes in the consumption of animal fat in Britain during the present century could be related to changes in the incidence of coronary atheroma as recorded at the London Hospital, but they showed no relation to the Registrar-General's figures of mortality from coronary heart disease. The trend of consumption of butter-fat in Britain showed less than no relation; the steep increase in coronary deaths since 1943 was only one illustration of this.

Changes in the intake of vegetable fats resembled the mortality experience better, and those in hydrogenated fat much better, except that the distribution of coronary mortality by social classes disagreed with the class pattern of margarine intake. International experience was even more contradictory: Norwegians, who had a very high consumption of margarine, seemed to have far less fatal "coronary thrombosis" than New Zealanders, who ate very little. Perhaps the fish the Norwegians ate protected them, but this did not seem to help Aberdeen, which registered twice the coronary death rate of Oslo. In terms of total essential fatty acids the only data available for Britain gave no support to the hypothesis that the population was now suffering from an absolute or relative deficiency of these nutrients, and international comparison again showed anything but a homogeneous picture. Perhaps we were still dealing with rather a dim reflection of the true dietary causes; perhaps several

dietary factors were involved; perhaps diet was only one of several causes of ischaemic heart disease. More and better statistics of disease and food trends were urgently needed, said Dr. Morris in conclusion. It seemed to him a hopeful sign that the World Health Organization had now entered this field.

PSYCHOLOGICAL PRECIPITATION OF EPILEPSY IN CHILDREN

[FROM A SPECIAL CORRESPONDENT]

On February 14 the Child Psychiatry Section of the Royal Medico-Psychological Association, under its chairman Dr. K. CAMERON, discussed the role of psychological factors in the precipitation of epileptic attacks. Paediatricians were specially invited, and two of them, Dr. J. P. M. Tizard (Institute of Child Health) and Dr. Robert Shanks (Glasgow), opened the discussion with Dr. D. A. Pond (Maudsley Hospital).

Petit Mal and Temporal-lobe Epilepsy

Dr. POND referred particularly to two groups of children—those with petit mal and those with temporal-lobe attacks. The former type of attack could be precipitated almost instantaneously, he said, by certain disturbing situations or even by asking emotionally charged questions during an interview. The attack seemed to repress the unpleasant emotion from consciousness and sometimes even the question causing it. Of course, not all petit-mal attacks were so produced, and other more directly physical factors such as overbreathing, intermittent photic stimulation, and occasionally noise were usually more important. A rare condition of particular interest was that in which the child apparently discovered for itself the epileptogenic effect of photic stimulation, which he would then simulate by flickering his fingers across his eyes while staring at the sun or a bright light, thus producing brief petit-mal attacks. All of the opening speakers had seen one or two such cases and all stressed the compulsive nature of the act in these children. Dr. Pond's case, which had received three months' in-patient psychotherapy, had shown the same passivity and stubbornness he had previously described as characteristic of many children with petit mal.

By contrast with petit mal, the psychogenic precipitation of temporal-lobe attacks was never so instantaneous, but increase of emotional tension over days or weeks often greatly added to the number of attacks. This was more easily appreciated when children were discharged from hospital to emotionally disturbed homes than from retrospective histories from their parents.

Dr. Pond then turned to the mechanism of psychogenic precipitation, and mentioned briefly the older theories of the possible influence of emotion on the cerebrovascular system, the autonomic nervous system, and the endocrine glands. None of these theories could satisfactorily explain the instantaneous precipitation of petit mal. During the attack the abnormal activity was bilaterally synchronous and probably related to the normal symmetrical activity of waking and sleeping that was controlled by the so-called centrencephalic system. This similarity, he thought, helped one to understand the mechanism of the seizures. But to explain their precipitation by emotion it was necessary to postulate a further process akin to conditioning. Temporal-lobe seizures originated, it seemed, in those parts of the cerebral cortex where was to be found the highest level "representation" of the somatic concomitants of emotion. But here again the mechanism of the seizures was better understood than their psychological triggering. The stimulus appeared to be a build-up of emotional tension, and sometimes the stimulus was quite specific, as in those cases of epilepsy where the attacks were provoked by particular pieces of music.

Breath-holding Attacks

Dr. J. P. M. TIZARD first spoke of the breath-holding spells of infants. These were certainly precipitated by frustration,

he said, and occurred in children who seemed unusually bad-tempered and irritable. Some of the spells ended in a brief tonic-clonic attack, presumably as a result of anoxia from the breath-holding. But a small proportion of such babies developed epileptic attacks in later years. He thought that fright was the most important emotion precipitating petit-mal attacks. One of his children with compulsive autophotic stimulation had been seen by Dr. D. W. WINNICOTT, who made the interesting suggestion that the compulsive flickering was an attempt by the child to bring the spontaneous attacks under some sort of voluntary control. Dr. Tizard went on to say that he thought the psychogenic precipitation of major seizures was much less obvious, since there was nearly always an interval of hours between the fit and the preceding emotional upset. In these cases the emotion usually seemed to be related to anger and rage rather than fright. He also wondered if the fact of major seizures being commoner by night than by day was related to night terrors acting as precipitating factors.

Dr. ROBERT SHANKS also thought that major seizures were precipitated, if at all by emotions, only by fear and rage, whereas anxiety produced petit mal. He contrasted the older view of epilepsy as a psychological illness with typical personality changes with the current view that all fits were caused by lesions, some of which, if in the temporal lobe, also produced personality change. Breath-holding produced major seizures by anoxia, whereas the apparently opposite state of overbreathing produced petit mal. Both paediatricians agreed with Dr. Pond that the frequency of attacks of petit mal depended closely on the patient's emotional state.

Television and Photic Stimulation

In the ensuing discussion several speakers expressed similar views supported by case histories. Dr. MARGARET LOWENFELD (London) made the interesting point that sometimes one had to choose between controlling the patient's fits, or leaving him psychologically more normal and alert though having seizures. Dr. R. W. TIBBETTS (Birmingham) and others had seen cases of epilepsy, both major and minor, apparently precipitated by watching television, but these might be a special instance of intermittent photic stimulation.

Your correspondent was impressed by the unanimity of paediatricians and psychiatrists on the facts of the psychogenic precipitation of seizures, but much remains to be learnt about the underlying mechanisms, both physiological and psychological.

Further details have now been released about the research laboratories for medical physics and urology at Leeds General Infirmary, towards the cost of whose building the Wellcome Trust has made a grant of up to £60,000 (see *Journal*, February 2, p. 295). The total cost of the laboratories and their equipment is put at about £120,000, and both the United Leeds Hospitals Board and Leeds University will be contributing substantially to the extra cost. The urological unit was formed in 1950, under Mr. L. N. PYRAH, who was appointed to a personal chair in urological surgery last October, with departments at the General Infirmary and St. James's Hospital. Last year the Medical Research Council accepted major responsibility for the unit's research programme and assisted in creating an associated clinical research unit with Professor Pyrah as honorary director and Dr. F. M. PARSONS as assistant director. The university department of medical physics was also established in 1950, Dr. F. W. SPIERS being appointed to the chair, and increasingly its clinical and research programmes have been associated with those of the urological unit. In addition, the department is carrying out research on electromyography and electroencephalography, the application of electronic scanning to radiology, the measurement of whole-body radioactivity for such purposes as the estimation of occupational hazard, and the physical aspects of x-ray and radium therapy.

Correspondence

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

Vagotomy for Duodenal Ulceration

SIR,—Restoring gastric digestion and bodily nutrition to as near a normal state as possible at the minimum risk is our aim in the surgery of duodenal ulcer. Analyses of follow-up records, discussions, and correspondence, such as have appeared recently, continue to contribute to this end, but there is yet no general acceptance of one operation which so fulfils our criteria that standardization seems in sight. I would like space in your columns to endorse one point of view and hope that something useful may be added.

Since Dr. George Crile told me some five years ago of their large and encouraging experience with gastro-jejuno-stomy and vagotomy at Cleveland, I have used this procedure increasingly until now it is routine, and up to date there have been no exceptions to the content of our patients. Dr. Crile said, if I remember him rightly, that up to 7% might develop marginal ulceration, and these cases were cured by gastrectomy, still leaving the scales weighted heavily in favour of the less mutilating operation. He also made the point that there was a definite economic advantage, since these patients were out of hospital and back to work in a shorter time. This, too, has been our experience—most are out of hospital within ten days and back to work within the month. Nutrition is unaffected and post-prandial discomforts are rare. In all hands it is a safer operation, even in these days of safe gastrectomy. In the very young patient, on whom most surgeons are reluctant to perform a major reaction, it makes the decision less onerous. Results are excellent in women, whereas they do not seem to take kindly to gastrectomy for duodenal ulcer. Incidentally this operation, in addition to apposition of the hernia syndrome and is particularly applicable if a duodenal ulcer is present. Last, and of course least, but not unimportant, is that vagal section and short circuit is a much less time-consuming technique, and this factor cannot be regarded of small significance when the waiting time for these patients in some hospitals is over three years.

These advantages are countered only by the threat of marginal ulceration. However, the published incidence in this country has shown a remarkable variation, and the highest figure quoted is difficult to reconcile with personal experience. It would seem that this operation deserves a more extensive trial under scrutiny. I believe myself that to-day a duodenal ulcer patient is offered his best chance by finding a keen physician, who uses a reluctant surgeon, who in turn uses gastro-jejuno-stomy and vagotomy as his first line in surgical treatment.

As to other procedures, let it be said categorically that the Billroth I resection and vagotomy achieves results as good, in terms of function, morbidity, and mortality rate, as the best by any other operation. The factor which militates against its general use, and which has not been sufficiently emphasized, is that exceptional skill and experience are required if it is employed in all cases. The modern Polya comings in spite of a well-formed valve. A modification which embodies Mr. Capper's recommendations and does seem to mitigate these troubles is to use the original Billroth II, in which the stomach remnant is closed: the distal end is then brought across to the right side and sutured in the region of the right free margin of the lesser omentum so that the axis of the gastric remnant approximates to that of the normal stomach. A short loop, small stoma, iso-peristaltic gastro-jejuno-stomy is then added.—I am, etc.,

London, W.1.

D. LANG STEVENSON.

Vaginitis

SIR,—The clinical trials of Dr. R. F. Jennison and Dr. J. D. Llywelyn-Jones (*Journal*, January 19, p. 145) have shown that a 1% watery solution of gentian violet applied to the vagina was not effective in monilial vaginitis. In my experience the inefficacy is probably due to the acid reaction of the vagina: an acid reaction is known to decrease the permeability of living bacteria and fungi for basic substances.

Recently I advanced a general principle of pharmacodynamics. The efficacy of any drug or chemical will be increased or decreased by diminishing or increasing respectively its solubility in the solvent or vehicle in which it is applied.¹ Based on this principle, a very effective fungicidal paint was evolved, consisting of an alcoholic solution of methyl violet (1–2%), which is diluted before use with an equal part of 0.1% solution of bicarbonate. I found this paint to give rapid curative results, apparently without recurrences, in athlete's foot, pityriasis versicolor (axillaris), and in chronic subungual fungus infections. For monilial vaginitis I would suggest the use of a 0.1–0.5% alcoholic solution of methyl violet to be applied immediately after rinsing the vagina thoroughly with a weak solution of NaHCO₃. I am confident that this method will give highly satisfactory therapeutic results.—I am, etc.,

London, N.W.11.

M. G. GOOD.

REFERENCE

- Good, M. G., *Indian med. Rec.*, 1956, 76, No. 5.

SIR,—In the annotation on vaginitis (*Journal*, January 19, p. 155) mention is made of the difficulty of treating vaginitis due to *Candida albicans*, because of the rapidly developing resistance of this organism to the various antifungal agents: "The difficulty with all these preparations lies not in finding an effective fungicide . . . but in overcoming the drug resistance which the organisms acquire with such rapidity and persistence." While this may be true of chemotherapeutic agents, although I am not aware of any work showing actual drug resistance, this has not been the case with nystatin. Some of the cases treated by Dr. J. D. Llywelyn-Jones and myself and reported in the same issue (p. 145) did recur after treatment, but the strain of *C. albicans* isolated at the time of the recurrence was still sensitive by laboratory tests to nystatin, and the recurrence should most probably be called a reinfection. During the last year in the St. Mary's Hospitals we have tested more than 200 strains of *C. albicans*, including those from recurrent cases of monilial vaginitis, and have so far found no change in the original sensitivity of *C. albicans* strains to nystatin. This has always seemed to us a particular asset of nystatin treatment.

Since the publication of the series reported in your issue of January 19 we have in fact increased the course of local nystatin treatment to 14 days, but have not used oral therapy because of complaints of nausea. The results with this system of treatment have been better than any other form of therapy used in this hospital for some years, and there have been no patients showing sensitivity to the drug.

I should also like to confirm the observations of Drs. R. D. Catterall, E. M. C. Dunlop, and Eva Gallagher (*Journal*, February 2, p. 287) that oral aminotriazole therapy by itself is completely ineffective in the treatment of vaginal trichomoniasis. In a series of 30 patients treated with 100 mg. aminotriazole three times a day for 10 days and controlled by a similar number of patients given placebo tablets, one patient was "cured" in each group.—I am, etc.,

Manchester, 13.

R. F. JENNISON.

SIR,—I agree with your correspondents, Drs. R. D. Catterall, E. M. C. Dunlop, and Eva Gallagher (*Journal*, February 2, p. 287), that oral trichomonocides are so far not of proved value in the treatment of trichomonas infection, either alone or in combination with local treatment. Further, statements in the annotation (*Journal*, January 19, p. 155) on this subject require modification. Monilial infection seems

to be essentially a disease of "clean" people. An interesting point has been the apparent increase of thrush infection in relation to trichomonas in this area. *Candida albicans* often worries husbands and gives them pruritus, and I cannot agree with your statement that this is rarely found. As regards the use of nystatin, it has not been employed long enough for its value to be fully assessed, and it occasionally gives rise to reaction. "Pruvagol" is not mentioned in treatment, but it has proved its worth as a bland and efficient therapy over the last few years, unlike other suggested treatments.—I am, etc.,

Cheltenham.

STANLEY A. BOND.

Fever after Mitral Valvotomy

SIR,—Your annotation (*Journal*, February 9, p. 332) on the post-commissurotomy syndrome (p.c.s.), while referring to American papers, omits reference to the only British publication on the subject.¹ Though this appeared a few months after the paper of Dresdale and his colleagues,² the results were made public in a joint communication with Dr. M. M. Zion at the annual meeting of the British Cardiac Society in May, 1955.³ We were then able to prove that the p.c.s. was not, as hitherto believed in America, a super-added rheumatic pericarditis, but was the accentuation, persistence, and recurrence of the normal post-operative sequelae, of which traumatic pericarditis is one. Since the pleural effusion, contrary to what happened in the uncomplicated cases, remained blood-stained for weeks after the operation in the p.c.s. cases, we believed that oozing from the auricular wound was responsible for the recurrent pleuro-pericarditis. Loculation of the effusion and left basal lung consolidation were additional factors in some of our patients. At the time when our material was collected the incidence of p.c.s. was 20%. At present, when loose suture of the pericardium has been adopted, as suggested by your leader writer, the syndrome has become a rarity.—I am, etc.,

London, N.W.3.

Pathogenesis of Rheumatic Endocarditis

SIR,—The leading article on the pathogenesis of rheumatic endocarditis (*Journal*, February 2, p. 273) contains several misleading and controversial statements and omits discussion of the evidence against the views expressed. While the work of Magarey¹ and Tweedy² describes one mechanism for the production of rheumatic valvular deformities—i.e., the deposition of fibrin on the surface and its incorporation into the valves—Tweedy is on much more debatable ground with his view that the eosinophilic material found deep in the valves in acute rheumatic disease is entirely due to the same mechanism. Having shown that it is possible to have fibrin incorporated into valves from the surface, Tweedy's main argument appears to be based on the comparative absence of a fibrin-staining component in Aschoff nodules in the myocardium. He omits, however, to describe the type of lesion called "reticular" Aschoff body by Gross and Ehrlich³ which appears to correspond with the "Früh-infiltrat" of Klinge.⁴

In this type of lesion there is an interlacing group of eosinophilic homogeneous fibres, many of which are continuous with uninvolved collagen fibres at the periphery of the lesion, and these eosinophilic fibres frequently stain with all the usual fibrin stains. This material is similar in staining properties to the eosinophilic material found in the valves. This is an uncommon type of lesion, and, according to Gross and Ehrlich, is found only in acute rheumatic fever, usually in children, and most frequently in a first acute attack. Similar material is also found in the joints, blood vessels, and subcutaneous nodules. Because of the variations in morphology and staining reactions this material has been called "fibrinoid." The debate on the nature of this substance in rheumatic fever still continues, and substances with similar staining characteristics are found in other diseases—rheumatoid arthritis, disseminated lupus erythematosus, dermatomyositis,

polyarteritis nodosa, etc. There is considerable evidence that these substances do not consist of fibrin and may not be the same in different diseases.⁵⁻⁸ The fibrinoid hypothesis, however unsatisfactory the name, does not depend on the nature of the lesions in the valves of acute rheumatic disease. It is a concept based on the changes in many tissues in many diseases. The views expressed by Tweedy on the "myxomatous" material in the valves of acute rheumatic disease are also open to question. A certain amount of mucoid material is present in many normal heart valves, and this is greatly increased in active rheumatic disease, where it may also be found in the subendocardium, mainly on the left side of the heart, the myocardium, and around and within blood-vessel walls. It is commonly associated with developed Aschoff lesions in these situations, and, according to Talalajew⁹ and others, precedes the deposition of the eosinophilic material. My own observations on this mucoid material will be published shortly. It is found in situations where organizing thrombus can be ruled out. Organizing thrombus also contains similar material. It may not be justified to interpret its appearance in the valves as due to organizing thrombus.

The most recent evidence of rheumatic heart disease has been provided by biopsy material from patients undergoing valvotomy. These patients have no clinical evidence of rheumatic activity, and in this centre approximately half give no history of a previous attack of acute rheumatic fever. The surprisingly high incidence of histologically active lesions (approximately 64% of 350 cases in this centre), which include some of the earliest described forms of lesions, makes it likely that subclinical active rheumatic disease may be just as important a factor in producing valvular deformities as organizing thrombus. As Tweedy himself admits, definite Aschoff nodules are found in the valves of some cases of rheumatic heart disease. It seems a more reasonable hypothesis that both factors—repeated attacks of subclinical rheumatism and organization of deposited fibrin—contribute to the valvular deformities.

The fibres demonstrated by the electron microscope in normal aorta and atheromatous plaques by Levene¹⁰ and in the endocardium in fibro-elastosis by Still and Boulton¹¹ have a 230 Å banding similar to fibrin, but Porter¹² has shown that tissue cultures of fibroblasts grown in media containing no fibrinogen produce fibres with a periodicity of 200–220 Å, and these thicken and mature to fibres with a 640 Å periodicity. It appears from this work that young collagen fibres have electron-microscopic appearances similar to that of fibrin. More evidence will be required before one can accept the conclusions of Levene and Still and Boulton.—I am, etc.,

Birmingham.

Synthetic Amino-acid Diet

SIR,—Cases exist where intolerance to protein develops so swiftly and severely that it is difficult to supply sufficient nutrition to keep the patients alive. The use of cortisone preparations or protein hydrolysates, such as "hepovite," is often of use. However, when all else fails it has been found, in the case of two twin children at least, that a diet made of pure synthetic amino-acids is of value. The formula used was: glycine, 30 parts by weight; L-arginine, 30; L-histidine, 20; L-lysine, 70; glutamic acid, 120; L-aspartic acid, 70; L-α-alanine, 10; DL-valine, 60; L-leucine, 100; L-isoleucine, 10; L-proline, 40; DL-β-phenylalanine, 40; DL-serine, 40; DL-threonine, 40; L-tyrosine, 30; L-tryptophan, 4; L-cystine, 40; L-methionine, 20. This was supplemented with glucose and vitamins to make the complete diet. A major dis-

advantage is the high cost (£180 a kilogram) of the treatment. However, the symptomatic improvement is considerable. It is hoped to publish a fuller report in due course.—I am, etc.,

Marlow, Bucks.

B. JAMES.

Translumbar Aortography

SIR,—Mr. H. Gaylis and Dr. J. W. Laws (*Journal*, November 17, 1956, p. 1141) are to be congratulated on their fine demonstration of dissection of the aorta as an occasional complication of translumbar aortography. Recently I analysed the possible causes of spinal cord damage during aortography,¹ and I would like to mention several points relevant to the present discussion.

The cord may be damaged either by ischaemia, secondary to occlusion of a lumbar artery, or by a chemotoxic effect of the contrast medium. Occlusion of a lumbar artery during aortography may occur in a number of ways. First, the lumbar arteries, as they run posteriorly around the vertebral bodies, are particularly exposed to the risk of trauma during the introduction of the needle. Secondly, an atheromatous plaque, such as is commonly found surrounding the mouth of a lumbar artery, may be disturbed so as to block the artery. Thirdly, an intramural collection of contrast medium or blood may occlude the artery, as shown by Mr. Gaylis and Dr. Laws. Thus, although I agree that the instances of paraplegia reported by Antoni and Lindgren² and by Boyarsky³ were probably the result of ischaemia, it is not necessary to postulate that this was the result of aortic dissection. Occlusion of a lumbar artery will result in spinal cord damage only if that artery supplies blood to the cord substance and probably only if the collateral circulation is poor; this is the likely explanation of the rarity of such an injury. However, the risk is inherent in the method when aortography is performed by the translumbar route. This is one reason why the retrograde method of Seldinger⁴ should be used where possible.

Chemotoxicity of the contrast medium was almost certainly the cause of spinal cord damage in the case which I reported, and I believe that this is responsible for the recent increase in the incidence of complications following aortography. However, the incidence may be minimized by a careful technique. In this regard I heartily endorse the opinion of Dr. David Sutton (*Journal*, January 26, p. 225), that a test injection is essential to show that the tip of the needle is centrally placed in the aorta, at the correct level. If this is done, and a short bevelled needle used, dissection of the aorta should be rare and the risk of chemotoxic injuries reduced. The latter is diminished further by lowering the volume and rate of injection, as suggested by Dr. Sutton. In addition, as a summation effect of the contrast medium on the tissues probably exists,⁵ it is unwise to repeat the injection at the one examination. Finally, the trend towards selective angiography by the Seldinger method, using small injections, should be associated with a very low incidence of complications. It is only by careful analysis that the cause of these complications can be elucidated, and in this manner Mr. Gaylis and Dr. Laws have made a valuable contribution.—I am, etc.,

Melbourne, Australia.

SIR,—We would like to comment on the correspondence which has followed our article on aortic dissection as a complication of translumbar aortography (*Journal*, November 17, 1956, p. 1141).

We agree with Dr. David Sutton (*Journal*, January 26, p. 225) that a trial injection of a small quantity of contrast medium to localize the needle point is a precaution of value in that it will prevent the injection of the bulk of the contrast medium into a major branch of the aorta. But, as Lindgren¹ has already pointed out, although this

precaution will reduce the incidence of extra-luminal injection it will not prevent it altogether. As Dr. Sutton has stated, we do not use a hand-pressure pump in order to inject the contrast medium unduly rapidly, but simply as a matter of convenience. We use a long length of tubing in order to keep at a distance from the patient during the exposure of the films. This naturally increases the resistance to the flow of the concentrated contrast medium and makes hand injection difficult. While we deprecate unduly rapid injection, our experiments have shown that it requires very little pressure for an intramural injection to cause dissection. It can occur even with gentle hand injection.

Dr. Sutton refers to two cases in which paraplegia followed aortography, one reported by Boyarsky² and the other by Antoni and Lindgren.³ We attributed these cases of paraplegia to aortic dissection, but Dr. Sutton suggests that excessive doses of contrast was the major factor. We find this suggestion difficult to accept since reference to the original papers gives no evidence that excessive quantities were used. In the case reported by Antoni and Lindgren the dose is not stated, and in that of Boyarsky a total of 15 ml. of 70% sodium acetate was used. Moreover, from the description of both aortograms there is strong evidence of aortic dissection. In the case described by Boyarsky there was technical difficulty and the left common iliac artery was not outlined. This was not due to thrombosis of the left common iliac artery, since before the procedure all "peripheral pulsations were symmetrical and normal." These appearances are very suspicious of aortic dissection and are similar to those in Case 2 described in our paper. Incidentally, it should be noted that in this case a trial injection was given; a pressure apparatus was not used, and the injection was given by hand. In the case described by Antoni and Lindgren "an increased resistance was felt during the injection which was therefore interrupted, but a certain amount of contrast medium had, however, been injected paravascularly. . . . Contrast injection showed that only a part of the aorta down to the superior border of L 2 and the vessels in the upper part of the abdomen became contrast filled." Not only is there no evidence that excessive contrast was used, but it seems clear that some of the contrast was injected outside the lumen. It should be noted, in this case too, the injection was made by hand.

The case of paraplegia reported by Hare,⁴ and referred to by Dr. Sutton, is quite different in that a large volume of contrast medium was injected, and we agree that this may well have been the major factor in this case. But it should be noted that Hare himself states that an intramural injection causing blockage of a lumbar artery and ischaemia of the cord is a possible explanation. Hare considers this analogous to the "transverse lesion of the spinal cord which may accompany a dissecting aneurysm of the aorta which almost certainly results from occlusion of the mouths of intercostal arteries," a point not mentioned by Dr. Sutton.

Again we would stress that aortic dissection in minor or major degree is not uncommon, and that its significance in the past has not been universally appreciated even by experienced radiologists. Two recent examples will suffice. A recent American textbook on peripheral vascular disease⁵ illustrates an aortogram in which the bulk of the contrast was injected into the superior mesenteric artery. The patient died from infarction of the bowel, allegedly from the toxic effects of the contrast medium. A close study of the illustrated aortogram, however, shows a double contrast shadow extending along the superior mesenteric artery and some of its branches—clear evidence of arterial dissection. Again, in the *British Medical Bulletin*⁶ there is an illustration of "a normal arteriogram of the left kidney" in which a minor degree of aortic dissection is clearly shown but not commented upon. The letter from Mr. R. E. Horton and Dr. F. G. M. Ross (*Journal*, February 9, p. 340), in which they quote Dr. Sutton, may give the impression that we consider the toxicity of contrast media to be of no importance. This is not the case. A discussion of the toxicity of contrast media, a subject of which much has been written already, was outside the scope of our original paper, which was concerned solely with the complication of aortic dissection. We make no claim that dissection is responsible for all the complications of aortography, but simply that it is important because it "may give rise to misinterpretation in diagnosis if its true significance is not appreciated; there may be serious sequelae; and it may occur in spite of the most scrupulous technique. Furthermore, we believe that

this event is not uncommon and that it offers an explanation for some of the complications of aortography usually ascribed to arterial thrombosis or to the direct toxic effect of the contrast medium." In our opinion, some complications are caused by the toxicity of the contrast medium, some by dissection, and some by a combination of these two potential hazards.—We are, etc.,

H. GAYLIS.

Cancer of the Bladder and Tobacco

SIR,—An annotation in your *Journal* (January 26, p. 218) discussed the reported increase in incidence of carcinoma of the bladder in males (as opposed to females) in Denmark and England. The trends are regarded as so similar in type to those which have been reported for cancer of the lung that it was thought that a common factor might be operative for the two types of cancer. Two pieces of evidence were brought forward to support this concept: an American investigation into the smoking histories of hospital patients, in which it was shown that more men with cancer of the bladder had been smokers than had those with benign bladder disease, no disease, or prostatic cancer; and an experiment performed by L. R. Holsti and P. Ermala in Finland.¹ These authors swabbed the lips and oral cavity of mice with tobacco tar for 140 consecutive days and observed the animals for 12 months from the beginning of treatment. They claimed that papillomatosis of the urinary bladder was present at death in 35 of 40 mice and that in 6 animals there was malignant papillary carcinoma. It is not stated that the bladders were distended before fixation, and the one photomicrograph of a benign papilloma presents the appearance observed with a mucosa folded as a result of muscular contraction. The other photomicrograph illustrating the paper is open to interpretations other than that of infiltrating carcinoma.

I know of only one chemical which after oral administration has induced true papillomas and carcinomas of the bladder in mice. This is 2-acetylaminofluorene,² a carcinogen potent to other species. In groups of approximately 20 mice of different strains the yield of tumours ranged from 22 to 78% of animals surviving 20 to 77 weeks, and most of the tumours arose after 52 weeks of treatment. Both benign and malignant tumours could be demonstrated in the distended bladder, some of the latter invading completely the muscular wall.

My desire is to advise caution in accepting experimental data as supporting evidence for the carcinogenic activity of tobacco tar until convincing experiments have been performed.—I am, etc.,

Cancer of the Larynx in Women

SIR,—Sir Ernest Kennaway, F.R.S. (*Journal*, February 9, p. 299), draws attention to the peculiar "reversed gradient" in statistical graphs of cancer of the larynx in women. He suggests as a possible explanation the consumption of white bread, and tea by the rural housewife. I do not know whether there are any records available to show that more white bread is consumed in the agricultural areas; if there are I would be inclined to think that the feeding of bread to poultry would account for it, since white bread is an excellent food for chickens. The country housewife spends a great deal of her time indoors of necessity, probably more than her city sister. The urban housewife has clean electricity and gas to assist her in cooking and in laundry work. The air of the countryside is clean, but any doctor

visiting a rural house on wash-day, or any day for that matter, will know how much "smog" can be confined in the kitchen. The drudgery of stoking the stove and cleaning the grate must surely produce its morning dose of carcinogen. The chronic bronchitic is often benefited when his spouse persuades him to let her have a modern solid-fuel cooker. The drudgery is hastily abandoned when electricity is made available to the rural housewife, a change proceeding apace. If this is one of the factors, there should soon be an alteration in the graph.

During the last few decades there has been another change in the customs of the rural dweller—the advent of the pressure paraffin mantle lamp and pressure stove. These two have possibly altered the home atmosphere, adding hotter fumes to the living-rooms at night. These "transitional" rural amenities will, of course, gradually give way to electricity. The rural housewife, of course, might take up cigarette smoking to while away the time and idle hours brought by electricity, and so transfer the carcinogen from the upper to the lower respiratory tract.

It occurs to me that, in all the various reports on the search for a carcinogen in cigarette smoke, the mode of ignition has apparently been neglected. The 40-a-day smoker, after all, might use 40 matches a day. Lighter, fusee, humble match, or safety-match—is there any difference? Is the safety-match really safe?—I am, etc.,

Camborne, Cornwall.

S. W. V. DAVIES.

Poliomyelitis Vaccine

SIR,—As a general practitioner who expects to be using the poliomyelitis vaccine as soon as it becomes available, I feel that the nature of the contaminant which has held up distribution should be revealed to the profession; all we have to go on so far is the statement in general terms put out recently by the press and B.B.C. Assuming, as anticipated in this statement, that the batch will get through after further tests, it would be important also to let us know if the antigenic action of the vaccine will be in any way impaired.—I am, etc.,

Huddersfield.

LESLIE BALLON.

Intramedullary Nailing

SIR,—Mr. A. E. Stevens and Mr. J. Pett Turney (*Journal*, January 26, p. 208) describe intramedullary nailing as the ideal treatment for fractures of the shaft of the femur. A method which involves the risks of an open operation is being advocated for the treatment of a fracture which commonly unites without difficulty when simply immobilized with sufficient traction to restore reasonable length to the limb. If no other protest is heard, mine shall be: not against the method, for which there are certain indications, but against its indiscriminate employment, which betrays a lack of any sense of proportion.

They mention that four of their patients died; they say that blood for transfusion should always be ready when this operation is performed; and then use the operation for fractures in Paget's disease, the pathological fracture above all others which is known to unite whatever else happens. The powerful muscle spasm which is revealed by a bent nail and delayed union means nothing, except that a bigger and better nail should be inserted. They do not mention that variety of fractured femur where the muscles are completely stripped from one or both fragments, which usually occurs in the upper third of the shaft, and where deformity is quite uncontrollable except by an intramedullary nail. Such fractures are not common, but when encountered the risks of major operation weigh less in the balance than persistent crippling deformity. Intramedullary nailing is very clearly indicated in these fractures.

The truth is that most fractures of the femoral shaft unite readily with simple treatment and at little risk to the patient. Furthermore, the result is a good functional limb. The radiographic appearances are not always very pretty; and therein, I suspect, lies the trouble.—I am, etc.,

Liverpool, 1.

E. N. WARDLE.

Methyltestosterone Therapy

SIR,—In reply to the letter from Drs. G. L. Foss and S. L. Simpson (*Journal*, December 15, 1956, p. 1426), I report a case of a woman aged 56 with generalized osteoporosis attributed to 20 years' immobilization in bed for supposed spinal disease. In the course of rehabilitation she was treated, *inter alia*, with methyltestosterone 30 mg. daily. After five months on this dosage she developed deep jaundice with pruritus and the general picture of obstructive jaundice. Investigation one month after the onset showed: serum bilirubin, 4.4; direct positive van den Bergh; alkaline phosphatase, 20; thymol turbidity, 2; serum albumin, 2.68; globulin, 3.12; E.S.R., 25; blood count normal. Testosterone had been stopped immediately at the onset of jaundice, and this began to subside in about a month; it has since completely disappeared and the patient is apparently well. There is no proof that jaundice was due to testosterone, and infective hepatitis is a possibility, but the sequence of events is suggestive.—I am, etc.,

Leamington Spa.

W. M. PRIEST.

Stereotaxis as an Aid to Neurosurgery

SIR,—In your annotation (*Journal*, February 9, p. 333) on stereotaxis as an aid to neurosurgery, the credit for the application of the Horsley and Clarke¹ stereotaxic technique to human neurosurgery is given correctly to Spiegel, Wycis, and their co-workers.² It should also be emphasized, however, that these workers recognized from the outset the impossibility of defining the co-ordinates of human sub-cortical structures from bony landmarks alone. Thus, while Horsley and Clarke defined the position of a point in the animal brain solely by reference to the interaural, mid-sagittal, and Reid's basal (through external auditory meati and inferior margins of the orbits) planes, Spiegel and Wycis made use of the auditory meati and orbital margins solely in the preliminary step of fixing the basal part of their apparatus to the skull. The co-ordinates of the target nucleus were then based on a "reference point" within the brain and not in the skull. The use of such a point was necessitated by the observation that the centre of the pineal might lie anywhere from 4 to 20 mm. behind the interaural plane, and thus the position of the whole diencephalon would exhibit a corresponding variation in position. The pineal, as identified in a lateral x-ray film (with or without encephalography), was in fact chosen as the reference point, and the antero-posterior co-ordinate of the target was measured from this at right angles to the interaural plane.

It may thus be concluded, from the wide variation in pineal position alone, that the neuroanatomist will never be able (as suggested by your annotator) to provide the neurosurgeon with an atlas of the human brain "based on the type of co-ordinates used in the experimental animal." Further, individual variation affects not only the position but also the size of diencephalic structures. An attempt to take into account variations in thalamic size has been made by Hassler and Riechert,³ who employ a ventricular "base line" connecting the interventricular foramen and the posterior commissure. This line is drawn and measured (with adjustment for x-ray magnification) in the patient's lateral encephalogram and in a normal formalin-fixed brain used as an "atlas." The ratio between these two lengths is used to correct the antero-posterior co-ordinate of the target nucleus as measured from the posterior commissure in the atlas brain.

It will be apparent that the use of any co-ordinate system based upon the posterior commissure must involve the assumption that this structure maintains a constant relationship to thalamic and other nuclei. An investigation designed to test the validity of this assumption is nearing completion in the neuropathology department laboratory, Institute of Psychiatry. In a series of 50 hemispheres from 35 normal, formalin-fixed, and suspended brains the ventricular "base line" was marked and coronal cuts made at right angles to this at the posterior commissure and at other more anterior levels. The nuclei present at each level have

been identified in frozen sections stained for nerve cells and for myelin sheaths. It has been found that the coronal planes representing the extreme anterior and posterior positions of the posterior commissure in the series, when identified in any one normal brain (1,350–1,400 g.), are separated by a distance of about 6 mm. It is thus clear that the use of the posterior commissure as a reference point may lead to quite undesirable errors in needle placement. Preliminary studies suggest that the tip of the pulvinar of the thalamus is a more reliable point from which to measure the antero-posterior co-ordinate in that the various thalamic nuclei appear to occupy relatively constant positions along the antero-posterior axis irrespective of its length.

Individual variation within the diencephalon, recognized by Spiegel and Wycis and most subsequent workers, remains nevertheless the central problem in human stereotaxic brain surgery. Until this variation can be accurately measured and corrected for, any one stereotaxic "atlas" used in conjunction with any one apparatus (however mechanically accurate) can only lead the neurosurgeon to believe that he employs a technique endowed with a degree of precision that has all too little basis in fact.—We are, etc.,

Mild Endogenous Depression

SIR,—Dr. C. A. H. Watts (*Journal*, January 5, p. 4) has performed a valuable service in again emphasizing the frequency and importance of endogenous depression. But, like Dr. R. J. T. Woodland (*Journal*, January 19, p. 167), I believe that most endogenous depressive illnesses do not clear up spontaneously as quickly as could be desired. I agree that the understanding support of the family doctor can be of great help to the depressed patient, but this support alone is not likely to curtail the illness, and I consider that E.C.T. should be considered in even quite mild depressive states.

In the course of seven years' experience with E.C.T. as a therapeutic tool used in the out-patient departments of general hospitals, I have repeatedly met patients who have been depressed for many weeks or months before finally being referred to a psychiatrist. One patient referred recently had been depressed for about 12 years, and so retarded that he had developed a severe postural oedema of the feet (with incipient gangrene of the toes) before being referred; he required only four out-patient attendances for E.C.T. to gain a complete remission of his depression. Even quite "mildly" depressed patients may become more seriously ill, and even suicidally so, if treatment is unduly delayed. Dr. Watts himself tells us that, of his patients who took overdoses of sedatives, "it must be admitted that three of the four cases were viewed before this episode as cases of mild depression." Again, Dr. Watts's patient, described as simulating gastric carcinoma, was diagnosed as being in need of E.C.T., and had not recovered until eight months later because he refused to enter a mental hospital for E.C.T. Had out-patient E.C.T. been available to him, he might have been saved a long period of illness.

My plea is twofold: first, for the establishment in all districts of clinics where E.C.T. can be given on an out-patient basis to suitable patients; and, secondly, that practitioners faced with depressed patients, showing the symptoms so admirably recounted by Dr. Watts, should refer them without delay for a psychiatric assessment with a view to E.C.T. in suitable cases. I am sure that by this means a great deal of unnecessary suffering and perhaps a number of suicides can be averted. It is dangerous to delay E.C.T. pending the development of a more serious depression, and it should be remembered that many depressed patients feel ashamed of their symptoms, and therefore cover them up as much as they can; these patients may be far more ill than they appear. A suicidal attempt in an endogenous

depressive illness is the commonest cause of suicide in older people; but suicidal attempts in a depressed patient undergoing E.C.T. are rare.—I am, etc.,

Coulsdon, Surrey.

H. E. S. MARSHALL.

SIR,—In view of the interesting correspondence which has arisen on this subject, I wonder if you can spare room to publish a few more observations. In my opinion this condition is a mild psychosis, and not a form of neurosis as suggested by Dr. R. Macdonald Ladell (*Journal*, January 26, p. 226). At any rate it does not respond to the kind of psychotherapy I am used to giving to anxiety states. I realize that there is sometimes great difficulty in arriving at an accurate diagnosis, and that at times we all attach the wrong label. In a personal note on my paper (*Journal*, January 5, p. 4) an eminent consultant suggested that many of these cases were wrongly diagnosed by the psychiatrists, and exposed to psychotherapy of a kind which they find hard to bear because it asks too much of them. It is as well to realize that psychotherapy, as well as the physical forms of treatment, has its dangers.

Dr. R. J. T. Woodland (*Journal*, January 19, p. 167) agrees with the high incidence of the condition in general practice, and together with Dr. R. Thompson (*Journal*, February 16, p. 401) he suggests that these patients should be given immediate E.C.T. This form of treatment is a traumatic operation, and about 30% of my patients who have had it have failed to respond adequately. While I am grateful for the relief that it gives to most, at this stage of our knowledge I would hesitate to recommend it for all my mild cases. I feel that it is important to take time to observe the patient, to win his confidence, and in general to size the case up. I think that I may have misled readers when in my paper I suggested that a depression which had not cleared after three months needed E.C.T. This does not mean that I sit and watch the case for that period of time. Most of them have been ill for weeks before they consult me, and that time is taken into account. If every mild depression was sent along for E.C.T. the present psychiatric services would be overwhelmed. About five cases in every thousand patients at risk would require E.C.T. every year. They do not all need it. The condition can be very short-lived. I have a patient who has had a dozen severe episodes, and in her case there is no doubt about the diagnosis. Usually the attacks only last for two weeks. On the two occasions when E.C.T. was given the disease lasted longer.

It seems to me that there should be a further stage in this investigation. These depressed patients, all of them, must be seen by both the psychiatrist and the general practitioner. The diagnoses can be cross-checked, and a policy as regards E.C.T. can be undertaken. I am not prepared to come down on either side of Dr. Ladell's fence. I would prefer to sit on it.—I am, etc.,

Leicester.

C. A. H. WATTS.

Fatal Reactions to Local Anaesthetics

SIR,—In days when new drugs and, indeed, new groups of drugs are being offered to the profession with quite extraordinary frequency, it is highly commendable that you should issue yet another warning on the dangers of these useful agents unless they are used with the utmost respect and care.

It is difficult to come upon an explicit and complete setting forth of the multiplex posology of procaine hydrochloride, lignocaine hydrochloride, etc. Nevertheless, one does know that the stronger—e.g., 2%—solutions of lignocaine hydrochloride become, by virtue of the drug's relatively slow destruction, about half as toxic again as procaine hydrochloride; 500 mg. thus becomes a maximum dose for lignocaine hydrochloride—i.e., 25 ml. of 2% solution. Without adrenaline this maximum should be substantially reduced to, say, 200–300 mg. (10–15 ml. of 2% solution). This is not to say that these doses may not, in experienced hands, be exceeded. I feel, nevertheless, that your annotation implying that the dose of 2% lignocaine hydrochloride solution

for injection can be 30 ml. errs on the side of buoyancy, bearing in mind the notorious history of accidents surrounding this class of drugs. Rather than an upper limit dose, surely it would be perhaps wiser to advertise that the occasions on which it is necessary to use more than a few ml. of so strong a solution are infrequent indeed. Furthermore, to give a simple and unqualified number of ml. below which the drug is safe and above which it is presumed to be highly dangerous takes no account of the many factors of patient variation.—I am, etc.,

London, N.3.

ERIC K. GARDNER.

The Black Sheep

SIR,—There is a saying "Fingers were made before forks." It is equally true, and less futile, that forks are an improvement on fingers. I am a retired general practitioner, and, still retaining a car, can be a little helpful visiting the shops. I have been astonished at the lax way of dealing with the sale of cooked meats, and have come to the conclusion that they should not be sold as a sideline in butchers' shops without more stringent supervision by the sanitary authorities.

I have seen cooked meats cut with the knife used for cutting raw meat and handled by hands which are still "sanguinary." I have also seen corned beef, boiled ham, roast pork, and jellied veal cut on the machine used for cutting raw bacon, and meat pies lifted by the same unclean fingers. The idea of using a separate knife and fork for these cooked meats is never thought of by the butchers, nor enforced by the authorities.

Confectioners and grocers are often remiss in their handling of these goods. The other day I saw some boiled ham being cut by a grocer, and watched him almost daintily arrange the pieces on the wrapping-paper with fingers in marked contrast to his movements. I noticed also that he sold potatoes. As to confectioners, at this time of the year with its colds and many nasal-borne organisms, one's imagination boggles at the thought of diminutive handkerchiefs, furtively used, and the handling of cakes and bread. Why cannot uncut bread be wrapped in the same way as cut bread? And why not cake-lifters?

I have turned this over in my mind for a long time, and now felt that this would be a good opportunity for its insertion between the profound technical and clinical comments of the well-informed.—I am, etc.,

Bradford, 5.

ALLEN GLENN.

SIR,—It is only necessary to look closely at plug handle or lever in public lavatories to appreciate how gross contamination of the right hand can be. Washing can save oneself from any consequence, but the crowds that would fail to wait for free tap or basin at peak periods in market towns and holiday resorts defy estimate. Pedal flush control appears to be the solution of this chain of infection. A pedal lever is relatively foolproof, far more difficult to remove than chain or handle; manufacturers stock them and say that they need not cost more than pull plugs if the sale were greater. The demand for installation in public lavatories is almost non-existent. Why is that? Should not the medical profession express an opinion on the matter?—I am, etc.,

London, W.2.

ANNIS GILLIE.

Rh-Hr Nomenclature

SIR,—Logic does not seem to be Dr. A. S. Wiener's strong point lately (*Journal*, February 9, p. 339). 50% of letters go against him, so his committee is fortified "in its conclusion that the C-D-E notations must be discarded." A lesser man might have thought that such a response showed the need for a compromise, using both systems, in the United States at any rate.

Sometimes he uses specious arguments,¹ which can often be turned against him.² All too frequently, however, he descends to rhetoric rather than make any pretence at scientific argument, and the last paragraph of his letter to you

is a good example of this. He has used the word phenotype for a list of antiserum reactions, and has separated C from $\bar{c}$, and E from e, thus making his hypothetical student do an entirely unnecessary mental anagram. There is no problem so simple that it cannot be made difficult by being expressed badly. Even Dr. Wiener would not, I hope, use the Red Queen's arithmetical problem as an argument for abolishing the numeral 1 or the process of counting.

Dr. Wiener should remember that rhetoric is the harlot of the arts; what she will do for him she will do equally well for his opponents—in this case even better. Let us rewrite his question in his own nomenclature, misusing the word phenotype just as he does: "What genotypes correspond to the phenotype little rh single prime plus, large Rh nought minus, little rh double prime plus, little hr single prime minus, little hr double prime plus?" asked the professor.

If one is to take parallels from Lewis Carroll, Jabberwocky is a more appropriate one than the Red Queen's question, which is, after all, as simple as counting up to ten.—I am, etc.,

Colchester.

Non-ulcer Dyspepsia

SIR,—In your comment (*Journal*, February 16, p. 391) on the excellent paper by Dr. A. Wynn Williams and his colleagues on the investigation of non-ulcer dyspepsia by gastric biopsy (p. 372) you point out that "this procedure [of gastric biopsy] does not seem likely to enter into routine medical practice for the investigation of dyspepsia." May I therefore suggest that their observations could be usefully extended by co-ordinating the x-ray appearance of the motor function of the stomach with its secretory function?

In a recent monograph¹ I have summarized the evidence which supports the view that the secretory and motor functions are parallel manifestations which respond simultaneously and in an identical manner to a given stimulus and that they cannot be dissociated; the gastric motility (which should not be confused with the emptying time of the gastric content) gives, therefore, a fair indication of the gastric secretion.

The authors also show how difficult it is to classify gastritis on a histological basis. I have suggested² that the behaviour of the gastric secretions provides a basis for a clinical classification, because hypersecretion and hyposecretion are manifestations of two unrelated disease entities and not simple quantitative variations due to the same causes.—I am, etc.,

Incidence of Tuberculosis

SIR,—I note from your report of the proceedings of the Consultants and Specialists Committee of the B.M.A. (*Supplement*, February 16, p. 66) that the Ministry of Health takes the usual attitude of complacency regarding the question of tuberculosis in this country. We are always reading statements in the press that tuberculosis is on the way out and that it is practically non-existent in an infectious form. The presumption is that chest clinics will soon not be required. I would draw your readers' attention (let us hope some of them are M.O.s from the Ministry of Health) to the fact that, in one London Borough alone, 100 cases of active infectious tuberculosis were found through mass x-ray examination from February, 1955–6, making a rate of 6.4 per 1,000. In addition, another 72 cases of active tuberculosis were found by the Islington Chest Clinic unit in people working, but not living, in the borough. This quite aside from the fact that 45 cases of bronchial carcinoma were also discovered by the unit.—I am, etc.,

London, N.19.

J. WALLACE CRAIG.

Treatment of Herpes Zoster

SIR,—There have been numerous letters and articles concerning the treatment of herpes zoster, and textbooks differ in their advice regarding treatment.

We in this practice have treated over 21 cases in the past year, and, except in two cases, there has been no post-herpetic pain, and in these two cases the post-herpetic pain lasted three months. In no cases did we have to resort to prolonged use of sedatives or analgesics, nor at any time did we have to use powerful analgesics—e.g., morphine, pethidine, amidone, etc. In most of the cases the eruption had been present for two or three days, but in one case it had been present for five days, completely involved T.8, and in addition the patient was seven months pregnant. The method we used was injections of cyanocobalamin, 100 μ g. daily for six days, and we painted the eruptions with flexible collodion twice a day, not removing the old paint. If the pain was troublesome the patients were given tab. codein. co., 2 as required. In all cases it was observed—except in the two cases mentioned above—that the pain ceased towards the end of the injections and not later than ten days. The two exceptions were cases in which we tried (1) one injection of cyanocobalamin (1,000 μ g.) on the first and third day, and (2) three injections of cyanocobalamin (250 μ g.) on three alternate days. In both cases we noticed that the pain was more severe and there was post-herpetic pain.

We are of the opinion that this condition appears to respond to daily injections of cyanocobalamin (100 μ g.) and painting with flexible collodion, and that bigger doses do not have the same effect.—We are, etc.,

Tibial Traction

SIR,—All orthopaedic surgeons will agree with Dr. W. L. Turner (*Journal*, February 9, p. 344) that it is regrettable how many patients, having been treated for a fractured femur, are left with a stiff knee-joint. Unfortunately the cause of this stiffness is more complex than she suggests, and the remedy she advocates—the insertion of skeletal traction devices through the femur instead of the tibial tubercle—would have little effect on the end-result.

The truth of the matter is that some restriction of knee flexion is very often seen after a femoral-shaft fracture, however it has been treated. Adherence of the quadriceps muscles, and a fibrosis in their substance, at the fracture site is apparently the most important cause of this disability, and this often occurs even in cases in which no traction has been applied. Muscle wasting leading to joint instability and retropatellar adhesions are frequently encountered ancillary features.

Even so, and merely on commonsense-grounds, it may at first sight appear desirable to drill the Kirschner wire and Steinmann pins commonly used through the lower end of the broken bone itself rather than through the tibia. But such a procedure has risks of its own—the wire may enter the fracture haematoma or even one of the synovial recesses of the knee-joint. The penalties of infection at either site are such as to make most of my colleagues frown upon the method.—I am, etc.,

London, W.C.1.

RICHARD HARRISON.

Haemoglobin Measurements

SIR,—It is becoming a practice in writing, in giving communications, and sometimes in routine reports from laboratories, to record the haemoglobin in grammes rather than the traditional percentage. While not wishing to depreciate purist tendencies, the value of this terminology alone is questionable. It may be easy for the erudite to think in terms of grammes, but many reactionaries like myself still prefer to think in percentages. There was an excellent purpose in insisting on grammes when the scale in different laboratories varied, but this is now uniform (14.8 g. = 100%), so that a return to a percentage scale would be

reasonable. Preferably, both should be given, as measurement in grammes is necessary for calculation of the absolute values. At any rate, may I beg that the habit of certain laboratories in sending out their reports with the haemoglobin in grammes only should cease? It can lead to the bewilderment of the general practitioner, and sometimes the consultant, and bespeaks of "one-upmanship" on the part of the laboratory. My impression is that most directors of clinical laboratories still think and dream of haemoglobin in percentages rather than grammes, or is this accusation unfair?—I am, etc.,

Birmingham.

C. F. HAWKINS.

Suxamethonium and Post-operative Muscle Pain

SIR,—The article by Drs. D. D. B. Morris and C. H. Dunn (*Journal*, February 16, p. 383) describes ways of reducing muscle fasciculations following suxamethonium. They mention chlorpromazine, tubocurarine, procaine, and slow administration of the drug. I have an article awaiting publication which describes a further means of reducing or abolishing these fasciculations. It is based on the slow administration of a diluted solution of suxamethonium under thiopentone narcosis of moderate depth.

The technique for an adult is as follows: Two 20-ml. syringes are used; the first contains 1 g. thiopentone in 20 ml. water (5%), the second contains 100 mg. suxamethonium in 20 ml. water. Thiopentone solution is injected intravenously at the rate of 1 ml. every 5 seconds until the patient is on the verge of respiratory arrest, actual arrest being avoided; oxygen is given from a face-mask from the time that the patient loses consciousness. Suxamethonium solution is now injected at the same rate until respiratory paralysis occurs. By this method muscle fasciculations can, with practice, be abolished in every case. A far simpler method to abolish fasciculations is, of course, to use gallamine or tubocurarine. For an adult I use 50 mg. of the former, and 10 mg. of the latter, given before the thiopentone, or mixed with it; time has to be allowed for the curarizing drug to act if the fasciculations are to be abolished entirely. Bizarre effects may, of course, occur from using two different types of relaxant in one case. If 10 ml. suxamethonium is injected rapidly fasciculations will occur, and this possibly accounts for the failure of this method as described by Drs. Morris and Dunn.

While I do not believe that the intensity of visible fasciculations is the whole story as regards post-operative muscle pain, I do think that abolition of the visible fasciculations reduces it. I have no figures to offer for the incidence of post-operative pain in my practice, as, for some reason, no case has ever been drawn to my attention. Perhaps this is because I almost invariably use more than 0.5 g. thiopentone for induction.—I am, etc.,

Dartford, Kent.

JOHN BULLOUGH.

Compound Aspirin and Steroid Tablets

SIR,—The argument, as presented in your annotation (*Journal*, February 16, p. 395), tends to be slightly one-sided, and, in addition, contains certain inaccuracies requiring correction. Presumably, this is because the writer did not have all the relevant information at his disposal. In view of this, you may wish your readers to have the following information so that they will be in possession of all the available evidence and thus able to draw valid conclusions.

Using the "cotton pellet" test¹ and the "granuloma pouch" test,² it has been shown that approximately the same anti-inflammatory effect is produced by a combination of aspirin and prednisolone as that produced by double the amounts of either ingredient alone. The conditions of these tests differ slightly, but the findings suggest that the combination results in an additive anti-inflammatory effect. Thus there would appear to be reasonable grounds for believing that the combination would be more effective clinically than either ingredient alone.

Reports of clinical studies^{3,4} indicate that the combination of 0.3 g. aspirin and 0.5 mg. prednisolone is effective in the control of cases of rheumatoid arthritis and allied conditions. Further, some investigators⁵ find that the highest daily maintenance dose of cortisone tolerated by post-meno-

pausal women is 25–30 mg., by pre-menopausal women 35–40 mg., and by adult males 40–50 mg. (these doses correspond respectively to 5–6 mg., 7–8 mg., and 8–10 mg. prednisolone). They state that they prefer to keep below these maximum doses, and so it is reasonable to infer that doses of prednisolone below these levels can be effective. Thus, if the additive factor is taken into consideration, the recommended daily dose of this combination of aspirin and prednisolone can reasonably be expected to produce a therapeutic effect.

The above evidence tends to suggest that this particular combination of aspirin and prednisolone may well deserve a place in therapeutics—at least it is founded on a rational basis.—I am, etc.,

Bowel Obstruction

SIR,—Recent letters on the above subject prompt me to record the following case. A man, age 50 years, who had had a polya gastrectomy performed in 1949 for a chronic gastric ulcer, consulted me at my morning surgery, which he had to pass on his way home from work. I may add that he was cycling. He complained of abdominal pain of a gripping character. There had been no vomiting at that time, although he did vomit before he arrived in hospital. The bowels were said to be open that morning and the stools loose. On examination there was very marked visible peristalsis in the right iliac fossa and extreme tenderness. He was admitted to the General Hospital, Northampton, under the care of Mr. R. O. Lee, by whom the partial gastrectomy had been performed. At operation three segments of orange were found impacted in the terminal ileum. The patient subsequently remembered eating a rather dry, pithy orange some fifteen hours previously.

The object of this note is to suggest that, with the increasing popularity of surgical treatment for peptic ulcer, it is extremely important that we should warn these patients how important thorough mastication of the food can be. Previous letters have recorded cases of small-intestine obstruction with a green fig and with a brussels sprout. These patients had a normal pylorus. How much greater must be the hazard of the patient whose pylorus has been removed.—I am, etc.,

Wellingborough.

JOHN T. CORBETT.

Neostigmine-resistant Curarization

SIR,—Dr. K. H. Oldfield's letter (*Journal*, December 29, 1956, p. 1544) is of great interest, but whether it offers proof that intracellular potassium loss is not concerned in neostigmine-resistant curarization is questionable. Should one be influenced by the evidence of this one case; or accept the contradictory findings of an experimentally proved antagonism between potassium and curare, coupled with not infrequent clinical accounts of improvement or reversal of persistent curarization by potassium infusions? In fact, it is doubtful whether the case he reports bears more than a superficial resemblance to the type of case in which neostigmine resistance occurs.^{1,2} Further information, not provided in Dr. Oldfield's abridged report, would be needed to decide this matter, but his account suggests his patient's illness resembled a condition of primary aldosteronism as described by Conn^{3,4} and later by others.^{5–10} Recent reviews suggest a well-defined syndrome^{11,12} with a long history (usually over a year), and a low serum-potassium level falling below 2

mEq/l., but with surprisingly inconstant muscle weakness. Marked weakness often occurred only during an infective episode, and spared respiration. Hypertension is a constant feature, and acidosis has not been encountered; metabolic alkalosis is frequent, with the appearance of tetany.

This picture is very different from that of the patient dying after his anaesthetic: he is starved, weak, and has a hypotension that responds poorly to vasopressors—a state characteristic of hypokalaemia.¹³ Electrolyte depletion has been rapid, and there is a metabolic acidosis which contributes considerably to the intracellular potassium loss and hinders its replacement. The endocrinological background of these two types of case is probably different: secretion of aldosterone is largely independent of the pituitary influence that promotes secretion of other corticoids.^{11,14,15} The acutely ill patient generally shows a strong pituitary-adrenal type of response producing a different range of steroid hormones.^{16,17} If the development of neostigmine resistance is due to a defect of neuromuscular transmission, then certain of these differences become important.

Hypokalaemia with alkalosis is less likely to produce paralysis than with acidosis.^{12,18} Acidosis is accepted as causing a loss of intracellular potassium,¹⁹ and it is known that alkalosis raises the intracellular potassium at the expense of extracellular levels.²⁰ The muscle end-plate potential is closely linked to the ratio of extracellular to intracellular potassium.²¹ Rapid alterations of this ratio could lead either to hyperpolarization or to partial depolarization of the end-plate, thus interfering with the muscle's response to nerve impulses.^{22–24} Such a swing between the two extremes may have been achieved by Dr. Bourne and Dr. Shackleton by rapid transition from respiratory acidosis to respiratory alkalosis (*Journal*, December 22, 1956, p. 1485). Perhaps this is the connexion between persistent curarization and respiratory acidosis that several of your correspondents recently have remarked.

It appears that the body can readjust the potassium ratio about the plasma membrane towards normal, but with lower total values, only when the loss from the body is slow. This is suggested by experimental findings that rapid potassium loss frequently produces weakness or paralysis that is seldom seen when the loss is slow,²⁵ and the importance of the rate of potassium depletion in producing weakness has also been noted clinically.¹² If function is maintained with smaller total quantities of potassium, one could expect it to be disturbed more readily than normal by such changes as respiratory acidosis or depolarizing relaxants may produce.

In the case of primary aldosteronism reported by van Buchem *et al.*^{9,12} there had been no complaint of weakness despite a serum potassium level under 2 mEq/l. However, marked weakness appeared in the immediate post-operative period when serum potassium levels had been returned to normal. This may well have resulted from a state of relative hyperkalaemia in a person whose intracellular potassium had become adjusted over many years to a low serum value. The serum level is much more easily restored than the intracellular store.²⁶

Therefore it would be interesting to learn whether Dr. Oldfield's case did not have a long history of developing hypokalaemia with an associated alkalosis. Indeed, this woman may have been in a state of relative intracellular potassium excess, despite a total deficiency, so that the vigorous pre-operative potassium replacement produced a patient requiring relatively large quantities of relaxant because of a curare-potassium antagonism. The muscle potassium level quoted was indeed low, and one wonders whether the biopsy specimen was not taken from traumatized muscle at the abdominal wound edge during closure of the incision. Muscle biopsy figures reported by Chalmers *et al.*⁷ showed an increased chloride content; possibly this shows that the extracellular fluid space was enlarged, making the true intracellular potassium loss less than it at first appears.

The postulated penetration of the C.N.S. by curare to produce a picture of neostigmine resistance² might also not occur if alkalosis accompanies the potassium loss. In any

Obituary

S. S. BARTON, O.B.E., F.R.F.P.S., M.R.C.O.G.

Mr. S. S. Barton, consultant in obstetrics and gynaecology to the Liverpool and the Welsh Regional Hospital Boards, died at Walton Hospital, Liverpool, on February 17 from injuries received in a motor accident near Holywell, North Wales, on February 4. He was 66 years of age.

Samuel Saxon Barton was born at St. Michael's, near Liverpool, on August 29, 1890, and was educated at Green Bank School, Liverpool, and Loretto School, Musselburgh, receiving his medical training at the University of Liverpool and at Edinburgh. He qualified by taking the Scottish triple qualification in 1917, and three years later was elected a Fellow of the Royal Faculty of Physicians and Surgeons of Glasgow. After qualification he held the appointments of house-surgeon at the Hospital for Women and house-physician at the David Lewis Northern Hospital, Liverpool, before entering the Royal Navy as a temporary surgeon lieutenant for service during the remainder of the first world war. He served in H.M.S. *Dwarf* in the waters of the Cameroons and off the west coast of Africa, being appointed O.B.E. in 1919.

After the war Barton settled in Liverpool. In addition to the work of his practice he became honorary clinical assistant at the Hospital for Women, and he also served on a medical board of the Ministry of Pensions as a specialist in tropical diseases. Later he was appointed honorary assistant surgeon to the Hospital for Women and to the Samaritan Hospital for Women. After relinquishing the latter post he was elected honorary obstetrical and gynaecological surgeon to the Hahnemann Hospital (now the Liverpool Homoeopathic Hospital), an appointment which he held until his death. When an opportunity arose to join a gynaecological and obstetrical partnership in Llandudno he gave the larger part of his medical services to North Wales and built up a large practice there. In 1933 he was elected a Member of the Royal College of Obstetricians and Gynaecologists, and in 1941 became consultant in obstetrics and gynaecology to the Liverpool and Welsh Regional Hospital Boards. His wife, Dr. Dorothy Atherton Barton, and three sons survive him.

H. R. writes: Saxon Barton will be remembered particularly as an antiquarian and as an able artist in oils and water colours. At the Royal Cambrian Academy of Art he founded a prize awarded annually to encourage young artists to exhibit their work. A recognized authority on King Richard III, he founded the Fellowship of the White Boar (the Plantagenet coat-of-arms), and, as president of the society in 1934, erected a stained-glass window in Middleham Church, Yorkshire, to commemorate the last of the great Plantagenets. His latest ambition was to erect a monument to Richard III in Bosworth Field. Barton was also a former president and secretary of the Historic Society of Lancashire and Cheshire, and a Fellow of the Society of Antiquaries of Scotland, and published several works on the subject of antiquities.

W. H. WILSON, D.M.

The obituary of Professor W. H. Wilson was printed in the *Journal* of February 16 (p. 406).

B. G. P.-S. writes: Everyone knew him in Mataria, so we had no difficulty in finding his house in a street named in Arabic after him. We turned, leaving all the dust behind

case, the brain is probably resistant to a slow potassium loss, but may be markedly depleted by a rapid loss such as could have occurred in the cases which died.^{27,28} There is also evidence that mucoproteins are concerned in the integrity of the blood-brain barrier.^{29,30} These substances, being constituents of collagen tissue, may have their physico-chemical characteristics influenced by adrenal steroids.^{31–33} Glucocorticoids and mineralocorticoids appear to have opposing actions on glycoproteins,³⁴ so that the response seen in a case such as Dr. Oldfield's could well be different from that seen in the patients who slowly deteriorated and died after relaxants.

The uninvestigated problems posed by the present discussion bring one near the limits of practicable argument; but it would be a just concession to the dynamic nature of nerve and muscle function if one were to attempt to express body electrolyte levels in the ratios in which they exist about the plasma membrane, and not in total, dead, weights.—I am, etc.,

Bellville, C.P., S. Africa.

Wagner-Jauregg's Symptom

SIR,—March 7 will be the centenary of Professor Wagner-Jauregg's birth. His name will for ever be remembered in connexion with the malaria treatment of general paralysis of the insane, for which discovery he received the Nobel Prize. There is also a "Wagner-Jauregg's symptom," but no record of this symptom is to be found in any standard textbook. Professor Stefan Jellinek,¹ pioneer in electropathology, who in 1904 discovered a brownish pigmentation in many cases of hyperthyroidism (Jellinek's sign), and at 86 is still doing research work at Queen's College, Oxford, described the "Wagner-Jauregg's symptom": if one exercises gentle pressure on the eyeball, the zygomatic muscle will contract, drawing the angle of the mouth upward and laterally. In a case of hemiparesis this trigeminal-facial reflex is lost and the musculature of the paralysed side of the face remains uncontracted. This symptom is especially valuable in the differential diagnosis of hysterical and organic hemiparesis of the face.—I am, etc.,

London, E.17.

B. JUHN.

REFERENCE

- Jellinek, S., *Wien. klin. Wschr.*, 1916, **29**, 1546.

Mr. G. NABARRO (Kidderminster, Con.) said: While wishing warmly to congratulate my right hon. Friend, may I ask him to make it perfectly clear, in framing the terms of reference for the Royal Commission, that a primary purpose should be to endeavour to eliminate all the legal and other uncertainties which have arisen during the last few years from the Spens Report and the Danckwerts award made under it, all of which are responsible for the present difficult position with the doctors?

Mr. MACMILLAN answered: One of the purposes of the Royal Commission will be to clear up this situation and to lay down a system which, through the years, will be more workable and more acceptable.

Dr. EDITH SUMMERSKILL (Warrington, Lab.) asked: As this is virtually a repudiation of the recommendations of the Spens Report, could the Prime Minister say what was the reaction of the professional organizations towards this new suggestion?

Mr. MACMILLAN said: No, sir. The discussions between the representatives of the profession and the Minister of Health are another matter. To-day, I have simply preferred to confine myself to stating that I have recommended the appointment of the Commission, that Her Majesty has been pleased to accept the recommendation, and that the terms of reference and the membership will be announced. I think that all the detailed questions had better be put to the Minister responsible.

Statement in House of Lords

After Lord SALISBURY (Lord President of the Council) had given to the House of Lords the same statement as the Prime Minister gave to the House of Commons, Lord ALEXANDER OF HILLSBOROUGH (Lab.) said: My Lords, I am much obliged to the noble Marquess the Leader of the House for making here on behalf of the Government the statement that is now being made by the Prime Minister in another place. I must say that the first impressions of this statement upon me are not very cheerful. Having regard to the long, outstanding application of the great profession of medical men and women to the State service, I feel it is extraordinary that, after this length of time, the question of their remuneration should be referred to a Royal Commission. That is a most extraordinary procedure to adopt. It was only last week that the noble Marquess, in that very difficult hour when he performed so brilliantly at the Box, said how much he deprecated the long delays and the odd form of inquiry which would be brought about by applying a Royal Commission to such a comparatively simple question as the roads in Oxford. Here we are dealing with something which is urgent, outstanding, and necessary to retain the good will of the medical profession in maintaining a great national service to the people. To me, it seems like cowardice on the part of the Government for them not to deal with, and decide their policy upon, what is an urgent matter. Instead of that, they refer it to a Royal Commission.

There was no such reference to a Royal Commission, no such delay, before the Government made the statement in the other place the other day about the increased costs of welfare milk and the weekly contribution of the worker to the Health Service as there is going to be in regard to the remuneration of the doctors. There was no sort of cowardice or hesitation in referring that matter to a Royal Commission. Those are people of a different type. But here it looks as if the medical profession may be "got at" with a view to putting up with a Royal Commission. Having regard to his former association with the great medical profession, no doubt the Chancellor of the Duchy of Lancaster will be busy trying to spin the necessary story of glamour to his professional colleagues. I only hope that the country will take as strong and as sincere a view about this sort of thing as I do myself.

The MARQUESS OF SALISBURY said: My Lords, if the noble Viscount the Leader of the Opposition was asking a supplementary question, it is what I might call a rhetorical question. He referred—I rather expected he would refer to it—to a debate which took place last week on the Oxford roads,

in which the Government rejected the idea of a Royal Commission. The noble Viscount must remember that the circumstances were entirely different in that case, as I explained—or, at least, I hoped I had explained—to the satisfaction of the House. There was in existence under the Town and Country Planning Act alternative machinery which was already in operation, and the fact that it was a very limited question—a limited problem, as the noble Viscount has said—made it easy to use that machinery. This is a very wide and complex question. I would remind the noble Viscount that I said in the statement I have just made:

"... the time is opportune for a full review of medical remuneration through an independent inquiry which would take into account the position of the medical profession in relation to other professional classes in the community."

That is, indeed, one of the great problems which has to be faced. It is no good the noble Viscount and others saying that the medical profession can be dealt with entirely in isolation; it cannot be done. This is one of the most complicated questions that exist, as I know from my connexions with the research bodies in this country, and it is an eminently suitable question to be dealt with by a body of this kind.

Viscount ALEXANDER OF HILLSBOROUGH asked: How long did it take the Government to discover that this was so complicated a question in comparison with others? For months and months this matter has been under discussion with the medical profession, and it has certainly been within the knowledge of the Ministry of Health from the moment the State scheme was launched. Now, at this stage, when the doctors are in a very poor position—at least, some of them are—in relation to the increasing cost of living, that they should be dealt with by means of a Royal Commission seems to me almost unthinkable. Will the noble Marquess say whether, while the Royal Commission is sitting, any adjustment is going to be made to ease the position of the doctors?

The MARQUESS OF SALISBURY: My Lords, I think I can say something about that. I understand that my right honourable friends the Minister of Health and the Secretary of State for Scotland have told the doctors and dentists that they are willing to agree to the granting of an interim increase to the junior hospital medical and dental staff. This is on the basis that they can justifiably be regarded as underpaid at present. The offer will be negotiated through the established Whitley machinery. It will not be extended beyond this limited class to, for example, the lower-paid general-practitioner doctors or dentists; it is meant to apply to those who are in most need at the present time.

Lord WILMOT OF SELMESTON (Lab.) said: My Lords, in view of what the noble Marquess the Leader of the House says, and in my view rightly says, about the bearing on research workers, may I take it that consideration of those bearings will be included in the terms of reference of the Royal Commission?

The MARQUESS OF SALISBURY answered: My Lords, the actual terms of reference I hope to be able to announce later. As I have said, anything which is done with regard to doctors and dentists has a bearing on these wider categories, though, obviously, there is a limit even to the subjects with which a Royal Commission can concern itself. But there are categories outside the limits of such terms of reference which have a bearing on the recommendations which such a Commission could make.

Lord AMULREE (Lib.) said: My Lords, I thank the noble Marquess for the statement he has made. I must agree that the questions raised by the medical profession have been going on for a long time, and I hope that the Royal Commission will now settle them quickly. Secondly, I and dentists, which the noble Marquess states is under consideration, will come under the terms of reference of the Royal Commission. We were told during a debate on the Oxford roads that some Royal Commissions could report in six months, while others might take six years. This is a

matter of some urgency, and I trust that in this case the period will be one of six months and not a longer period.

The MARQUESS OF SALISBURY said: My Lords, the period which the Royal Commission will take is a matter for the Commission. Her Majesty's Government desire, as much as the noble Lord, that it shall be as rapid and efficient as possible in its work. With regard to the other question, perhaps the noble Lord will allow me to let him know exactly what will be included within the terms of reference when I am able to do so. I will certainly bear in mind the point that he has made.

Lord CONESFORD (Con.) said: My Lords, may I ask my noble friend whether, in settling the terms of reference of the Royal Commission, he will consider the advisability of making them wide enough to enable the Royal Commission to compare, not only professional earnings as between different professions, but professional earnings with non-professional earnings? The MARQUESS OF SALISBURY said there had to be some limitation of the terms of reference, even of a Royal Commission.

Viscount ALEXANDER OF HILLSBOROUGH said: My Lords, on this important matter we should be glad to know the date by which we may have the terms of reference and (although this is a question we may then ask) how long the Royal Commission will sit. This is such an extraordinary announcement that we should be informed of these terms of reference as soon as possible.

The MARQUESS OF SALISBURY said: My Lords, I can assure the noble Viscount that we will let him know as soon as we are in a position to do so.

Antidote to Nerve Gases

Mr. S. AWBERY (Bristol, Central, Lab.) asked the Minister of Supply what experiments had been made at the Chemical Defence Station, Salisbury Plain, on the use of atropine as an antidote to nerve gases; what was the purpose of these; to what extent volunteers were used for the experiments; and what proposals he had for issuing this drug to soldiers to be used for self-injection. Mr. W. J. TAYLOR, the Parliamentary Secretary, replied that comprehensive experiments had been carried out over a number of years by the Chemical Defence Experimental Establishment to assess the value of atropine as an antidote against nerve gases and to determine the tolerance of effective dosages by men. The results of these trials, which included experiments with volunteers, had been published in the scientific press from time to time. No decision had yet been taken to issue this drug to soldiers for self-injection.

Benefit for Respiratory Disease

Dr. BARNET STROSS (Stoke-on-Trent, Central, Lab.) asked the Minister of Pensions and National Insurance whether he would pay benefit under the Industrial Injuries Act to those who suffered from respiratory disease as a result of living in areas where the atmosphere was heavily contaminated by commercial processes. Mr. J. BOYD-CARPENTER replied on February 18 that the proposal, which raised wide questions, went far beyond the provisions of the Industrial Injuries Act, 1946.

Alcoholic Psychosis

Mr. SOMERVILLE HASTINGS (Barking, Lab.) asked the Minister of Health on February 22 for an estimate of the number of cases of mental disease admitted to hospitals under his direction during 1955 in which alcohol was the principal or contributory cause, respectively. Mr. D. VOSPER stated that during 1955 there were 1,053 admissions to mental hospitals which were recorded as principally due to alcoholic psychosis or alcoholism. No estimate could be made of the number of admissions to mental hospitals in which alcohol was a contributory cause.

Homicide Bill

The House of Lords accepted without a division, but not without dissent, the Homicide Bill on second reading on February 21. The MARQUESS OF SALISBURY, for the Government, said it was hoped the House would not wish to make any drastic amendments, but any that were proposed would be considered on their merits, and the Government were free to accept any which they considered would be an improvement in the Bill. Lord GODDARD, the Lord Chief Justice, indicated during the debate that he would call attention in committee to some drafting difficulties; and Lord SILKIN expressed the Opposition's hope that it would be possible to "improve" the Bill along the road to complete abolition of capital punishment.

Lung Cancer

Mr. SOMERVILLE HASTINGS (Barking, Lab.) asked the Minister what communication he had received from the Standing Medical Advisory Committee or the Central Health Services Council as to the relationship between cigarette smoking and cancer of the lung, and as to any action to be taken accordingly. Mr. VOSPER replied that at their meetings in December last these bodies repeated the advice already given to his predecessor. Like him, he proposed to ensure that the public were kept informed of all relevant information as and when it became available.

Health Service Cost

Mr. ARTHUR LEWIS (West Ham, North, Lab.) asked what was the total cost of the Health Service in 1950 and at the latest convenient stated date respectively; and, taking the pound sterling as having a purchasing value of 20s. in 1950, what was the relative purchasing value of the current National Health charge compared with 1950, after allowing for the depreciation of the purchasing value of the pound sterling. Mr. VOSPER told him that the total cost of the Health Service in 1949-50 was about £450m., of which £345m. was met by the Exchequer. The corresponding figures estimated for 1957-8 were about £690m. and £550m. respectively. The equivalent of these latter figures in terms of the purchasing value of the pound in 1949-50 (measured by the estimated change in the Consumer Price Index between 1949-50 and December, 1956) were about £515m. and £410m.

Whitehaven Hospital.—The Minister of Health has authorized the regional hospital board to proceed with the site works for the new hospital at Whitehaven. The total estimated cost of the hospital is £2,500,000, and plans for the first stage are nearing completion.

Hospital Confinements.—During 1955 the number of institutional confinements in England and Wales was 440,857, which was 64.75% of the total.

Universities and Colleges

UNIVERSITY OF OXFORD

The following have been reappointed University Demonstrators from October 1, 1957, to September 30, 1962, in the subjects indicated in parentheses: Dr. R. Barer (Human Anatomy), Dr. J. M. Walker (Pharmacology), Dr. E. M. Vaughan Williams (Pharmacology), Dr. D. S. Parsons (Biochemistry), Dr. D. J. C. Cunningham (Physiology).

Dr. D. St. C. Roberts has been reappointed Clinical Tutor in Ophthalmology and Dr. G. M. Ardran radiologist at the Nuffield Institute for Medical Research, both from October 1, 1957, to September 30, 1962.

In Congregation on January 24 the following degrees were conferred:

B.M.—G. R. Pate, D. A. Wheelwright, D. W. Boyd, P. Owen-Lloyd, Jennifer L. Murray, H. M. Williams (in absence).

UNIVERSITY OF ST. ANDREWS

The following candidates have been approved at the examination indicated:

M.B., B.S.—I. M. Aitkenhead, L. R. Butler-Manuel, D. C. Crawford, R. A. Haddow, P. Hossen, M. J. Illingworth, *D. W. Jarvis, J. L. Maddison, J. P. M. Penney, D. J. Sutherland, *T. T. Thompson, H. E. G. Thomson, Mrs. Elinor M. Whyte.
*In absentia.

UNIVERSITY OF GLASGOW

On January 7 the degree of M.D. was conferred, *in absentia*, on the following candidates: *D. I. Buchanan, *M. B. Divertie, J. M. Smith, *C. M. Wylie.

The following degrees were conferred on January 12:

M.D.—Mary G. Coyle, *Margaret M. Kerr, *R. Lannigan, *C. J. Mackinlay, *R. G. Whitelaw.
M.B., Ch.B.—A. V. Anderson, A. Auld, Evelyn F. Barclay, H. Bart-Plange, J. Caplan, B. C. Colvin, A. H. Frame, S. MacF. Gaird, D. S. Gilchrist, H. K. Gooding, J. C. Gray, A. Hare, Moira B. M. Hendry, T. P. Howat, Christine M. Hyslop, Anne P. Johnstone, J. Lee, J. W. Little, W. MacDonald, R. E. McIntosh, G. D. Mackenzie, D. G. Muirhead, A. M. Orr, T. Orr, M. C. G. Rennie, A. E. Roberts, A. P. Scott, R. G. Stark, Helen J. Stewart, P. M. Stoker-Murdy, Seana R. Sutherland, G. J. Thomson, R. J. Wylie, W. J. Young.

*With high commendation. *With commendation.

ROYAL COLLEGE OF PHYSICIANS OF LONDON

At the quarterly comitia of the College held on January 31, with the President, Sir Russell Brain, in the chair, the death on December 20, 1956, at St. Thomas's Hospital, of the Treasurer of the College, Professor W. G. Barnard, was recorded with deep regret.

Dr. E. R. Boland, Dr. J. B. Harman, and Dr. T. C. Hunt were reappointed College representatives on the Central Medical Recruitment Committee, Dr. Janet Vaughan on the Advisory Board on Nursing Education of the Royal College of Nursing. Dr. Neville Goodman was appointed College representative at the Health Congress of the Royal Society of Health to be held at Folkestone from April 30 to May 3, 1957.

Licences

Licences to practise were conferred upon the following 84 candidates who have passed the final examination in medicine, surgery, and midwifery of the Conjoint Board and who have complied with the by-laws of the College:

K. A. Anderson, E. L. R. Andrews, M. V. R. Appa Rao, J. B. G. Arthur, P. Atkins, S. E. August-Moffatt, A. G. Barrow, E. E. Basse, G. P. E. Beange, P. G. Benson, G. T. Birchall, A. J. Blakeman, J. J. B. Brand, T. J. Carter, J. V. F. Catto, A. M. A. Clark, C. Cook, E. J. Cooney, Mary Corbett, Barbara C. Dean, I. E. Doney, J. I. Edwards, M. W. Everitt, K. Finney, A. F. Fleming, M. E. Gloster, W. I. M. Goodrick, C. J. Goodwill, Z. Grahovac, B. J. G. Greenhill, Jean A. Hagger, D. W. Hall, T. L. R. Hall, Rosalie M. Harrison-Bloom, Veira F. A. Hauxwell, L. P. J. Holt, Y. E. Hsia, C. M. Jadwat, P. Knight, Audrey M. Lake, C. W. Landon, Patricia O. Lane, Jean C. Le Riche, I. Lewis, W. J. Lush, I. McColl, C. A. G. Mackenzie, K. P. Mehta, A. H. Miller, C. P. Monty, D. R. Morgan, E. B. Morgan, B. R. P. Murray, Norma G. Newbury, Lotte T. Newman, J. D. J. Parker, P. C. C. Pitt, D. R. Potter, Sheila M. Power, Edna O. S. Renwick, R. B. Roberts, David S. Robertson, Donald S. Robertson, Charmian A. Russell, R. de K. G. Samuel, T. D. Sayer, J. H. Scotson, Mary P. Shepherd, I. D. Simpson, J. F. Tattersfield, S. G. Taylor, J. G. Teall, J. A. P. Trafford, J. Tudor, Joyce Warner, C. Wastell, B. Weinstein, W. M. Weir, P. S. Welch, P. B. Whatmore, S. R. Williams, Susan M. Wilson, T. Woodward, A. J. Zuckerman.

Diplomas

Diplomas in Laryngology and Otolaryngology, in Anaesthetics, in Psychological Medicine, in Tropical Medicine and Hygiene, in Pathology, and in Medical Radiotherapy were granted, jointly with the Royal College of Surgeons of England, to the successful candidates whose names are printed below in the report of the meeting of the Royal College of Surgeons of England held on January 10.

Diplomas in Medical Radiodiagnosis were granted, jointly with the Royal College of Surgeons of England, to B. W. A. Leeming and to the other successful candidates whose names are printed below in the report of the meeting of the Royal College of Surgeons of England held on January 10.

The following diplomas were granted jointly with the Royal College of Surgeons of England:

DIPLOMA IN CHILD HEALTH.—Uda S. Ellis, C. G. Gallagher.
DIPLOMA IN INDUSTRIAL HEALTH.—D. R. Belletty, D. E. Marchant, R. G. Orr, J. S. Robertson, F. G. M. Seager, O. P. Verma.
DIPLOMA IN PUBLIC HEALTH.—H. Bancroft, E. E. Bowen, Seonaid C. Cameron, J. C. Chakrabarti, D. M. Dignes La Touche, C. P. A. Dupont, C. B. Higgin, C. D. Hopkins, W. G. J. Hughes, I. Khan, Audrey J. Lacey, Hilda E. McNamara, R. K. Mukhopadhyay, W. L. Palmer, Brenda K. Rimmer, M. Ryan, S. W. Smith, R. A. Stenhouse, I. O. Taylor, R. W. Watton, P. A. C. Wright.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

At a meeting of the Council of the College held on January 10, with Sir Harry Platt, President, in the chair, Mr. A. C. McEarchern (Adelaide) was awarded a Hunterian Professorship.

A diploma of Fellowship was granted to W. G. Lucas. The following diplomas were granted, jointly with the Royal College of Physicians of London:

DIPLOMA IN LARYNGOLOGY AND OTOLARYNGOLOGY.—M. A. K. Afridi, J. A. Coombes, J. T. Dunn, J. A. Fajemisin, T. Fazleabas, Hla Saw Khine, C. M. Jain, J. McKenzie, A. G. May, N. R. Sarkar, S. Sarkar, P. A. Shah, E. G. Weyhausen, M. Y. Wipat.
DIPLOMA IN ANAESTHETICS.—D. A. L. Ashforth, Anne Bewley, P. Borg-Brigid, M. J. Brennan, J. F. Burdon, J. K. A. Burn, Rhoda M. R. Burt, G. H. Bush, M. P. Cardew, W. B. Chamberlain, J. Chari, Elizabeth F. H. Clarke, E. M. Coates, R. A. Davidson, W. MacF. Davidson, D. S. Dick, Diana F. J. Duncan, Barbara C. Edwards, L. Essex, J. N. T. Evans, Phillida M. Frost, M. R. Golin, Joyce Y. Graham, J. O. Hancock, Maureen E. Hardean, Margaret A. Hayes, Catherine Henderson, June R. Hill, Mary G. C. A. Hunter, Ruth Hutchinson, D. S. Hutton, Mary C. Irvine, J. M. James, W. H. James, Elsie Jaques, S. G. Jones, Lila Kalappa, A. N. Kalra, A. Mel, K. Kelly, F. M. Kinsman, Margaret A. Lawrence, Julia I. Leitch, A. B. Lodge, Joyce B. H. Longmore, Krystyna M. Lubomirska, G. W. Macnab, A. S. Manavalan, G. C. Mansfield, M. B. Marshall, Renate M. Meyer, N. K. Misra, D. D. Moir, A. Moore, D. K. R. C. Nainby-Luxmoore, F. Nimmi, G. K. Nixon, J. S. Ogilvie, R. C. Oliva, J. G. Opie, B. G. Pirie, Caroline R. F. Port, C. H. Pryor, Marion G. Ralston, Margaret E. Riddoch, E. D. T. Ross, H. N. Sadhu, G. Screech, B. C. Sengupta, J. G. Sheehy, F. B. Singleton, A. J. Slim, W. D. A. R. V. Li. Thomas, R. A. Truesdell, M. Urshan, L. Walker, D. A. Walmsley, P. T. Watters, K. P. Williams, E. G. Wilson.
DIPLOMA IN PSYCHOLOGICAL MEDICINE.—P. J. F. Aaronicks, P. T. Marie, L. S. Beesley, S. McC. Cannicott, N. S. Capstick, Cho-Man Chunz, Brigid M. R. Clark, M. J. Craft, P. J. Dally, R. Davidson, J. E. Dessart, D. C. W. Jenkins, R. E. Lovelace, A. M. Gregory, Isobel H. Hunter, Morzan, A. Orwin, Shera Samarawera, G. Stroth, J. D. Waldman, E. D. West, V. O. Williams, M. E. Y. York-Moore.
DIPLOMA IN MEDICAL RADIO-DIAGNOSIS.—A. T. Abdel-Messieh, W. M. C. G. J. H. Everard, S. N. Banerjee, S. Banerji, J. H. Comfy, F. H. Doyle, Harman, A. H. Isaacson, D. C. James, B. Lall, S. Nissanga, A. A. J. Potasnick, W. T. Rothman, T. Selvarajah, F. W. G. Snell, S. A. Sobhan, J. A. M. F. Veiga-Pires, A. C. Young.
DIPLOMA IN TROPICAL MEDICINE AND HYGIENE.—B. K. Basu, R. L. Bell, J. P. Crowdy, E. J. F. De Oliveira, D. S. R. Gunawardane, S. T. Hasan, J. G. P. Power, W. T. Richardson, R. R. Sidelsky, R. C. Watson.
DIPLOMA IN PATHOLOGY.—H. N. Dutta, S. Hameed, J. T. Hughes, A. J. Lewis, J. G. Paranjpe, R. A. Rimington.
DIPLOMA IN MEDICAL RADIO-THERAPY.—I. G. Emmanuel, W. E. Freeman, N. Gupta, H. Horwitz, S. F. Huq, Elizabeth M. Kingsley Piliers, R. Li, Morgan, D. L. Phillips, T. K. Rithuparnan, A. D. Shetty, H. D. Suit.

Vital Statistics

Influenza in Armed Forces

The only notable outbreaks of influenza so far this winter have been in Service units. An outbreak of virus A influenza has occurred in the R.A.F. at Halton, Bucks, and small outbreaks are reported from Army units at Chelsea and Wellington Barracks, at the Tower of London, and in two training units at Rhyl, Flintshire. Virus isolated so far has been of the Dutch 1956 group.

Week Ending February 16

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 830, whooping-cough 3,163, diphtheria 2, measles 19,710, acute pneumonia 676, acute poliomyelitis 37, dysentery 1,274, paratyphoid fever 6, and typhoid fever 1.

Infectious Diseases

In England and Wales during the week ending February 9 the largest rises in the notifications of infectious diseases were 3,744 for measles, from 13,008 to 16,752, 193 for dysentery, from 1,097 to 1,290, and 59 for acute pneumonia, from 661 to 720; the only large fall was 154 for whooping-cough, from 3,302 to 3,148.

The largest increases in the incidence of measles were 501 in Lancashire, from 2,937 to 3,438, 382 in London, from 971 to 1,353, 348 in Durham, from 1,088 to 1,436, 343 in Essex, from 1,113 to 1,456, 231 in Northumberland, from 734 to 965, 197 in Surrey, from 525 to 722, 175 in Yorkshire West Riding, from 755 to 930, 151 in Middlesex, from 501 to 652, 146 in Gloucestershire, from 220 to 366, and 135 in Staffordshire, from 386 to 521. The largest fluctuations in the trends of whooping-cough were a fall of 90 in Kent, from 250 to 160, and a rise of 45 in Sussex, from 55 to 100. The notifications of scarlet fever numbered 869, 4 more than in the

preceding week, and there were no large fluctuations in the local returns. 9 cases of diphtheria were notified, being 4 more than in the preceding week; 2 of the cases were notified in the metropolitan borough of Islington.

34 cases of acute poliomyelitis were notified during the week, and these were 7 fewer for paralytic and 4 more for non-paralytic cases than in the preceding week. The largest returns were London 8 (Kensington 2), Kent 4, and Lancashire 4.

The largest centres of dysentery were Lancashire 337 (Stretford M.B. 111, Accrington M.B. 106, Droylsden U.D. 15, Urmston U.D. 15, Blackburn C.B. 10), Yorkshire West Riding 174 (Rotherham C.B. 31, York C.B. 27, Dewsbury C.B. 24, Leeds C.B. 20, Bradford C.B. 17, Sheffield C.B. 15), Warwickshire 75 (Coventry C.B. 38, Birmingham C.B. 18, Nuneaton M.B. 12), London 67 (Chelsea 22, Hackney 15), Durham 61 (Gateshead C.B. 22, Blaydon U.D. 14), Yorkshire East Riding 51 (Kingston-upon-Hull C.B. 26, Haltemprice U.D. 25), Northumberland 50 (Blyth M.B. 23, Alnwick U.D. 22), Nottinghamshire 45 (Arnold U.D. 25, Nottingham C.B. 15), Surrey 40 (Mitcham M.B. 17, Surbiton M.B. 12), Staffordshire 38 (Kidsgrove U.D. 13, Stoke-on-Trent C.B. 11), Essex 38 (East Ham C.B. 13, Chigwell U.D. 10), Glamorgan-shire 35 (Cardiff C.B. 13, Rhondda M.B. 13), Bedfordshire 32 (Luton M.B. 30), Middlesex 31 (Hayes and Harlington U.D. 14), Wiltshire 27 (Calne and Chippenham R.D. 19), Berkshire 21 (Wokingham R.D. 13), and Leicestershire 20 (Hinckley U.D. 10).

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the years 1948-56 are shown thus ----, the figures for 1957 are shown as a solid line. Except for the curves showing notifications in 1957, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Drinks and Smokes

Since the end of the second world war the consumption of beer in the United Kingdom has tended to decline slightly, while that of spirits has risen. The amount of tobacco consumed has steadily increased from 1947-8, though without yet reaching the figure for 1946-7. The Table below gives details. The figures are from the *Forty-Seventh Report of the Commissioners of Her Majesty's Customs and Excise for the Year Ended March 31, 1956* (H.M.S.O., 7s. 6d.).

Year	Beer Brewed in U.K., Bulk Barrels* (Millions)	Spirits Retained for Consumption, Proof Gallons (Millions)	Tobacco Retained for Consumption, lb.† (Millions)
1946-7	29.23	9.99	255.57
1947-8	30.01	9.98	211.79
1948-9	27.05	8.91	212.33
1949-50	25.76	9.77	213.19
1950-1	24.75	11.40	214.88
1951-2	24.67	9.67	218.81
1952-3	24.39	10.22	220.11
1953-4	24.20	10.64	224.22
1954-5	23.61	11.51	232.43
1955-6	24.12	12.35	239.26

* 1 bulk barrel = 36 gallons (164 litres). † 1 lb. = 0.45 kg.

The consumption of sugar, both home-grown and imported, has also increased in the last decade, as the following Table shows. Figures are given in the same Table to show the great increase in use of heavy fuel oils by road vehicles.

Year	Sugar Retained for Consumption, Cwt.* (Millions)	Heavy Fuel Oil for Road Vehicles, Gallons† (Millions)
1946-7	32.76	147.60
1947-8	37.72	175.30
1948-9	37.73	200.39
1949-50	39.05	230.15
1950-1	39.65	259.33
1951-2	40.43	283.79
1952-3	38.71	294.88
1953-4	41.48	321.86
1954-5	47.12	364.26
1955-6	47.60	421.07

* 1 cwt. = 50 kg. approx. † 1 gallon = 4.5 litres.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending February 9 (No. 6) and corresponding week 1956.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES in Countries and London	1957					1956

* Measles not notifiable in Scotland, whence returns are approximate.

† Includes primary and influenza pneumonia.

§ Includes puerperal pyrexia.

Medical News

Mass Radiography of Hungarian Refugees.—Mass miniature radiography of several hundred Hungarian refugees has disclosed a higher incidence of pulmonary tuberculosis than is general in Britain. The Ministry of Health has therefore advised medical officers of health to offer mass radiography to those Hungarians who are still housed together in sufficient numbers to justify a visit by a mobile unit. Hostels with a hundred or more refugees are mentioned as suitable for such a visit. For small hostels it is suggested that the refugees should go to a convenient centre. It is emphasized in the Ministry's letter, which was dated February 7, that the examination is voluntary.

Medical School at Durban.—Natal University and the local branch of the Medical Association of South Africa have protested vigorously against the Union Government's decision to remove the non-European medical school at Durban from the control of Natal University, writes the *Times* correspondent in Durban. It appears that the school is to be administered by the Department of Native Affairs. According to the *Times* correspondent, protests have been filed by the whole of Natal University's medical faculty. The heads of all the other faculties, and student bodies. The heads of faculties are reported as stating: "Assurances previously given are apparently no longer valid. At the official opening of the new medical school the present Minister of Education emphasized that the Government would not interfere with the University's development of this faculty. If transfer of control of the faculty without interference, then moral values have little meaning." The Natal coastal branch of the Medical Association of South Africa is quoted as declining "to co-operate in any way with any authority other than the University of Natal in the staffing of the medical school." Dr. E. G. MALHERBE, Mr. STRYDOM, the Prime Minister, is heading a delegation to medical school.

Triple Course for Nurses.—A comprehensive 4-year course in nursing leading to the triple qualifications of S.R.N., Health Visitor, and Queen's District Nurse begins at Hammersmith Hospital in September. The course is described as probably the most important experiment in the training of nurses since the 1949 Nurses Act. The aim is to bring together the preventive and curative aspects of nursing by The course will be held at Hammersmith Hospital (Post-graduate Medical School of London), Battersea College of Technology, and the Queen's Institute of District Nursing. Besides the three qualifications mentioned, the students will also take Part I of the Central Midwives Board Certificate. Candidates for this course will be required to hold a General Certificate of Education in three subjects at ordinary level and two other subjects at advanced level.

"Medical History."—The first issue of a new quarterly journal, *Medical History*, made its appearance in January. It is edited by Mr. W. J. BISHOP, formerly librarian of the organ of the Cambridge University History of Medicine Society, the Norwegian Society for the History of Medicine, the Scottish Society of the History of Medicine, and the Osler Club of London. Its stated purpose is to record the history and bibliography of medicine and the related sciences. The publishers are William Dawson and Sons Ltd., 4, Duke Street, Manchester Square, London, W.1, from whom it may be obtained for £2 10s. or \$7.50 a year (single and eight full-page art plates. On the attractively designed Linacre, inset into the binding of a book in the Wellcome Historical Medical Library. Besides six original articles,

the first issue of *Medical History* has sections headed: Texts and Documents; Society Reports; News, Notes, and Queries; Book Reviews; and Medical Anniversaries of 1957. Among the principal journals in English now current in this field besides *Medical History* are the *Journal of the History of Medicine and Allied Sciences* (New York; started in 1946), the *Bulletin of the History of Medicine*, Johns Hopkins University (Baltimore; started in 1933), *Centaureus* (Copenhagen; started in 1950), and in the *Proceedings of the Royal Society of Medicine* (London) the records of the Section of the History of Medicine which first appeared there in 1913.

Chair of Therapeutics at Belfast.—Dr. O. L. WADE, senior lecturer in medicine at Birmingham University, has been appointed to the Chair of Therapeutics and Pharmacology at Queen's University, Belfast. He succeeds Professor E. B. C. MAYRS, who is retiring. His appointment is from April 1, and the duties of the post include charge of beds in the teaching hospital. Dr. Wade is 35. He was a scholar of Emmanuel College, Cambridge, where he gained a double first in the Natural Sciences Tripos, thereafter proceeding to University College Hospital, London, where he was Acheson scholar. After a series of junior hospital appointments he became for a short time clinical assistant at the Medical Research Council's pneumoconiosis research unit at Cardiff. Since 1951 Dr. Wade has been a member of the medical professorial unit at the Queen Elizabeth Hospital, Birmingham. In 1954 he held a Rockefeller Traveling Fellowship in Medicine, which he spent with Dr. Robert Loeb and Dr. Stanley Bradley at the Columbia Medical Centre, New York. Dr. Wade's investigations have been into the haemodynamics of the pulmonary and hepatic circulations.

Empire Rheumatism Council.—To celebrate its 21st birthday the Empire Rheumatism Council has launched an appeal for £250,000 for research. The fund is under the chairmanship of Lord ASTOR OF HEVER, and the appeal is mainly being directed to industry. In a pamphlet entitled "Industry and Rheumatism," issued in connexion with the appeal, rheumatic diseases are stated to account for 10% of all working days lost through illness. In the year beginning June, 1953, 27.5 million days were lost to industry from rheumatic disorders compared with two million from industrial stoppages. Tuberculosis and bronchitis each accounted for a loss of 25.5 million days, and industrial accidents for 16 million days. These figures for illness are minimum estimates, as absences of less than four days are not included.

Poliomyelitis Research.—The National Fund for Poliomyelitis Research allocated £69,000 in research grants during the year ended October 31 last. All grants were made after consultation with the Medical Research Council. The largest grant, £50,000, was for the M.R.C. virus production laboratory at Carshalton (see *Journal*, December 1, 1956, p. 1315). The net income raised by the Fund during the year was £109,000. Further details of the Fund's work and the investigations towards which grants have been made are given in the Fund's fourth annual report. The address of the National Fund for Poliomyelitis Research is Vincent House, Vincent Square, London, S.W.1.

Deteriorated Poliomyelitis Vaccine.—A few phials of the latest batch of poliomyelitis vaccine ready for issue have been found to show signs of possible deterioration during storage. The Ministry of Health states that distribution will be deferred while the matter is investigated.

Royal College of Surgeons in Ireland.—At a ceremony held at the College on the occasion of the Charter Day dinner the College's honorary fellowship was conferred on Mr. T. J. D. LANE, visiting surgeon at the Meath Hospital, Dublin. On February 11 Mr. E. W. RICHES, of the Middlesex Hospital, delivered the second Abraham Colles post-graduate lecture. He lectured on the management of carcinoma of the bladder.

M.R.C.P. (London).—The following were elected Members of the Royal College of Physicians of London at the quarterly comitia on January 31: S. Ahmed, G. L. Asherson, N. H. Ashton, A. I. Cheyne, Etain A. Cronin, W. J. Fessel, R. F. Fletcher, G. Harris, Marion Hildick-Smith, I. A. Horton, J. W. Howie, N. L. Jones, H. Keen, L. Kreel, Lesley P. Leader, J. T. Leeming, M. H. Lees, R. D. Lele, A. H. E. Marshall, P. R. Montgomery, J. A. Parrish, K. Schwarz, E. D. Sever, T. P. Telfer, A. G. Wallace, J. C. Willan, and L. Wollner.

Consultant Haematologist to Army.—The Army Council has appointed Dr. R. BODLEY SCOTT as honorary consultant in haematology to the Army at Home, in succession to the late Sir LIONEL WHITBY.

London University.—Dr. M. J. BLUNT, senior lecturer in anatomy at St. Bartholomew's Hospital Medical College, has been appointed to the university readership in anatomy tenable there.

B.M.J. Index.—The half-yearly indexes to Volume II of the *Journal* and the *Supplement* for 1956 are now being sent to members who receive them regularly and to subscribers. Members who have not previously asked for the indexes to be sent regularly to them can obtain copies, post free, on application to the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1; those wishing to receive the indexes regularly should mention this.

COMING EVENTS

Oliver-Sharpey Lectures.—Professor J. R. SQUIRE will deliver the Oliver-Sharpey Lectures on March 12 and 14 at 5 p.m. at the Royal College of Physicians, Pall Mall East, London, S.W.1. His subject will be "The Functions of the Plasma Proteins."

Manchester University Medical Dinner.—Annual dinner on March 14 in the Manchester University Unions. Tickets, graduates 25s., from Mr. T. G. RAMSELL, Medical School, University, Manchester, 13.

Grey Turner Surgical Club.—Meeting at Leeds, March 25-27. Details from Mr. GORDON N. BAILEY, F.R.C.S., 2A, Lancaster Road, Harrogate.

NEW ISSUES

British Heart Journal.—The new issue (Vol. 19, No. 1) is now available. The contents include:

- TRICUSPID INCOMPETENCE AND RIGHT VENTRICULAR OUTPUT IN CONGESTIVE HEART FAILURE. Paul Korner and John Shillington.
- DIAGNOSIS OF CONGENITAL ANEURYSM OF THE VENTRICULAR SEPTUM. Israel Steinberg.
- PATENT DUCTUS ARTERIOSUS. A FOLLOW-UP OF 73 CASES. J. A. Cosh.
- EFFECTS OF INTRAVENOUS DIGOXIN IN AURICULAR FIBRILLATION. John Hammond and William Whitaker.
- VENTRICULAR EXTENSION INTO THE ABDOMINAL WALL. Clifford Parsons.
- BARORECEPTOR RESPONSES TO ACUTE RHYTHM CHANGES. Sheila Howarth and E. P. Sharpey-Schafer.
- ADRENALINE SENSITIVITY OF PERIPHERAL BLOOD VESSELS IN HYPERTENSION. Robert S. Duff.
- RADIATION REACTIONS IN THE HEART. A. G. W. Whitfield and P. B. Kunkler.
- ELECTROCARDIOGRAPHIC CHANGES IN HYPOTHERMIA IN MAN. Peter R. Fleming and Frank H. Muir.
- EXTRA-CORPOREAL CIRCULATION AND HEART SURGERY. Ch. Dubost, R. Heim de Baisac, R. de Wall, C. Lenfant, J. Guery, J. Passelecq, M. Weiss, and J. Rouanet.
- CLINICAL, PHYSIOLOGICAL, AND PATHOLOGICAL CONSIDERATIONS IN IDIOPATHIC PULMONARY HYPERTENSION. John T. Shepherd, Jesse E. Edwards, Howard B. Burchell, H. J. C. Swan, and Earl H. Wood.
- IDIOPATHIC PULMONARY HYPERTENSION. Donald Heath, William Whitaker, and James W. Brown.
- SOLITARY PULMONARY HYPERTENSION. William Evans, D. S. Short, and D. Evan Bedford.
- TOTAL AND PERIPHERAL BLOOD FLOW IN ACUTE MYOCARDIAL INFARCTION. G. J. Lee.
- THE GRAPHIC CONFIGURATION OF INNOCENT SYSTOLIC MURMURS. B. G. Wells.
- CASE REPORTS:
- CONGENITAL ARTERIOVENOUS FISTULA OF THE INTERNAL MAMMARY VESSELS. B. G. Wells and R. L. Hurt.
- RUPTURE OF AN ANEURYSM OF THE RIGHT AORTIC SINUS (OF VALSALVA). Leonard Weiss.
- ANEURYSM OF AN ANOMALOUS RIGHT SUBCLAVIAN ARTERY. W. C. D. Richards and C. E. Elliott.
- THE SECOND EUROPEAN CONGRESS OF CARDIOLOGY.
- ABSTRACTS OF CARDIOLOGY.

Issued quarterly; annual subscription £2 2s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

British Journal of Industrial Medicine.—The new issue (Vol. 14, No. 1) is now available. The contents include:

- THE DANGER OF DERMATOSES DUE TO COLD-SETTING ETHOXYLINE RESINS (EPOXIDE RESINS). E. Grandjean.
DECOMPRESSION SICKNESS DURING THE SINKING OF A CAISSON. H. E. Lewis and W. D. M. Paton.
THE EFFECTS OF THE TEMPERATURES OF THE FLOOR SURFACE AND OF THE AIR ON THERMAL SENSATIONS AND THE SKIN TEMPERATURE OF THE FEET. F. A. Chienko.
FOOT RINGWORM IN COAL-MINERS. J. C. Gentles and J. G. Holmes.
AN EXPERIMENTAL STUDY OF THE PATHOGENESIS OF SILICOTIC GRANULOMA IN THE ANTERIOR EYE CHAMBER IN RABBITS AND CHANGES IN ITS DEVELOPMENT INDUCED BY THE ACTION OF A.C.T.H., INSULIN, COMBINATIONS OF BOTH, AND SALICYLATES. Jiri Vyskočil.
THE PREVALENCE OF TUBERCULOSIS AT NECROPSY IN PROGRESSIVE MASSIVE FIBROSIS OF COAL-WORKERS. D. Rivers, W. R. L. James, D. G. Davies, and S. Thompson.
THE INFLUENCE OF THE SHAPE OF DUST PARTICLES ON THE RATE OF PHAGOCYTOSIS IN VITRO. A. Lengertová, V. J. Lengert, M. Esslová, R. Tuscany, and M. Volfová.
THE TOXICITY OF FUMES FROM A DIESEL ENGINE UNDER FOUR DIFFERENT RUNNING CONDITIONS. R. E. Pattie, H. Stretch, F. Burgess, K. Sinclair, and J. A. G. Edginton.
DELAYED DEATH CAUSED BY GASSING IN A SILO CONTAINING GREEN FORAGE. F. M. Troisi.
OBITUARY: HUBERT WYERS, M.D.
MISCELLANEA:
ASSOCIATION OF INDUSTRIAL MEDICAL OFFICERS: 21ST ANNIVERSARY MEETING.
INDUSTRIAL MEDICINE AND HYGIENE: A Review by L. G. Norman.
PERCIVAL PUTT (1714-1788) AND CHIMNEY SWEEPERS' CANCER OF THE SCROTUM. John R. Brown and John L. Thornton.
MEDICAL PLANNING AT ALDENHAM WORKS.
BRITISH OCCUPATIONAL HYGIENE SOCIETY AND ERGONOMICS RESEARCH SOCIETY. D. Turner.

Issued quarterly; annual subscription £2 2s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

Abstracts of World Medicine.—Issued in the first week of each month, this journal contains abstracts of important papers selected from the current medical literature of the world. Annual subscription £4 4s., single copy 8s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged of a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Friday, March 1

LIVERPOOL UNIVERSITY.—At Surgery Theatre, Medical School, 5.15 p.m., Faculty of Medicine Lecture by Dr. H. M. Sinclair: Dietary Fat and Human Disease.

Monday, March 4

MARLBOROUGH DAY HOSPITAL.—8.15 p.m., Mr. M. M. Simmons, M.A., and Dr. D. R. Davis: The Intelligent Offender: His Treatment in an Approved School.

UNIVERSITY COLLEGE LONDON: DEPARTMENT OF BIOCHEMISTRY.—At Physiology Theatre, Gower Street, W.C.2, 5 p.m., public lecture by Dr. G. J. Popják: Biochemistry of Fatty Acids and Cholesterol—Biological Oxidation of Fatty Acids.

UNITED HOSPITALS CATHOLIC SOCIETY.—At 13, Devonshire Place, W., 6.15 p.m., Mr. L. H. W. Williams: Abortion.

Tuesday, March 5

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Mr. B. E. D. Cooke: Disorders of Buccal Mucosa.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—3.45 p.m., Erasmus Wilson Demonstration by Dr. A. J. M. Reese: Atheroma.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Institute Theatre, 5 p.m., Mr. R. M. Feroze: Dysfunctional Uterine Haemorrhage.

WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Mr. G. C. Knight: Diagnosis of Cerebral Tumours.

Wednesday, March 6

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. W. Riddell: Problems of Therapy in Fungus Diseases.

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. B. G. B. Lucas: Man and His Ventilation.

INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Mr. G. F. Murnaghan: Congenital Hydronephrosis.

MIDLAND MEDICAL SOCIETY.—At 154, Great Charles Street, Birmingham, 8.15 p.m., Dr. C. G. Parsons: General Practitioner and the Chesty Child.

OXFORD UNIVERSITY.—At Radcliffe Infirmary, 5 p.m., Litchfield Lecture by Dr. P. H. Wood: Pulmonary Hypertension.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Dr. R. E. B. Hudson: The Heart Septa.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—5 p.m., Finlayson Lecture by Mr. D. W. Currie: Results of Twenty-one Years of Surgical Treatment of Cancer of the Cervix.

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—3.30 p.m., Dr. B. G. C. Ackner: Emotional Aspects of Bodily Complaints.

ROYAL SOCIETY OF HEALTH.—2.30 p.m., symposium by Professor A. C. Frazer and Dr. H. M. Sinclair: Composition and Nutritive Value of Flour.

SOCIETY FOR ANALYTICAL CHEMISTRY: BIOLOGICAL METHODS GROUP.—At the Feathers, Tudor Street, E.C.2, 6.30 p.m., discussion to be introduced by Dr. A. Spinks, Ph.D.: Experimental Assessment of Tranquillizers.

WELSH NATIONAL SCHOOL OF MEDICINE.—At Reardon-Smith Lecture Theatre, Park Place, Cardiff, 8 p.m., Sixth William Sheen Memorial Lecture by Sir Harry Platt, P.R.C.S.: Backache-Sciatica Problem.

Thursday, March 7

FACULTY OF HOMOPATHY.—5 p.m., Dr. A. E. Strigener: Similarity and the Synergistic Action Observed Between Hypnosis and Homoeopathy. Joint LIVERPOOL MEDICAL INSTITUTION.—At Liverpool University, 5.15 p.m., Joint History of Medicine Lecture by Mr. J. B. Oldham: Two Centuries Ago. MIDLAND THORACIC SOCIETY.—At Queen Elizabeth Hospital, Birmingham, 7.30 p.m., Dr. W. W. Jones: Pneumococcosis.

ROYAL INSTITUTE OF CHEMISTRY: THAMES VALLEY SECTION.—At Reading University, 5.15 p.m., joint meeting with Reading University Chemical Society. Professor E. J. King: Use of Enzymes in Medical Chemistry.

ST. JOHN'S HOSPITAL DERMATOLOGICAL SOCIETY.—5 p.m., symposium: Psychiatry as an Aid to Dermatology.

Friday, March 8

●INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. P. J. Hare: clinical demonstration.

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Air Commodore C. A. Rumball: Some Problems in Cardio-respiratory Assessment.

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—3.30 p.m., Mr. A. Radcliffe: Nasal Catarrh.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—10 a.m., Mr. S. H. Wass: Present Position of Surgery in the Treatment of Ulcerative Colitis.

ROYAL MEDICAL SOCIETY, EDINBURGH.—8 p.m., Valedictory Address by the Senior President.

Saturday, March 9

KENT PAEDIATRIC AND CHILD HEALTH SOCIETY.—At Royal Star Hotel, Maidstone, 3 p.m., Presidential Address by Mr. Richard Church: The Humble Layman.

●ST. STEPHEN'S HOSPITAL.—At Rheumatism Unit, Fulham Road, S.W., March 9 and 10, 10 a.m. each day, concentrated week-end course in the "Rheumatic Diseases."

NORTHAMPTON MEDICAL SOCIETY.—8 p.m., Dr. D. Evan Bedford: Common Errors in the Diagnosis of Heart Disease.

Sunday, March 10

APPOINTMENTS

EAST ANGLIAN REGIONAL HOSPITAL BOARD.—J. T. Bergin, M.B., B.Ch., Senior Registrar in Mental Deficiency and Child Psychiatry, Little Plumstead Hospital Group; J. Ghoshal, M.B., B.S., Registrar in Psychiatry, Suffolk Mental Hospitals; A. S. F. Butcher, M.B., B.Chir., Registrar in Obstetrics and Gynaecology, East Suffolk and Ipswich Area; N. B. Das, M.B., B.S., T.D.D., Medical Registrar, Papworth Hospital; V. J. Coffey, M.B., B.S., D.P.M., Assistant Radiotherapist, Ipswich and East Suffolk Hospital; Wendy A. Cook, M.B., B.S., D.Obst.R.C.O.G., Registrar in Obstetrics and Gynaecology, Peterborough Group of Hospitals; W. D. Proudman, M.B., B.S., Surgical Registrar, Ipswich and East Suffolk Hospital; J. R. Kirkup, M.B., B.Chir., Orthopaedic Registrar, Norfolk and Norwich Hospital.

NORTH-WEST METROPOLITAN REGIONAL HOSPITAL BOARD.—D. R. McPherson, M.B., D.T.M.&H., D.M.R.E., Consultant Radiologist, Harefield Hospital; Judith M. Watelow, M.B., B.S., Child Psychiatrist (S.H.M.O.), Bedfordshire Child Guidance Service; Eithne J. O'Riordan, M.B., B.Ch., D.O.M.S., Ophthalmologist (S.H.M.O.), St. Pancras School Treatment Centre.

SOUTH-WESTERN REGIONAL HOSPITAL BOARD.—J. B. Gordon-Russell, M.B., Ch.B., M.R.C.P., D.P.M., Medical Superintendent at Roundway Hospital, Devizes; Grace E. Woods, M.D., D.P.H., D.C.H., Deputy Medical Superintendent at Northam Hospital, Almondsbury, near Bristol; Marguerite A. R. King, M.B., Ch.B., Registrar in Department of Pathology at Frenchay Hospital, Bristol; Patricia M. Russell, M.D., D.Obst.R.C.O.G., D.C.H., Registrar in Obstetrics and Gynaecology at Southmead Hospital, Bristol; Audrey Halloran, M.B., B.S., F.R.C.S.Ed., Surgical Registrar at Gloucestershire Royal Hospital, Gloucester; N. P. Lancaster, M.D., D.P.M., Consultant Psychiatrist at Bristol Mental Hospitals; M. T. Statner-Dunne, M.B., B.S., Registrar in Psychiatry at Bristol Mental Hospitals; M. G. Cox, M.B., B.Chir., F.R.C.S., Registrar in Ear, Nose, and Throat Department at South Devon and East Cornwall Hospital, Plymouth; M. W. Reece, M.B., B.S., F.R.C.S., Senior Surgical Registrar at Royal Devon and Exeter Hospital, Exeter (joint appointment with the United Bristol Hospitals); C. H. Talbot, M.B., B.Chir., F.R.C.S., Senior Surgical Registrar at Southmead Hospital, Bristol (joint appointment with the United Bristol Hospitals); E. S. Watkins, M.D., Surgical Registrar at Weston-super-Mare General Hospital.

BIRTHS, MARRIAGES, AND DEATHS

DEATHS

Body.—On January 28, 1957, Thomas Munn Body, M.R.C.S., L.R.C.P., D.L., J.P., of 22, The Grove, Marton-in-Cleveland, Yorks, aged 80.

Daniel.—On January 27, 1957, at Essex House, Chard, Somerset, Francis Rennie Daniel, M.C., M.B., Ch.B.

Hillery.—On January 20, 1957, at the Devonshire Royal Hospital, Buxton, Derbyshire, Maureen Elizabeth Hillery, L.R.C.P.&S.Ed., L.R.F.P.S., of 24, Princes Street, Bishop Auckland, Co. Durham, aged 29.

Kerby.—On January 28, 1957, at Victoria Hospital, Blackpool, Lancs., Clement Carlyon Kerby, M.R.C.S., L.R.C.P., late of Truro, Cornwall, M.D., of 151, Brigstock Road, Thornton Heath, Surrey, aged 74.

Preston.—On January 31, 1957, John Alexander Preston, M.D., of Dromore, Maresfield, Sussex.

Sunderland.—On January 29, 1957, at Runcion House, Haverhill, Suffolk, Edward Benjamin Sunderland, M.R.C.S., L.R.C.P.

Walker.—On January 25, 1957, Harry Bertram Walker, M.C., M.B., F.R.C.S., of 34, The Avenue, Minehead, Somerset.

Watt.—On February 1, 1957, at Drumduan, Royal Esplanade, Margate, Kent, Arthur John Watt, M.B., Ch.B., formerly of Reading, Berks, aged 75.

Wharton.—On January 29, 1957, Effie Adela Wharton, M.R.C.S., L.R.C.P., of Buckhurst Cottage, Withyham, Sussex.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Severe Depression during Rauwolfia Therapy

Q.—Severe mental depression may occur during the treatment of hypertension with Rauwolfia alkaloids and ganglion-blocking compounds. Do any of the recent "antidepressive" drugs allow treatment to be continued safely? Or will changing the Rauwolfia preparation or reducing the dose relieve the depression?

A.—Severe mental depression occurs in a small proportion of patients taking Rauwolfia alkaloids, either alone or in combination with ganglion-blocking compounds. It may occur after the administration of reserpine, rescinnamine, or mixed alkaloidal preparations. Mental depression occurs more frequently when large doses are taken. The dose of reserpine should not exceed 0.25 mg. twice daily, and the dose of rescinnamine should not exceed 0.25 mg. thrice daily. The usual dose of the mixed alkaloid preparations is 250 mg. twice daily.

When mild depression is noted another preparation may be substituted, for some patients seem less liable to develop depression with one substance than with others. If the depression persists, or if it is initially severe, Rauwolfia therapy should be stopped immediately. There is as yet no evidence that any of the agents recently introduced to combat mental depression enable Rauwolfia therapy to be continued safely, once severe depression has occurred.

Gynaecomastia from Oestrogen Therapy in Prostatic Cancer

Q.—A patient who had a carcinoma of prostate is now stabilized on 5 mg. daily of dienoestrol after bilateral orchidectomy. He has very considerable resulting gynaecomastia which causes him physical inconvenience and much psychological distress. What treatment is advised for the gynaecomastia? The question of having the breasts amputated has been raised in this case.

A.—The occurrence of troublesome gynaecomastia in this case raises the fundamental question how far it is necessary to supplement castration by giving oestrogens. Theoretically the latter are believed to act mainly by reducing pituitary gonadotrophic activity and to have little effect on extra-gonadal androgen production. On this assumption, if all functional testicular tissue has been removed, their value would appear doubtful. On the other hand, statistical studies indicate a significant prolongation of survival in some cases where both methods of treatment have been given, though it is not always clear from the reports to what extent and in what manner they have been combined.

It is assumed from the description of the present case that the addition of dienoestrol after castration has afforded tangible evidence of improved control. If so, it cannot lightly be discarded merely on account of the inconvenience of the side-effect produced. Breast changes during treatment are often ephemeral, however, and even with sustained dosage of a higher order partial or complete resolution may occur in due course. Failing this, the use of an alternative oestrogen such as chlorotrianisine ("tace") might be considered. This preparation has been recommended as less likely to induce gynaecomastia, although in a small series of cases treated by the writer there was no significant reduction in the incidence of this complication. Furthermore, there is some doubt whether its control of prostatic malignancy is either as positive or as rapid as with other oestrogens, and in general the liability to breast changes

seems roughly related to the general efficacy of the oestrogen preparation employed. While it is thus evident that the effective suppression of prostatic cancer will in some instances be accompanied by mammary enlargement and discomfort, the latter seems a small price to pay for avoiding the dangers of active malignancy. Viewing the matter in this light may help to alleviate the patient's psychological distress, and, since any physical abnormality should be capable of easy concealment on all formal occasions, mastectomy would seem avoidable.

Control of Haemophilia

Q.—What specific therapy is of value in the prevention and treatment of bleeding episodes in haemophilia? Is any other drug therapy of value? Claims are made for a preparation of egg white, for instance.

A.—Haemophilia is caused by a congenital deficiency in the blood of a factor (antihæmophilic globulin) required for normal coagulation. The only treatment which can prevent or cure bleeding is the replacement of this substance in the patient's blood. The substance may be supplied by the transfusion of whole fresh blood or fresh plasma. To be effective it is necessary to use large amounts of blood or plasma. For an adult patient haemostatic levels of antihæmophilic globulin are not achieved with less than a litre of fresh plasma, and most of the activity disappears from the patient's blood in 24 hours. For this reason it is most desirable to have a concentrated form of antihæmophilic globulin. Unfortunately it has so far not been possible to make concentrated material from human blood. Antihæmophilic globulin made from animal blood has been made and used successfully for volunteers and for dangerously ill patients at Oxford,¹⁻⁴ but the material is impure and antigenic and is not available for general use.

It seems to be the general experience of medical workers that the egg-white preparation mentioned in the question has no effect on the coagulation defect in haemophilia.

Medico-Legal Aspects of Artificial Insemination

Q.—If artificial insemination with husband's semen is to be undertaken, what precautions should the doctor take to guard himself against subsequent medico-legal difficulties? Is it essential, for instance, to obtain written permission from both husband and wife, and is it necessary to establish the origin of the semen in any way? Should it be established, before carrying out the insemination, that the wife is not in fact already pregnant?

A.—It is certainly necessary to exclude pregnancy so far as possible, especially if the insemination is intracervical. In practice this means paying attention to the date of the last menstrual period and restricting insemination to the fertile period—that is, avoiding the premenstrual phase.

The medico-legal aspects of insemination with the husband's semen only will be considered here, not those where the donor is some other person. The procedure is probably then to be regarded as any other operation or treatment, the parties being protected by the usual laws relating to negligence and malpractice. There might, however, be difficulty in establishing the origin of the semen for certain. If the specimen is presented to the doctor by the husband himself, and especially if it is collected on the doctor's premises, it seems reasonable to assume that it has been obtained from the husband and not from someone else. The temperature and viscosity of the specimen might be confirmatory evidence of the time of collection: it takes approximately half an hour for semen to liquefy and to become homogeneous.

In view of the possible ethical if not medico-legal difficulties, most general practitioners avoid procedures of this kind and, when such treatment seems indicated, prefer to send their patients to a gynaecologist or to an infertility clinic. If the general practitioner in this case decides to proceed with artificial insemination he would be well advised to: (a) Obtain from the patient and her husband a document signed by both, giving consent to the operation. This document should clearly state the nature of the operation, the reasons for it, and the origin of the semen to be used. (b) Only carry out the operation in the presence of a third party, preferably a nurse. After the operation the nurse should be asked to sign the document of consent. (c) Keep a careful record of the details of the procedure.

Painless Local Analgesia

Q.—Is there any completely painless way of administering a local analgesic? I need such a method to allow the insertion of needle electrodes into children for electromyography. Is there not an instrument for giving subcutaneous injections that dispenses with the need for a needle?

A.—A subcuticular skin weal can be raised quite painlessly. A syringe is fitted with a fine, short-bevel hypodermic needle. The flat of the bevel is placed against the skin, and while the local analgesic solution (which must be isotonic) is gently forced out through the needle the point is slid under the cuticular layer. A tiny white bleb appears without any pain. Through this bleb a heavier gauge needle can be passed painlessly. Confirmation that the method is painless can be obtained by doing it on one's own arm. The success of this method in children will naturally depend on how well the administrator can prevent any fear or strain on the part of his young patient.

The instrument for giving subcutaneous injections without a needle is the "hypo-spray" described by R. A. Hingson.¹ The solution to be injected was contained in a small round-nosed metal ampoule with a tiny orifice of about 75 microns diameter. A powerful spring inside the instrument generated a pressure sufficient to force the liquid in the ampoule through the tiny orifice and through the skin into the subcutaneous tissues. The injection, though very nearly, was not always entirely painless. In addition, unless the instrument was held absolutely still the tiny puncture in the skin might be converted into a slit. So far as is known, neither the instrument nor the necessary ampoules were ever made available on the British market.

Urinary 17-ketosteroids

Q.—What is the normal range for urinary 17-ketosteroids in men and women, respectively? In what clinical conditions does the information gained from this estimation justify its use?

A.—The normal range for 17-ketosteroids in the urine differs in the two sexes, owing to their being derived partly from adrenal cortical sources and partly from testosterone in the testes. Slight differences in the normal range depend upon differences in the techniques used for analysis. The most generally used technique gives values for men of 8-23 (average 14.5) mg. daily and for women 5-18 (9.5) mg. daily.

The commonest causes of elevation of these values are certain adrenal cortical tumours and the prepubertal virilizing syndrome associated with hyperplasia of the adrenal cortex. Low values may be obtained in a variety of non-specific chronic disease processes and in myxoedema and anorexia nervosa. Particularly low levels are found in women with Addison's disease, and to a less extent in men because of the presence of functioning testes. In well-established hypopituitarism a value of only 1 or 2 mg. per day is often found in either sex. The subject has been recently discussed in *Clinical Pathology in General Practice* (1955; B.M.A., London).

NOTES AND COMMENTS

Dental Caries During Pregnancy and Lactation.—Dr. B. J. BOUCHÉ (London, S.W.19) writes: Your expert's answer to the question on dental caries during pregnancy and lactation ("Any Questions?" January 26, p. 239) does not appear to be complete or comprehensive. The questioner asks what "dietary supplements" are advised during pregnancy and lactation to prevent dental caries in the ordinary case, but your expert talks only about supplementing the intake of minerals, which he states is unlikely to prevent caries of the mother's teeth. Is it not true to say that the enamel ameloblasts and dentine odontoblasts take up calcium and phosphorus from the maternal blood to make enamel or dentine in the developing foetus and for this vitamins D, A, and C are all necessary? Can it not be imagined that if antenatal care does not provide these items adequately the result may be disastrous for both mother and baby? In addition to pregnancy and lactation, would it not be reasonable to add prolonged illness also when such a need must be met?

OUR EXPERT replies: Dr. Bouché is quite correct in thinking that, if an antenatal diet does not provide adequate amounts of calcium, phosphorus, and vitamins A, D, and C, the result may be disastrous for both mother and baby. The teeth, however, would be one of the structures least likely to be affected in such a disaster. It would also be correct to add vitamins A, D, and C to the list of dietary supplements which have been tested for power to protect teeth against caries and found ineffective in adults. The only dietary agent to date which has been clearly shown to protect against caries is the fluoride ion, and it would have little effect on the mother, as its protection appears to be conferred during the period when the teeth are calcifying.

Local factors seem to be of more importance than systemic ones in causing caries. The best advice that can be given to prevent dental caries in the ordinary case is to pay regular attention to cleaning the teeth and to have the dental practitioner attend to any particular places in the mouth where food debris might stagnate. This need for oral hygiene is particularly important in pregnancy in view of the possibility of pregnancy gingivitis causing tender gums and so discouraging the use of the toothbrush. It is also of great importance in illnesses where the natural cleansing action of saliva may be lost owing to impaired function of the salivary glands.

Flowers in the Sickroom.—Dr. GEORGE GRAHAM (London, W.1) writes: Your expert has given the reasons for thinking that it is unnecessary to remove flowers from the sickroom because they excrete carbon dioxide at night ("Any Questions?" January 26, p. 239). But he does not offer any explanation for this widespread belief which few nurses would dare to brave. Many years ago I had a patient with asthma who had to be discharged from the ward because he said that flowers caused his attacks. I suspect that this happened to someone many, many years ago, and that the authorities at the time did not know that the pollen of some flowers caused attacks of asthma in some patients. They knew that flowers gave off carbon dioxide at night which they thought, very foolishly, was harmful, and banned all flowers from all sickrooms irrespective of whether the patient had asthma or not. This belief causes much unnecessary work for the nurses who have to remove the flowers, which in some cases are very numerous, to draughty corridors and bathrooms. This change of temperature and the knocking about which the flowers and plants receive may damage them. I hope your expert's authoritative answer will stop this practice, but I fear the belief is too ingrained in nurses and all nursing authorities to be stopped by any explanation.

counting the cost...of living

It is estimated that over 50 per cent of the average practitioner's patients show some degree of anxiety neurosis. Such is the price exacted by the tempo of today. In this type of case MILTOWN meprobamate has far-reaching applications. MILTOWN is superior to other conventional sedatives and is remarkably free from side reactions. It acts safely and selectively to ease emotional and muscular tension without autonomic effects. MILTOWN helps to 'unwind' the patient relieving his worry, agitation and anxiety. It induces true sedation by day and natural sleep without narcosis at night.

THE ROLE OF VALVULAR INCOMPETENCE IN HEART FAILURE*

BY

J. McMICHAEL, M.D., F.R.C.P.

Professor of Medicine, Postgraduate Medical School of London, Ducane Road, London, W.12

AND

J. P. SHILLINGFORD, M.D., M.R.C.P.

Lecturer in Medicine, Postgraduate Medical School of London, Ducane Road, London, W.12; Member of External Staff, Medical Research Council

Within fifty years of Laennec's introduction of the stethoscope a practical understanding of the meaning of cardiac sounds and murmurs had been reached and auscultation held a pre-eminent place in cardiac diagnosis. Then early in this century Mackenzie, having made by his polygraph the most spectacular advances in clinical analysis of cardiac irregularities, began to preach his doctrine of the all-important myocardium to the detriment of interest in the meaning of murmurs. His pupil, Lewis, perpetuated this policy, and the authoritative position of these two men discouraged further auscultatory studies. Since 1945 phonocardiography has become accepted as a diagnostic technique, and, by focusing interest on the auscultatory signs of valvular disease, has led to renewed interest in an old and important subject.

As the left side of the heart is more sheltered from our modern instrumental methods it is better to begin this discussion on the place of valvular incompetence in heart failure on the right side, where observation can be made with greater ease and frequency.

Historical Note on Tricuspid Incompetence

In 1836 Benson noted accurately some characters of the systolic venous pulsation in the neck in a case of tricuspid incompetence proved at necropsy. King (1837), of Guy's Hospital, expressed the view that "on occasions of most copious influx [the right ventricle] becomes distended; upon which the curtains of the tricuspid valve are drawn aside, an aperture of reflux is produced, and the force of the ventricle is diverted from the pulmonary circulation." He termed this the safety-valve action of the tricuspid valve. Rosenbach (1878) recorded that avulsion of the tricuspid valve in the dog was followed by a loud systolic murmur. Byrom Bramwell (1884) was able to give a nearly perfect clinical account and haemodynamic interpretation of tricuspid incompetence, and pointed out that "the tricuspid sphincter is thinner and weaker than the muscular wall of the left ventricle, and relative and muscular incompetence are therefore more

readily produced at the tricuspid than at the mitral orifice. Relative incompetence secondary to an obstruction either in the lungs or at the mitral orifice is extremely common... it may be a temporary and curable condition."

James Mackenzie (1908), though recognizing the rarity of organic affections of the tricuspid valve, thought that functional tricuspid incompetence was extremely common, "so common indeed that I am inclined to look upon the valves as being unable to close the orifice properly." He showed in jugular phlebograms the stages of development of the systolic venous wave of tricuspid incompetence, though in later years neither he nor Lewis paid much attention to the condition. Because of the confusion of tricuspid with other systolic murmurs more recent French writers, such as Laubry and Routier (1928) and Soulié *et al.* (1952), have been hesitant in recognizing the importance and frequency of tricuspid incompetence. Fishberg (1937) took a somewhat similar view of the difficulties of diagnosis and regarded systolic pulsation of the liver as the only unequivocal sign of tricuspid incompetence.

Methods of Study

Right Atrial Pulse

Gross incompetence of the tricuspid valve has long been associated with positive systolic pulsation in the jugular veins; detection of lesser degrees of tricuspid incompetence, however, has only recently been made possible by the analysis of right atrial pressure pulses recorded through a cardiac catheter (Korner and Shillingford, 1954). The normal right atrial pulse consists first of the "a" wave, which occurs at the time of right atrial systole. Then towards the end of atrial diastole ventricular contraction pulls the closed valvular diaphragm towards the left, and, as the atrium is becomes elongated and a further drop in pressure in the right atrium (the X descent of Mackenzie) occurs. With continuing inflow into the atria from the great veins the atrial pressure again rises (V ascent) until, with relaxation of the ventricles, the tricuspid valve opens and blood passes from the atrium to the ventricle. This again

produces a fall in atrial pressure (the Y descent). Normally the X descent is much greater than the Y. In atrial fibrillation without tricuspid regurgitation the same pattern is found but without the "a" wave (Fig. 1).

Fig. 1.—Right atrial pulse in patients with sinus rhythm and atrial fibrillation. The dotted line shows the point at which the X descent begins.

As tricuspid incompetence develops the normal fall in pressure in the right atrium during ventricular systole is counteracted by the blood regurgitating through the incompetent valve. A higher pressure than normal is then built up in the right atrium, which in turn falls more rapidly when the tricuspid valve opens. With the development of tricuspid regurgitation, therefore, the X descent becomes less and the Y descent greater, and as the regurgitation becomes gross the X descent is obliterated and is replaced by the familiar positive systolic pulsation (Fig. 2).

Fig. 2.—Right atrial pressure curves in sinus rhythm and in atrial fibrillation. Top line: normal X descent. Middle line: impaired X descent. Bottom line: X descent replaced by a positive systolic wave.

Some modern writers are still impressed by the difficulty of differentiating the jugular pulse of atrial fibrillation from that of tricuspid incompetence (Scherf and Boyd, 1948; Wood, 1956). Daley *et al.* (1955) claimed that the experimental production of atrial fibrillation in dogs in fact produced mitral incompetence. Using a somewhat similar technique, Friedman *et al.* (1956), however, failed to confirm their findings. The tracings in

Fig. 1 show quite clearly that a true X descent can occur in the presence of atrial fibrillation. In pathological conditions of the heart it is apparent that atrial fibrillation and tricuspid incompetence may occur together not infrequently; no doubt this association has added to the confusion. Any doubts should be readily resolved by observing the ease with which the poor descent of the base pattern is converted to a positive systolic pulse by mild exercise or even by deep inspiration.

Blood Flow in Right Atrium

The direction of blood flow in the right atrium and great vessels from moment to moment during the cardiac cycle can be demonstrated by using a double-lumen cardiac catheter as a Pitot flow-meter (Müller and Shillingford, 1955). The catheter is placed with the end hole in the right atrium and the side hole in the superior vena cava. The other end of the catheter is then connected to a differential manometer and the recording apparatus, so arranged that if the pressures in the side hole and end hole are the same there is no deflection; if the pressure in the end hole is greater than in the side hole the instrument will record downwards, while if it is higher in the side than in the end the deflection will be upwards. In this way direction of flow can be indicated. Fig. 3 shows a flow curve between

Fig. 3.—Blood flow between the superior vena cava and right atrium in patients with and without tricuspid incompetence.

the superior vena cava and right atrium in a normal patient and in one with tricuspid incompetence. When tricuspid incompetence occurs the normal forward flow during ventricular systole and descent of the base of the heart is replaced by a back-flow. Although this method shows the presence of a regurgitant flow it does not accurately measure the amount of blood passing back.

Estimation of Valvular Incompetence by Dye Dilution Curves

The quantitative estimation of the part played by valvular incompetence in cardiac failure has been made possible by the recent observation that indicator dilution curves are altered in a specific way by the presence of valvular insufficiency (Korner and Shillingford, 1955, 1956). Stewart (1894) and later Hamilton *et al.* (1932) showed that if an indicator substance—for example, Evans blue—was injected into the venous side of the circulation and collected on the arterial side the dye particles would spread out during their passage through the heart and vessels and produce a time-concentration curve at the point of sampling. They pointed out that from this curve it was possible to measure not only the cardiac output but also the volume of blood through which the dye had passed. Korner and Shillingford (1955) have demonstrated that for a given calculated cardiac output and volume the spread of the dye particles is constant, but that the addition of valvular incompetence causes an increase in the spread of the particles quite apart from that produced by variations in the cardiac output and cardio-

pulmonary volume. This effect can be used to compute the amount of regurgitant flow, and, tested in a model circulation, has been found to be accurate, with a maximum error of 15%.

This new approach to the problem of valvular incompetence in cardiac failure has enabled us not only to recognize valvular incompetence of lesser degree than was formerly possible, but also accurately to assess the part it plays in the haemodynamics of cardiac failure.

Functional Tricuspid Incompetence in Congestive Cardiac Failure

Functional tricuspid incompetence has long been recognized as a frequent late development in congestive cardiac failure. A recent analysis (Korner and Shillingford, 1955) of the right atrial pressure pulse in a series of 50 patients with various forms of heart disease with and without congestive cardiac failure has revealed a remarkably close relationship between the level of the mean venous pressure and the development of functional tricuspid incompetence. As the venous pressure rises so the normal X descent becomes impaired and takes on the form of a positive systolic pulsation. The critical level of venous pressure at which tricuspid incompetence becomes recognizable is approximately 8 mm. of mercury above the normal mean zero pressure. Development of functional tricuspid incompetence takes place about this level of venous pressure in many aetiological varieties of heart failure, and when the venous pressure becomes more grossly raised functional tricuspid incompetence is even more obvious and beyond argument (Fig. 4).

Fig. 4.—Relationship between mean venous pressure and the form of the atrial pulse in 50 cardiac patients.

Fig. 5.—Forward output and phasic regurgitant flow estimated by the indicator dilution method in 12 patients with varying degrees of congestive cardiac failure.

Thus a considerable number of cardiac patients with grossly raised venous pressure also have functional tricuspid incompetence. The only exceptions to this are found in constrictive pericarditis and conditions with a very rapid venous inflow (anaemia, early thyrotoxicosis). The importance of these clinical phenomena has been overlooked, probably because of the difficulty of timing the pulse waves in the neck at the bedside, especially when the heart is beating rapidly. Only by graphic recording methods is it possible accurately to assess the form of the venous pulse.

The magnitude of the back-flow through the functionally incompetent tricuspid valve in cardiac failure can be con-

siderable. As the right ventricle and the tricuspid valve dilate, the aperture of reflux may become as great as, or greater than, the pulmonary valve orifice when fully open (Lottenbach and Shillingford, in press). As the mean right atrial pressure is considerably lower than the mean pulmonary arterial resistance to back-flow the oscillating back-flow may easily exceed the forward flow into the pulmonary vessels. Measurement of this back-flow by dye-dilution methods shows it in some cases to reach 6 or 7 litres a minute, while the forward cardiac output is only 2 or 3 litres a minute (Fig. 5). In other words, the stroke regurgitant flow oscillating backwards and forwards through the valve would be of the order of 60–70 ml. back and 80–100 ml. forward at a pulse rate of 100 beats a minute. This observation of a total high right ventricular output in the presence of heart failure and a low forward cardiac output can be appreciated by palpating the excessively large right ventricular pulsations even in patients in advanced congestive cardiac failure.

The physical signs correlate with the presence of this backward flow in congestive failure. The systolic wave in the venous pulse is apparent on careful examination; a systolic murmur heard best at the lower end and just to the left of the sternum is present in most cases; and in the same area, when the phasic regurgitant flow is great, there may be a low-pitched early diastolic murmur; this murmur is probably associated with the rapid inflow of blood from the right atrium to ventricle during this phase of the cardiac cycle, and does not necessarily denote an organic change in the valve itself. It must be remembered that diastolic inflow to the right ventricle under these circumstances equals the sum of backward and forward flow and may therefore be very large. Liver pulsation becomes apparent to nearly all clinical observers if the regurgitant stroke output exceeds 40 ml.

The regurgitant flow through an incompetent valve is not a fixed reflux but is varying from minute to minute under the influence of rest and exercise, emotion, respiration. The effect of these factors may be studied clinically or by means of the newer techniques for quantitative measurement of regurgitant flow.

Influence of Changing Inflow: Respiration: Rest: Exercise

Functional tricuspid incompetence varies with the degree of distension of the right ventricle. It may be seen to vary from beat to beat; for example, under the influence of respiration a deep inspiration may produce or intensify the tricuspid systolic murmur and bring out a strong systolic venous pulse in the jugular vein (Fig. 6). In atrial fibrillation a long diastolic pause may permit an increase in right

Fig. 6.—Effect of deep inspiration on jugular pulse and tricuspid systolic murmur in a patient with congestive heart failure.

FIG. 7.—Effect of exercise and rest on jugular venous pulse in a patient with chronic rheumatic heart disease and early congestive cardiac failure. A, before exercise. B, after three minutes' mild exercise, showing development of positive systolic pulsation and increase of functional tricuspid systolic murmur (phonocardiographic record taken at lower end of sternum). C, after three minutes' rest. D, after six minutes' rest, showing return to X descent pattern and diminution in intensity of tricuspid murmur.

ventricular distension which makes the valve more incompetent; and as a result tricuspid systolic murmurs may diminish in intensity after a short diastole and increase again when the pause is long between ventricular beats.

Rest and exercise have a profound effect on the amount of regurgitant flow through the tricuspid valve (Figs. 7 and 8). Fig. 9 shows two examples of this in patients with

FIG. 8.—Effect of exercise on blood flow between superior vena cava and right atrium in a patient with chronic rheumatic heart disease and early congestive cardiac failure. The development of a regurgitant flow through the tricuspid valve on exercise is shown by the deep downward deflection in systole (measured by differential manometer).

FIG. 9.—Effect of rest and exercise on right ventricular output in congestive cardiac failure with functional tricuspid incompetence (see text).

chronic rheumatic heart disease and mild or moderate venous congestion. It will be seen in the second patient (M. B.) that the regurgitant flow on the first dye injection was 2.2 litres a minute, while the forward output was 3.7 l./min. The mean jugular venous pressure was 10 mm. Hg. On resting quietly for 20 minutes the venous pressure had fallen to 7 mm. Hg and the regurgitant flow to 0.5 l./min., but the forward cardiac output had risen to 4.6 l./min. Gentle exercise by moving the legs for two minutes reversed this process and diminished the forward cardiac output to 4.3 l./min., with a rise in the regurgitant flow to 3.6 l./min. and the jugular venous pressure (Fig. 6). This increase in regurgitant flow is confirmed by measurements by the flowmeter (Fig. 8).

It will thus be seen that exercise in congestive heart

failure may increase the total right ventricular output but decrease the forward output of the heart, while rest has the opposite effect.

Organic Tricuspid Incompetence

Although functional tricuspid incompetence is common, organic lesions of the valve are comparatively rare. Rheumatic disease affects the tricuspid valve in 10 to 15% of all our cases of chronic rheumatic heart disease coming to necropsy. Nearly all these have more incompetence than stenosis, valve-cusp fusion being limited to the margins. In the earlier stages it is possible to have all the signs of tricuspid incompetence without much dilatation of the right ventricle. In fact, the right ventricle may be able to carry the additional load of mild regurgitant flow for many years without signs of failing; the patient during this time has a raised venous pressure and may even have cardiac cirrhosis, ascites, and oedema.

Influence on General Haemodynamics of Cardiac Failure

The study of cardiac output in heart disease has revealed that the resting output often remains in the normal range until the last bedridden stage, when it falls towards half the normal; at this last stage the venous pressure is grossly raised. Venesection in these patients may be followed by a rise in cardiac output, while exercise, producing elevation of the venous filling pressure, often engenders a fall in cardiac output.

More than a decade ago McMichael and Sharpey-Schafer (1944) compared these changes with the measurements made by Starling and his school on the isolated dog heart. An elevation of venous filling pressure which normally increases the cardiac output may, if pushed to extremes, have the reverse effect of bringing about a fall in minute-volume. It was thought that possibly this fall in output resulted from some breakdown of the cardiac contractile mechanism, because it was at this stage of human heart failure that favourable digitalis and venesection responses were often encountered.

Sarnoff and Berglund (1954) have made extensive studies of the conditions under which Starling's law becomes applicable. They have demonstrated its general validity when applied to a single ventricle—for example, the left—and have reconstructed curves which show the rising cardiac output curve flattening off in a plateau with continuing elevation of venous pressure, but a falling output response was seen only when atrio-ventricular valve incompetence was induced by overstretching.

If we accept this finding and link it to our own more recent observations the following tentative suggestions seem permissible:

1. The falling cardiac output with gross venous congestion may almost entirely be accounted for by reduction of forward cardiac output consequent on the development of tricuspid incompetence.
2. The improvement in cardiac output after venesection is simply the result of a decreased filling pressure which diminishes right ventricular dilatation; the tricuspid valve becomes more competent and back-flow is reduced.
3. Falling output and elevation of venous pressure on exercise—for example, like that noted by Hickam and Cargill (1948)—may result from increased distension of the right ventricle increasing the tricuspid leak, while the reverse occurs with rest.
4. There is no necessity to postulate a metabolic breakdown of the myocardium at this stage. Such a breakdown invoked by our earlier hypothesis was subject to the criticism that it would have entailed "vicious circle" consequences, increasing venous pressure leading to further and further degrees of myocardial breakdown.

A further comment may be made in relation to the flow-work of the right ventricle. In the presence of tricuspid incompetence the bidirectional output of this chamber at each systole may be nearly double the normal. The falling forward output may thus reduce only the work of the left ventricle, while the right ventricle is maintaining a greatly increased output. No doubt this local overload imposed by an incompetent tricuspid valve helps to produce the final right ventricular breakdown. It is amazing sometimes to see how long it may be tolerated—six or seven years—before final dissolution. We must think again about low cardiac output states. It may be only the forward output which is reduced, as an incompetent valve may actually increase the total output of the affected chamber. Older subdivisions of heart failure into "high" and "low" output types will give way to the concept that nearly all failing hearts have been overworking for a very long time against the mechanical embarrassments of diseased valves or increased pressure loads.

Valvular Incompetence and Failure of the Left Ventricle

Owing to the technical difficulties encountered in studying left atrial and ventricular pressures the information on left heart failure is not so complete as that on the right. It is likely, too, that there is a considerable basic difference in the haemodynamics of the two sides in cardiac failure. Whereas the tricuspid valve probably only just closes in normal subjects and is readily made incompetent by dilatation of the right ventricle, the mitral valve attached by its chordae to the thicker-walled left ventricle does not seem to become functionally incompetent so easily. At the same time the venous reservoir of the left atrium and lung bed is considerably less than that of the right atrium, caval veins, and their large valveless tributaries. This results in a difference in pressure-volume relationships in the veno-atrial systems on the right and left sides which tends to limit the amount of blood regurgitating through the mitral valve compared with that which may flow back through the tricuspid valve.

Recent work on organic mitral incompetence has shown that the to-and-fro regurgitant flow in established cases may be 2 or 3 litres a minute, which, added to the forward flow, makes a high total output of the left ventricle. The regurgitant flow is not constant, but varies from moment to moment. Any factor tending to lower the peripheral resistance and thus lessen the obstruction to the aortic outflow will at the same time reduce the back flow through the mitral valve relative to the forward flow through the aortic valve; this occurs in exercise. The administration of amyl nitrite causes the forward output to increase considerably, while the regurgitant flow becomes less, a finding which may also be suspected clinically by noting the diminution in the intensity of the murmur of mitral incompetence. The administration of a vasoconstrictor substance, on the other hand, produces an increase in the regurgitant flow. Rest and exercise may thus have opposite effects on the volume of regurgitant flow through the tricuspid and mitral valves.

Aortic Incompetence

The haemodynamics of aortic incompetence present several important differences from those of the atrio-ventricular valves. The regurgitant flow in the latter takes place during systole and is dependent on the full force of ventricular contraction during the part of the cardiac cycle. In aortic incompetence the regurgitant flow depends on the potential energy built up by distension of the aorta and its branches during systole; the amount of this energy developed depends on the stroke volume of the left ventricle, and on resistance and elasticity of the arterial system. In the first part of diastole this energy is rapidly expended forwards through the peripheral arteries and backwards through the incompetent aortic valve. As in mitral incompetence, therefore, lowering peripheral resistance re-

duces the regurgitant flow through the valve, and so does loss of elasticity in the aorta. The peripheral resistance in aortic incompetence is in fact reduced by physiological reactions producing vasodilatation and thus reducing the back-flow. The mechanism of this is not clear, but may well be a reflex initiated in the pressor-receptor areas in the arch of the aorta and carotid sinus. This vasodilatation also has the effect of accommodating a high stroke output of the left ventricle over and above that due to the additional load of regurgitant flow.

Without detracting from the importance of the myocardium it is clear that the volumes of back-flow involved in valvular incompetence are often very large, and constitute a factor of major importance in the development of the syndromes of heart failure. While measurements of valvular regurgitation on the right side of the heart may be made with relative ease and safety by a variety of complementary methods, the techniques applicable to the problems of the left side are more restricted and difficult of application. Observations made so far suggest that the anatomical and haemodynamic factors differ on the left and right sides and indicate somewhat different mechanisms in the process of final cardiac breakdown.

Summary

The part played by valvular incompetence in cardiac failure is discussed.

Functional tricuspid incompetence often occurs in congestive cardiac failure when the venous pressure is raised above 8 mm. of mercury. This regurgitation can be demonstrated by the form of the venous pulse, the tricuspid systolic murmur, and special techniques to demonstrate direction and volume of flow between the right ventricle and atrium during the cardiac cycle.

The development of tricuspid incompetence causes an increase in the total output of the right ventricle at the expense of the forward cardiac output, and even in advanced clinical congestive failure with low cardiac output the right ventricular output remains high.

Exercise increases the functional tricuspid incompetence, with a corresponding fall in forward cardiac output, and probably explains both the phenomena of fixed or falling cardiac outputs on exercise in congestive cardiac failure and the breakdown of Starling's law with a rising venous pressure.

The haemodynamics associated with mitral and aortic insufficiency are discussed and are shown to differ considerably from those involving the tricuspid valve.

STAPHYLOCOCCAL DIARRHOEA

WITH AN ACCOUNT OF TWO OUTBREAKS IN
THE SAME HOSPITAL

A. M. N. GARDNER, F.R.C.S.

Late Senior Registrar in General Surgery,
Radcliffe Infirmary, Oxford

During the years 1953-5, 31 cases of diarrhoea following antibiotic therapy were investigated in the Radcliffe Infirmary. *Staphylococcus aureus* was cultured from the faeces of 20 of them (Table I). Fourteen of the 31 patients died. Of the 31, 14 had had partial gastrectomies, and seven of these were among the 14 who died (Table I).

Of the total number of cases, 17 occurred in one male surgical ward, where the incidence of the disease reached the proportions of a small outbreak in the spring of 1954 (see Chart). The epidemic nature of this condition has not been stressed in previous reports, though the parts which *Staph. aureus* and the antibiotics play in the genesis of the disease are generally acknowledged.

The epidemiology, bacteriology, diagnosis, and treatment of the condition are discussed below, where the term "staphylococcal diarrhoea" is applied to those cases in which *Staph. aureus* was isolated from the diarrhoeic stools. Special culture methods were used to isolate the *Staph. aureus* to prevent its being overgrown by other organisms (see Appendix).

The term "staphylococcal enterocolitis" has been avoided because evidence was not always available, even at post-mortem examination, that both the small and the large bowel were affected. Similarly, the term "pseudomembranous enterocolitis," which is a descriptive term of pathology and not a disease entity, has also been avoided except in those cases in which pseudomembrane was actually found. From many reports it is seen that pseudomembranous lesions are found in many patients who have not had diarrhoea.

Review of the Literature

Finney (1893) gave what is possibly the earliest report of a similar condition, in a young woman, which developed 15 days after a gastro-enterostomy. She had severe diarrhoea and died, a "diphtheritic" membrane being found over the mucosa of the lower bowel. Descriptions of numerous cases of pseudomembranous enterocolitis have been published (Penner and Bernheim, 1939; Penner and Druckermann, 1948; Dixon and Weismann, 1948). The consensus of opinion of these authors was that shock was probably the cause of pseudomembranous enterocolitis, and no mention was made of bacteria except as secondary invaders.

Pettet *et al.* (1954), at the Mayo Clinic, reviewed 107 cases occurring during the 27 years prior to 1952 and did not think then that the incidence of pseudomembranous enterocolitis had significantly increased since the advent of antibiotics, but they acknowledged the possibility of disturbance by antibiotics of the normal balance of intestinal flora. At the post-mortem examination most of the cases were shown to have a pseudomembrane. *Staph. aureus*, though not specifically sought for, was found in the stools of five of them.

It is difficult to compare these series with those more recently described, because the clinical features are often very different—for example, intestinal obstruction, colonic carcinoma, and generalized peritonitis were common; diarrhoea was often not present; bacteriological examination of the stools was seldom reported; and antibiotics, of course, were not available for many of the early cases.

Kramer (1948) reported what is probably the first case of staphylococcal diarrhoea associated with oral streptomycin.

During the last few years many authors have reported cases of diarrhoea or enterocolitis following the use of antibiotics, more especially the "broad-spectrum" types. Disturbance of the balance of the normal bacterial flora, or its elimination, has usually been thought to be the cause, but more recently infection by *Staph. aureus* has been emphasized.

It is interesting to note, in retrospect, a warning given by the Council of Pharmacy and Chemistry of the American Medical Association (1951): "The new antibiotics, chloramphenicol, aureomycin and terramycin are highly bacteriostatic for many bacteria. Susceptible bacteria are suppressed and monilia and other yeast-like organisms may replace the normal or abnormal bacterial flora. This most frequently occurs in the large bowel and is of little consequence." (There followed a brief warning of possible infections of the lungs and other organs by fungi but no warning of invasion by bacteria resistant to these antibiotics.)

Since then there have been many reports, from both sides of the Atlantic, of fatal intestinal infections with *Staph. aureus* following the use of antibiotics in various conditions: Jackson *et al.* (1951) in treating pneumonia with oxytetracycline ("terramycin"); the same group (Womack *et al.*, 1952) in using oxytetracycline for urinary infections; Hay and McKenzie (1954) in treating dysentery in children with oxytetracycline; Dearing and Heilman (1953) in employing oxytetracycline and chlortetracycline ("aureomycin") in medical and surgical conditions. The last-mentioned authors found erythromycin effective in eliminating *Staph. aureus*, resistant to other antibiotics, from the faeces. From Greece, Choremis *et al.* (1954) reported 22 cases of severe diarrhoea, with 14 deaths, in 195 children with measles treated by antibiotics. Other affected children who did not receive antibiotics had no diarrhoea. Of the 22 cases, only six were studied bacteriologically, and in only two was *Staph. aureus* found in the faeces.

There are several similar reports of deaths, after various operations, due to staphylococcal diarrhoea following antibiotic therapy (Terplan *et al.*, 1953; Fairlie and Kendall, 1953; Wakefield and Sommers, 1953; Gardner, 1953; Williams, 1954; Fowler, 1955). *Staph. aureus* resistant to the antibiotics employed was often cultured from the faeces. Chlortetracycline and oxytetracycline were most frequently used, but in Fairlie and Kendall's series all but one of their five cases (three of them fatal) received penicillin and streptomycin. Pettet *et al.* (1955) described a case of staphylococcal enterocolitis following pre-operative preparation of the bowel with neomycin.

Not all authors agree that *Staph. aureus* and antibiotics together are the chief cause of severe post-operative enterocolitis—for example, Williams and Pullan (1953), although *Staph. aureus* was found in five of their severe cases examined bacteriologically. Their 10 fatal cases all occurred after partial gastrectomy. Dawson-Edwards and Morrissey

(1955) found *Staph. aureus* in only one of their 35 cases of enterocolitis following gastro-intestinal operations, but it was not sought routinely.

The epidemic nature of staphylococcal intestinal infection is illustrated by the report of Todd and Hopps (1955), who recorded two deaths from enterocolitis—one after partial gastrectomy, the other in a case of erythema multiforme. Both patients were in the same ward and died within seven days of one another, both received "broad-spectrum" antibiotics, and both were infected with *Staph. aureus* of the same phage type. The same strain of staphylococcus was widespread over the ward furnishings.

The Radcliffe Infirmary Outbreaks

During six weeks of the spring of 1954, in one male surgical ward (B) of this infirmary, six "good risk" patients developed severe diarrhoea following partial gastrectomy, and four of them died. Their progress after operation was uneventful until the onset of diarrhoea on the second or third post-operative day. A similar time of onset was described by Williams and Pullan (1953). During the next six weeks three more patients in the same ward—one after prostatectomy and two after partial gastrectomy—were similarly afflicted and one died. Unfortunately four cases were not fully investigated bacteriologically, but in retrospect it seems likely from the clinical features that they were staphylococcal infections.

During the following 15 months 20 other patients undergoing various treatments developed diarrhoea of varying severity. All of them, in addition to the above-mentioned 11 early cases, had been treated with antibiotics. The relevant details of these 31 cases are summarized in the epidemiological Chart and in Table I. Seventeen were patients in the same male surgical ward (B). Fourteen had operations for partial gastrectomy, and seven of them died following severe diarrhoea. All these cases were fully investigated bacteriologically.

The squares represent the 31 individual cases and the letters in them the seven wards involved. No phage-typing of the strains of *Staph. aureus* was done during the years 1953-4. See also Table II.

TABLE I.—Summary of 31 Cases of Diarrhoea, Giving the Incidence of *Staph. Aureus* in the Faeces

Operations Performed	Severe Diarrhoea		Moderate Diarrhoea	Total
	Fatal	Recovered		
Partial gastrectomy	7 (1:4)	5 (3:4)	2 (0:2)	14 (4:10)
Other gastro-intestinal operations	2 (1:2)	0	1 (1:1)	3 (2:3)
Others	5 (5:5)	1 (1:1)	5 (5:5)	11 (11:11)
None	0	1 (1:1)	2 (2:2)	3 (3:3)
Total	14 (7:11)	7 (5:6)	10 (8:10)	31 (20:27)

Note.—The carriage rate of *Staph. aureus* in the faeces of 49 patients, before and after operation, who did not develop diarrhoea was 12%. Figures in parentheses are the proportion of the specimens which gave *Staph. aureus* on culture—for example (2:3) indicates that 2 specimens out of 3 cultured were positive for *Staph. aureus*.

Clinical Features.—The cases may be divided into two groups. (A) *The 21 severe cases*:—Severe watery diarrhoea usually developed suddenly, sometimes with a premonitory tachycardia or a fall in blood pressure. The small bowel was distended and hyperactive, although in the later stages it became paralysed. The stools were often of the "rice-water" type, the patient being incontinent. In many cases the temperature rose to 101-102° F. (38.3-38.9° C.) at the onset, but some patients remained afebrile. Within a few hours the patient was collapsed, with circulatory failure, but occasionally he remained calm and almost euphoric. Few of these patients recovered. (B) *The 10 less severe cases*:—These ranged from severe diarrhoea with little systemic upset to milder cases in which the diarrhoea was troublesome for a few days, but ceased spontaneously. Recovery in this group was usual.

Diagnosis

In those cases presenting with tachycardia and a fall in blood pressure, other conditions—for example, pulmonary atelectasis or embolism, coronary thrombosis, a leaking suture line, or internal haemorrhage—were suspected until the onset of abdominal distension and diarrhoea made probable the diagnosis of staphylococcal intestinal infection, especially in those patients who had been given antibiotics.

A specimen of diarrhoeic stool which had been allowed to stand in a glass jar often showed three layers: a lower layer consisting of dirty white flakes of mucus and sometimes mucus membrane; a middle layer of faecal detritus; and a supernatant layer of murky fluid. A Gram-stained film of the faeces often showed large numbers of Gram-positive cocci and pus cells. Cultures of *Staph. aureus* and other pathogens were made from the faeces (and gastric aspirates if a tube was in place), and the sensitivity to antibiotic drugs was determined for all strains isolated.

Typical Cases

Case 11.—This reasonably fit man of 71 years had a Billroth I partial gastrectomy carried out for a chronic duodenal ulcer. Penicillin and streptomycin were given post-operatively. Two days after the operation he developed a profuse watery diarrhoea accompanied by severe systemic upset, fever, and tachycardia. The diarrhoea, with tympanites, persisted for nine days but eventually cleared up. *Staph. aureus* was isolated from the faeces. Treatment was by massive intravenous replacement of the lost fluid, pil. codein., and chlortetracycline, to which the staphylococcus was sensitive. Though this was one of the most severe cases of post-operative diarrhoea the patient recovered.

Case 13.—This fit man, aged 63, had a transthoracic repair and vagotomy for a large intrathoracic stomach. Penicillin and streptomycin were given prophylactically and his condition was satisfactory until the second post-operative day, when his pulse rose to 130 a minute with a fever of 101° F. (38.3° C.). It was thought that he had a pulmonary infection, and oxytetracycline was given. The next day he began to pass melaenic stools and collapsed. He was resuscitated by blood transfusion and laparotomy was then performed. There was marked congestion of the splanchnic veins and

the small bowel was purplish in colour. No bleeding-point was found in the stomach or duodenum. He died the same evening. At necropsy was seen the typical appearance of pseudomembranous enterocolitis, all the large and small bowel being affected. There was, in addition, a large chronic gastric ulcer which could have been the source of bleeding. A penicillin-resistant *Staph. aureus* was isolated from the intestinal contents at necropsy.

Case 14.—This man, aged 53, had had a nephrectomy for renal tuberculosis 20 years previously, but was otherwise fit. He was admitted to hospital on February 24, 1955, and an elective Billroth I partial gastrectomy was performed for a chronic duodenal ulcer. The operation and the patient's early progress were straightforward until the evening of the second day, when some abdominal distension was noticed. The pulse rate was 100 all day, the temperature 99–100° F. (37.2–37.8° C.). Early on the third day he developed a profuse offensive watery diarrhoea, appeared very ill, and showed a mild degree of peripheral circulatory failure. A provisional diagnosis of staphylococcal enteritis was made and treatment with intravenous fluids, erythromycin, 300 mg. six-hourly, and oral yoghurt four-hourly was started. He had been fed by jejunal tube for the first 48 hours after operation and had been given penicillin and streptomycin during that time. These measures were discontinued. On this regime his condition improved dramatically and the diarrhoea ceased after four days. No obvious membrane was ever found in the stools, but there were numerous suspicious shreds in most specimens. *Staph. aureus*, resistant to streptomycin, oxytetracycline, and penicillin was found in the faeces and in the nose.

Case 23.—This healthy man, aged 30, was struck by a car and received a moderately severe head injury and dislocations of the left acromioclavicular and knee joints. He was transferred to hospital three days later because of deepening coma, the chief cause for which seemed to be a severe bronchopneumonia with a temperature of 104° F. (40° C.). Nasal swabs and tracheal aspirate showed a *Staph. aureus* sensitive only to erythromycin. He had already been treated with chlortetracycline. Oxytetracycline and chloramphenicol improved his chest condition, but a week later he developed a very severe watery diarrhoea and *Staph. aureus* was grown from the stools. Erythromycin was then given with excellent results and he made a complete recovery.

Treatment

Antibiotic therapy in current use was discontinued. Fluid loss was replaced by intravenous infusions guided by daily biochemical estimations. One patient who survived produced over 47 pints (26.7 litres) of fluid faeces in 12 days, and was given in that time 141 pints (80 litres) of intravenous fluid. If the patient was seriously ill and had not previously received erythromycin, this drug was given (300 mg. six-hourly) by stomach tube without waiting for the bacteriological report. The patient was nursed in an isolation ward in order to minimize the spread of erythromycin-resistant staphylococci. This is extremely important, because Lepper (1953) reported that five months after the introduction of erythromycin into his hospital the nasal carrier rate of *Staph. aureus* resistant to erythromycin rose to 75%.

To several patients yoghurt, which contains lactobacilli, was given in the hope of replacing the pathogenic bacteria (Lancet, 1954a). Rettger and Cheplin (1921) showed that it was possible to create and maintain a lactobacillary intestinal flora in normal subjects by strenuous efforts at feeding cultures of lactobacilli and large amounts of lactose. Although from one patient given yoghurt a lactobacillus was cultured from the stools (Case 20) no evidence of the value of this treatment in staphylococcal diarrhoea was obtained.

Epidemiology

Staph. aureus was isolated from the diarrhoeic stools of 20 of the 31 patients in the present series. Six of the

remaining 11 were not investigated bacteriologically; from the stools of the other five no pathogenic bacteria were isolated (Table II). It should be noted that nine of these cases occurred before the special culture methods for faecal *Staph. aureus* were being used. Since then *Staph. aureus* has been isolated from the stools of 17 out of 19 cases of diarrhoea in surgical patients in this hospital. (It is noteworthy that in any given patient it may not be possible to isolate *Staph. aureus* from every specimen of faeces.) In every case antibiotic therapy had preceded the diarrhoea and in every case the patient's faecal *Staph. aureus* was resistant to the antibiotic he had received. Penicillin and streptomycin were given in 14 cases; penicillin or penicillin and sulphonamides in 10; streptomycin and sulphonamides in one; penicillin, streptomycin, and oxytetracycline in two; penicillin and chlortetracycline in two; penicillin, streptomycin, and chloramphenicol in one; and erythromycin and sulphonamides in one. The usual doses were: penicillin 500,000 units b.d. intramuscularly; streptomycin 0.5 g. b.d. intramuscularly; chlortetracycline, oxytetracycline, and chloramphenicol 250 mg. six-hourly orally.

Of our 31 cases, 17 occurred in ward B and 29 fell into one of two outbreaks. The first outbreak, comprising 10 cases (nine of which were in ward B), occurred in the period April to July, 1954; the second outbreak, comprising 19 cases (eight of which were in ward B), occurred in the period February to July, 1955. It was during the latter outbreak that a more comprehensive epidemiological picture was obtained.

Of the 19 cases in the second outbreak, seven gave *Staph. aureus* of phage type 6/47, three type 7/47/54, two type 77, one each of types 7/47 and 54, and four were not typed. From one case *Staph. aureus* was not isolated. Seven of these 18 strains were resistant to penicillin, streptomycin, chlortetracycline, and oxytetracycline, three in addition being resistant to erythromycin and three to chloramphenicol. Of the remaining five only one was sensitive to penicillin (Table II).

The staff of ward B were swabbed during the second outbreak and *Staph. aureus* type 6/47 with a typical pattern of resistance to antibiotics was found in the noses of the house-surgeon, ward sister, two nurses, and five unaffected patients. Type 54 was also found in the nose and on the hands of one nurse. The majority of the rest of the staff were carrying other strains of *Staph. aureus* in their noses, but none of these strains was isolated from the diarrhoeic stools.

The environment of the patients was also examined. In ward B *Staph. aureus* was isolated without difficulty on three occasions from dust, furniture, soft furnishings, and blankets.

On May 30, 1955, ward B was closed, cleaned, and repainted. On June 30 the ward was again tested and no *Staph. aureus* was isolated from some 40 swabs taken from every situation that might have harboured the organism. Patient No. 24, who had been transferred to an isolation hospital, was then readmitted and nursed in isolation in a side ward. However, in three days the immediate environment of the patient was heavily contaminated with *Staph. aureus* phage type 77 and the same organism was found in other situations in the ward.

In ward C patient No. 16, with a fractured femur, was infected with *Staph. aureus* phage type 6/47 and succumbed. The side ward in which he had been nursed was cleaned and fumigated with formalin. Patient No. 17, eight days later, after a craniotomy, was nursed in the same bed, developed staphylococcal diarrhoea from organisms of the same phage type, and also died.

From 6 of the 19 cases occurring in 1955, *Staph. aureus*, of the phage type corresponding to that grown from their faeces, was grown from the nose prior to the disease developing. In only 2 of the 13 nasal carriers tested was *Staph. aureus*, of the phage type corresponding to that grown from their faeces, grown from the gastric aspirate before the disease developed.

TABLE II.—Summary of 31 Cases of Diarrhoea

Case No.	Ward	Sex and Age	Diagnosis and/or Operation	Stomach Tube	Pre-diarrhoeal Chemotherapy	Diarrhoea			Faecal <i>Staph. aureus</i> and Phage Type†	Resistance Pattern	Erythromycin Therapy	Outcome

P.=penicillin. S.=streptomycin. C.=chloramphenicol. A.=aureomycin (chlortetracycline). T.=tetracycline (oxytetracycline). E.=erythromycin. Sul.=sulphonamides.
* Number of days either after operation or after commencement of antibiotic treatment that diarrhoea began.
† N/D=not done—i.e., not cultured. The phage type where known is given in parentheses.

Aetiology

The present series of cases points to *Staph. aureus* being the chief cause of post-operative diarrhoea in this hospital; it was isolated from the faeces of 20 of the 31 cases. Of these cases 17 were consecutive. Six cases, four of them fatal, were not investigated bacteriologically (Table II).

The arguments brought against *Staph. aureus* as the aetiological agent are as follows: (1) the presence of *Staph. aureus* is not significant of disease, as it is found in 17% of normal adult stools (Brodie *et al.*, 1956); (2) the staphylococci become significant only after the patient has been weakened already by some other initial cause of the diarrhoea; and (3) the resistance of the *Staph. aureus* to the antibiotics in use is not in itself necessarily significant, since its very survival implies resistance.

However, in three severe and three moderately severe cases in this series erythromycin seemed to stop the diarrhoea and cleared the faeces of *Staph. aureus*. This was also the experience of Dearing and Heilman (1953) in 21 of their cases. In three of our cases erythromycin proved ineffective, but two were by that time moribund. The successful use of erythromycin is therefore strong evidence for *Staph. aureus* as the cause of the diarrhoea.

In a given patient it may not be possible to isolate *Staph. aureus* from every specimen of faeces. For example, in one of the worst cases of the series (No. 25) *Staph. aureus* was not isolated from 4 of the 11 specimens of faeces cultured. There may even be cases where, although the *Staph. aureus* is not isolated, it is nevertheless the cause of the condition. Similar difficulty is sometimes experienced in isolating *Salmonella* or *Shigella* organisms from infected faeces.

The relationship between staphylococcal diarrhoea and pseudomembranous enterocolitis is not clear. Penner and Bernheim (1939) and Penner and Druckermann (1948) suggested that the pseudomembrane was caused by submucosal vasospasm resulting from post-operative shock. However, it must be stressed that many of their cases, and those of Pettet *et al.* (1954), did not have diarrhoea. Shock and peritonitis were often present, and in many cases occurred before the advent of antibiotics. The role of bacteria was not thought to be important. Moon's (1938) observation may be relevant here; he noted bloody mucous

diarrhoea with congested oedematous bowel mucosa after severe experimental shock in animals. Possibly some of the cases of necrotizing haemorrhagic jejunitis described by Fick and Wolken (1949) are similar to these animal cases, for profound shock and similar intestinal changes were reported. In addition they found *Clostridium welchii* in all cases. However, in this present series severe staphylococcal diarrhoea occurred in patients who were not previously shocked.

Pseudomembranous enterocolitis has also been described in other conditions—for example, diphtheria and poisoning with heavy metals (Lancet, 1954b). Many fatal cases of diarrhoea following antibiotic therapy and showing pseudomembranous lesions at post-mortem examination have been attributed to staphylococcal infections (Terplan *et al.*, 1953; Wakefield and Sommers, 1953; Dearing and Heilman, 1953). It is probable that formation of pseudomembrane is a non-specific reaction of the body to a variety of noxious and exhausting stimuli, staphylococcal diarrhoea being one of them. However, we believe that *Staph. aureus* is likely to be incriminated more often if special cultural methods are used in investigating cases of diarrhoea following antibiotic therapy.

At the 14 post-mortem examinations which we made in this series a macroscopic pseudomembrane was found lining the intestines in two cases, macroscopic inflammatory changes without pseudomembrane formation in four, and of the other eight, although inflammatory changes had occurred in the intestines, autolysis prevented histological examination in these. An excellent account of the typical pseudomembranous lesions is given by Dawson-Edwards and Morrissey (1955).

We believe that the indiscriminate prophylactic use of antibiotics, chiefly penicillin and streptomycin in combination, was the chief predisposing cause of the diarrhoea in the outbreak in the spring of 1954, when five deaths occurred in one ward. A strain of *Staph. aureus* resistant to the antibiotics in use at the time was presumably able to establish itself in the usually sterile small bowel and to dominate the complex and usually stable flora of the large bowel.

The portal of entry of this resistant organism may have been the mouth or nasopharynx, or any or all of the

processes of ingestion, inhalation, and intubation. The organism itself may have been exogenous or, less often, endogenous (from the nose of the patient himself). The prevalent use of antibiotics, it seems, substantially assisted these organisms to invade the intestines of their victims. In order to appreciate the changes in bacterial population which occur during these abnormal states, it is necessary to consider first the normal intestinal flora.

The normal flora of the human small and large intestine has not yet been fully investigated. Cushing and Livingood (1900) noted that patients with perforations of the lower bowel succumbed rapidly to peritonitis, but that those with perforations of the stomach or upper intestine often recovered well. This observation led them to investigate the bacterial flora of the gut. They took samples direct from the intestines of many animals and patients, and concluded that the upper and middle small intestines were virtually sterile, and that any bacteria present had been ingested. Kendall *et al.* (1927) confirmed these findings.

Bacteriological examination of the contents of the gut at necropsy has been shown to be unreliable because the whole of the small intestine is invaded by coliform bacteria shortly after death (Blacklock *et al.*, 1937).

Cregan and Hayward (1953), of Melbourne, by taking samples direct by syringe from the healthy gut at various levels during abdominal operation, concluded that the whole length of the small intestine contains only a transient flora, chiefly of Gram-positive species that are more commonly associated with the mouth than with the large intestine. However, of 14 specimens from the lower ileum, three contained *Bact. coli* type 1, and one *Bact. aerogenes* type 1—that is, large-bowel organisms. In a second similar series of investigations (Cregan *et al.*, 1953) on 22 patients with gastric lesions, with varying gastric acidity and gastric bacterial flora, they again found few bacteria in the small intestine. *Staph. aureus* was found twice. They concluded that the small intestine has an antibacterial mechanism independent of the gastric barrier.

We have been able to confirm, in a small series, the findings of Cregan and Hayward (1953), using their technique. Eleven aspirates from normal small intestines gave no growth, and five gave scanty growth of mouth organisms—for example, *Streptococcus viridans*, and diphtheroids. One of the latter group of five gave a scanty growth of *Bact. coli* also, and gave another scanty growth of *Staph. aureus* sensitive to penicillin.

Colonic bacteria are, however, found in the small intestine in abnormal conditions. For example, *Bact. coli* type 1 (faecal) was cultured from the aspirated intestinal contents of three patients with strangulated or obstructed small bowel and also from one patient with symptomless jejunal diverticulosis.

Broadly speaking, then, the healthy human being has a small bowel which is largely free of bacteria and a large bowel which has an extremely large and complex flora. Although the flow of intestinal contents in the large bowel is unidirectional, organisms can invade it from the anal end, and the last few inches of the small bowel often contains organisms typical to the flora of the large bowel. Thus an exchange of organisms between the large and small bowels can occur, but presumably, under normal conditions, some mechanism maintains the difference in flora between the two.

The oral administration of antibiotics active against coliform organisms can bring about a profound though usually temporary reduction in the coliform flora of the faeces. This has been demonstrated by Zintel *et al.* (1947), Morton and Smith (1948), Hertfort and Standard (1948), Spaulding *et al.* (1949), and Metzger and Shapse (1950). It is difficult to see, however, how antibiotics can influence the susceptibility of the small bowel to infection. Possible reasons for the increased tendency to infection include: (1) a lowered general resistance of the patient due to operation or illness, or possibly due to toxic action of the antibiotic on the protoplasm of the host; (2) a lowering of

local resistance in the intestinal tract by interference with the natural defences—for example, by the removal of gastric acidity, by intestinal ileus, or possibly by the local action of antibiotics themselves on the tissues; (3) suppression of normal intestinal flora by antibiotics, enabling antibiotic-resistant organisms to flourish; (4) an increase in "virulence" of the organism stimulated by exposure to sublethal concentration of antibiotics, or of the changed metabolism of a resistant organism exposed to full concentration, enabling it to infect the small bowel (Garrod, 1951); and (5) the introduction of staphylococci direct into the bowel by means of a transnasal stomach tube.

An experiment illustrative of this increased tendency to infection is described by Freter (1955), who was able regularly to produce cholera in adult guinea-pigs, which are normally resistant to *Vibrio cholerae*, by preparing the animals with oral streptomycin.

Prevention of Staphylococcal Diarrhoea

The most important preventive measures in our view are the restriction of the use of antibiotics and reduction of the numbers of *Staph. aureus* present in the environment.

Since June, 1955, our use of antibiotics has greatly diminished (other routine therapeutic procedures not having been changed) and since then there has been no severe case of staphylococcal diarrhoea in ward B. That the use of the newer antibiotics is no guarantee against staphylococcal enterocolitis is seen from a case following neomycin therapy, quoted by Pettet *et al.* (1955). We feel that these drugs should be used only if specific indications exist, and then only with the patient in isolation. Antibiotics remain effective only as long as bacteria are sensitive to them.

During the period under review, owing to structural alterations there was no ward in the hospital in which septic surgical cases could be isolated. Isolation of such cases in the side wards of general wards was ineffective, *Staph. aureus* spreading rapidly from them to the whole ward area, particularly when it was being excreted in large numbers in the faeces. Thus it is obviously desirable to separate completely infected and "cold" surgical cases, and this should be done wherever possible.

Since October, 1955, the staff of ward B have had hands and noses swabbed every fortnight for the presence of *Staph. aureus*. This was done for the twofold purpose of research into the epidemiology of *Staph. aureus* in the ward and to try to eliminate heavy carriers. Local application of such antiseptics as chlorhexidine ("hibitane") may help to lessen the spread of organisms from these carriers.

The floor of ward B had been treated with spindle oil for some years before staphylococcal diarrhoea became a problem. This method of laying dust has been continued to the present time. Vacuum cleaners with air filters are used to remove any loose dust from the floor.

Since October, 1955, the problem of blankets has also been investigated. The findings will be published elsewhere, and it will suffice to say here that with the ordinary woollen blankets the method of cleaning described by Blowers and Wallace (1955) was adequate, provided that each patient was issued with a freshly laundered set of blankets on admission to the ward.

We feel that mattresses and pillows should also receive attention and that they should probably both be made of foam rubber with sealed air cells and be enclosed in rubber sheeting for easy swabbing with lysol after use by each patient.

The provision of more cubicles, single wards, and smaller nursing units generally will also militate against the spread of staphylococcal infection.

Gastro-intestinal aspiration may be a cause of spread of *Staph. aureus*, and all tubes must be boiled after being used for this purpose. A sterile syringe should be supplied for each aspiration, and any feeds given by this route should also be sterile and handled aseptically.

It will probably never be possible to eliminate *Staph. aureus* completely from patients and staff, but, by the measures outlined above, conditions under which resistant organisms can invade and flourish in post-operative and medical cases may be avoided.

Conclusions

Staphylococcal diarrhoea is a common and often fatal post-operative complication when antibiotics are being used prophylactically as a routine. In the Radcliffe Infirmary it became the major cause of death after elective partial gastrectomy. In medical patients, too, prolonged courses of antibiotics—for example, in chronic respiratory infections—are fraught with danger, especially when given in hospital. We submit, therefore, that the routine prophylactic use of these antibiotics is not justified. The relatively insoluble sulphonamides provide adequate preparation for colonic surgery, and it is unnecessary, and even dangerous, to use antibiotics in order to prepare the patient for operation either on the stomach or on the unobstructed small bowel.

However, if post-operative complications ensue, or if definite indications are present at operation (for example, a grossly soiled peritoneal cavity), the appropriate antibiotic should be used—at full strength and in short courses. Garrod (1955) outlined the principles for the correct use of antibiotics. Their abuse may lead to tragedy.

In conjunction with these measures, every effort must be made to reduce the numbers of *Staph. aureus* in the environment of the patient, not only to avoid surgical sepsis but to allow the safe and effective use of antibiotics when this is necessary.

Summary

Thirty-one cases of diarrhoea are described. Fourteen patients died, seven from one surgical ward. Fourteen cases occurred after partial gastrectomy.

Infection with *Staph. aureus* following antibiotic therapy was the chief cause of diarrhoea in this series.

The literature concerned with enterocolitis and staphylococcal diarrhoea is reviewed.

The epidemiology of two outbreaks of staphylococcal diarrhoea is described. Of the 31 cases, 29 occurred in two short periods in 1954 and 1955.

The aetiology of the condition is discussed and an account is given of an investigation into the bacteriology of the small bowel.

It is strongly recommended that antibiotics should not be used as a routine prophylaxis in abdominal surgery, but should be restricted to cases with special indication and then in isolation.

Measures to reduce the numbers of *Staph. aureus* in the ward environment are discussed.

We thank the surgeons and physicians who gave permission to publish details of their cases; Dr. A. H. T. Robb-Smith for the post-mortem and histological reports; Dr. R. E. O. Williams, of the Central Public Health Laboratory, Colindale, for the phage-typing report; Professor A. D. Gardner for his helpful criticism; and Miss M. C. McLarty for drawing the Chart.

APPENDIX: METHOD OF BACTERIOLOGICAL EXAMINATION OF THE FAECES AND GASTRIC ASPIRATES

The faeces and aspirates were plated on to blood agar, one plate for aerobic and another for anaerobic incubation. They were also plated on to nutrient agar containing an added 7% of sodium chloride and inoculated into Robertson's cooked-meat medium containing an added 10% of sodium chloride. The latter was plated out after 24 hours' incubation at 37° C. on to blood agar (aerobic) and salt agar. Suspicious colonies after 24 and 48 hours' incubation were tested by the coagulase test and their sensitivity to antibiotics was determined.

EXPERIENCE OF THE BURNS UNIT A REVIEW OF 520 CASES

BY

A. J. EVANS, F.R.C.S.

Senior Registrar, Plastic and Jaw Unit, Basingstoke

Colebrook (1950) advocated the establishment of special burns units where difficult and often long-term cases could be treated by trained teams and full use made of special facilities and equipment. In 1952 the Ministry of Health recommended the setting up of special centres in all regions. Burns have been treated at the Basingstoke Plastic Unit since 1940, but not until 1950 was it decided to form a burns unit within the hospital where these cases could be grouped together for the necessary specialized attention. The unit consists of 18 beds, divided into one six-bed ward, one four-bed ward, a five-bed nursery, and three single rooms. A major dressing-room includes a saline-bath unit; a minor dressing-room is available for ambulant and less severe cases, and skin-grafting operations are performed in one of the major operating-theatres normally set aside for that purpose.

Up to the end of 1955, 520 cases had been admitted to the unit, the admission rate gradually increasing up to the present level of 120–130 cases annually.

In Table I the cases are classified according to age groups, and also according to the percentage area of body surface burnt.

The majority of cases are referred direct from neighbouring practitioners or transferred within a few hours

TABLE I

from hospitals in the eastern area of the S.W. Metropolitan Region. Some of the latter may be held in the referring hospitals for the two to three days of the shock period, advice on early treatment often being given by telephone or the case being visited by one of the staff of this unit.

Those admitted within 72 hours are classified as "fresh cases" and constitute two-thirds of all admissions. The remainder are referred after a longer period, possibly in many cases because of initial failure to recognize the severity of the injury. Commonly the presence of full-thickness skin destruction is not appreciated, and the case is transferred only after a delay of two to three weeks, when it is increasingly obvious that spontaneous healing is not going to occur. In this group unsuitable dressings or abortive attempts at skin grafting may have been carried out, and the importance of a high-protein high-calorie diet has not always been appreciated. It is here that one may still occasionally see the picture of the "chronic burn" with offensive dressings, anorexia and weight loss, low morale, and continued dependence on analgesics.

In Table II the cases are divided into these two groups. The average in-patient stay of 34.5 days for the fresh cases compares favourably with the national average of

TABLE II

Fresh Cases (admitted within 72 hours)	Delayed Cases (average delay, 17.8 days)
Total No. 348	Total No. 172
Fatal cases 30	Fatal cases 16
Surviving cases 318	Surviving cases 156
Average total in-patient stay, 34.5 days	Average total in-patient stay, 65.5 days

50 days (Colebrook, 1950). It will be seen that in the delayed cases the average (total) in-patient stay is 65.5 days, an increase of 31 days. The cost to the N.H.S. of this prolonged hospitalization can only be guessed at, but it provides strong support to the Ministry's recommendation for the establishment of these units. It will be appreciated also that delayed healing increases the degree of harmful scarring and the production of severe deformities which may require prolonged reconstructive treatment by the plastic surgeon.

The general principles of treatment have become well established in the post-war years, and, broadly speaking, differ from unit to unit mainly in matters of detail. As so much has been written on this subject recently, the following brief account deals only with salient points, and much technical detail has been omitted.

Treatment of Shock

The rapid and severe depletion of blood volume consequent on fluid loss from damaged capillaries is made good by controlled intravenous fluid replacement. This is necessary in all burns greater than 18% of body surface burnt in the adult, and 12% in the child, and the intravenous drip must be maintained for a period of 48 hours from the time of the burn. Fluid balance is carefully recorded and an indwelling catheter is employed if there is any difficulty in assessing renal output.

There is an increasing tendency to rely on a formula for dosage control and these formulae are tending to become simpler. The following schemes of dosage are in use at this unit:

Fluid Replacement Formula in Adults

120 ml. dextran for 1% body surface area burned. This gives total quantity of intravenous fluid in 48 hours, and is divided as follows:

one-half in first 8 hours after burn
one-quarter in next 16 hours
one-quarter in final 24 hours
(N.B.—Ceiling figure—6 litres)

Deep burns: Up to one-third of total quantity given as whole blood. Metabolic requirements: Given as additional oral fluids 50 ml./kg. daily (in a 10-stone (63.5-kg.) adult, approximately 3 litres daily).

Fluid Replacement Formula in Children*

A. Burns less than 30% of body surface area

Age	Months				Years										
	<3	3-6	6-9	9-12	1-2	2-3	3-4	4-5	5-6	6-7	7-8	8-9	9-10	10-11	11
Dextran†	15	21	24	27	30	42	48	54	63	69	81	87	93	102	111

The above figure multiplied by the % area of the burn gives the total quantity of intravenous fluid in 48 hours, and is divided into three equal portions:
one-third in first 8 hours after burn
one-third in next 16 hours
one-third in final 24 hours

B. Burns greater than 30% of body surface area

Calculate 10% of body weight. This gives total quantity of intravenous fluid in 48 hours, and is divided as follows:

one-half in first 8 hours after burn
one-quarter in next 16 hours
one-quarter in final 24 hours

Deep burns: Up to one-quarter of total quantity given as whole blood. Metabolic requirements: Given as additional oral fluids daily.

<2 years 160 ml./kg. 5- years 80 ml./kg.
2- " 100 " 8-11 " 50 "

* Developed from a chart published by Wallace (1951).
† In millilitres for each 1%.

It will be noticed that no extra electrolytes are provided for, the emphasis being on restoration of the circulating blood volume by dextran, with inclusion of whole blood if there is much destruction of deep tissue. Plasma has been completely replaced by dextran and has not been used in this unit for six years.

It is well at this point to underline the danger of overheating these patients when treated in first-aid or casualty department, and certainly the electric "shock cradle" should never be used. Surface heating accelerates the circulation through damaged capillaries and thus intensifies the depletion of blood volume.

Local Treatment

Once the shock state is under control attention is paid to the burned areas, which are treated by exposure, and in this unit it is regarded as the method of choice in all fresh cases. It gives the greatest opportunity for damaged tissues to heal, and maintains the deeper lesions in that state of dry necrosis which makes surgery so much more favourable. Some difficulty has been experienced in the past with circumferential burns of the trunk, but considerable improvement has been achieved by nursing on the special frame shown in Fig. 2. This is strung with rug canvas (4-in. (6-mm.) mesh), and the patient lies on sections of "polythene" sponge which are directly in contact with the burns. This allows maximum evaporation from the surface in contact, and there is practically no adhesion. The polythene sponge is changed daily and is re-sterilized. A cradle is placed over the patient to prevent draughts, and the air under the frame is warmed with hot-water bottles or, better still, a fan heater which circulates slightly warmed dry air.

Involved limbs are, of course, suspended to reduce oedema, and the necessity of relieving incisions must be borne in mind where there are deep circumferential burns of the extremities.

In superficial burns the coagulum usually comes away in 12-16 days, when healing is found to be complete. The deeper burns will require excision and skin-graft replacement.

There is no doubt in this unit that the introduction of exposure has led to a definite lowering of infection, less pain and discomfort, and a marked improvement in the general condition of the extensively burned patient.

Surgical Excision and Skin Grafting

The procedure usual with most closed-dressing techniques of awaiting separation of moist sloughs and then grafting the resulting granulation tissues is employed here only in those late infected cases in which dry treatment is no longer practicable on admission. It is felt that in all fresh cases the areas of full-thickness skin destruction should be excised at the optimum time for the particular case (often the 14th-16th day) and maximum skin cover achieved at the same operation.

This extensive but necessary operation on a patient, whose general condition has been maintained only with considerable difficulty, is not undertaken lightly. Although the procedure has been made shorter and safer by technical advances such as the use of electric or pneumatic dermatomes, more rapid excisional techniques, etc., the greatest emphasis must always be placed on theatre team-work. Excision and grafting of a major burn should not be attempted unless a team of at least two surgeons and two sisters is available, and even with an experienced team it is often advisable to rehearse the various stages beforehand. It will be appreciated that most burns of 30% and upwards will require application of skin grafts on more than one occasion, although these secondary operations are comparatively minor. Full skin cover may not be achieved at the first operation, and areas of patchy graft failure are not uncommon.

Homografting is sometimes resorted to as a means of increasing the area of skin coverage possible in a patient whose own donor sites are limited, usually a child with extensive deep burns. The donated skin is preferably applied in the form of strips alternating with the autografts.

General Treatment

A high-protein high-calorie diet has long been regarded as essential for these patients, and this has recently been emphasized by the nutritional studies carried out in Wallace's unit in Edinburgh (Sutherland, 1953). The pronounced stress response of the burned patient in the early stages leads to a rapid and extreme loss of nitrogen in the urine, and this may be accentuated by the continuing loss of protein from the extensive areas of skin destruction. If this negative nitrogen-balance is not countered rapidly and efficiently, weight loss is soon apparent, the general condition deteriorates, and healing is considerably retarded. It is not possible to achieve the necessary levels of intake by ordinary diet, and reliance must be placed on supplementary feeds.

The recent introduction of "complan" has greatly simplified this problem and has almost completely removed the difficulty of meeting protein and calorie requirements. One pound (450 g.) of complan contains 140 g. of protein and provides 2,000 calories, and this daily quantity is easily managed by even the most difficult of patients. As this is supplementary to solid diet, and in addition may be given in milk, it is easy to maintain daily levels of 3 g. of protein per kg. of body weight and the equivalent number of calories. Even higher levels have been achieved where necessary and without having to resort to tube-feeding.

In addition haemoglobin levels must be watched, and repeated blood transfusions may be called for to combat the anaemia to which these patients are prone. Physiotherapy is employed to maintain joint movements, and occupational therapy may assist in this and also help to maintain morale.

Complete cessation of healing is fortunately a rare but extremely difficult complication, and appears to be predisposed to by inadequate early treatment.

A 20-year-old man was admitted from the Middle East some six weeks after he had sustained a 60% burn, most of which was full-thickness skin loss. Nine months later healing was still

far from complete in spite of repeated grafting operations and intensive supportive therapy. Investigation showed that his urinary excretion of 17-ketosteroids was down to 1.5 mg. daily (normal, 9-24 mg.), and a course of systemic cortisone, 100 mg. daily, together with methyltestosterone, 10 mg. daily, was started. Within three weeks more healing occurred than in the previous four months, and previously grafted skin became obviously more stable.

Experiments are also being made with local hydrocortisone applied to similar areas of slow healing, and it is obvious that further investigation is required in this type of case. In passing, it may be noted that this form of graft failure and instability is similar to that seen after unsuccessful homografting.

The Late, Infected Case

A somewhat different approach may be necessary for these patients. Frequent saline baths are combined with closed dressings, and there may be some delay before raw surfaces are suitable for skin grafting. Anaemia and protein deficiency may be pronounced and require intensive treatment as described above.

Illustrative Case

Only the following case has been chosen for detailed presentation, as it exemplifies most of the important features of present-day treatment of the more difficult type of case—the circumferential burn of the trunk.

A German maidservant aged 19 was admitted to the unit on February 12, 1956, after her nightdress had caught fire one and a half hours previously. She had sustained burns of both surfaces of the body, both thighs, the left arm, and the right hand. The posterior surface was the more severely involved, the burn extending almost completely from the neck down to just above the knees (Fig. 1). The extent of the burn was estimated at 45% of the body surface area, about two-thirds of this representing full-thickness skin destruction. Her weight shortly after admission was 67 kg.

FIG. 1.—Photograph of a girl aged 19 with burns of 45% of the body surface area, taken on admission.

FIG. 2.—Exposure treatment of extensive circumferential burn on special frame. The polythene sponge is not visible in the photograph.

The delay of the first heart sound (Q-1 interval) was measured from the beginning of the QRS complex of the electrocardiogram to the beginning of the maximal vibrations of the first heart sound. These vibrations are of high frequency and are usually quite clearly distinguished from the coarser and smaller vibrations of the diastolic or pre-systolic murmurs and the first component of the first heart sound. The delay of the opening snap (2-O.S. interval) was measured from the beginning of the second component of the second heart sound (Rappaport and Sprague, 1942) to the beginning of the opening snap. The length of the preceding cardiac cycle was measured from the R-R interval of the electrocardiogram. The intervals were measured in at least 20 cardiac cycles in each patient, and were plotted against the previous cycle length (Fig. 1). From this graph the Q-1

FIG. 1.—Graphs of the interval between the onset of the QRS complex of the electrocardiogram and the onset of the maximal vibrations of the first heart sound (Q-1), the interval between the second sound and the opening snap (2-O.S.), and the length of the preceding cardiac cycle. From such graphs drawn for each patient the values for the Q-1 and 2-O.S. are estimated for a cycle length of 0.8 second. Cycle lengths in tenths of a second, and Q-1 and 2-O.S. in hundredths of a second.

and 2-O.S. intervals were determined for a cycle length of 0.8 second. This cycle length was chosen because it was such that an extrapolation of the graph was rarely necessary. The figures appropriate to this cycle length were called the "corrected Q-1" and "corrected 2-O.S." The other measurements taken from the phonocardiogram were the heart rate, the diastolic filling period, and the duration of systole per minute. The diastolic filling period is the total duration in one minute of the intervals between the opening snap and the next first heart sound. The remainder of the minute was taken as the duration of systole per minute.

The size of the mitral orifice was assessed at operation by the surgeon. The area of the orifice was calculated from its length and breadth by multiplying these by pi over 4. The pressure gradient across the mitral valve has usually been obtained at operation by a Sanborn electromanometer by simultaneous needle puncture of the left atrium and the left ventricle. The mitral gradient has been taken as the mean left atrial pressure during ventricular diastole minus the mean left ventricular pressure in diastole. In a few cases only the mean left atrial pressure by a saline manometer was available, and in these cases the mitral gradient was taken as this figure minus 5 mm. of mercury.

The cardiac output was estimated by means of Gorlin's formula (Gorlin and Gorlin, 1951). This formula uses the pressure gradient across the mitral valve, the size of the mitral orifice, and the diastolic filling period. In the calculation of cardiac output the diastolic filling period was not measured at the time of operation but was obtained from the pre-operative phonocardiogram. This will introduce some error, but it will not be large, as the total variations of the diastolic filling period are small.

There is a definite relationship between the pre-operative "corrected Q-1 minus 2-O.S." and the pressure gradient across the mitral valve at operation. The relationship is shown in Fig. 2. When the "corrected Q-1 minus 2-O.S." lies between $+5\frac{1}{2}$ and $-1\frac{1}{2}$ the mitral pressure gradient is found to be high, while for figures between $-1\frac{1}{2}$ and $-4\frac{1}{2}$ the gradient is found to be low. The pressure gradient may therefore be predicted by the pre-operative phonocardiogram. Such a prediction appears valid despite the modifications of the pressure gradient that are caused by anaesthesia, thoracotomy, and pericardiectomy. These modifications are not well understood, but their presence is indicated by an increase in pulse rate and a reduction in pulse volume and systemic blood pressure. A reduction of cardiac output is probably present, and this would mean that the pressure gradient across the mitral valve would be lower than before operation. For this reason the cases in which the systemic blood pressure fell below 70 mm. Hg at the time the mitral pressure gradient was measured, rendering the estimation of the gradient misleading.

FIG. 2.—Graph showing the relationship between the "corrected Q-1 minus 2-O.S." and the pressure gradient across the mitral valve (in mm. Hg). The crosses denote patients with sinus rhythm and the dots patients with atrial fibrillation. Those cases enclosed in a ring had a systemic blood pressure of below 70 mm. Hg at the time the mitral pressure gradient was measured, rendering the estimation of the gradient misleading.

When the corrected Q-1 and the corrected 2-O.S. are considered separately they do not give as accurate a prediction of the mitral pressure gradient as when they are combined. This could be due to the fact that the combination reduces the error of measurement to a half. Fig. 3 suggests that the corrected Q-1 and the corrected 2-O.S. are too poorly related to each other for this explanation to be satisfactory.

Since the stroke volume in mitral stenosis is reduced (Gorlin *et al.*, 1951) it is possible that the abnormality of the heart sounds might reflect the altered form of the left ven-

FIG. 3.—Graph showing the corrected Q-1 and corrected 2-O.S. Crosses=sinus rhythm. Dots=atrial fibrillation.

Results

tricular pressure curve. Studies of the left ventricular pressure tracings show that after a brief period of ventricular filling the onset of pressure rise is not delayed but the rise is slower than it is after a long period of filling (Fig. 4). The fall of ventricular pressure is slower and earlier after a short period of filling. Such curves might explain the variations of the Q-1 interval but would not explain the variation of the 2-O.S. interval.

FIG. 4.—Left ventricular pressure curves after long and short diastolic intervals superimposed for contrast. With synchronous onset of QRS the first sounds are separated by 0.04 second, the second sounds by 0.03 second, and the opening snaps by 0.06 second.

the exposed heart at operation together with synchronous pressure tracings from the left atrium and the left ventricle. It is difficult to obtain satisfactory sealing of the microphone bell to the surface of the exposed heart without causing ventricular premature beats which confuse the investigation. Such tracings as have been obtained show that the delay of the first heart sound is due to a number of factors. The raised atrial pressure delays the time of crossover of atrial and ventricular pressures; the slow rise of ventricular pressure after a brief period of ventricular filling increases the delay; and, finally, the delay is further increased by an interval between the crossover of pressures and the first heart sound. The last factor is probably due to the difficulty of closure of the deformed mitral valve cusps when there is a small volume of blood in the left ventricle. This is supported by the observations of Smith *et al.* (1950), who

FIG. 5.—Graph showing the "corrected Q-1 minus 2-O.S." and the cardiac output estimated from the mitral orifice size, the mitral pressure gradient, and the diastolic filling period (using Gorlin's formula). Crosses=sinus rhythm. Dots=atrial fibrillation. Cardiac output in litres a minute.

showed that in the case of the normal mitral valve it is necessary for blood to flow between the cusps and the ventricular wall before closure of the valves is possible.

The 2-O.S. interval is not prolonged by the reduced rate of fall of the ventricular pressure in the isometric relaxation period following a short diastolic interval. Indeed, the 2-O.S. interval is actually shorter in these circumstances than after a longer diastolic interval. There are three reasons for this.

Firstly, the reduced stroke volume of such a beat causes the second heart sound to occur at a lower ventricular pressure and consequently nearer to the opening snap, as has been pointed out by Bayer *et al.* (1956). Secondly, the raised left atrial pressure causes an earlier crossover of atrial and ventricular pressures. Finally, the higher pressure gradient between atrium and ventricle appears to reduce the delay between the crossover of atrial and ventricular pressures and the occurrence of the opening snap.

A further measurement made in this study has been the duration of systole per minute. Normally the duration of systole is measured from the onset of ventricular contraction to the beginning of the second heart sound. In mitral stenosis there is still a pressure gradient and probably a flow of blood between the left atrium and the left ventricle after the onset of ventricular systole. In addition to this the period of isometric relaxation is reduced so that ventricular filling starts earlier than is normal. In view of these features the duration of systole was measured from the beginning of the first heart sound to the beginning of the opening snap. The "duration of systole per minute" was then calculated by finding the number of seconds in each minute occupied by systole. The heart rate was also measured, and the two were recorded on a graph. Fig. 6 shows the findings in the present series, and indicates that there is no difference between the patients with atrial fibrillation and those with normal rhythm. Fig. 7 shows the same patients separated into those with low and those with high mitral pressure

FIG. 6.—Graph showing the heart rate and duration of systole per minute. The latter is expressed in seconds, being the number of seconds in each minute that the mitral valve is closed (first heart sound to opening snap). Crosses=sinus rhythm. Dots=atrial fibrillation.

FIG. 7.—Graph showing the heart rate and duration of systole per minute as in Fig. 6. Open circles=cases with low mitral pressure gradient. Small dots=cases with high mitral pressure gradient. The line should separate the cases with a low gradient from those with a high gradient, and might do so more accurately if the duration of systole were measured at the time of measuring the mitral gradient.

gradients. When the duration of systole is long for a given heart rate the pressure gradient across the mitral valve is usually small.

No mention has so far been made of the patients who had mild degrees of mitral regurgitation, aortic valve disease, or hypertension. In none of this series were any of these additional abnormalities considered to be significant from the clinical point of view. The cases have nevertheless been carefully watched throughout the study, and they have shown no feature to distinguish them from the cases of uncomplicated mitral stenosis.

Discussion

The assessment of the severity of mitral stenosis involves the evaluation of a large number of symptoms and signs and special investigations. The precise obstruction at the mitral orifice is indicated by the pressure gradients across the mitral valve considered in conjunction with the cardiac output. The closest approach to this information short of direct puncture of the heart is provided by cardiac catheterization. This test requires an expert team, and even then is not always reliable. Although the present study only shows that the pressure gradient can be predicted by the phonocardiogram it is nevertheless of great practical importance. It also demonstrates that the information hitherto obtainable only by cardiac catheterization may in future be obtained very much more simply.

The 2-O.S. interval has been considered by Bayer *et al.* (1956) to indicate the left atrial pressure. These workers have made no correction for cycle length, which is particularly necessary in the presence of atrial fibrillation. They have demonstrated the changes that occur on exertion, but these are changes that may also occur from increase in the heart rate. In the present study the 2-O.S. interval has not provided as good a correlation with the mean mitral pressure gradient in ventricular diastole as the combination of Q-1 and 2-O.S. One reason for this is that while the 2-O.S. interval may indicate the pressure gradient at the beginning of diastole it will not indicate the gradient at the end of diastole. It does not therefore give an indication of the mean pressure gradient in ventricular diastole. Another reason for subtracting the 2-O.S. from the Q-1 is the theory that the rigidity of the valve material may alter the timing of opening and closing. In the presence of rigid valve cusps a delay of the first heart sound after the crossover of atrial and ventricular pressures could be associated with a delay of the opening snap after the second crossover of pressures. This would explain the wide scatter of Q-1 and 2-O.S. in Fig. 3. When the one interval is subtracted from the other any such factor would be eliminated.

There is much to be learned about the form of atrial pressure curves. When the valve cusps are freely mobile and can be displaced far into the atrial cavity the pressure curve in mitral stenosis may suggest the presence of mitral regurgitation even when this is not present. In these circumstances the tall V wave starts to fall well before the crossover of atrial and ventricular pressures occurs. This pattern is abolished by valvotomy, and the crossover of pressures now occurs near the apex of the V wave. When the mitral valve is rigid there is less rise of left atrial pressure during ventricular systole. When the left atrial cavity is very large the size of the V wave is small even when considerable mitral regurgitation is present.

The pressure gradient across the mitral valve is not constant throughout ventricular diastole but usually increases rapidly to a maximal gradient and then falls at first with moderate speed and then more slowly. When there is sinus rhythm there is usually an increase in gradient during atrial systole. The variations of pressure gradient are indicated by the variations in intensity of the diastolic murmur. The murmur does not, however, indicate the degree of pressure gradient. This information may be provided by the timing of the first heart sound and the opening snap.

Experiments have shown that in the normal subject there is an increase in the duration of mechanical systole if the

previous cycle length is long, but that a greater increase occurs if the diastolic volume of the left ventricle is increased (Hafkesbring and Ashman, 1928). Other workers have found that the duration of systole is normally dependent not on the cycle length but on the initial ventricular pressure and stroke volume (Wiggers, 1921; Remington *et al.*, 1948). When the duration of systole is reduced by increasing the arterial resistance there is a lengthening of isometric contraction. The changes in the duration of systole in mitral stenosis have received little attention since Lewis (1913) stated that it was practically the same as in normal subjects. The present study shows that the duration of systole is short and the period of isometric contraction is confused by the fact that there is a considerable interval between the onset of systole and the closure of the mitral valve. The period of isometric relaxation is shortened. Other workers have found the stroke volume low (Meakins *et al.*, 1923; Gorlin *et al.*, 1951) and this would suggest a shortening of the duration of systole. Although the degree of shortening of systole has not hitherto been used as a measure of the severity of mitral stenosis the present study shows that it may be possible in future to assess the severity of mitral stenosis by this measurement alone.

Summary

A pre-operative phonocardiogram is compared with the operative findings in 100 patients undergoing mitral valvotomy.

The mean pressure gradient across the mitral valve in ventricular diastole may be predicted from a measurement of the time relationships between the electrocardiogram and the heart sounds.

The delay between the QRS and the first heart sound and the interval between the second heart sound and the opening snap are estimated for a cycle length of 0.8 second. The intervals are called "corrected Q-1" and "corrected 2-O.S."

The corrected Q-1 is not related to the corrected 2-O.S., but the difference between the two (corrected Q-1 minus 2-O.S.) enables a prediction of the mean mitral pressure gradient to be made.

A simpler but less accurate prediction can be made from the duration of systole per minute.

I am indebted to Mr. O. S. Tubbs and Mr. I. M. Hill for their assistance, and for permission to make this study on their patients. I am also indebted to Miss L. Farrar for her technical assistance.

The Deaf Children's Society has started a quarterly magazine called *Talk*. Its aim is to increase knowledge and understanding about deaf children, both among those working in this field and among the public generally. The second issue contains articles by an educational psychologist and an otologist, descriptions of the school for deaf children at Penang and of the B.B.C. programmes for deaf children, and the story of a deaf girl who has made a successful career for herself as a fashion model. *Talk* is distributed free to those interested, and copies may be obtained from the Deaf Children's Society, 1, Macklin Street, London, W.C.2.

SERUM TRANSAMINASE DETERMINATIONS AS A DIAGNOSTIC AID IN MYOCARDIAL INFARCTION

BY

RALPH SHABETAL,* M.R.C.P.Ed.

Resident in Medicine, the Jewish Hospital, Cincinnati, Ohio, U.S.A.

ARNOLD IGLAUER, M.D., F.A.C.P.

Assistant Professor of Medicine, University of Cincinnati; Attending Physician, Cincinnati General Hospital; Attending Physician, the Jewish Hospital, Cincinnati, Ohio, U.S.A.

AND

DAPHNE M. ANDERSON, A.S.C.T.

Research Assistant in Cardiovascular Diseases, Cardiac Laboratory, Cincinnati General Hospital, Department of Internal Medicine, University of Cincinnati, Ohio, U.S.A.

In 1955 La Due and Wróblewski observed that the serum level of glutamic oxalacetic transaminase (transaminase) activity rises after acute myocardial infarction. Thus to the well-established criteria of clinical history and examination, together with the changes in the electrocardiogram, blood sedimentation rate, white-cell count, temperature chart, and urobilinogen excretion, a new biochemical test has been added which helps to determine whether or not recent myocardial infarction has occurred. Since that time several other reports describing increased serum transaminase activity following myocardial infarction have been published (Chinsky *et al.*, 1956; Kattus *et al.*, 1956; Merrill *et al.*, 1956).

Transaminase is present in many mammalian tissues and was found by Cohen and Hekhuis (1941) to be particularly abundant in cardiac and skeletal muscle. Brain, liver, and kidney follow muscle in decreasing order in transaminase content (La Due *et al.*, 1954). These authors define transamination as the enzymatic catalysed reversible transfer of the alpha-amino-nitrogen of an amino-acid to the alpha-keto-acid, with the synthesis of a second amino-acid and a second alpha-keto-acid.

The transaminase reaction—which may be written thus—

is coupled *in vitro* to a second reaction, the reduction of the oxalacetate (produced in the transamination reaction) to malate by reduced diphosphopyridine nucleotide (D.P.N.H.). The light absorption peak of D.P.N.H. at 340 mμ is used to measure the transamination reaction spectrophotometrically by observing the decrease in light absorption at that wavelength as D.P.N.H. is oxidized. The Beckman D.U. model spectrophotometer is employed. In this study the details of the method described by Karmen *et al.* (1955)

*Now Fellow in Cardiology, University of Cincinnati and the General Hospital, Cincinnati, Ohio.

have been followed. Transaminase activity is expressed as units per ml. of serum per minute. One unit equals a decrease in optical density of 0.001.

Nydick *et al.* (1955) produced experimental myocardial infarctions in dogs. They demonstrated that the enzyme activity of infarcted muscle is reduced to 2–10% of that of normal cardiac tissue, and they conclude that serum transaminase activity increases significantly following myocardial infarction because transaminase is released into the blood stream as a result of an increase in the permeability of the injured heart-muscle cells. They also showed that ischaemia of 45 minutes' duration failed significantly to influence the transaminase activity. It follows that increased activity may be predicted only in the presence of tissue destruction and not where ischaemia has been insufficient to cause necrosis. There have also been reports on transaminase levels in liver disorders and other conditions (Chinsky *et al.*, 1956; Wróblewski and La Due, 1956).

Present Investigation

The present study has been limited to the application of the test to patients with coronary sclerosis. Twenty patients were studied in order to determine the normal range of serum transaminase activity in our laboratory. Six of these attended the long-term anticoagulant clinic, and none of them was suspected of a recent thrombo-embolic incident. They all had serum transaminase values within the normal range of previous workers—that is, 10–40 units.

A group of five random post-operative patients was also studied. Each had undergone operation within the 24 hours preceding transaminase determination. All except one showed results within the normal range. This patient had had cholecystectomy for obstruction of the common bile duct and showed evidence of jaundice and impaired liver function. In her the level was raised to 64 units.

A further random group of nine were medical in-patients without evidence of recent myocardial infarction. The results in all but one were within the normal range. The one exception was an elderly man admitted with haematemesis. His electrocardiogram was abnormal, and although not diagnostic did not exclude myocardial infarction. He underwent partial gastrectomy and died a few days later. Post-mortem examination revealed that there was a small recent myocardial infarction. The pathologist reported that its age was consistent with the occlusion having occurred shortly before the specimen for transaminase determination was drawn.

Normal values were thus obtained in 18 control patients, including four who had had operations within the previous 24 hours. In two patients abnormal values were obtained, but one of these had liver disease and the other was eventually shown to have suffered acute myocardial infarction.

Determinations were made on an additional group of 39 patients who were suspected of coronary artery disease. In 13 of the 39 the clinical and electrocardiographic findings were typical of acute myocardial infarction. Of this group all but one had increased serum transaminase activity (Table I). The exception was a patient whose only sample was drawn two hours after the onset of pain, and who died before further samples were obtained. Necropsy revealed a massive posterior myocardial infarction.

In 4 of the 39 cases the electrocardiograms made upon admission to the hospital were not helpful in diagnosing or excluding the presence of acute myocardial infarction. In two of these the clinical findings also were atypical. In all patients of this group a final diagnosis of acute myocardial infarction was eventually made after several days by a critical survey of the clinical and electrocardiographic course. The results in this group are shown in Table II, from which it is seen that positive transaminase levels were found in all.

39	—	—	60	22	33

In Case 9 serial electrocardiograms over a period of a month never showed a pattern diagnostic of myocardial infarction, but in this patient the clinical history and subsequent course were in every way typical.

In Case 2 the patient was a 76-year-old woman with chronic lung disease who was admitted with acute pulmonary oedema and whose electrocardiogram on admission showed complete right bundle-branch block. There were marked ST-T shifts, but it was not possible to tell whether these were primary and due to developing infarction or whether they were merely secondary to the large QRS complexes. Inspection of serial records made over a period of a week revealed changes in the shape and deflection of the ST-T segments and allowed of a retrospective diagnosis of myocardial infarction.

In Case 13 the patient had been suffering from prolonged anginal attacks, and the onset of infarction was impossible to date. It was not until several days after admission that a high postero-lateral infarction pattern was demonstrated on her electrocardiogram.

Case 39 was clinically in every way typical, but T-wave inversions were the only electrocardiographic abnormalities demonstrable in serial records.

Twelve patients on admission to hospital were suspected on clinical and electrocardiographic grounds of having sus-

TABLE III.—Serial Serum Transaminase Activities in Patients Initially Suspected of Myocardial Infarction

tained acute myocardial infarction. Follow-up did not substantiate the diagnosis in any patient in this group. The negative results of serum transaminase determinations, together with the diagnosis upon discharge, are shown in Table III. The results of transaminase determinations were not taken into consideration by the physicians making the final diagnoses.

In Case 4 a 63-year-old man had complained for some months of pain in the chest and was admitted complaining of severe xiphisternal and epigastric pain. He had had previous electrocardiograms showing complete right bundle-branch block. The electrocardiogram made on admission was similar, except that there was depression of ST-T in lead aVF. A provisional diagnosis of posterior myocardial infarction was made, and it was not until a week after the onset that a large palpable mass in the right upper abdominal quadrant betrayed the diagnosis of hydrops of the gall-bladder.

In Case 18 the patient was a 35-year-old man who one year previously had sustained a steering-wheel accident, with injury to his sternum and with the development of an acute antero-septal myocardial infarction pattern in an electrocardiogram recorded immediately after the accident. He was admitted to hospital complaining of severe precordial pain of one hour's duration, and his electrocardiogram showed ST-T elevations in leads V2, V3, and V4, and Q waves in leads V5 and V6. No change was observed in serial records made over a three-weeks period.

In Case 32 the patient was a 39-year-old woman with profound coronary insufficiency and hypercholesterolaemia. An infarction pattern was not observed on any of several electrocardiograms. No sample of serum showed abnormally elevated transaminase activity, but the falling titre from the upper toward the lower limit of the normal range suggested the possibility that minimal infarction may in fact have occurred.

Single specimens from six patients with classical angina pectoris were drawn on a day in which there had been at least one attack. The results are shown in Table IV. All were negative.

TABLE IV.—Serum Transaminase Activity in Patients With Severe Angina Pectoris

Case No.	23	24	30	31	34	38
Result in units	16	9	14	20	16	14

Raised serum transaminase activity was demonstrated in a patient with intractable cardiac failure and a very large congested liver (44 units), in a patient with cirrhosis of the liver and ascites (72 units), and in a patient with acute pancreatitis (serum amylase 1,600 units, serum transaminase 238 units).

One patient, a 65-year-old man with arteriosclerotic heart disease, was admitted with shock, pulmonary oedema, and cold, pale, pulseless lower extremities. A diagnosis of saddle embolus of the aorta and possible complicating myocardial infarction was made, but the transaminase determination on a sample drawn 15 hours after the onset was negative (8 units). He died 48 hours after the onset, and permission for necropsy was refused. The negative result was unexpected, as Merrill *et al.* (1956) recorded high levels in two patients, one with a saddle embolus at the aortic bifurcation and the other with severe diabetic gangrene of the lower extremities.

Discussion

The discovery of a test useful in the recognition of myocardial infarction and the extraordinarily high incidence of coronary sclerosis among the patients admitted to a private hospital in a busy American city prompted us to test the value of the method on our own patients and in our own laboratory and to report our results.

No "false positives" or "false negatives" were recorded. The test found its greatest application where myocardial

infarction was suspected, but could not be proved, and in cases where infarction was not strongly suspected but had to be excluded.

In myocardial infarction the peak values of heightened activity occurred early, being found 12 to 24 hours after the clinical onset. Normal values were found in samples taken within the first few hours following the onset of pain. Values were again normal in samples withdrawn five to eight days following myocardial infarction. The Chart illustrates the curve obtained in two typical cases when the serum transaminase is plotted against time. These time relationships agree closely with those reported by La Due and Wróblewski (1955) and by Kattus *et al.* (1956).

Curves for two typical cases.

The test is most useful in myocardial infarction if a sample can be obtained within a few hours after the onset. Such a sample will show a normal transaminase. One and preferably more samples should be obtained over the ensuing 36 hours to demonstrate high levels and a final sample tested a week after infarction to demonstrate return to normal levels.

Liver and renal disease are unlikely to cause confusion, since they can be differentiated on clinical grounds. Furthermore, Wróblewski and La Due (1956) have shown that, as would be expected in these conditions, abnormal values persist not for a few days but over prolonged periods. Acute pancreatitis may be responsible for very high levels, as in our own case and in the cases of Chinsky *et al.* (1956). Unfortunately, therefore, the test is of no value in making the important differential diagnosis of this condition from myocardial infarction.

Our results suggest that a major surgical operation does not cause enough muscle damage to influence the serum transaminase activity. This observation may be helpful in cases where sudden collapse following operation has occurred and the transaminase test is employed to help determine whether or not the cause is acute myocardial infarction. We have not as yet studied a large post-operative group with serial determinations.

The persistently negative results recorded in patients with angina pectoris of greater or lesser severity, especially where interpretation of the electrocardiogram is difficult because of previous infarctions or left bundle-branch block or arrhythmia, is particularly helpful for the exclusion of acute myocardial infarction.

Case 1 was complicated by a pulmonary infarction on the fifth day following myocardial infarction. This event did not disturb the smooth descent of the transaminase to normal. A rise in serum transaminase was not to be anticipated, since Agress *et al.* (1956) produced massive infarction experimentally in dog lungs without a significant rise in their serum transaminase activity.

Summary

Serial serum transaminase activity determinations were made on 39 patients. Abnormally high levels were recorded in 16 out of 17 cases of acute myocardial infarction. One patient did not survive long enough for serial samples to be obtained. Four patients in this group were clinically atypical.

Normal values were obtained from 12 patients who were suspected of having acute myocardial infarction at the time of their admission to hospital but whose subsequent courses negated this diagnosis. Most of these patients were the subjects of coronary sclerosis.

In six cases of classical angina pectoris the serum transaminase activity was normal.

In one patient with acute pancreatitis the level was very high.

Serial serum transaminase determinations serve as a useful test in distinguishing cardiac pain caused by ischaemia alone from that in which necrosis of myocardial cells has occurred.

The time relationships found by previous workers are confirmed. Normal levels may be anticipated during the first 6 to 10 hours; thereafter, and up to the third day, abnormally high values are found. The peak level usually occurs between 12 and 24 hours after infarction. High levels sometimes persist into the fourth day. Serum transaminase activity returns to normal within a week from clinical onset of pain. The importance of obtaining early samples is evident.

Liver disorders and conditions other than coronary sclerosis were not studied.

Recent surgical operation did not interfere with transaminase levels.

We are grateful to all physicians referring cases for this study. We gladly acknowledge the courtesy of Dr. H. Schiro, Director of the Department of Internal Medicine, Jewish Hospital, Cincinnati, in allowing us to study patients under his care and to publish this report.

"We intend to use every legal means within our power to protect consumers from being victimized by this worthless treatment," states the U.S. Commissioner of Food and Drugs, Mr. G. P. LARRICK, in a statement on the Hoxsey cancer treatment. The statement was issued by the Federal Department of Health, Education, and Welfare. "For the second time," continues Mr. Larrick, "a Federal court has determined that the Hoxsey medicines for internal cancer are worthless. On November 15, 1956, after a six-week trial in the Federal court at Pittsburgh, the jury returned a verdict that these medicines, in pill form, were illegally offered as an effective treatment for cancer. On November 16 U.S. District Judge JOHN L. MILLER signed an order of condemnation stating that the pills were misbranded as charged by the Government and ordering their destruction."

TERMINATION OF PREGNANCY ON
PSYCHIATRIC GROUNDS

BY

JAMES ARKLE, B.M., M.R.C.P., D.P.M.

Consultant Psychiatrist, Reading Group of Hospitals

Whilst there is general agreement that certain physical illnesses may justify the termination of a pregnancy, there is a wide divergence of opinion on what may be held to justify the operation on so-called "psychiatric grounds." As the field of psychiatry has enlarged to embrace wide biological issues, so has there been a tendency for the psychiatrist to condone the operation of abortion for reasons which appear to deviate from both the ethic of medicine and the law of the land. That this has confused the general practitioner is indicated by the frequency with which psychiatrists are called into consultation in cases in which the therapeutic termination of pregnancy is the point at issue. It is true that in many consultations the practitioner is merely seeking a second opinion in order to support his own refusal to interfere, but in some cases there is genuine surprise at the information that social considerations have no place in the consultation or that mental symptoms of one kind or another are not necessarily a justification for emptying the uterus.

The consultant who refuses to recommend the operation will sometimes be suspected of allowing his religious scruples to override his medical judgment, but, in point of fact, the Christian opposition to therapeutic abortion is far less securely based than that of the physician whose sole interest is the preservation of life and health. The Christian opposition is based to some extent on a mistranslation of the abstract laws of the ancients, whilst the medical opposition is based wholly on a scientific appraisal of the actual results of pregnancies in the sick. A survey of this kind was carried out by A. L. Robinson in 1933, and nearly a hundred alienists answered his questionnaire. The majority opposed the induction of abortion in the treatment of mental disorder, but it is probable that a similar survey at the present time would reveal a larger proportion of psychiatrists as being in favour of the operation, the treatment of mental disorder having become adulterated with considerations which have little bearing on the actual course of a particular illness in a particular patient.

My own experience in a small series of cases supports the view that therapeutic abortion is hardly ever justified on psychiatric grounds. The subject is, however, so surrounded with personal prejudices, often founded on a misinterpretation of history or the law, that it is worth while outlining the historical background and the present legal position.

Historical Background

There would appear to be a primordial revulsion from the destruction of the embryo, and most of the early religious and legal authorities condemned it; thus we have the Vedidad of Zoroaster and the Manu of the Hindus expressing unqualified disapproval over a thousand years before the birth of Christ. Centuries later we find the Greeks divided in their views. Whilst Hippocrates was expounding the Medical Ethic, "I will not give to a woman a pessary to produce abortion," Aristotle was teaching, "If in marriage couples have children in excess, then shall abortion be procured before life and sensation have commenced; what may or may not be lawfully done in matters of this kind depends on this question of life and sensation." The Romans were

even more liberal in their views. Intentional abortion was not only legal but fashionable. By the Lex Aquilia, the inducing of abortion was treated only as a personal attack upon the mother, and if she consented to the assault there was no offence.

The ancient Hebrews, too, allowed the operation if the husband agreed: thus in the Hebrew version of Exodus (Ch. XXI, v. 22) we find, "If men strive together and hurt a pregnant woman so that she hath a miscarriage and yet no harm to her result, he shall be fined, as the woman's husband shall determine, and he shall pay for the miscarriage." It follows that if the woman was unharmed and the husband agreed to the operation, there was no punishment. The passage continues, however, "But if any harm follow then shalt thou give life for life, eye for eye," etc. This comparatively liberal point of view was mistranslated in the Septuagint, and the Christians were subsequently to base their own doctrine on this inaccurate Greek version of Hebrew law. Instead of laying down that punishment should depend on whether the mother is harmed or unharmed, as in the Hebrew version, this translation maintains that it depends on whether the foetus is formed or unformed (Kent, 1907). This led the Christians to formulate much more uncompromising laws than was intended by those who framed the original passage in Exodus. It also had the disadvantage of focusing too much attention upon the embryo as a separate unit rather than upon the pregnant woman as a whole.

Thus Tertullian, following the teaching of Aristotle, devoted all his ingenuity to deducing when the embryo became "formed," that is to say, when it acquired a soul. As the ritual purification after delivery was laid down as 40 days for a male child and as 80 days for a female child, he concluded that a male embryo acquired its soul 40 days after conception and a female after 80 days. This astonishing piece of logic was translated into Latin by Jerome, extolled by St. Augustine, and perpetuated in the 1st Section of the Corpus Juris Canonici (Cap. 9). Legislation in the various European countries followed the teaching of the Church: thus in Germany the Bamberg Enactment of 1507 regarded abortion as murder if the foetus were animate (that is to say, more than 40 days old), and in England the Ellenborough Act of 1803 adhered to the difference between the "quick" and the "not quick." The first revolt against this artificial distinction had come from the medical profession in protestant Germany. Thus at the beginning of the eighteenth century August Leyser, Professor at Wittenberg, had stressed that there was no special moment of animation, and a century later the lawyer Philip van der Broecke was to claim that the foetus was merely part of the mother's body and, as such, had no special privileges.

Present Legal Position in England

Against this background various Statutes on the subject have been drawn up and various important judgments given. In this country, 1861 marked the introduction of the Offences Against the Person Act, in which Section 58 gives almost unequivocal protection to the embryo. In 1929 the Infant Life (Preservation) Act was introduced to legalize destructive operations on the foetus of 28 weeks or more, such an operation being allowed unless it should be shown that the act causing the death of the child was not done in good faith for the purpose only of preserving the life of the mother. It will be noted that there is still undue emphasis on the age of the foetus, the embryo of less than 28 weeks being protected by the older and more conservative Statute; even this, however, implying by the nature of its wording that there are lawful indications for "procuring a miscarriage," although these are not defined.

The task of interpreting these Statutes, and of supporting lawful indications as they arise, has fallen to the courts. Mr. Justice Macnaghten, summing up in the case against Bourne in 1938, was able to digress from purely physical indications in order to give support to the view that termination is also

lawful in those cases where the mental health of the mother is seriously threatened. After indicating that the wording of the relevant Acts threw the onus of proof of bad faith upon prosecution, the learned judge concluded:

"Mr. Oliver wanted you to give what he called a wide and liberal meaning to the words 'for preserving the life of the mother.' I should prefer the word reasonable to the words wide and liberal. . . . Apparently there is a great difference of opinion, even in the medical profession itself. Some there may be, for all I know, who hold the view that the fact that a woman desires the operation to be performed is a sufficient justification for it. Well, that is not the law; the desire of a woman to be relieved of her pregnancy is no justification at all for performing the operation. On the other hand, there are people who, from what are said to be religious reasons, object to the operation being performed in any circumstances. That is not the law either. On the contrary, a person who holds such a view ought not to be an obstetrical surgeon for, if a case arose where the life of the woman could be saved by performing an operation and the doctor refused to perform it because of his religious opinions and the woman died, he would be in grave peril of being brought before this court on a charge of manslaughter by negligence. . . . If pregnancy is likely to make the woman a physical or mental wreck, the jury is entitled to take the view that a doctor, who in the circumstances and led by his belief operates, is operating for the purpose of preserving the life of the mother."

For the psychiatrist, the importance of this statement is that it makes it justifiable for him to recommend termination if he honestly believes that continuation of a pregnancy will make a woman a mental wreck. Lesser degrees of emotional upset are not enough, nor are social disturbances of any magnitude nor eugenic forebodings of any kind. More recent attempts to extend his scope have not succeeded; thus Lord Amulree's Bill, which was introduced to the House of Lords on January 26, 1954, was withdrawn, and a recommendation by the Magistrates' Association that abortion should be per-

mitted if there is a grave risk of the child being born mentally defective has not yet been given the authority of law (*British Medical Journal*, 1955).

Present Investigation

The cases here reviewed were assessed entirely in the light of Mr. Justice Macnaghten's observations, and, in point of fact, in none was there considered to be sufficient justification for termination. The patients were seen consecutively during a period of two years, but they have been classified in the Table in a different order from that in which they were seen.

Patients fell broadly into one of three classes. First, there were those who were known to have had a previous psychotic episode associated with a pregnancy; secondly, there were those who were known to have had treatment for serious mental illness not associated with pregnancy; finally—and this was by far the largest group—there were those who were referred, not on the basis of their previous history, but on account of the symptoms present when seen.

The diagnosis given is in each case that of the predominant condition when seen. The remarks which cover the course of the pregnancy have likewise been simplified to indicate only whether the behaviour of the patient was such as to require hospital care or such that could be tolerated at home: "domestic disturbance only" could be of severe degree, for it included one patient who jumped down a flight of stairs regularly until she sprained her ankle and had to abandon this method of drawing attention to her plight.

Similarly, the social summary illustrates only the extent of the mother's failure in the home a year after her confinement. In the highest category, and the one which can be regarded as normal, are those mothers who are able to look after a baby themselves with only slight neglect of other household duties; in the second category are those who can

Analysis of Cases

manage their home only if the child is cared for by someone else; in the third group are those who grossly neglect their home whether their child is there or not. The lowest category was to have included those who had deteriorated to such an extent that more or less permanent hospital care was required, but fortunately there were no such examples in this series.

The assessment of the changes in mental state which occurred as the result of each pregnancy presented great difficulties. The patients were reviewed one year after their confinement, but few had been assessed from a psychiatric standpoint prior to becoming pregnant, and their state in the early stages of pregnancy was not a fair guide. The comparison is intended to be with their mental state immediately before the pregnancy under review and is based largely on accounts given by relatives and family doctors, the gradings being the simplest possible—"improved," "no change," "worse," and "grossly deteriorated."

The inevitable conclusion to be drawn from these results is that in the vast majority of cases the decision not to intervene was the correct one as judged by the law in this country. Not a single one of these patients has become a mental wreck to the extent that mental hospital care is now required. In the one case which appeared to show deterioration the impression gained was that this deterioration was the natural progress of the disease and that the pregnancy had had little effect on it. In some cases, indeed, the mental state of the mother appeared to show improvement, and it seems likely that, to an unbalanced woman, the stimulus of a normal pregnancy is less deleterious than the sudden interruption by operation of the normal physiological changes taking place.

Discussion

It will be seen from the above results that, although the various confinements produced no serious ill effects from the purely medical standpoint, there were, nevertheless, unsatisfactory repercussions in the general social field. This aspect of the problem has received special attention in the legislation of certain other countries. Thus in Sweden, by Statutes dating from 1946, abortions are permitted to an extent unequalled by the laws of any other country. There the operation may be performed for any one of four reasons—medical, social-medical, humanitarian, or eugenic. The first, or medical, consideration permits abortion for the same reasons as it is permitted in this country—that is, to preserve the life or health of the mother if the pregnancy directly endangers her. The second, or social-medical, consideration allows the operation if the mental or physical health of the mother is likely to be severely impaired as the result of childbirth or even by the subsequent care of the child. The third, or humanitarian, consideration justifies abortion in cases where the mother has been raped or is under age. The fourth, or eugenic, consideration allows the operation if there is reason to believe that either of the parents of the child may be causing the hereditary transmission to the offspring of insanity, mental weakness, or any other serious disease.

The emergence of these laws in a country freer than most from interference by Church, if not by State, is bound to cause us to ask whether our own legislation takes too little account of social-medical, humanitarian, and eugenic considerations.

In the above series, in only about half of the cases could the social aspect of the situation be regarded as even moderately satisfactory; in several cases, indeed, the mother appeared to be permanently incapable of looking after the child. The humanitarian motive for terminating pregnancy in the case of a young schizophrenic (Case 5) was almost irresistible, and the possible eugenic justification for termination stood out in several cases, notably in the known psychotics and defectives.

Be that as it may, the lack of deterioration in the mental state of these patients as the result of their pregnancies does not give support to the recommendation of termination as a

therapeutic measure in the mentally disturbed. This absence, or otherwise, of mental deterioration can be the only criterion in this matter. If once other considerations are allowed to obtrude, then there is no end to the catalogue of the various degrees of social inconvenience or of genetic undesirability that may result from a pregnancy. The psychiatrist must not allow the sociologists and the geneticists to deceive him into exceeding his duty as a physician. The law of the land should be sufficient guide to those who cannot accept the Hippocratic tradition. Some further observations by Mr. Justice Macnaghten do, indeed, sum up the whole matter: "The killing of the unborn child was, by the Common Law of England, a grave crime. The protection which the Common Law afforded to human life extended to the unborn child in the womb of its mother. But, as in the case of homicide so also when an unborn child is killed, there may be justification for the act." For the medical practitioner the only justification is the protection of his patient from harm; and let it never be forgotten that the amputation of her child is the most harmful operation that the soul of woman can be asked to bear.

Summary

Attention is drawn to the frequency of requests by patients and practitioners for termination of pregnancy on psychiatric grounds.

The historical background and the present legal position are outlined, and the results of pregnancy in a series of cases referred for consultation on account of the mental state of the patients are summarized.

The conclusion is drawn that termination of pregnancy on account of the mental state of a patient is rarely justified by the law of this country, and the doubtful wisdom of extending the indications for abortion, as in certain foreign countries, is discussed.

I am indebted to my general-practitioner colleagues not only for much help in the assessment of these cases, but also for the example they set in managing the more histrionic patients with such forbearance and humour.

Dr. J. F. SKONE, M.O.H. of West Bromwich, Birmingham, gave some figures about coloured immigrants in his area at a recent sectional meeting of the Royal Society of Health. By 1955, he said, it was apparent that the number of coloured people in West Bromwich was beginning to increase rapidly. Last year a census had shown a total of 838 in the area, of whom 505 were West Indians. The remainder were Indians (248) and Pakistanis (85). As immigrants from the Commonwealth who are not aliens are not subject to a detailed medical examination on arrival in Britain, a local survey of their health and welfare problems was carried out. Since 1951 17 had been notified as suffering from tuberculosis, but, said Dr. Skone, there was nothing to suggest they had the disease on arrival in Britain. Of the 17 cases only one was in a West Indian. Coloured persons formed the majority of patients seen at the local V.D. clinics in 1955 and 1956. West Indians formed the majority of those with gonorrhoea, and an increasing number of cases of granuloma inguinale were being seen—a disease formerly only rarely encountered here. One Indian had been diagnosed as having non-infectious leprosy. He had returned to India.

CLINICAL FEATURES AND PATHOGENESIS OF MACROGLOBULINAEMIA

Serum protein abnormalities may be classified into "dysproteinemias"—quantitative alterations in normal serum components—and "paraproteinemias," in which serum globulins normally absent or present in only minimal concentration (myeloma globulins, cryoglobulins, and macroglobulins) are found in greatly increased amount. Macroglobulins are globulins of high molecular weight (over one million) whose presence is associated with a definite syndrome, "macroglobulinaemia," which requires ultracentrifugal analysis of the serum for conclusive diagnosis (Waldenström, 1944, 1948).

This paper describes three new cases of macroglobulinaemia and refers briefly to one (Case 4) previously reported (Mackay, 1956). The condition cannot be regarded as rare in Australia, for these four cases came under notice in Melbourne in a period of eight months. Patients are elderly, and males exceed females. The outstanding symptoms are lethargy and a bleeding tendency (epistaxis, oral bleeding, and easy bruising). There may be a history of vague ill-health for several years, with recurrent infections, often of the respiratory tract. Examination discloses slight painless enlargement of the liver, spleen, and lymph nodes in most cases, but bulky lymphoid hyperplasia seldom occurs (Mackay, 1956; Jahnke *et al.*, 1956).

Peripheral blood examination reveals some degree of anaemia, and usually pancytopenia. Despite the pronounced bleeding tendency, no consistent coagulation defect is observed (Jahnke *et al.*, 1956). A skeletal survey shows, at most, osteoporosis, but no focal translucencies. Many of the laboratory findings depend on the hyperglobulinaemia, which ranges from 4 to 8 g. per 100 ml.: these include rouleaux formation in blood smears, a high erythrocyte sedimentation rate, a positive formol-gel test, and a myeloma-like protein component on filter-paper electrophoresis of serum. The serum viscosity increases with a fall in temperature, often with the formation of a gel which redissolves on warming; this gel represents one type of cryoglobulin. The Sia test (a dense white precipitate on adding a drop of serum to distilled water) is a useful screening test, although false positives may occur, notably in multiple myeloma.

*Working with the aid of a grant from the National Health and Medical Research Council of Australia.

A suspected diagnosis is supported by the myelogram showing gross marrow invasion (40–80%) by so-called "lymphocytoid" cells (Waldenström, 1944), often indistinguishable from true lymphocytes. Many show cytoplasmic loss or irregularity ("protoplasmic shedding," "naked nuclei"), but this feature does not differentiate them from lymphocytes seen in the marrow in other conditions. Ultracentrifugal analysis of serum will demonstrate one or more components of high molecular weight, the major one having a sedimentation coefficient of 14–20 Svedberg (S.) units, depending on the protein concentration in the ultracentrifugal cell.

Methods

The erythrocyte sedimentation rate (E.S.R.) was read in a Westergren tube after one hour. The serum glucosamine was estimated by the Elson-Morgan (1933) method. The plasma of three patients was tested for a factor stimulating lymphocytosis in baby mice (Metcalf, 1956a). This factor is demonstrable only in chronic lymphatic leukaemia, lymphosarcoma, and myelofibrosis (Metcalf, 1956b). Ultracentrifuge analyses were carried out with a Phwyre air-turbine ultracentrifuge at 830 r.p.s. for 60 minutes, with serum dilutions of 1 in 8 in 0.2/M saline. Sedimentation coefficients are expressed in conventional Svedberg (S.) units.

A highly elevated serum glucosamine has been found only in macroglobulinaemia and, occasionally, in multiple myeloma and Hodgkin's disease; it thus appears to be a useful diagnostic test. In three of the following cases (Nos. 1, 2, and 4) a highly raised serum glucosamine was present.

Case 1

A woman aged 56 who was first seen in 1956 had noticed enlargement of the cervical lymph nodes five years previously. She experienced "fuzzy heads" and weakness for one year, frequent prolonged spontaneous nose-bleeds for three months, and extreme lethargy for one month.

Examination showed several walnut-sized lymph nodes in the neck, axillae, and groins, and enlarged lacrimal and salivary glands. The liver and spleen were just palpable. Defective hearing was associated with impaired vestibular function tests. There were many spider angiomas about the face and neck. Laboratory findings included pancytopenia, hyperglobulinaemia (7.2 g. per 100 ml.), and a normal bromsulphthalein retention test. E.S.R., 73 mm. per hour; serum glucosamine, 286 mg. per 100 ml. (normal range 70–124 mg.); myelogram, 81% lymphocytes. A skeletal survey showed no significant changes. An electrophoretically homogeneous gamma-globulin component was proved by ultracentrifugal analysis to be a 14.8-S. macroglobulin. A lymph-node biopsy was characteristic of lymphosarcoma. A mouse-lymphocyte-stimulating factor was not detected. The patient is being maintained in moderate comfort with frequent blood transfusions.

Comment.—The clinical findings and course are characteristic of macroglobulinaemia. Anaemia developed rapidly, although there was no evidence of haemolysis or gross blood loss. The suspicion of liver dysfunction aroused by the florid facial telangiectasia was not confirmed. Histological appearances were in keeping with a diagnosis of lymphosarcoma.

Case 2

A 55-year-old farmer consulted a physician in October, 1955, because his relatives were concerned about him. He had felt weak for about five years, had bruised easily for two years, and had lost one stone (6.4 kg.) in weight. He was moderately deaf. The cervical, axillary, and inguinal lymph nodes were enlarged, the liver was felt 2 in. (5 cm.) below the costal margin, and the spleen tip was palpable.

A lymph-node biopsy was diagnosed as "lymphosarcoma," and three courses of x-ray therapy were given. In June, 1956, he complained of weakness and severe nose-bleeds. The physical findings were unchanged. Blood examination showed pancytopenia and a monocytosis. Myelogram, 40% lymphocytes; E.S.R., 103 mm. per hour; serum glucosamine, highly elevated to 284 mg. per 100 ml. A skeletal survey was negative. A mouse-lymphocyte-stimulating factor was present in the plasma. Electrophoresis showed a "spike" component with beta-globulin mobility, which by ultracentrifuge proved to be a macroglobulin with a sedimentation coefficient of 14.2-S. units.

In September he developed personality changes and irritability. In hospital he became irrational and had delusions of persecution; a gross tremor of both hands was noted. An electroencephalogram showed a mildly abnormal record without specific diagnostic implications. Psychological testing suggested reduced intellectual activity and a type of thought disorder indicative of deterioration of "organic" origin.

Comment.—The clinical manifestations are again typical; the long preceding history of weakness is noteworthy. Of particular interest is the occurrence of neuropsychiatric disturbance with abnormal serum globulin—the Bing-Neel syndrome (Bing and Neel, 1936; Mandema, 1954). Later, Bichel, Bing, and Harboe (1950) reported the case of a patient with established macroglobulinaemia, who was shown at necropsy to have perivascular invasion of cerebral vessels by lymphocytes.

Case 3

A 50-year-old woman presented with tiredness of two years' duration. Five years previously hysterectomy had been performed for menorrhagia; the wound took three months to heal. She had noticed splenic enlargement for eighteen months. No x-ray therapy or chemotherapeutic agents were given.

Examination showed an enormously enlarged spleen, and a few small nodes in the left cervical region. Blood examination: pronounced rouleaux formation; anaemia; granulocytopenia; lymphocyte count of 5,670 per c.mm.; platelet count, 777,000 per c.mm. Bone marrow: 56% small lymphocytes, many appearing as "naked nuclei." Other significant findings included Bence Jones proteinuria, a positive Sia test, and a negative skeletal survey. Serum glucosamine was moderately elevated to 172 mg. per 100 ml. Electrophoresis and ultracentrifugal analysis of serum revealed a macroglobulin component in high concentration. Splenic aspiration biopsy was performed with a Franseen needle. Examination of smears showed that 91% of the nucleated cells were lymphocytes and naked lymphocytic nuclei, similar to the cells present in the bone marrow; tissue fragments showed diffuse lymphocytic infiltration without obliteration of the follicular pattern. The appearances were compatible with lymphosarcoma.

Comment.—Serum macroglobulins were detected in a woman with lassitude and splenomegaly who showed characteristic findings on bone-marrow smear and paper electrophoretic analysis of serum. Gross splenomegaly and the absence of a bleeding diathesis are unusual features. Splenic biopsy suggested the diagnosis of lymphosarcoma.

Case 4

A man aged 50 had an eight-months history of lethargy following an unresolved pneumonia, petechiae, bruising, and prolonged bleeding from superficial wounds. The liver, spleen, and lymph nodes were moderately enlarged. A pancytopenia was associated with an absolute lymphocytosis (16,000–50,000 lymphocytes per c.mm.), with some primitive cells and "smear" cells, suggesting chronic lymphatic leukaemia. Hyperglobulinaemia (5.6 g. per 100 ml.), a positive Sia test, and Bence Jones proteinuria were present. Serum glucosamine, 228 mg. per 100 ml. Myelogram, 80%

small lymphocytes and rouleaux formation. Ultracentrifugal analysis late in the illness revealed macroglobulinaemia. A mouse-lymphocyte-stimulating factor was present in the plasma. Triethylene melamine, cortisone, and finally splenectomy were only of temporary benefit. Histological examination of the spleen suggested the diagnosis of lymphosarcoma. A persistent haemorrhagic left pleural effusion followed an attack of pneumonia, and death occurred after an illness lasting 15 months. A necropsy was not performed.

Comment.—An illness simulating chronic lymphatic leukaemia progressed to a fatal termination within 15 months. Macroglobulins were demonstrated late in the illness, after treatment with cytotoxic drugs. The association of macroglobulinaemia with a leukaemic blood picture is unusual (Waldenström, 1952); however, the histological changes in the spleen were those of lymphosarcoma.

Discussion

The clinical features of macroglobulinaemia are fairly distinctive and largely depend on the presence in the blood of abnormal proteins. Although a low-grade non-specific increase in serum macroglobulin ("secondary macroglobulinaemia") occurs in various conditions (Mackay *et al.*, 1956; Jim and Steinkamp, 1956), a massive increase of pathological macroglobulin ("primary macroglobulinaemia") is almost invariably associated with diffuse involvement of the lymphocyte/plasma-cell system. However, the morphological basis of primary macroglobulinaemia remains poorly defined, and histological diagnoses accompanying published case reports serve to illustrate the current confusion in nomenclature of the "reticulosis" and "lymphoma" group of diseases. These mostly suggest a lymphocytic proliferative disorder, and include "atypical lymphatic hyperplasia" (Dalgaard, 1950), "lymphoid leucosis" (Layani *et al.*, 1955), "aleukaemic lymphadenosis" (Schaub, 1952), and "lymphosarcoma" (Abrams *et al.*, 1949), whereas occasional diagnoses such as "aleukaemic plasmacytosis" (Bianchi *et al.*, 1949) and "diffuse plasmacytosis" (McFarlane *et al.*, 1952) incriminate the plasma cell.

In a collected series of 25 cases of macroglobulinaemia (Mackay, 1956) the histological picture was that of lymphocytic hyperplasia in 12, lymphocyte and plasma-cell hyperplasia in 7, transitional-cell types in 4, and no abnormal cells were identified in 2. Plasma cells may rarely appear in the blood and bone marrow in the late stages of the disease (Waldenström, 1944; Bianchi *et al.*, 1949), and the histological appearances of the lymphoid tissues may change from a lymphocytic to a plasma-cell reaction during the course of the illness (Schaub, 1952; Jahnke *et al.*, 1956).

Mixed lymphocyte and plasma-cell proliferations may well be a result of the close relationship in the differentiation processes of lymphocytes, and plasma cells from a common precursor (Marshall, 1956). The occurrence of these morphological variants of a single cell system justifies an attempt to classify the disease on the basis of cell function (macroglobulin synthesis) rather than cell structure.

Mandema (1954) states that macroglobulinaemia is a variant of multiple myeloma despite differences in the cell morphology and the physicochemical properties of the globulins in the two diseases; however, most authors maintain that macroglobulinaemia is a single independent disease entity, possibly related to the lymphoreticular hyperplasias (Kanzow, 1954; Layani *et al.*, 1955; Jim and Steinkamp, 1956). Consideration of the clinical and pathological features of the present cases, and of others previously reviewed (Mackay, 1956), suggests that primary macroglobulinaemia may, in fact, be an epiphenomenon in the course of lymphosarcoma. Macroglobulinaemia resembles lymphosarcoma in its clinical features, in the occurrence of marrow invasion by lymphocytes, and in the presence of a mouse-lymphocyte-stimulating factor in the plasma. Moreover, the available histological material (lymph nodes and spleen) from these four patients was interpreted as a classical

lymphosarcoma. Finally, synthesis of macroglobulins by lymphosarcoma tissue *in vitro* has been described by Abrams *et al.* (1949).

Malignant lymphosarcoma tissue may acquire the functional capacity to synthesize "paraproteins" following the occurrence of a somatic mutation. Habich (1953) and Kanzow *et al.* (1955) have performed immunological experiments with human macroglobulins which supports this concept. They found, by precipitin testing, that the abnormal proteins from different cases of macroglobulinaemia differ antigenically (and therefore chemically) from each other. Moreover, a rabbit sensitized to a human macroglobulin developed anaphylactic shock when the same macroglobulin was reinjected, but not when challenged by a macroglobulin from a different patient (Di Guglielmo and Salvini, 1954). Immunological differences among macroglobulins must reflect genetic differences in the cells synthesizing these proteins; such genetic differences are best accounted for by postulating the occurrence of a somatic mutation in the malignant cell line (Mackay, 1956). This mutation may occur independently or result from the disturbing effects of x-rays or chemical agents on cell mitoses. Macroglobulins were detected after such therapy in two of our four cases, but may have been present before therapy was given. A similar suggestion of a mutation process has been invoked by Rosenthal *et al.* (1955) to account for the development of haemolytic antibiotics in lymphomas.

Thus macroglobulinaemia is considered to result from an independent or an induced mutation in a malignant lymphoma which is usually, if not always, a lymphocytic lymphosarcoma. This concept of macroglobulinaemia most adequately accounts for the observed features of the disease. Moreover, it provides evidence suggesting that the occurrence of somatic mutation does, in fact, play a general part in the evolution of cancer (Mackay, 1956).

Summary

Four cases have been described to illustrate the clinical features of the syndrome of primary macroglobulinaemia. The diagnosis was established by ultracentrifuge analysis in each case. The condition should be suspected in lympho-reticular hyperplasias simulating lymphosarcoma with evidence of an abnormal protein in the serum (rouleaux formation, elevated sedimentation rate, cryoglobulinaemia, and positive Sia test). Filter-paper electrophoresis of serum reveals a component indistinguishable from a myeloma protein; if the bone marrow shows a marked lymphocytic increase (40–80%), with scanty plasma cells, the diagnosis is almost certain.

The disease may be an individual entity, although there is a strong resemblance to lymphosarcoma. Histological and immunochemical evidence suggests that macroglobulin synthesis may be the result of a somatic mutation in malignant lymphocytic tissue, which may occur independently or be induced by x rays or cytotoxic drugs. This concept is in harmony with the general somatic mutation theory of cancer.

The concept of the origin of macroglobulinaemia in a somatic mutation was developed in discussions with Sir Macfarlane Burnet. We are indebted to Dr. Ian Wood for assistance in the preparation of this paper, and to Professor R. H. Lovell, Dr. Eric Clarke, Dr. Leslie Hurley, Dr. T. H. Hurley, and Dr. J. H. Bolton for kindly allowing us to study patients under their care. We are indebted to Miss Sara Weiden for glucosamine analyses.

CLINICAL TRIAL OF GLUTETHIMIDE IN LABOUR

BY

T. M. ABBAS, M.D., F.R.C.S.Ed., M.R.C.O.G.

Lecturer in Obstetrics and Gynaecology, University of Bristol

The new drug glutethimide (α -phenyl- α -ethylglutarimide; "doriden") has been described as a rapidly acting non-barbiturate hypnotic and an effective sedative producing minimal side-effects. These qualities, coupled with encouraging results obtained from a small pilot survey, suggested its possible value as a sedative in the management of the first stage of labour. Accordingly, a clinical programme was drawn up, and answers to the following four questions were sought for and ascertained from the collected data: (1) Is glutethimide an effective sedative early in the first stage of labour, and how does it compare with the more commonly employed drug, chloral hydrate? (2) Will the use of glutethimide reduce the amount of analgesic drugs required during labour? (3) Is there evidence that glutethimide is effective in lessening the apprehension which is commonly a feature of the first stage of labour, particularly in primiparae? (4) Are there any maternal or foetal hazards associated with the administration of glutethimide in labour?

Literature.—Since the introduction of α -phenyl- α -ethylglutarimide by Hoffmann and Kebrle (1952), several papers have appeared in the literature confirming its sedative and hypnotic value. It has been successfully employed in cases of insomnia by Rushbrooke *et al.* (1956), in neuropsychiatric anxiety states, and as a pre-anaesthetic medication by Matlin (1956). Electroencephalograms have also shown that a dose of 0.5 g. of the drug compares favourably with that of 1½ gr. (0.1 g.) of quinalbarbitone sodium (Ladwig, 1955). An extensive pharmacological study of glutethimide has been made by Gross *et al.* (1955), and few toxic side-effects were recorded. There are no reports in the literature on its possible value in labour.

Method and Procedure

This study is based upon a survey of 100 normal parturient patients aged between 16 and 43 years, admitted to the professorial unit at Southmead Hospital, Bristol. There were equal numbers of primiparae and multiparae. All patients were given two tablets of glutethimide (each containing 250 mg.) early in the first stage of labour, when it

was certain that labour was well established and uterine contractions were causing some distress. Before each administration cervical dilatation was assessed per vaginam or per rectum.

Of the 100 cases reviewed, 91 received two tablets of glutethimide, eight had two such doses within four hours, and one required three doses in eight hours. Dilatation of the cervix in the latter case had not exceeded four finger-breadths when the third dose was given.

The effect of this form of sedation was studied from the subjective and objective points of view, and all results were appraised according to the degree of relief of pain, relaxation, sleep, and general well-being of the patient. Regular observations of blood pressure, pulse rate, foetal heart rate, and uterine contractions were made, and notes taken of any untoward side-effects. The duration and complications of all three stages of labour, the need for additional sedation or the administration of analgesic drugs, and the condition of the infant at birth were carefully noted.

For control purposes a second series of 100 cases, also normal parturient patients within a similar age range and comparable in other respects, were treated with 30 gr. (2 g.) of chloral hydrate in the form of the syrup. The choice of this drug as a yardstick was made because of its traditional use as a sedative in early labour.

Evaluation of Results in the Treated Group

Subjective Reactions.—Each patient was interviewed within two hours of the administration of glutethimide and subjective reactions were recorded as poor, where no relief was experienced whatsoever; fair, where patient noted some relief; good, where the pain was considerably alleviated; and very good, where only slight pain was noticed at the height of each contraction. Of the treated patients, 9 were rated very good, 61 good, 42 fair, and 18 poor.

Objective Reactions.—These were also noted within two hours of the administration of glutethimide, and were as follows: poor, where the patient remained restless; fair, where restlessness was reduced but patients were unable to sleep between contractions; good, where mental and physical relaxation were sufficient to permit sleep between contractions; and very good, where, in addition to good mental and physical relaxation, the patient was very cheerful and optimistic. Eighteen were rated as poor, 10 as fair, 63 as good, and 9* as very good.

Effect on Labour

Of the 100 patients reviewed in the glutethimide group, 98 had their infants presenting by the vertex, and, of these, 88 confinements terminated spontaneously. There were 10 forceps deliveries (nine occurred in primiparae), and in six of these the indication was malrotation with occipito-posterior position of the foetal head. In the remaining two cases the babies presented by the breech; one had a caesarean section on account of relative disproportion, the infant weighing over 9 lb. (4 kg.) at birth, and the other was delivered successfully per vaginam.

In the control series, 79 had a spontaneous delivery and 16 required forceps. In nine of the forceps deliveries the occiput was posterior in position. Two cases had a caesarean section on account of disordered uterine action and foetal distress respectively. There were also three assisted breech births.

Table I shows the comparative length of the various stages of labour. In the glutethimide group the average length of labour was 12 hours for primiparae and 7½ hours for multiparae. In the control series the corresponding figures

*One of these nine cases which showed very good subjective and objective reactions was that of a young unmarried mother who was particularly apprehensive and depressed on admission. Shortly after the administration of glutethimide there was a dramatic change in mood and she became euphoric. This persisted throughout labour.

were 13½ and 8 hours. The apparently shorter labours in the glutethimide cases may well have been due to the rapid cervical dilatation brought about by the calming and relaxing effect of the drug.

The total amount of blood loss in the third stage of all cases treated with glutethimide was 920 oz. (26.1 litres), as compared with 895 oz. (25.4 litres) in the control group. Examination of these figures, however, revealed that there was no significant difference in the incidence of post-partum haemorrhage in the two groups (see Table II).

TABLE I

Stage of Labour	Time	Glutethimide Group	Chloral Hydrate Group

Effect on the Newborn

The effect on the newborn infant of glutethimide sedation as employed in this study is shown in Table III. Class A consisted of infants who breathed and cried immediately after birth, appeared in no way narcotized or cyanotic, and

TABLE III

	Chloral Hydrate Group	Glutethimide Group

" D	0	2
Total	100	100

required no resuscitation. Class B included infants who were cyanosed and at no time gave cause for anxiety, and responded well to oxygen administered by face-mask and aspiration of the upper respiratory passages by catheter. Infants failing to respond to whiffs of oxygen and appearing deeply narcotized, apnoeic, and showing a fair degree of anoxia, but responding satisfactorily within half an hour, were classed as C. Those failing to respond adequately within half an hour were regarded as severely affected, and were grouped as class D.

No infant in the glutethimide group was placed under class D, thus substantiating the impression obtained in the pilot survey that infants born of mothers receiving glutethimide were quite alert and active. The two babies classed under C were born after a general anaesthetic had been administered to the mother, in one case for a caesarean section and in the second for a forceps delivery after manual rotation of the head. Absence of any harmful effect of glutethimide on the newborn infants was particularly notice-

able in the 16 infants born within three hours after administration of the drug. All the 16 infants were classed as A.

Discussion

In this series of cases treated with glutethimide there were no maternal or foetal deaths and no significant untoward effects attributable to the drug. Four patients complained of nausea and a further five vomited within three hours of administration of the drug. These figures are more striking when one considers that the corresponding incidence of vomiting in the chloral hydrate group was 77.

Sleep ensued about 30 minutes after administration of the drug in 65 cases, and in 17 of these the level of the systolic blood pressure fell by 10 mm. Hg and the diastolic by 5 mm. This drop in blood pressure was maintained for three hours.

Table IV shows that the total amount of pethidine needed for additional sedation and analgesia in the glutethimide group was substantially below that required in the control

TABLE IV

Amount of Pethidine Required	Glutethimide Group	Chloral Hydrate Group
None	9	2
100 mg.	78	63
200 "	11	28
Over 200 mg.	2	7

For the purpose of the χ^2 test, two classes only were formed: (1) none and 100 mg.; and (2) 200 mg. and over. χ^2 corrected for continuity results as 12.08, which, on pure chance, would arise less often than about 1 in 1,000. It is therefore regarded as highly significant of a real difference in the amount of pethidine required.

series. In the glutethimide group, 87 patients required 100 mg. or less of pethidine, while 13 required 200 mg. or more. In the control group, 65 patients required 100 mg. or less, whilst 35 required 200 mg. or more.

Glutethimide was well tolerated by all patients, and none showed any allergic reaction. The normal course of labour in the glutethimide series was unaffected, the average duration of each stage of labour (see Table I) being slightly less—though not significantly so—than in the control group, and the general management of the first stage was greatly facilitated by the mental and physical relaxation induced by the drug. All patients who initially were apprehensive lost their fear and became fully co-operative shortly after administration of the drug.

There was no significant difference in the incidence of post-partum haemorrhage between the two groups (see Table II).

Conclusion and Summary

Administered in early labour, glutethimide was found to be an effective sedative, and was more easily administered and showed less evidence of gastric irritation than chloral hydrate.

It greatly reduced the requirements of pethidine for analgesia and additional sedation, the difference being statistically significant.

It alleviated apprehension, thereby encouraging relaxation and co-operation, and produced no evidence of any maternal or foetal hazard.

I am indebted to Ciba Laboratories, Ltd., for the supply of doriden employed in this trial and to their medical adviser, Dr. A. K. Pittman. I thank the sisters in charge of the labour ward for their assistance during this clinical trial. I am also indebted to Dr. G. Hurden for his statistical analysis of this paper. I am grateful to Professor G. G. Lennon for helpful advice and criticism.

Medical Memoranda

Chronic Bromism

Although there are four mixtures containing potassium bromide in the *National Formulary* 1955, the drug is not so frequently prescribed as previously. Barbour, Pilkington, and Sargent (1936) found that 14% of 200 consecutive prescriptions contained potassium bromide. For the year 1949, in England, the figure of 5.8% has been quoted by Dunlop, Inch, and Paul (1953). These authors, in a survey of prescribing in Scotland in 1951, found a further decline in the use of bromide; in that year 1% of prescriptions contained potassium bromide. This 1%, however, represents an appreciable number of prescriptions, since in the month of October, 1951, alone 4,000 prescriptions containing bromide and chloral hydrate were dispensed in Scotland. A personal scrutiny of 10,000 prescriptions issued by general practitioners in Aberdeen between January and December, 1954, revealed 1.1% with potassium bromide as a constituent.

It is well known that the long-continued use of bromide may produce symptoms of "intoxication," but because of the decline in its use chronic bromism may be forgotten and overlooked. Attention is again drawn to the insidious onset and clinical picture of that condition.

CASE REPORT

A housewife aged 52 was admitted to hospital in October, 1953, suffering from mitral stenosis and congestive heart failure, manifest by dyspnoea, venous congestion, hepatomegaly, and slight oedema. She was successfully treated, and was discharged a few weeks later on a regime which included digitalis, 2 ml. of a mercurial diuretic intramuscularly once a week, and a diet of ordinary food with no added salt.

On October 13, 1954, she was readmitted at the request of her general practitioner on account of dysarthria, ataxia, and fatigue. After leaving hospital in 1953 she had complained of increasing tiredness. In August, 1954, progressive slurring of speech was noted by the patient and by her friends. At no time was there weakness of any one limb, but she complained of generalized stiffness, and in September her gait became unsteady. By this time she was spending most of the day in bed, rising at 9 a.m. and returning to bed again at 11 a.m. because of overwhelming fatigue. When she was readmitted in October she was unable to stand without support and was complaining of inability to express her thoughts in words; she also had difficulty in using her arms because of tremor.

On examination she was drowsy, lethargic, and uncooperative. She wept frequently, and was completely disinterested in her surroundings, but at no time were hallucinations or delusions noted. Speech was slurred, but there was no nominal aphasia. There was a coarse tremor of the hands and some apraxia was present. The gait was grossly ataxic and she was quite unable to stand without support. There were no other abnormal neurological signs. The mouth was dry and salivation scanty. There was no skin rash. Mitral stenosis was present, associated with mild congestive heart failure, the neck veins being distended and the liver palpable; there was no oedema.

Further inquiry revealed that for a year she had been taking a dose of a mixture containing, in each fluid ounce (30 ml.), 30 gr. (2 g.) of potassium bromide, 30 gr. (2 g.) of chloral hydrate, and 30 minims (1.8 ml.) of tincture of opium every night. She regularly took ½ oz. (15 ml.) of this mixture, but on many occasions repeated the dose. During this period she was having a diet low in sodium chloride and was being given a mercurial diuretic, 2 ml. weekly by intramuscu-

lar injection. Latterly she had been eating very little food. It seemed likely that these factors, which tend to decrease the chloride content of body fluids, would lead to retention of bromide. A clinical diagnosis of chronic bromism was confirmed by a serum bromide estimation of 175 mg. per 100 ml. (17 mEq).

The bromide mixture was discontinued on October 14, and sodium chloride, 1 g. daily, was given by mouth. The signs of congestive cardiac failure increased and the sodium chloride was discontinued six days later. On October 19 there was some improvement in speech, but she was still drowsy, querulous, and ataxic; tremor was still present. By October 26 she was more alert and taking an interest in herself and her surroundings. On November 2 the serum bromide level was 100 mg. per 100 ml. (9.7 mEq). At this time she was much improved, although still drowsy and unable to walk unaided. Five weeks after discontinuing the bromide mixture she had recovered and was transferred to a convalescent hospital. Her personality had reverted to normal; she was alert and co-operative, and no longer had tremor, ataxia, or slurring of speech. On December 2 the serum bromide level was 10 mg. per 100 ml. (0.97 mEq). Subsequently a mitral valvotomy was performed, resulting in improvement in exercise tolerance.

COMMENT

Several aspects of the diagnosis of chronic bromism mentioned by Barbour *et al.* (1936) can usefully be re-emphasized. Of their five cases, ataxia occurred in three, and tremor, speech difficulty, and depression in two. Memory impairment and hallucinations were common symptoms. None of the five had a skin rash. Patients with atherosclerosis, anaemia, impaired renal function, and organic heart disease are more susceptible to bromide intoxication. There is a wide individual variation in the level at which symptoms appear—for example, a patient suffering from one of the above conditions may develop symptoms of bromism with a serum bromide level of 150 mg. per 100 ml. (14.5 mEq), whereas a healthy young man is able to tolerate the same level with no symptoms at all.

Barbour *et al.* point out that bromide acts by replacing chloride in the body and that the rate of substitution depends on the quantity of bromide given, the fluid and electrolyte intake, and the renal efficiency of the patient. Therefore a patient on a low-fluid and low-chloride regime will develop a higher level of bromide in the serum more quickly than a patient on a normal diet receiving the same amount of bromide. Rosenheim (1951) and Holt and Litchfield (1951) point out the dangers of giving a low-salt diet to patients with hypertension receiving hexamethonium bromide. A high ratio of bromide to chloride in the body fluids will also develop in a patient taking bromide and little or no food (Nabarro, 1954).

Chronic bromism of slight or moderate degree is easily overlooked because of the insidious development of the clinical picture. Vague symptoms such as fatigue, depression, and memory impairment may be attributed to senility, mental disorder, cerebral atherosclerosis, or the cerebral anoxaemia of congestive heart failure. The dangers of giving bromides to patients taking a diet low in sodium chloride or undergoing treatment with mercurial diuretics cannot be too strongly emphasized.

I thank Dr. Ian Gordon for permission to publish this case report.

Lactosuria following Burns

Baar and Bull (1952) reported lactosuria in severely burned patients treated with a local application of penicillin lactose powder. The following report of a similar case illustrates again the absorptive capacity of "raw" cutaneous areas and indicates the danger of applying toxic substances to such damaged surfaces. In this case, however, the absorbed substance was harmless.

CASE REPORT

A woman aged 56 was admitted with burns of the back, buttocks, and thighs—approximately 2% of the surface area of the body. Her general condition was found to be satisfactory and the burns were dressed. The following day routine ward-testing of the urine with Benedict's reagent showed the presence of a reducing substance. In addition, it was noticed that both Rothera's test and Gerhardt's (ferric chloride) reaction were positive.

The presence of glycosuria in the first 36 hours after burning is not an uncommon occurrence, but, in order to eliminate the possibility of a coincident diabetes mellitus, a glucose-tolerance test was undertaken, the blood-sugar method of Kingsley and Reinhold (1949), with tungstic acid filtrates, being used.

Specimen	Glucose-tolerance Test			
	Venous Blood	Urine		
	Blood-sugar Level (mg./100 ml.)	Reducing Substance (Approx. % as Glucose)	Rothera	Gerhardt
Fasting	105	0.5	Positive	Positive
1 hour after 50 g. glucose	150	0.5	"	"
2 hours after 50 g. glucose	105	0.5	"	"

The test showed no impairment of glucose tolerance, so the condition was obviously not diabetes mellitus. The positive Gerhardt (ferric chloride) reaction resulted from the administration of tab. codein. co. The positive Rothera reaction was explained by the mild ketosis that might be expected from the patient's condition.

The presence of a reducing substance in approximately constant concentration in all the urine samples prompted investigation into the nature of this substance.

Paper chromatography of the urine showed the following: fasting, lactose; at 1 hour, lactose and glucose; at 2 hours, lactose. The solvent used was *n*-butanol 60%, acetic acid 15%, distilled water 25%; the spray reagent was 3:5 dinitrosalicylic acid.

The lactosuria was found to be associated with the use of lactose as a bland dressing for the burned areas. It was thought, at first, that the urine samples had been contaminated with lactose at the time of collection, but a catheter specimen of the urine again showed the presence of lactose. Lactose was absent from a specimen of urine obtained one week after cessation of the lactose dressings.

There is no doubt that the lactose had been absorbed from the burned areas and excreted by the kidney. I am unaware of any evidence suggesting that such a temporary lactosuria is at all harmful.

My thanks are due to Mr. D. H. Patey for permission to publish this case.

Reviews

A GREAT HUMANITARIAN SERVICE

The International Refugee Organization: A Specialized Agency of the United Nations. Its History and Work, 1946-1952. By Louise W. Holborn. (Pp. 805+xi; maps and charts. 45s.) London, New York, Toronto: Oxford University Press under the auspices of the Liquidation Board of the International Refugee Organization. 1956.

It is a lamentable fact that the work of assisting refugees is once more on the increase, and the Hungarian tragedy serves to emphasize the need for international collaboration. A comprehensive and fully documented book, *The International Refugee Organization*, presents the brief history of a great humanitarian service undertaken by a specialized agency of the United Nations. Although it is essentially a reference work for the expert, this exhaustive study brings together much matter of human interest. The chapters on medical care, counselling, and the problems of adaptation to a new life are all of interest and value; and the longer anxieties and achievements of resettlement are fully discussed.

The organization was created in 1947, replacing and extending the work of the Army authorities and of U.N.R.R.A. During its period of operation its expenditure amounted to \$430 million, of which nearly \$400 million was contributed by 18 governments—a remarkable achievement in a distracted world already oppressed beyond belief by intensely nationalistic movements and tending to regard refugees as in some sense traitors. At the same time the participation of voluntary societies contributed immeasurably to the human solicitude which could not be readily fitted into the huge organization. They filled the crevices admirably.

The provision of medical care alone was a colossal task, but fortunately, in war areas at all events, actual hospitals were sufficient for basic needs. The essential basis of the service was, as it should be, the clinic providing preventive care, including immunizations, for mothers, infants, and children. In addition, a great deal of simple health education was carried out, especially in relation to infant and child care and the prevention of tuberculosis. In its health programme the I.R.O. relied greatly on the services of refugees and displaced persons. In the first year more than 2,500 refugee physicians and 2,000 nurses worked with the small staff of professional I.R.O. personnel. Good as their service was, it was found that there was a serious lack of medical staff trained in health and in administration, and special courses had to be set up in these subjects.

It was realized from the start that the work of I.R.O. was a temporary measure; this led to the wise decision that it should undertake its own liquidation and not leave such a vital task to the haphazard efforts of individual Governments. The I.R.O. was set up to perform a particular function. When that work was finished it went out of existence. It had coped with 1½ million refugees, and has made a pattern for any future action for refugees.

J. M. MACKINTOSH.

POLIOMYELITIS IN DENMARK

Management of Life-threatening Poliomyelitis, Copenhagen, 1952-1956. With a Survey of Autopsy Findings in 115 Cases. Edited by H. C. A. Lassen, M.D. (Pp. 176+xi; illustrated. 22s. 6d.) Edinburgh and London: E. and S. Livingstone Ltd. 1956.

In 1952 Denmark experienced an outbreak of poliomyelitis of unprecedented severity, as many as 1,250 cases of the paralytic form of the disease being admitted to one hospital under Dr. Lassen's direction. There was no adequate preparation for such a situation, and no fewer than 345 patients developed insufficiency of respiration or paralysis of swallowing. The dramatic and courageous measures taken to deal with this situation made a profound impression in many countries, and have led to the establishment of many

special centres for the handling of the dangerous types of the disease. The most startling news regarding the methods employed was that tracheotomy was used very freely, and that where necessary artificial respiration was maintained by intermittent positive-pressure respiration through a cuffed tracheotomy tube, while tank types of respirator were discarded. These revolutionary measures were not everywhere approved of, but great interest was aroused, and this had a most valuable effect in encouraging the development of respiration units.

This book is more concerned with what happened in 1952 than with the most up-to-date developments of the subject, and most of what is presented has already been published elsewhere. The reader therefore gets the impression that the authors are content "to rest on their laurels," and there are few references to work after 1952. This is unfortunate, as many hoped that Copenhagen would maintain a leading position in this research. Nevertheless those working on poliomyelitis will wish to have a copy of this book.

W. RITCHIE RUSSELL.

EDUCATING SPASTIC CHILDREN

Educating Spastic Children: The Education and Guidance of the Cerebral Palsied. By F. Eleanor Schonell, M.A., Ph.D. (Pp. 242+xv; illustrated. 21s.) Edinburgh: Oliver and Boyd. 1956.

This book is, as its publishers claim, an eminently practical contribution to the care of children with cerebral palsy. Dr. Schonell quotes mainly her detailed survey of 354 cases seen with Dr. Asher from November, 1947, to March, 1949, in the West Midland area of England, but has drawn also on her observations in America, Canada, and New Zealand and further work in Australia.

Her custom of calculating a modified I.Q. with alterations in the standard tests as required by physical handicaps, and if necessary on estimated I.Q. using any available evidence of a child's intelligence, is interesting. Her opportunities of checking the reliability of these alterations, both by retesting the children concerned and studying their progress at Carlson House School, add considerably to their value. This appears to be an important method of recording formally the allowances which many psychologists make in testing athetoid children especially.

Dr. Schonell puts at 70 the I.Q. level above which children with cerebral palsy can be expected to benefit from educational opportunities of a scholastic type. This dividing line means that five out of every ten of these children merit special education, just over half of them in the level from 70 to 89 I.Q., which some educational psychologists would exclude from special arrangements of this type. The results in teaching reading and other subjects to a group in Carlson House School justify this optimistic attitude to the problem which is of the greatest importance to parents and to educational and medical authorities. The final part of the book contains a sensible and helpful discussion of the psychological and social aspects of cerebral palsy, with due regard to the importance of the part which parents must play.

Altogether this is a most encouraging and useful discussion of the problem of cerebral palsy and can be heartily recommended to all who are interested in this difficult and many-sided but fascinating field of study.

MARY O'DONNELL.

INFANT FEEDING

Feeding in Infancy and Early Childhood. By Ursula James, M.R.C.P. (Pp. 135; illustrated. 10s. 6d.) London: Faber and Faber Ltd. 1956.

This is a useful little book which can be carried in the pocket. It provides abundant information about proprietary feeds of all sorts and has an excellent list of recipes for young children and for patients with nephrosis, coeliac disease, fibrocystic disease of the pancreas, and diabetes. Breast-feeding is well discussed, as are some of the feeding problems. There is little to criticize in the advice given, although the feeding of premature babies is not always as easy as

suggested. The statement, "The average premature baby will take 50 calories per lb. of body weight every 24 hours by the end of the first week of feeding," depends for its veracity on the definition of "average." The recommendation that mixed feeding should be started for premature infants at approximately three months "regardless of the baby's weight" clearly overlooks the difficulties encountered with very small premature infants. There are 15 illustrations, but these could have been omitted without detriment. The book is suitable for health visitors, midwives, and nursery nurses, and indeed for anyone who undertakes the professional task of caring for infants and small children.

WILFRID GAISFORD.

OBSTETRICS

The Queen Charlotte's Textbook of Obstetrics. By members of the Clinical Staff of the Queen Charlotte's Maternity Hospital, London. Ninth edition. (Pp. 547+xi; illustrated. 45s.) London: J. and A. Churchill Ltd. 1956.

New editions of this book have appeared at approximately three-yearly intervals since 1927. It now represents the work of 15 members of the staff who include a physician, paediatrician, pathologist, radiologist, psychiatrist, and anaesthetist as well as nine obstetricians. The initials to the preface suggest that Mr. S. G. Clayton has acted in an editorial capacity; otherwise it is impossible to guess the contribution of each individual obstetrician. This speaks well for the blending of what must inevitably be differing opinions to make a harmonious whole. The book is well balanced as well as harmonious, and has a practical approach to subjects which generally keep well within the range of what is expected of the present-day undergraduate. For such a reader it can fairly be described as a sound textbook, as up to date as any textbook ought to be, and at the same time possessing clarity and logic which make for easy reading and learning. The subject-matter is orthodox without being too conservative; indeed, it is interesting to see how much it contains which would have been regarded as unorthodox (or even heresy) five years ago. Moreover, the modernization is consistent and there is no sign of one section lagging behind another. The result is a book which, even though it contains only the bare essentials, should, if used in conjunction with clinical work, see any student through the midwifery part of a qualifying examination.

T. N. A. JEFFCOATE.

MANAGEMENT OF FRACTURES

The Management of Fractures, Dislocations, and Sprains. By John Albert Key, B.S., M.D., F.A.C.S., and H. Earle Conwell, M.D., F.A.C.S. Sixth edition. (Pp. 1,168; illustrated. £7 10s.) London: Henry Kimpton. 1956.

The first edition was published in 1934, and both authors have been responsible for all editions of this book on fracture management, which has been read in many countries. This is not just a reprint, for revisions have been drastic, particularly of the chapters concerned with spinal, hip, and ankle injuries. The treatment of compound fractures is now up to date in regard to the systemic use of antibiotics and the suitable local treatment. There are many additions and deletions of illustrations.

The book is easy to read, descriptions are clear, and nearly all the illustrations are helpful. The names of Pott, Thomas, Jones, and Colles survive, but Lane is not mentioned. Bankart, Bennett, and Bryant are not forgotten. The management of injuries is orthodox, and all the methods described are used in British clinics. It would appear that the authors are little interested in rehabilitation, in particular in physiotherapy. As some clinics favour a basic principle, such as skeletal traction, in the treatment of many fractures, whereas others will employ manipulative reduction with plaster splintage, resorting to open operation should this fail, a book of this type has to describe a number of methods of treatment. The authors recognize this and often state which method each author himself uses. The latter is helpful, but the description of several methods does make it

difficult for the young surgeon who feels he must resort to a textbook when faced with difficulty. Further, this book, in common with others, seldom indicates what procedure should be adopted if the first method fails.

Readers will find useful the description of the first-aid and emergency hospital treatment of injury, especially of compound fractures. There is a comprehensive section on spinal injuries, based largely on British teaching. There is excellent advice on injuries around the hip, including the dislocation and fractures of the femoral neck, although the number of methods available for treatment of the latter tend to confuse the reader. The latter is also the case with the difficult compression fracture of the os calcis. The description and treatment of the upper limb fractures are most helpful and the brief remarks on Volkmann's contracture valuable. It is interesting that at early open operation absorbable material or wire is used for holding bones in place (for example, radius or ulna), since many people think that non-union is more liable to occur with such small fixation.

This book records the practice and teaching of two experienced orthopaedic surgeons and is of particular value to the trainee and young surgeon. It is well produced and illustrated, and should replace the former edition on library shelves.

ST. J. D. BUXTON.

PAINFUL HEEL

Der Fersenschmerz: Funktionelle und Organische Störungen im Bereich der Ferse und Achillessehne. By Professor Dr. Med. Kurt Stucke. Foreword by Professor Dr. Med. Werner Wachsmuth. (Pp. 163+xv; illustrated. D.M. 29.70.) Stuttgart: Georg Thieme. 1956.

All monographs on an anatomical basis suffer from the disadvantage of not being able to explore fully a particular disease affecting the region under consideration without overburdening the volume. In this volume injuries around the calcaneus and to it get scant attention. As have many monographs, this has an air of omniscience. But some complaints still defy explanation. Thus, although there is an excellent description of the heel pad and its anatomical construction, no mention is made of the diffuse fatty tenderness which is often found, which can be distinguished from most other causes of pain, and which is often peculiarly resistant to treatment. Admission of its occurrence and its inexplicability, perhaps together with some indication of the cases which might be confused with it, would encourage the doctor lacking in diagnostic over-confidence.

The text includes too many reference names (hence the common preference for small reference numbers). On one page twenty-two names follow one another, occupying one-eighth of the page. No one wishes to deprive an author of the credit for his work, but it can be given elsewhere than in the text. Many are chosen here for reference, few for special mention. The effect of the height of the heel on calcaneal weight-bearing is not discussed. There is not more than an occasional reference to footwear as a cause of heel disability, and no description of alterations in the heel which might offer relief. The calcaneal spur is rightly relegated to a secondary position as a cause of pain and encouragement given in seeking the primary cause of irritation.

These are no more than minor blemishes. The book is a stimulating review of a limited field, well produced and set out and neatly illustrated. The bibliography is compendious and satisfactory. It merits more than a rapid perusal and relegation to a library shelf.

J. G. BONNIN.

A Practical Manual of Medical and Biological Staining Techniques, by Mr. Edward Gurr, F.L.S., is a compendium of formulae and instructions for the use of stains in microscopy. The second edition, 1956, which appeared three years after the first, is larger and includes a new section on histochemical methods. It is published by Leonard Hill Books Ltd. for 42s.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY MARCH 9 1957

CONNECTED OCCUPATIONS

Mr. R. A. Butler is fond of explaining each governmental blunder as just a question of faulty public relations. He can add the present crisis with the profession to his list. Mr. Turton for seven months went on saying No! Mr. Vosper had barely a week or two in office before he had to echo this instruction from the Treasury. Then Mr. Macmillan announced the setting up of a Royal Commission, and left it to Lord Salisbury to state in the House of Lords that an interim increase could be granted to junior medical and dental staffs in hospitals. After the public statement of the G.M.S. Committee about a possible withdrawal from the Health Service Mr. Macmillan told the joint chairmen of the Negotiating Committee that the work of the Royal Commission would not preclude some interim adjustment, apparently over and above any interim increase for junior hospital staff. Only six years before the present claim was put forward the then Minister of Health (Mr. Aneurin Bevan) informed the B.M.A. through the Secretary to the Ministry that the Spens Report remained the basis of remuneration of general practitioners until some other basis was substituted after the usual consultations. The present Government has ignored this completely. Without any consultation at all it sets up a Royal Commission with the following terms of reference.

"To consider:

"(a) How the levels of professional remuneration from all sources now received by doctors and dentists taking any part in the National Health Service compare with the remuneration received by members of other professions, by other members of the medical and dental professions, and by people engaged in connected occupations.

"(b) What, in the light of the foregoing, should be the proper current levels of remuneration of such doctors and dentists by the National Health Service.

"(c) Whether, and if so what, arrangements should be made to keep that remuneration under review.

"And to make recommendations."

The absence of reference to changing values of money, or to the status of doctors, means the Govern-

ment has discarded Spens. "We leave to others," says the Consultant Spens Report, "the problem of the necessary adjustments to present-day values of money, but we desire to emphasize as strongly as possible that such adjustments should have direct regard not only to estimates of the change in the value of money but to the increases which have in fact taken place since 1939 in incomes both in the medical and in other professions." The Royal Commission is being restricted solely to a comparison with the incomes of other professions *and connected occupations*. The G.M.S. Committee were in no doubt that the Government was determined to ignore the recommendations of the Spens Reports. The Royal Commission's terms of reference remove any doubts on this. The Prime Minister himself has revoked the Spens recommendations without any consultation with the profession. The unfortunate Minister of Health, Mr. Vosper, is left with the power—"at an appropriate moment"—to negotiate an interim increase with the profession's negotiators. At least so it appears. But on what basis? On a comparison with the incomes of other professions, on the changed value of money, or on both? Or is the Government thinking of offering a sop to the profession—"at an appropriate moment"—in order with an appropriate bribe to confuse their counsels?

The Joint Consultants Committee and the Public Health Committee have backed to the full the decisions of the G.M.S. Committee. And to these the Council of the B.M.A. has added the weight of its great authority. The profession is completely united in its opposition to the Government's action. It is angry and distrustful, and has lost faith and confidence in an employer who breaks pledges with the abandon of the traditional bull in a china shop. The Council last week, under its Chairman, Dr. S. Wand, was clear that more was at stake than the settlement of the present claim—a claim it is quite willing to submit to arbitration but the Government is not. What is at stake is the future of the profession—not only the future welfare of those working in it but its future power to attract able men and women into it, a matter which was one of the principal concerns of the two Spens Committees. The medical profession continues to be willing to discuss, to negotiate, and if negotiations break down to submit the points of dispute to arbitration. And surely this is a reasonable attitude. It refuses to be pushed on one side as of no account. It refuses to accept the appointment of a Royal Commission, with terms of reference which prejudice the issue, as a proper approach to the problem, an approach severely criticized by the whole of the national press. It refuses to yield to Government dictatorship

on the terms and conditions of service of doctors in the Health Service, and will agree to these only on the democratic basis of discussion, negotiation, and, if necessary, arbitration by an independent adjudicator.

The Council does not consider that the Prime Minister's implied promise of an interim increase alters the fundamental position. Faced with broken pledges and promises, what steps can the profession take? It has already taken one, and that is to call meetings of the Conference of Representatives of Local Medical Committees and of the Representative Body of the B.M.A. They will be asked to consider the withdrawal of general practitioners from the Health Service. This has been wrongly described as a threat to strike. A strike means withholding of services from the public. If railwaymen strike trains don't run. If general practitioners withdraw from the N.H.S. they will continue to work, continue to look after their patients. Details of a scheme for withdrawal have been prepared and will be published, and if the Conference and the R.B. decide on a policy of withdrawal it should be made clear to the public that this decision has been forced upon it by the Government, by politicians. If politicians say that such an action is an attempt to wreck the Health Service, who is the wrecker? The Government. The medical profession does not wish to wreck the Health Service. It acknowledges that to-day some public organization of medical services is necessary, and it has played a large part in planning for them. Many wish to see a better Health Service, and no one is so conscious of the present defects of the N.H.S. as those doctors working in it; and the greatest of all defects is the intervention of the party politician between patient and doctor. Unfortunately there is no other way of bringing home to public and Parliament the present profound distrust of the profession with its employer than by action such as that recommended. The Government can break this deadlock to-morrow by redeeming its pledges, by negotiating directly with the profession, and by agreeing to arbitration if an impasse is reached.

IMMUNOLOGICAL TOLERANCE

In the past ten years immunology has been obliged, not for the first time, to change its tack. The chemical and analytical approach that made such splendid progress in the years before the war took immunology as far as it could go without a further transfusion of empirical knowledge, and much of the research going on to-day, in its exploratory style and broadly biological approach, recalls the pioneering work of

Bordet, Metchnikoff, and Ehrlich. Many immunologists now are particularly concerned with the specific inhibition of immunological responses—that is, with causing certain immunological reactions not to occur. The most promising and important of the four or five methods that have so far been devised for this purpose is that which is embodied in the concept of "immunological tolerance," the subject at a discussion meeting of the Royal Society held under Sir Macfarlane Burnet's leadership in March last year, and now published in the Society's *Proceedings*.¹

The train of thought which led to the idea of immunological tolerance can be traced back to R. D. Owen's² remarkable discovery of the phenomenon of red-cell chimerism in twin cattle. Cattle twins almost always share the same chorion; the consequence is that they can exchange blood and blood-borne cells from an early stage of foetal life until birth. When the twins are dizygotic they can be shown at birth to contain a mixture of each other's red cells; and, so far from being merely transient, the state of chimerism may last throughout their lives. The twins must therefore have exchanged blood-forming cells before birth, and these cells, in apparent defiance of the laws of transplantation immunity, must have survived in an alien environment and have continued to manufacture red blood corpuscles of their own distinctive antigenic type. Stable red-cell chimerism is probably the rule in twin chickens³—chickens which are of dizygotic origin, though uniovular in the sense that they hatch from a single egg—and probably a rare exception in twin sheep.⁴ In human beings it must be rarer still, for only one clear case has so far been described⁵: Mrs. McK., a woman now nearing 30, whose own group O corpuscles are mixed with corpuscles of group A₁, the legacy of a synchorial union with a long-dead twin.

Sir Macfarlane Burnet and F. Fenner⁶ were guided by their theory of antibody formation to predict that the phenomenon observed by Owen might be of general validity; to predict, in fact, that if an embryo

were to be exposed to an antigenic substance then its power to react against that substance when it grew up would be abolished or at least impaired. The prediction was fulfilled by the work of R. E. Billingham, L. Brent, and P. B. Medawar,⁷ who had already shown that dizygotic twin cattle were mutually tolerant of homografts of each other's skin^{8,9} and had expressed their determination to reproduce this strange state of affairs by artificial means. In short, they found that mice or chickens of different strains or breeds could be caused to accept skin homografts from each other in adult life, provided they had been injected in embryonic life with cells taken from their future donors, or from animals antigenically similar to their future donors. A detailed analysis of the phenomenon³ has shown, among other things, that actively acquired tolerance is highly specific, in the sense that an animal which has been caused to become unreactive towards one antigen will retain in full its power to react against any other; and that it is due to some kind of central failure of the machinery of reaction, for normal reactivity can be restored to a "tolerant" animal simply by re-equipping it with normal lymphoid cells.

It is clear then that Burnet and Fenner's concept holds good for transplantation immunity, and the work of Owen and of M. Hašek¹⁰ shows that it applies equally well to the immunological reactions provoked by red blood corpuscles. It is demonstrable, then, with immunological reactions of two entirely different types, for, as Medawar pointed out when opening the Royal Society discussion, transplantation immunity and red-cell immunity could hardly be more unlike. But does the concept hold good for still other immunological systems? There are some grounds for believing that it does. Several groups of immunologists¹¹⁻¹⁴ have shown that rabbits which have been injected with protein antigens from birth onwards lose—or rather never acquire—the power to make antibodies against those antigens when challenged to do so in adult life. The state of non-reactivity seems to persist after the disappearance of the antigen that produced it, a property which distinguishes it from immunological paralysis, which is now generally thought to be due to the persistence of antigen in excess.¹⁵ There is some evidence, too, of the production of tolerance by the injection of bacterial antigens.^{16,17} The term is perhaps unfortunate in this context, because tolerance might here be thought to bear the more usual connotation of "putting up with" virulent micro-organisms, the very faculty of which tolerance in its technical sense would deprive them. But then there has always been something rather odd about the semantics of immunology.

Other investigators, injecting antigens of various kinds into the embryos of chicks or rats, have not succeeded in demonstrating any subsequent impairment of response.¹⁸ The recent work of M. Simonsen¹⁹ may go some way towards explaining why they have failed. All investigators intent upon securing tolerance have been on their guard against injecting their antigens too late in life; Simonsen's work shows that an injection may also fail if it is done too early. Presumably there is some critical period of maturation during which the injection of an antigen will prevent the development of the power of response: if non-living antigens are injected too early, they may be disposed of before that period begins.

The papers delivered at the Royal Society's meeting give a foretaste of the uses to which the technique of inducing tolerance can be put. R. J. C. Harris, for example, has used it in a way that throws important light on the antigenic make-up of the Rous sarcoma virus, and H. Koprowski and his colleagues have used it to cultivate mouse tumours in alien strains, a process which leads to deep-seated cellular transformations of a type which should be studied by all who dream of a genetic theory of asexually reproducing adult cells. The phenomenon of tolerance is not yet explicable by any chemical theory of the immunological response; on the contrary, its ability to explain the phenomenon of tolerance will be a crucial test for the adequacy of any theory that immunochemists may eventually devise.

POLIO FANTASIES

Just over a year has passed since the then Minister of Health and his retinue trooped in front of the television cameras to announce the scheme for poliomyelitis vaccination in Great Britain.¹ The dream-like stage thus set before the arc lights has proved to be more fitting than seemed possible at the time. The medical profession in general was then in the dark about the precise nature of the vaccine, and remained so until the Medical Research Council was permitted some weeks later to issue some detailed information on its production, constitution, and testing.² Meanwhile the Ministry had announced that enough vaccine for 300,000 to 500,000 children would be ready for injection before the end of June.³ Events proved this figure to be optimistic, for so far, a year later, only 200,000 have been vaccinated, and some thousands of these have received only one injection. Fortunately

⁶ *Daily Express*, January 29, 1957.

the poliomyelitis outbreak last summer was a relatively small one. Not only were cases rather few, but as often happens they were patchily distributed. The Medical Research Council had been collecting statistics of reported cases in order to study the efficacy of the vaccine, but before—indeed, long before—the Council could publish an analysis of the figures the then Parliamentary Secretary to the Ministry had mangled them, in an analysis all her own, to the plaudits of a political audience.⁴ In December the Ministry announced that supplies of vaccine were expected to be available from the middle of January,⁵ but when the time came a batch of 200,000 doses was found to be faulty and had to be scrapped. The first news of this appeared in a daily newspaper⁶ as a result of its science reporter's acumen, and the Ministry later issued a statement. Last week the Ministry called a press conference to communicate the melancholy news that 47 vials in the next and latest batch showed an inexplicable change of pH towards acidity. The whole batch must therefore be held back for the time being. How many children can be vaccinated before the poliomyelitis season begins this year is at present conjectural.

The Medical Research Council and the manufacturers are naturally taking every precaution against letting defective vaccine reach the public; their standards, and those prescribed by statute, are such that only a faultless product can, so far as present knowledge goes, successfully pass all the tests. These are not only elaborate and time-consuming but make use of materials, such as live monkeys and tissue cultures, whose variability may be sufficient in itself to vitiate a test even though the product being tested is satisfactory. It is therefore impossible for anyone to predict with certainty, on the resources put into the manufacture of this vaccine, that a batch will be ready at any particular time. The manufacturers hope that another lot will be ready in about two to four weeks, but neither they nor anyone else can be blamed if it is not. What is open to censure is a Ministry that presents genial fantasies of the vaccination programme to the general public. Doubt about the scheme may lead to doubt about the product, while doctors have to suffer the ignominy of being unable to satisfy their patients' falsely raised expectations.

D.D.T. IN MAN

It is natural that concern should be felt about the possible harm to man of the many new chemicals in use to-day for a multitude of homely purposes. The possible toxicity of insecticides is a problem requiring continuous surveillance, according to the report of a Study Group recently convened by the World Health Organization.¹

The group considered the hazards arising from the use of insecticides both in public health and in agriculture. While effective insecticides are of necessity extremely toxic to insects, mammals may not necessarily be so susceptible to their action. An estimate of the acute toxicity or the size of a single fatal dose may be gained from animal experiments, and if no great variation in the sensitivity of different species is demonstrable it is reasonable to conclude that man will be as sensitive as these laboratory animals to any particular insecticide. This may sometimes be demonstrated accidentally as a result of exposure of man while working with insecticides or, more unexpectedly perhaps, as the result of accidental gross contamination of food. A good instance of the latter kind of episode was published in the *Journal* recently.² A large number of people were poisoned by a comparatively new insecticide named endrin which accidentally contaminated some flour subsequently used to make bread. Fortunately no one died, though many had severe convulsions from which they made a rapid and complete recovery. Unfortunately we do not know the actual dose of endrin the victims of this episode consumed.

Acute and subacute poisoning are readily recognizable, and also readily prevented by proper care in handling toxic materials. But concern is often felt that repeated small doses of a toxic material may cause chronic poisoning. This undoubtedly happens when the poison accumulates in the body or produces a progressive and irreversible change in the tissues. However, it remains problematical whether a substance like endrin, for example, which produces dramatic and short-lived effects in a single poisonous dose, can also have a chronic toxic effect when ingested over long periods in quantities that are not obviously poisonous. Endrin is a new insecticide, but for over ten years D.D.T. has been widely used in public health work and agriculture and for the treatment of stored crops. The only undisputed cases of poisoning have followed the ingestion of large doses accidentally incorporated in food.³ Though there is probably some D.D.T. in the food we eat, attempts to find out how much it is have not yet been made in Britain; in the U.S.A. analysis of restaurant meals gave an average D.D.T. content of 0.31 p.p.m.⁴ Conclusive evidence of the absorption of D.D.T. by people not occupationally exposed to it was provided by an analysis of human fat from otherwise healthy people⁵; an average of 5 p.p.m. of D.D.T. was found.

Because D.D.T. has been in use for a long period, and because it is still extensively used for all kinds of purposes, a deliberate study of its effects on man was undertaken by W. J. Hayes and his colleagues⁶ on 51 inmates of a Federal Correctional Institution. Six groups of men, including two control groups, received daily doses of D.D.T. either in a capsule or as an emulsion in milk for periods of up to eighteen months. The daily dose was 3.5 mg. in two of the groups and 35 mg. in the other

two groups. This last dose is about 200 times the dose ingested in the normal daily food. In addition to a general physical examination and a few special tests, many of the subjects submitted to fat biopsy before, during, and at the close of the experiment. The level of D.D.T. in the fat was related to the intake, reaching levels of 200–300 p.p.m. in those subjects on the highest dose, but the amount in the fat did not increase after about the first twelve months of the experiment. This finding agrees with observations on animals. At no time during the experiment did the subjects taking D.D.T. complain of anything that could not be attributed to an easily recognizable cause unrelated to their exposure to D.D.T. These findings are reassuring and to some extent confirm general observations on the safety of this particular material.

Naturally an experiment even of this duration does not cover every possibility. The problem of looking for possible long-term effects in men and women heavily exposed to insecticides was also considered by the exposed to insecticides was also considered by the W.H.O. Study Group. They point out the need for a continued watch to be maintained over the health of populations much exposed to pesticides. This will be a difficult procedure to initiate and maintain, and W.H.O. would require active support from member countries if such a study were ever considered worth making. Meanwhile, however, much more information is needed about the actual degree to which exposure does occur. Although data for American food are available, no comparable figures from other countries have been published. Some of the alarm sometimes expressed about pesticides in food might be allayed if quantitative data on their presence in food were obtained. Exposure arising during the manufacture and application of pesticides has been studied more widely, and the sensitive blood cholinesterase test is informative in cases of exposure to organo-phosphorus insecticides. Hayes and his colleagues used the opportunities provided by their experiment to develop the test for estimating urinary D.D.A. (bis (*p*-chlorophenyl) acetic acid), a water-soluble metabolite of D.D.T. A knowledge of the amount of D.D.A. excreted by a man will give some measure of his exposure to, and absorption of, D.D.T. If tests of this nature could be developed for the other insecticides of this group a valuable tool in preventive medicine would be provided, but success depends on further knowledge of the metabolism of these other insecticides. Experiments on man of the type described by Hayes and his colleagues are not usually performed in Britain, but we might at least make a start in assessing the magnitude of our problem by analysing prepared meals and examining the urine of exposed workers.

TRANSAMINASE IN MYOCARDIAL INFARCTION

The reversible transfer of amino-nitrogen from an amino-acid to a keto-acid in the intermediary metabolism of the body is known as transamination. One of the most active of these transfer processes is catalysed by an enzyme, glutamic oxalacetic aminophenase (trans-

aminase). It is present in many tissues, notably cardiac and skeletal muscle, brain, liver, and kidney. In 1955 workers at the Sloan-Kettering Institute in New York devised a spectrophotometric method for measuring transaminase activity in serum,¹ and they, together with a group at the University of California in Los Angeles, have subsequently defined experimental and clinical conditions in which abnormally high values may be encountered.^{2–6} Levels are raised when muscles or other tissues are extensively damaged—for instance, by certain operations and in particular by myocardial infarction. The levels are persistently abnormal, and often very high, in hepatic and renal disease. Severe brain lesions, such as cerebral haemorrhage, are likely to increase serum activity, though these have not yet been studied in such detail as have other conditions. The consensus of opinion is that serum transaminase remains normal in patients with coronary ischaemia, pulmonary infarction,⁷ and acute abdominal emergencies, the one important exception to the last being acute pancreatitis.⁸

The greatest interest has been aroused in the use of the serum transaminase as a test for myocardial infarction, and we publish this week (p. 555) an investigation by Dr. R. Shabetai, Dr. A. Iglauer, and Miss D. M. Anderson which substantiates much of the previous work. Normal values ranging from 10 to 40 units per ml. of serum per minute are found during the first few hours after infarction. The level then rises to a peak between 12 and 24 hours and gradually returns to normal by the end of the first week. The incidence of false positives and negatives is apparently negligible, though it may be difficult to avoid bias when diagnosis is of necessity retrospective. Perhaps the most important finding is that normal values occur in patients with coronary insufficiency, even during attacks of angina. If this is confirmed and the possibility of false negatives can be ruled out, then serum transaminase tests may be of value when the electrocardiogram is equivocal and other tests such as the white cell count and the erythrocyte sedimentation rate contribute no useful information. Serial values are obviously more useful than a single estimation. There is some evidence that the rise in serum transaminase bears some relation to the amount of myocardial damage, and if it could be applied quantitatively it might be used for assessing management and prognosis.

The disadvantage of the test in myocardial infarction is its lack of specificity. It is possible that other enzymes may prove to be more suitable, and lactic dehydrogenase is being investigated. A simple screening method, based on an enzyme as specific as that used in the latest tests for glycosuria, would certainly be valuable for the general practitioner in those puzzling cases when it is difficult to decide whether infarction has occurred or not.

ANTHRAX INQUIRY

It is nearly forty years since the problem of anthrax was examined in all its aspects, and the present Minister of Labour and National Service has decided that the time is now ripe for a full-scale investigation. As reported at p. 593, he proposes to set up a committee of inquiry "to consider the existing legal provisions concerning the importation of goods infected or likely to be infected with anthrax and the precautions to be taken in connexion with such imported goods for the protection of the health of persons, and to make recommendations." The disinfection of goods likely to be infected with anthrax, especially hides and skins, was considerably hampered in the early days by the possible destruction of their commercial value. The disease affected wool-sorters, furriers, felt-makers, rag-sorters, and others who come in contact with animals or their hides or fur. A departmental committee appointed in 1895 to consider disinfection found it in fact impracticable. It was not until 1921 that the Government Wool Disinfecting Station was established at Liverpool, following the Anthrax Prevention Act of 1919, which gave powers to make arrangements for the compulsory disinfection of materials of specified classes and origins, with certain exceptions—namely, imported goat hair and all goods mixed with goat hair. The Hides and Skins Regulations of 1921, enforceable under Section 79 of the Factory and Workshop Act, did not apply to all tan-yards, irrespective of the nature of the hides and skins, and it is noteworthy that between 1922 and 1926 eight cases of anthrax, one of which was fatal, occurred in workers not subject to the regulations.

The annual incidence of reported cases of anthrax has certainly shown a decline during the last three decades, as also has the number of fatal cases. From 1920 to 1930 the number reported annually varied between 40 and 48, with fatalities ranging from 11 in 1920 to 6 in 1930. Between 1930 and 1940 the annual average was from 30 to 40 cases, with between one and five fatalities, except for 1935, when the number of fatal cases rose to 8. From 1940 onwards the highest number was recorded in 1950 (36 cases, but none fatal), and 1955 showed the lowest incidence since 1946—15 cases, none fatal. In Great Britain, as in the U.S.A., the great majority of cases are cutaneous. This is the so-called malignant pustule, which is not necessarily associated with broken skin, and may develop within twenty-four hours from a small itching papule to a black necrotic sore, followed, in fatal cases, by anthrax septicaemia, sometimes within a few hours. Gastro-intestinal anthrax is usually contracted from the ingestion of spores in food contaminated by the hands, and the pulmonary variety, almost always fatal within four to ten days, from inhalation of infected wool or hair. Intravenous and intramuscular injection of serum of artificially immunized animals has almost entirely replaced surgical removal of the pustule, and penicillin is notably efficacious. Under the existing law not all goods likely to cause anthrax in human beings are subject to prohibition of import, to compulsory disinfection,

or even to rigid compulsory precautions at the factory where they are to be handled. It is to be hoped that the forthcoming inquiry will bring under control all imported goods which bear the risk of transmitting anthrax.

ENDOCRINES AND DISORDERED SEXUAL BEHAVIOUR

For many years opinion has been sharply divided on the causation of disorders of sexual behaviour. The contention that homosexuality, for example, is due to endocrine imbalance was firmly expressed by R. von Krafft-Ebing¹ and subsequently by many others writing after him; and in more recent years the assumption has crystallized that it is due to an oestrogen-androgen imbalance.² On the other hand, many other students of the subject have taken precisely the opposite view—namely, that homosexuality and other disorders of sexual behaviour are the results not of endocrine disturbance but of psychological maladjustments.³⁻⁶ In discussing the endocrinological aspects of homosexuality, G. I. M. Swyer⁷ reviewed the strong evidence against an endocrine causation and came to the following conclusion: "The capacity for sexual response is not primarily dependent upon the sex hormones, and the direction of sexual development is influenced mainly by psychological and environmental conditioning. The levels of sex hormones appear to do little more than modify the intensity of sexual activity. There is no convincing evidence that human homosexuality is dependent upon hormonal aberrations. The use of sex hormones in the treatment of homosexuality is mainly disappointing."

A notable further contribution to the literature on the excretion of hormones by patients with anomalies of sexual behaviour has been made by G. Garrone and S. Mutrux.⁸ These workers studied a group of 50 patients with anomalies of sexual behaviour including homosexuality, pedophilia, and exhibitionism, and sought evidence of suprarenal or testicular dysfunction by determining the urinary excretion of total 17-ketosteroids and their different fractions, 3- α -steroids, formaldehydogenic corticoids, "total corticoids," and 17,21-dihydroxy-20-ketosteroids. With a few exceptions (of more than doubtful significance) the daily excretion of these steroid metabolites did not differ from that of normal men of corresponding ages. The conclusion was therefore reached that this group of patients did not provide any evidence of endocrine disturbance such as could account for their disordered sexual behaviour. This was a careful and extensive study, which adds materially to the now almost overwhelming evidence against endocrine causes, and therefore for psychological causes, of these behavioural disorders.

HARVEY IN SPACE AND TIME*

BY

DOUGLAS GUTHRIE, M.D., F.R.C.S.Ed.

Lecturer in History of Medicine, University of Edinburgh

Since Andrew Duncan delivered the first of the Edinburgh Harveian Orations in April, 1778, on the 200th anniversary of the birth of William Harvey, there have been many memorable orations on a great variety of subjects. Only about one-fifth of the orations deal directly with Harvey and his work, because the Laws of the Society, very wisely, impose no restriction upon the choice of a topic. Each orator is faced with a problem which becomes steadily more difficult each year.

Every aspect of Harvey's life and doctrine has been subjected to the most detailed scrutiny, not once but many times. Notwithstanding all this, the oft-repeated tale may still prove stimulating to a new generation of "neophytes," as well as refreshing to mature and seasoned Harveians. I have therefore decided to stick to Harvey, and to delineate him against a background of geography and history, space and time. Under the first heading, some account is given of Harvey's three Continental journeys, and, in the second place, an attempt is made to trace the history of his discovery of the circulation and to explain the long delay in its acceptance.

During the past year I have made various pilgrimages in pursuit of Harvey; to his birthplace at Folkestone; his school at Canterbury; Caius College, Cambridge; St. Bartholomew's Hospital; and the Royal College of Physicians of London (though Harvey would scarce recognize any of those scenes to-day); to Oxford, where in the last stages of the Civil War he continued his studies in embryology, using the eggs of a hen which his friend George Bathurst obligingly accommodated in his rooms; and, finally, to Harvey's last resting-place in the little village church of Hempstead in Essex, now perhaps better known as the birthplace of Dick Turpin, the highwayman, than as the burial-place of William Harvey.

How vastly the British scene of Harvey's labours has changed. Abroad, he seems more clearly to fit the picture, especially in Padua, where, though the city is sadly scarred by bombing, one may still see the anatomical theatre where Harvey followed the demonstrations of Fabricius; and the pulpit used by Galileo. Almost certainly Harvey attended the lectures of Galileo, who did for science what Harvey did for medicine, replacing vague argument by accurate measurement.

Let me give you a brief account of Harvey's three visits to the Continent, as the influence of foreign travel upon his lifework is not always fully recognized.

I suppose Scotland at that time (as occasionally to-day) was regarded by the English as a foreign land. Harvey was with the Court when his Royal employer, Charles I, was crowned at Holyrood in 1633, and he came north again in 1634 and 1641.

But those Scottish journeys were so well described by Sir Henry Wade in a recent Harveian Oration¹ that I shall concentrate on the Continental wanderings, so significant in the colourful life of William Harvey.

*Oration to the Harveian Society of Edinburgh, met in the Royal College of Physicians of Edinburgh on June 15, 1956.
¹ Wade, Henry, *Edinb. med. J.*, 1938, 45, 761.

Student Days at Padua

The wandering physician is a familiar figure in history. Hippocrates, Galen, Paracelsus, and others were never very long in one place. The founders of the Edinburgh Medical School drew their inspiration from Leyden; and Sir William Osler, himself a mobile professor, was wont to say that permanence of residence, good for the pocket, was bad for the brain.

Harvey was fully aware of the advantages of study abroad, and it was fortunate for him that after he had taken his degree at Cambridge his father was eager to send him to the Continent and could well afford to finance such a venture. The choice of Padua as his postgraduate school was probably influenced by the fact that John Caius had studied there. To Padua, then, at the age of 19, William Harvey went, taking his degree in 1602, and, as representative of the English "nation," leaving his "stemma" or coat of arms, which was discovered by Professor George Darwin in 1892, in the cloister surrounding the old quadrangle of the University.

Unfortunately Harvey kept no diary, or, if he did, it has long since disappeared. Accordingly, in order to reconstruct for ourselves the Padua of that day we must refer to the records of contemporary travellers.

Boorde, Lithgow, and Coryat

Half a century before Harvey, the agile and versatile Dr. Andrew Boorde (or Borde), he who wrote the first medical book in English to be printed in England, *The Breviarie of Health*, in 1547, had journeyed far and wide, and had written *The First Boke of the Introduction of Knowledge* (1542), which may be regarded as the first Continental guide-book, a lively and informative account which is still well worth reading.

Another early traveller, not a medical man, was the Lanark-born William Lithgow, "lugless Willie," whose ears had been cut off because of a youthful misdemeanour. His book entitled *Rare Adventures and Painful Peregrinations*, 1632,² was very widely read in its many editions, although his information is not always accurate or credible.

More interesting than either of those, and more close to the time of Harvey, was Tom Coryat, son of the Rector of Odcombe, in Somerset. His was one of the most fascinating books of travel, under the title *Coryat's Crudities, Hastily Gobbled up in Five Months' Travels*, etc., and dated 1603, the year after Harvey left Padua. Coryat's description of Padua is interesting, although of course he had no special interest in the medical school. Venice he regarded as the most beautiful of all cities, "The richest paragon and Queen of Christendom," he called it. From there he walked all the way home, about a thousand miles, in one pair of shoes, which he hung up in his father's church, and there they remained for over a century. The exploit is recorded in verses contributed by his friends to the preface of his book. One of them wrote of Coryat,

How he did go at least nine hundred mile
With one poore paire of shooes, saving alone-a
He onely once did sole them at Verona
So that it grew a question whether
The shooes or feete were of more lasting leather.

Coryat mentions the Bills of Health, which, as we shall see, caused Harvey so much annoyance, and he may have

² The full title is: "The Totall Discourse, of the Rare Adventures, and painefull Peregrinations of long nineteene Yeares Travayles, from Scotland to the most Famous Kingdomes in Europe, Asia, and Affrica."

³ "Coryat's Crudities, hastily gobbled up in five moneths travells in France, Savoy, Italy, Rhetia commonly called the Grisons country Helvetia alias Switzerland, some parts of high Germany and the Netherlands: Newly digested in the hungry aire of Odcombe in the County of Somerset, and now dispersed to the nourishment of the travelling Members of this Kingdome."

been the first to introduce into England forks and umbrellas.⁴ He wrote, "The Italians cannot endure to have their food touched with the fingers, and do always use a little fork, of iron or steel or sometimes if they are gentlemen, of silver. Many do carry things they call umbrellas that minister shelter against the scorching sun." But let us return to Harvey.

There can be no doubt that the years in Padua had a profound influence upon his career. His teacher, Fabricius of Aquapendente, was a worthy successor of Vesalius, Colombo, and Fallopius. The work of Fabricius on the valves of the veins may well have initiated in the mind of young Harvey that train of thought which led to so spectacular a discovery.⁵

During the twenty-five years or so following his return from Padua, Harvey was busily engaged in London, as physician to St. Bartholomew's Hospital (1609), and in private practice, as Physician to the King, and as Lumleian Lecturer to the College of Physicians (1615). His title, be it noted, was that of Professor of Anatomy and Surgery. This period culminated in the publication of his book in 1628.

The Second and Third Continental Journeys

Harvey's second Continental journey took place in 1630, when he was chosen to accompany a wealthy young nobleman, the Duke of Lennox, on a grand tour of France and Spain. It was hoped to include Italy, but the visit was cancelled on account of plague. Of this tour there exists only the scanty detail contained in a letter from Harvey to Lord Dorchester. He writes from Spain, in a letter which reveals his inquiring mind, "We could scarce see a dog, crow, kite or raven or any other bird or anything to anatomise; only some few miserable people the relics of war and plague where famine had made anatomies before I came."

A few years later, in 1636, Harvey had the good fortune to make his third Continental journey, and of this tour we have a clearer record, revealed in a number of letters which came to light in 1911: letters from Harvey to Basil Fielding, afterwards Earl of Denbigh, who was, at the time, English Ambassador at Venice.

After he performed the famous post-mortem examination of Thomas Parr, the old countryman aged, or said to be aged, 152 years, who was brought from Shropshire to London by the Earl of Arundel, Harvey was invited by the Earl to accompany him on a political mission to Vienna, ostensibly an embassy, but also an expedition to acquire art treasures for the King. Harvey, a patron of the arts, and an expert critic, readily assented.⁶ The party left England on April 7, 1636, sailing from Margate in the ship *Happy Entrance*, and landing in Holland. They proceeded up the Rhine, then up the River Main, "in a boat drawn by nine horses." It was a leisurely journey, and Harvey had plenty of time to make observations on strange trees and plants, and would often wander so far that the Ambassador was angry with him, as there was real danger from thieves and wild beasts. Coryat, who had travelled by the same route, records the prevalence of robbers, and advises all travellers to carry a stout stick. At length they reached Frankfurt on May 3, and then Nuremberg May 11 to 22, where Harvey demonstrated the circulation of the blood to the Professor of Anatomy, Caspar

⁴ "Coryat's Crudities": *A Continental Tour in 1608*, by Douglas Guthrie. University of Edinburgh Journal, Autumn, 1943.
⁵ The Hon. Robert Boyle had an interview with Harvey in later years, and was told that this was so. It is mentioned in one of the rarest of Boyle's works—*Disquisition about final causes of natural things*, 1688, p. 159.

⁶ The journey is described by William Crowne, a member of the expedition, in a little book of 70 pages which is now rather rare. It is entitled "A true relation of all the remarkable places and passages observed in the travels of the Rt. Hon. Thomas Lord Howard, Earl of Arundel and Surrey, Premier Earl and Earl Marshall of England, Ambassador Extraordinary, etc. (1637). A more modern and extensive account is given in *The Life, Correspondence, and Collections of Thomas Howard, Earl of Arundel*, by Mary S. Hervey (1921), Ch. XXVI, pp. 357-395, which describes "The Great Embassy to Germany."

Hoffmann, who had been his fellow-student at Padua, but who was among those who misunderstood the discovery, saying that it was "contrary to the wisdom of Nature." "I beg you to observe," Harvey had written, "and to see the thing with your own eyes." Nevertheless Hoffmann remained unconvinced, and asked such stupid questions that eventually Harvey laid down his knife and left the theatre.⁷

Harvey in Quarantine

The second misfortune of this tour was of an entirely different nature. On the return journey from Vienna, Harvey had left the main party at Augsburg with the intention of travelling to Italy. He went by way of Munich and Innsbruck, then over the Brenner Pass, and on to Treviso on August 3, where, he writes, "I have received a very unjust affront." It was alleged that he had passed through a plague-stricken area without having his Bill of Health or "sede," the all-important passport, duly countersigned and cleared. Harvey, detained for this reason, writes to Lord Fielding, who expects him at Venice, "I am fallen into the hands of a base and evil people, and while they delight to exercise their tyranny, I am to lie in the open fields for God knows how long, and I fear it will do hurt to my health."

As a result of this letter Harvey was offered a roof and a bed, but this he declined, as he said "such offers were unseasonable, like physick when a man was dead"; and his next letter, on August 16, to Lord Fielding is even more doleful. "Their manners and cruelty have been shameful and I now have a sciatica that maketh me lame. I have never longed for anything so much as to be gone from this base place." It is difficult to understand why Harvey, then aged 58, a medical man, and a person of importance, should have been singled out and virtually imprisoned in quarantine for about a month. England was not held in high esteem on the Continent at that time. Perhaps the delay explains why Harvey did not return to visit his old friends at Padua. Besides, the thirty-five years which had elapsed since his student days must have brought many changes, and it is often very depressing to revisit the old scenes of one's youth.⁸

Eventually set free, he did reach Venice, where his reception was very different, as the next letter, dated from Florence on September 7, states, "I can never forget your many favours and your kind entertainment at Venice." He was joined at Rome by his friend Dr. George Ent in October, and although we have little knowledge of the homeward journey, we are told that Harvey visited the School of Anatomy at Leyden, that he had a rough crossing from Rotterdam, and that he landed at Deal on December 27, 1636.

Aubrey, who is at best a gossipy biographer, states that Harvey made a fourth journey to the Continent in 1649, but of this we have no certain knowledge.

The Slow Acceptance of Harvey's Discovery

Now let us turn to another aspect of Harvey's activity—namely, his work on the circulation of the blood, and the events which followed its publication. The foregoing references to Harvey as a traveller may be regarded as a fitting introduction to the adventures of his famous book and the curiously tardy acceptance of his great discovery.

⁷ The most significant reference of recent date to this journey is the paper by Sir D'Arcy Power on "A Revised Chapter in the Life of Dr. William Harvey, 1636," in *Proceedings of the Royal Society of Medicine*, Sect. Hist., 1917, x, 33. Sir D'Arcy suggests that the demonstration to Hoffmann may have taken place on the homeward journey, when Nuremberg was again visited, from November 10-13.

⁸ *Eleven Letters of William Harvey to Lord Fielding, June 9-Nov. 15, 1636*. Purchased from the Earl of Denbigh and presented to the Royal College of Physicians by Sir Thomas Barlow, Bt., President: October 18, 1912.

Comments upon the letters are given in a chronicle of the family of Lord Fielding called "Royalist Father and Roundhead Son, being the memoirs of the first and second Earls of Denbigh, 1600-1675," by Cecilia, Countess of Denbigh (1915). Chapter VI, pp. 111-121, deals with "The Tribulations of Doctor Harvey."

I do not propose to refer in detail to his second work, *De Generatione*, 1651, dealing with those researches which arose quite naturally as a sequel to his work on the circulation, which occupied many years and which was eventually published in 1651, at the urgent request of Harvey's friend Sir George Ent. This work advanced embryology as far as that science could have gone without the aid of the microscope. Harvey, who laid great stress upon comparative anatomy, tells us that he used "a magnifying glass" to study the prototype of the heart in insects, shrimps, and other creatures, but he was not familiar with the microscope. It was left to Malpighi in 1661, and to Leeuwenhoek in 1674, to supply proof of the existence of the capillaries which Harvey presumed to exist as "pores in the solid parts, permeable to the blood, connecting the arteries with the veins" (*De Motu*, Ch. XI).

Harvey's masterpiece, the *Anatomical Disquisition on the Motion of the Heart and Blood in Animals*, often called for short, *De Motu Cordis*,¹⁰ published at Frankfurt in 1628, was printed on poor paper and was full of printers' errors. As an example of book production it ranks very low, but as a clear, brief, and logical account of the author's researches it is beyond praise.

The first English translation appeared in 1653 and the first Dutch edition in 1650. Other translations were much later products—German 1878, French 1879, Russian 1927, Danish 1929, and Spanish 1936. I can find no translation into Italian—a strange yet significant fact.

You will recollect how Harvey begins his "Disquisition" with a concise review of the existing knowledge, although, as he tells us in the preface, he has no intention of making a large volume. "I teach anatomy," he writes, "not from books but from dissections: not from the positions of philosophers but from the fabric of nature." Then he proceeds to defend the three propositions of his thesis, and to develop and expound the argument which you all, as Harveians, know so well.

As we read this little classic, the most important medical book every written, we find the discovery so plainly set forth that we marvel why it was not immediately accepted. The philosopher Thomas Hobbes said that Harvey was one of the few pioneers who saw his discovery universally accepted during his lifetime; but this is hardly true. Indeed, the real significance of Harvey's work in the practice of medicine was not apparent for at least two centuries, and it took about fifty years before those best qualified to judge, the anatomists and scientists, appreciated its significance.

Delay in Publication

Why this long delay in the acceptance of a truth so obvious? For the first part of the delay the discoverer himself was responsible. Harvey had not rushed into print. Darwin waited 20 years, Jenner 18 years, and Lister 8 years before publishing their results. Their work was not fully appreciated for many more years. Lind's recommendations for the prevention of scurvy were ignored by the Royal Navy for 43 years.

Harvey, from the first, made no secret of his discovery. He lectured on the circulation, as Lumleian Professor to the College of Physicians, for 12 years before stating his views in print. Thus when the book did appear some of his pupils and friends were ready to accept the new teaching, but others regarded Harvey as a crank. As Aubrey remarks, "Twas believed by the vulgar that he was crack-brained and he fell mightily in his practice."

It is sometimes said that Harvey's discovery was a mere accident, that all the evidence was there, awaiting the genius who would grasp the opportunity of assembling the facts.¹¹ There could be no greater error. Since student days at

¹⁰ *Exercitatio anatomica de motu cordis et sanguinis in animalibus*.

¹¹ The full story is admirably discussed in a series of papers by the late Dr. H. P. Bayon, entitled *William Harvey, physician and biologist: his precursors, opponents and successors*, in *Annals of Science*, 1938-9.

Padua, and perhaps even then, Harvey had been continuously at work building up his argument and confirming each step by observation and experiment. His novel methods of investigation, so revolutionary in his day, and so different from the bookish methods of his predecessors, were in themselves deterrents to the acceptance of his results. It cannot be too strongly stated that Harvey had not only discovered the circulation of the blood, he had proved the efficiency of the scientific method in medical research, a proof which was to be stated even more clearly by Claude Bernard more than two centuries later. The discovery of a principle is always more important than the discovery of a fact, as it leads to further advances. Ehrlich's discovery of chemotherapy outshone his introduction of salvarsan as the remedy for syphilis. Lister's use of the antiseptic method was much more outstanding than was his use of carbolic acid, because here was a new principle, not just a new remedy. That is one reason for the long delay in belief in the circulation of the blood.

Tenacity of the Old Idea

And there is this further point—not only did the new discovery arise from the application of new methods of research; it could be accepted only by those who were prepared to discard the old beliefs. Before the new idea could be approved it was necessary to disprove the old. And at that time the dead hand of Galen still lay heavy upon medical science, if indeed it could be called "science." Prior to Harvey's day it was known that the blood moved, but with an ebb-and-flow motion in the veins, like the tides of the sea. The heart was not regarded as a pump; it drew to itself the blood as it dilated; in other words, diastole, not systole, was the important movement. The liver, not the heart, was the central organ concerned in the production and movement of the blood. It was thought that there were two kinds of blood—the dark variety, which originated in the liver and carried nourishment to the body, and the brighter-coloured blood, which came from the heart and supplied heat. The blood conveyed three kinds of spirit—natural, animal, and vital. The ideas were all very obscure and very hypothetical. It is to the credit of Servetus, the only real predecessor of Harvey, that he discovered that natural spirit and animal spirit were one, and that they became transformed into vital spirit in passing through the lungs.

Harvey himself stated that the cause of the change of colour was that the blood was "strained" as it passed through the lungs, just as earlier anatomists thought that the blood was strained, and thus altered in some way, as it oozed through the pores between the right and left ventricle of the heart. The foetal circulation was also ill understood, and Botallo (of Paris) in 1565 had added to the confusion by describing as a normal appearance a persistent foramen ovale which he found in an adult body.¹² It is true that Vesalius had shown that the septum between the ventricles was not porous; but the new anatomy of Vesalius had not been entirely accepted, and ancient textbooks with the Galenic descriptions were still in use. Many contemporary anatomists—Alexander Read at Barber Surgeons' Hall, Crooke and Collins at Cambridge, and Winston at Gresham College¹³—simply ignored Harvey's doctrine, and continued

¹² Castiglioni, A., *A History of Medicine* (Eng. trans.), New York, 1941, p. 428; Willins, F. A., and Dry, T. J., *A History of the Heart and Circulation*, Philadelphia, 1948, p. 45. (A pioneer in the anatomy of the foetus was Giulio Cesare Aranzio (1530-89) of Bologna.)

¹³ *The Reception of Harvey's Doctrine of the Circulation of the Blood in England as exhibited in the writings of two contemporaries*, by Sir Humphry Rolleston, in *Essays on the History of Medicine*, Sudhoff 70th Birthday Volume (1924). The two contemporaries are Winston and Power, and they illustrate the two extreme points of view. Thomas Winston, 1575-1655, repeats the description of pores in the septum which "cannot be seen in dead bodies because they fall together," but which serve to "strain" the blood. Henry Power, 1623-68, on the other hand, repeated and confirmed Harvey's experiments, and showed that "the partition wall is firm and compact, and absolutely devoid of any perforations."

to teach along the well-worn lines, refusing to abandon the old ideas. Others were actively opposed to the new explanation, for various reasons, and often for very little reason at all.

For example, there were the clinicians, the so-called "practical" folk, who asked what was to be the use of this teaching. Did it really matter which way the blood moved? Had the so-called discovery saved any lives? According to the loquacious Dean, Gui Patin, of Paris, it was simply "an ingenious piece of fiction." This demand for a clinical outcome of his discovery was anticipated by Harvey when he wrote, "Many questions in medicine, physiology, pathology, and therapeutics can be answered by the truth we have declared, on which I might expatiate, but my whole life would not suffice for the completion of the work." More than once he refers to his "Medical Anatomy, or Anatomy in its application to Medicine." Perhaps this manuscript, like his notes on the Generation of Insects, was lost when the College library was destroyed by fire or when his rooms in Westminster were raided by a mob during the Civil War: "Rapacious hands stripped my house of its furniture, and, a subject of far greater regret to me, my enemies abstracted from my museum the fruits of many years of toil." Those were calamities which he greatly deplored.

Thus was the propagation of Harvey's doctrine delayed, a very different state of affairs from that which obtains to-day, when the discovery of a new antibiotic reaches the practitioner almost in advance of its time and with a speed which may even be dangerous.

Early Printed Criticisms

One of the earliest critics of Harvey to state his views in print was James Primerose (Primrosius), a physician of Hull who had studied under Riolan in Paris, and who evidently wrote for the sake of writing, upholding the older views in a work printed in 1630.¹⁴ He would probably have attracted little attention had he not been answered in a thesis at Leyden, *De circulatione*, by Roger Drake, a Cambridge student who upheld Harvey's views. Drake was supported by one of his teachers, Hendryk du Roy (Henricius Regius), of Utrecht, who entitled his work "A sponge to wash away the dirt of Primrosius,"¹⁵ which called forth from Primerose a reply headed, "An antidote to the poisonous sponge of Henricius."¹⁶ Both are dated 1640.

Another antagonist of Harvey was Emilio Parigiano (Parisianus), of Venice, who was answered with more dignity by Dr. George Ent, Harvey's lifelong friend, in his work, *An Apology for the Circulation of the Blood*, 1641. Harvey took no part in those controversies, well knowing that none of the critics had taken the trouble to really understand his views, and that they based all their arguments on the old conception. The only critic who received a detailed reply from Harvey (a reply printed in English editions of *De Motu Cordis*) was Jean Riolan, of Paris, who had been his fellow-student in Padua. When Riolan remained unconvinced Harvey wrote a second letter in rather stronger terms. The duel of words ended in 1690, when Pierre Dionis, a supporter of Harvey and a teacher of his doctrine, assumed the Chair of Anatomy in Paris.

The famous anatomist Thomas Bartholin, 1616-80, was the first to introduce the knowledge of the circulation into Denmark,¹⁷ but he did not do so wholeheartedly, as he described in his textbook, *Institutiones Anatomicae*, 1641, both the old and the new view, apparently leaving the reader to form his own judgment. Harvey's views are contained in a Supplement by Jan de Wale (Walaesus), of Leyden.

Spain was one of the last countries to accept the new knowledge. It has been said that Harvey's work was banned by the Inquisition, but I have been unable to discover the source of this statement. Even in the eighteenth century, Galenic anatomy was still taught in Spain, and Professor Izquierdo, who in 1936 undertook the first translation of *De Motu* into Spanish, tells us that while Sobremonte, in 1649, and Morello, in 1678, accepted and wrote upon the Harveian view, Piquer, of Valencia,¹⁸ as late as 1751, was antagonistic, and still taught the older idea. Izquierdo also states that the first book on physiology written and printed in the New World in 1727 was the *Cursus Medicus Mexicanus*, by Salgado, of Los Angeles.¹⁹ It gave "a confused idea of the circulation," and probably the author had never seen Harvey's treatise. Nevertheless, Salgado's work was still used as a textbook at the end of the eighteenth century.

Harvey's First Supporters

From those critics, most of them slaves of the age-long teaching, and sworn Galenists, it is a relief to turn to those who were ready to free themselves from the influence of Galen, and to accept the new view regarding the circulation, or at least to ascertain for themselves by experimental methods whether it could be true. Of those supporters, one of the first was Robert Fludd, a man four years younger than Harvey, who was a leader of the so-called Rosicrucians, and whose mystical works were printed in Frankfurt by William Fitzer, who also published Harvey's masterpiece.²⁰ In his *Integrum Morbium*, of 1631, Fludd makes a favourable reference to the discovery of the circulation.

René Descartes, in his *Discours de la Méthode*, 1637, accepted Harvey's principles, and so did Francis Glisson, whose classic work on the liver, *Anatomia Hepatis*, 1654, reinstated the liver in correct perspective. As early as 1639 the renowned Francis de la Boe (Franciscus Sylvius) was giving demonstrations of the circulation, in dogs, to his class at Leyden.

Werner Rolfinck, of Jena, was a well-known anatomist who in 1641 believed and taught that the blood circulated, while Nathaniel Highmore introduced the new discovery into his book on anatomy, dedicated to Harvey, which gives one of the earliest descriptions of the circulation.²¹

Sir Thomas Browne, whose view must have carried weight, said that he regarded Harvey's discovery as better than the discovery of America, and few to-day would disagree with that opinion.

Of course the most helpful of the critics were those who took the trouble to repeat Harvey's experiments rather than merely argue about them. Such a one was Hermann Corning, of Helmstadt, whose book, *De Sanguinis Circulatione*, 1643, brought strong support to the doctrine, as also did the work of Henry Power, one of the first to use the microscope, whose experiments are described in his *Microscopical Observations on the Lamprey*, 1664 (see footnote 13). This, surely, was the only true method of appraising Harvey's work, by repeating his experiments, by applying to his results the method which he himself used to secure them.²²

No reference to Harvey's discovery is complete without some mention of the controversy regarding priority which continues unabated to this day, especially, perhaps, in Italy. All manner of absurd claims have been made, often on very slender evidence: that the circulation was known to the ancients—to the early Chinese and to Hippocrates, to

¹⁸ Piquer, Don Andres, *Institutiones Medicae*, Madrid, 1751.

²¹ Highmore, Nathaniel, *Corporis humani disquisitio anatomica in qua sanguinis circulationem . . . prosequitur est*, 1651.

²² There is an unpublished manuscript (Sloane MS., 1543) in the British Museum dated 1652 in which Henry Power describes experiments to demonstrate the circulation, performed by Harvey in 1614, two years before the usually accepted date of the discovery.

Arabian physicians and to a numerous band of anatomists, mainly of Italian birth, who lived shortly before the time of Harvey. The confusion of ideas was increased by frequent misinterpretation of the word "circulation," which at first simply denoted movement. Everyone who has driven a car in France must be familiar with the policeman swinging his baton and urging the traffic to move on. "Circulez, circulez," is his order.

Late Claims for Priority

It is sometimes forgotten that nothing was said of other claims to the discovery until Harvey's view was beginning to meet with general acceptance, about 1650. Not one of the earlier critics claimed that the circulation of the blood was already known, or had been discovered by someone else before Harvey.²³ The claim of Cesalpino was mentioned for the first time in 1655 by Nardi. There is a statue of Cesalpino in Rome, proclaiming him to be the discoverer of the circulation of the blood. This claim was followed by allegations that the discovery was made before the time of Harvey by Colombo, Ruini, Servetus, and others. It is true that Servetus had discovered the lesser circulation, as also had Colombo and the thirteenth-century Arab physician Ibn Nafis, whose work has come to light recently. But both Servetus and Colombo adhered to the pre-Vesalian anatomy: they believed that the blood was prepared in the liver, and then flowed through the heart to the veins.

The interest of Servetus in the blood stream arose from his desire to find a habitat for the soul. The physiological work of Servetus was first quoted by William Wotton in 1694²⁴; it had attracted no attention until then. The trend of Servetus was to theology rather to physiology, and it was on account of his Unitarian views that he suffered martyrdom in 1551. Edinburgh University, possessing one of the three surviving copies of his *Restitutio Christianismi*, has a peculiar interest in Servetus. Further discussion of those claims for priority of discovery, which continue to this day, would carry us far from the present theme—namely, the reasons for the long delay in the acceptance of the circulation of the blood.

Conclusions

An attempt has been made to explain this delay, which arose from a variety of causes. These may be summarized in conclusion as follows:

1. The so-called "practical" physicians of Harvey's time, who demanded that every new discovery should be immediately applicable as a life-saving or health-restoring measure, regarded the circulation of the blood as a matter of academic importance only.²⁵
2. The refusal to abandon the fixed age-long traditions, dating even from the days of Galen, prevented many from accepting, or even from studying for themselves, a conception so contrary to current opinion.
3. The new doctrine of the circulation involved not only a change of view regarding the motion of the heart and blood but also a revolutionary change in methods of investigation; a completely new outlook; the replacement of scholastic argument by direct observation and experiment. The change was so staggering that it could hope to gain acceptance only by slow degrees.

The delay in the acknowledgment of the circulation of the blood was a phenomenon peculiar to the age in which Harvey lived.

²³ Johannes Antonides Van der Linden, 1609-64, a famous Dutch physician, did all he could to discredit Harvey, and stated that it was George Heriot, 1563-1624, jeweller to James VI of Scotland, who first suggested to Harvey the idea of the circulation of the blood.

²⁴ Wotton, William, *Reflections upon Ancient and Modern Learning*, 1694.

²⁵ At first Harvey's doctrine exercised a more profound effect upon biology than upon medicine; it formed a starting-point for a vast number of further biological investigations.

Few were prepared to write, as Abraham Cowley did:

Thus Harvey sought for Truth in Truth's own book
The Creatures which by God himself was writ
And wisely thought 'twas fit
Not to read Comments only upon it
But on th' Original itself to look.

The experimental method of investigation, as novel to Harvey's critics, is now familiar to the most junior medical student. It has long since ceased to be a matter for argument. Moreover, increased facilities of transport and communication have made it possible for a new discovery to be known throughout the world in a matter of hours. Within a few weeks, or months at most, each addition to the existing knowledge is examined and assessed at its true value. Indeed, the speed of integration of new discoveries and new ideas has become almost terrifying. Thus, it is not only right and proper, but even salutary, for us to turn back the pages of history, to recall Harvey's experience, to assess his achievement, at this Festival when we are met to honour his memory.

Reports of Societies

HOW MANY HOSPITAL BEDS?

A FRESH APPROACH

The capital cost of providing one new hospital bed in Britain is now about £4,000. This fact was the background to two papers read to the Medical Section of the Royal Statistical Society at a meeting at Westminster Hospital on February 26. Dr. A. T. ELDER, deputy C.M.O., Ministry of Health and Local Government, Northern Ireland, described the use of "case-load" studies in estimating a community's need of beds. Mr. D. J. NEWELL, who is a lecturer in statistics at Durham University, dealt with the question of beds for emergency admissions, and was able to offer a novel solution to this knotty problem.

"Pooled Discharge Wards" and Emergency Beds

How many beds should a hospital keep for emergencies? What figure most nearly combined maximum preparedness with maximum economy? Mr. NEWELL had studied emergency admissions at a non-teaching hospital in the North-eastern Region. The number of such admissions, he said, followed a well-known statistical pattern, the "expected" level remaining remarkably constant on week-days throughout the year and only falling slightly on Sundays. Using this finding as a basis, he was able to show that each day a "unit" must set aside two more beds than the expected number of daily emergency admissions if it was to keep the chance of refusing a patient (or putting up an extra bed) below 5%. If, for example, a hospital had 10 units—and for this purpose male and female wards must be counted separately—each of which expected an average of two emergency admissions a day, then the hospital must set aside 40 beds every day. In these circumstances, on an average day about half the beds would be wasted. These calculations assumed that emergency admissions were not interchangeable between the units. But if all the emergency admissions, regardless of sex and specialty, went into a special ward set aside for the purpose, it would need only 22 beds to cope with the "expected" figure of 20 admissions a day—a daily saving of 18 beds.

Mr. Newell went on to point out the obvious disadvantages of such a "pooled admissions ward"—for example, the difficulty of providing special facilities and methods of nursing for all types of emergencies, and the dislocation involved in moving a patient at what was perhaps a critical stage in his treatment. In its place Mr. Newell suggested a

"pooled discharge ward." He calculated that in any hospital perhaps 10% of patients at any given time were known to be ready for discharge within a few days. If a ward were to be set aside for such patients, then the procedure would be that as soon as an emergency patient was admitted to the hospital a place would be found for him in the appropriate ward by transferring a patient to the "discharge ward." This ward would not need the same special facilities as would an admission ward; but it would need to have provision for male and female patients in any proportion. On a day when emergency admissions were normal they would be balanced by normal discharges from the discharge ward, but if there was an excess of emergencies a few patients from the discharge ward would have to go home a day or two earlier than planned. The effect of the scheme would be to transfer the difficulties and uncertainties involved in the admission of emergency patients from one end of their stay to the other, with, as Mr. Newell claimed, many advantages from the point of view of both the patient and the hospital. Mr. Newell emphasized that many administrative difficulties remained to be solved before such a scheme could be put into practice; in particular the discharge ward must not be made a dumping ground for patients who would not go home.

"Case-load" Studies

Dr. ELDER began by describing some of the studies made in Britain during the past 20 years to determine the ideal number of hospital beds per head of population. Estimates varied widely, but many of the differences were due to differences in definition. Taking "acute" beds only, and excluding those in maternity departments, there was some measure of agreement on a figure of 6-7 beds per 1,000 of population. The ideal figure for a particular community could only be determined, however, by studying existing hospitals and attempting to assess how far they met the community's needs. This involved a certain amount of mathematical juggling with average lengths of stay, turnover intervals, percentage occupancy, and lengths of waiting-lists. Dr. Elder then proceeded to give the results of some case-load studies he had made on these lines in Northern Ireland. The calculated requirements did not always agree with those made on general grounds by the people on the spot, and Dr. Elder gave examples to show how illuminating the comparison was in particular instances. The method was still in its infancy, but Dr. Elder felt that it had much to offer. An extension of the problem was to forecast the needs for 10 years ahead; this was obviously very much more difficult, particularly, for example, in the fields of tuberculosis and maternity. The demand for maternity beds depended largely on what length of lying-in was thought desirable at any given time.

In the discussion after Dr. Elder's paper many speakers pointed out the limitations of the "case-load" method of analysis: the differences between specialties, the uncertainty of what is meant by the length of a waiting-list, and so on. It was stressed that in forward planning flexibility offered the best chance of economy; in particular the provision of "bi-sexual" wards was urged.

DISORDERS DUE TO HEAT

Some new ideas on the role of water and salt in the production of heat cramps and heat exhaustion were put forward by Dr. W. S. S. LADELL at a meeting of the Royal Society of Tropical Medicine on February 21. Dr. Ladell was until recently in charge of the Hot Climate Physiological Research Unit at Lagos in Nigeria.

Dangers of Salt

Heat exhaustion and heat cramps were probably due to the strain of extra effort in a person chronically slightly

short of water, he said. At one time salt deficiency was thought to be the major factor, but now he believed that water debt—in people who consistently drank too little—was the predisposing cause. When it was hot, extracellular fluid was lost first. About two litres could be spared before the intracellular water was affected. The loss of much extracellular water made a person susceptible to heat exhaustion, while depletion of intracellular water was definitely dangerous.

The role of salt was complex. In the state of water debt, if water were taken but no salt, the intracellular fluid would be maintained and any deficit fall on the extracellular fluid; if, however, salt were taken, particularly in the absence of enough water, the intracellular fluid volume fell and the extracellular fluid volume was maintained at the expense of the intracellular fluid. This intracellular dehydration led to collapse. Treatment consisted in giving plenty of water and a controlled supply of salt; excess of salt would deplete the intracellular fluid and make the patient worse. Therefore in persons in slight but chronic water debt extra salt should never be taken, except in a sudden emergency demanding an extra output of sweat, and then only if ample water was drunk at the same time. Moreover, extra salt might also depress aldosterone secretion, and this could be dangerous. Man, said Dr. Ladell, had become addicted to salt as a habit, not as a necessity in the amounts normally consumed.

Tropical Asthenia and Heat Hyperpyrexia

Tropical anidrotic asthenia was seen at the end of the hot season; there was no collapse, but lack of energy, failure to sweat properly, and polyuria. The symptoms could be explained, first, by failure of the renal tubules to respond to antidiuretic hormone, which would lead to excessive production of that hormone, and this might suppress sweating. Secondly, there was diminished activity by the adrenal cortex, which resulted in electrolyte imbalance and asthenia. The condition was often associated with prickly heat or lichen tropicalis. The only satisfactory treatment was prolonged rest in the cool.

Heat hyperpyrexia, however, seemed essentially a physiological, not a pathological, process. Its aetiology was not clearly understood, but it might be related to "sweat-gland fatigue" (which, being reversible, was not true fatigue). Experiments had shown that the response of the sweat glands in the normal person became progressively less as the rectal temperature rose, and a critical point could be reached—for instance, after hard work in the heat, or if physiological cooling was prevented by too many clothes or lack of ventilation—at which sweating stopped and cooling ceased, with rapidly fatal results if untreated. Treatment consisted in cooling the patient by tepid sponging, wrapping in wet towels, and the use of fans to accelerate evaporation.

In the discussion Lieutenant-Colonel J. H. WALTERS quoted a series of cases of heat hyperpyrexia seen in Iraq and Kuwait. Some of the patients were middle-aged pilgrims or fat coolies, subject to great heat stress, and some were men with arsenical dermatitis after treatment for syphilis; in the latter sweating was inhibited. There might be an element of acute anoxia in heat hyperpyrexia, he thought, which would indicate the use of oxygen in treatment. In some patients who recovered there was evidence of serious damage to the nervous system. Major-General A. SACHS recalled the pathological findings in hyperpyrexia—haemorrhages into the suprarenals and cerebellum and circulatory collapse.

Mr. GEORGE WILSON, librarian of the Manchester University medical library, has been made an honorary member of the Manchester Medical Society. He has been associated with the Society's library, which forms a part of the university medical library, for more than forty years.

Correspondence

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

Erythromycin, Spiramycin, and Oleandomycin

SIR,—The time lag between the introduction of some of the newer antibiotics into the United States and into this country has not been without its advantages. We have been able to profit from American experience and possibly to avoid some of the American pitfalls. Especially has this been the case with erythromycin. The unrestricted use of erythromycin in one hospital in the United States was attended by the appearance of resistant strains within a month, and after five months the carriage rate for erythromycin-resistant staphylococci had reached 70%.¹ From other centres two years after the introduction of the drug 7% to 10% of hospital staphylococci were reported to be resistant.^{2,3} This experience does not appear to have been paralleled in this country. After 2½ years of use in the United Kingdom there have been, as far as we are aware, only two isolated reports of the development of erythromycin-resistant staphylococci.^{4,5} A variety of factors have no doubt contributed to our more favourable experience, among them stricter limitation of use, adequate dosage over short periods only, and the avoidance of local preparations. Thus in this country erythromycin remains an extremely valuable antibiotic, and, if used with intelligence and discretion, there seems to be no reason why it should not continue to be so for years to come.

It is therefore disturbing to find that there is a danger that such a valuable therapeutic weapon may be struck from our hand before we have had a chance to put it to full use. It has been reported that at least some degree of cross-resistance exists between erythromycin and both spiramycin and oleandomycin, and there is also evidence that the latter antibiotics are less effective than erythromycin.⁶ Spiramycin and oleandomycin have now been made generally available. In one commercial preparation oleandomycin is combined with tetracycline in the ratio of one part to two. Finland and Wilcox⁷ have shown that the combining of two antibiotics does not prevent resistance in the presence of an organism which is resistant to one of them. About 10% of hospital staphylococci are resistant to tetracycline, and it thus seems likely that the use of this combined preparation against these will result in the exposure of organisms already tetracycline-resistant to low concentrations of oleandomycin, encouraging the development of oleandomycin-resistance. Under these circumstances the very organisms for which erythromycin may be specifically needed—those resistant to the tetracyclines—may, because of cross-resistance between oleandomycin and erythromycin, be rendered erythromycin-resistant.

There would thus appear to be a great need for controlled trials to determine which, among the antibiotics erythromycin, spiramycin, and oleandomycin, is most effective, and for comparative investigations as to which is least likely to induce drug resistance. Until further evidence on these and other points is available the widespread use of all three antibiotics would appear to be fraught with danger, and there is likely to be a very real risk that in extending our antibiotic armamentarium we are in fact reducing it.—We are, etc.,

ABO Blood-group Substances in Gastro-intestinal Tract

SIR,—Dr. C. A. Clarke and his collaborators (*Journal*, September 29, 1956, p. 725) discuss the possible connexion between the sites of production of ABO substances in the gut and the incidence of ulcerative diseases in these regions. In this respect they refer to some of our work on guinea-pigs—namely, that gastric mucins show strong anti-agglutination activity whereas intestinal ones do not.^{1,2} We feel it worthy of note that a similar situation appears to exist in man: Witebsky and Neter³ and Satoh⁴ both find blood-group activity to be strongly displayed by the mucins of the stomach, and to decrease progressively in lower regions of the gut.

A chemical interpretation of these observations may be attempted. Blood-group substances contain several carbohydrate constituents, D-galactose, L-fucose, and the amino sugars, D-glucosamine and D-galactosamine, being the chief components. An examination of analytical data, made by three independent authors, indicates a correlation between the distribution of carbohydrate constituents and the site of mucin production in the gut. Thus, Werner⁵ and Whitehouse,⁶ using material obtained from pigs, and Satoh,⁴ working with human gastro-intestinal mucosa, all find a higher percentage of amino sugar in the mucins of stomach than in similar substances from lower regions of the intestine; Werner⁵ has also studied the distribution of D-galactose and L-fucose in such mucins, and finds the highest percentage of D-galactose in the stomach. Gastric mucin isolated by Whitehouse, moreover, was found to exhibit weak blood-group A specificity, whereas duodenal mucin was inactive.⁷ The activity of Satoh's preparations has already been mentioned.

If one compares these results with the recent findings of Côté and Morgan⁸ an explanation of the distribution of ABO activity in the gastro-intestinal tract emerges. Côté and Morgan have shown that the determinant structure in human blood-group substances apparently consists of two components, amino sugar and D-galactose. The nature of the amino sugar in this grouping seems to control the serological specificity of these substances: group A (and perhaps B and O as well) activity is conferred by D-galactosamine, type XIV pneumococcus cross-reactivity (frequently observed in derived blood-group substances) by D-glucosamine.⁹ We therefore suggest that a consideration of the D-galactose content, coupled with an evaluation of the D-galactosamine:D-glucosamine ratio (first proposed by Leskowitz and Kabat,¹⁰ may prove useful in the correlation of chemical constitution and biological activity in gastro-intestinal mucosubstances. In view of these observations it would be interesting to supplement the researches carried out by Dr. Clarke and his colleagues with a chemical study of intestinal mucins produced by secretors and non-secretors.—We are, etc.,

Material of Early Contraceptive Sheaths

SIR,—Dr. E. J. Dingwall published a short paper (*Journal*, January 3, 1953, p. 40) on a number of condoms (sheaths), dating apparently from between 1790 and 1810, found in a locked box in the muniment room of an English country house. The condoms were of three different sizes, in packets of eight. The paper contained much interesting information on the subject of early contraceptive sheaths,

but does not go into the question of the material from which these particular specimens were made, apart from stating that its thickness was 0.038 mm. (as against 0.075 mm. for a thin rubber sheath), and that it is somewhat permeable to water and to solutions of common salt. The objects are very stiff, and would have needed softening before use. This would explain Boswell's reference in his *Journal* to his dipping his "armour" in the Serpentine in the Park before using it.

One of these sheaths has now been examined by Professor J. Z. Young in the department of anatomy of University College, London. It proved to be made of a sheep's caecum. The pattern of the blood vessels in the material is clearly recognizable, and it was found possible to make similar objects in the laboratory by drying sheep's caeca on wood, curing in alum, scraping, oiling, and pressing. However, the original specimens were of rather finer texture than any Professor Young succeeded in making. It is known that some early condoms were made from the swim-bladders of fish and from various sorts of skin, and Dr. James Ziegler, of the New York University College of Medicine, has drawn my attention to two early references to the use of sheep's caeca for this purpose.

In Robley Dunglison's *A New Dictionary of Medical Science and Literature* (3rd edition, but including the preface of the 2nd edition of 1839), *Condom* is described as: "Armour, Posthocalypton, French letter, Cytherean shield, (Fr.) Baudruche, Redingote anglaise, Gant des dames, Calotte d'assurance, Peau divine, Chemisette. The intestinal caecum of a sheep, soaked for some hours in water, turned inside out, macerated again in weak alkaline ley [*sic*], changed every twelve hours, scraped carefully to abstract the mucous membrane, leaving the peritoneal and muscular coats exposed to the vapour of burning brimstone, and afterwards washed with soap and water. It is then blown up, dried, cut to the length of seven or eight inches, and bordered at the open end with a riband. It is drawn over the penis prior to coition, to prevent venereal infection and pregnancy."

In Grose's *A Classical Dictionary of the Vulgar Tongue*,² *Cundum* is defined as "the dried gut of a sheep, worn by men in the act of coition, to prevent venereal infection; said to have been invented by one Colonel Cundum." The entry adds the following interesting details: "These machines were long prepared and sold by a matron of the name of Phillips, at the Green Canister, in Half-Moon Street, in the Strand [*sic*]. That good lady having acquired a fortune, retired from business; but learning that the town was not well served by her successors, she, out of patriotic zeal for the public welfare, returned to her occupation; of which she gave notice by divers handbills, in circulation in the year 1776. Also a false scabbard over a sword, and the oil-skin case for holding the colours of a regiment."—I am, etc.,

Amphetamine Psychosis

SIR,—From time to time reports appear in the medical press of toxic reactions due to overdosage with amphetamine and related compounds. Since these drugs became available for therapy some twenty years ago there has been an increasing number of reports of psychotic illness as one of the manifestations of amphetamine intoxication. In Great Britain, however, there have been only six such reports, two of which were of psychotic illness following inhalation only. This form of toxic reaction might seem, therefore, to be rare in this country. The investigation of a case of a paranoid psychosis occurring after ingestion of the contents of a "methedrine" (methylamphetamine hydrochloride) inhaler led me to study the matter more fully. Forty-two such cases were discovered with comparative ease. The analysis of the physical and mental features of the

intoxication, the family and personal histories of the patients, their personalities, etc., together with biochemical studies of the excretion of the drug in the urine, can be seen elsewhere.^{1,2} These findings will be published as a Maudsley monograph.

It is the purpose of this letter to draw attention to the widespread abuse of amphetamine in this country, which has not previously been demonstrated, and to mention that a common result of amphetamine intoxication is the development of a paranoid psychosis indistinguishable from schizophrenia, during which the patient may be a serious social danger. A further point of general social importance is that many of the patients studied obtained the drug from inhalers freely available to the general public, each inhaler containing as much amphetamine as would be present in 110 5-mg. tablets of amphetamine sulphate. The anomaly of the law which permits the free sale of such inhalers while restricting the sale of tablets has been pointed out on a number of occasions,³⁻⁵ but there has been a lack of evidence demonstrating the real need for such a restriction. This evidence is now available. It is of interest to note that some drug firms withdrew their amphetamine inhalers from the market because of the considerable increase in the sale of inhalers which took place after amphetamine had been placed on schedule 4 of the poisons rules.—I am, etc.,

Benactyzine

SIR,—The article on benactyzine as an aid in treatment of anxiety states (*Journal*, February 9, p. 306) by Professor G. R. Hargreaves and Drs. M. Hamilton and J. M. Roberts is commendable as a contribution to the problem of designing a satisfactory method for drug trials in psychiatry. But the problem is a long way from being solved. In pointing out many of the weaknesses of previous studies the authors are, I think, doing a service to psychiatry, for it is largely by noting such criticism that workers in this difficult field learn to improve their technique. I hope therefore that the authors will not take it amiss if in turn—and with great respect—I list what seem to me certain weaknesses in their own valuable paper.

In 8 of the 14 patients receiving the drug there were side-effects of such severity that the dosage had to be reduced. We must inevitably suspect that the assessors guessed these patients to be on the drug and so may have been biased in their assessments. Such bias is always to be suspected where any drug with side-effects is tested against an inert control and, in general, can only be eliminated by the use of a positive control—i.e., another drug with similar side-effects. The bias might not be very serious if that such cases scored no better than those not under suspicion; but when it concerns more than half the group, and when the response of these particular cases is not mentioned, I think our confidence in the results must be shaken. This possibility of bias is especially unfortunate in the present trial on account of the following criticism.

Six cases were "rejected" from the trial before the drug code was known. Of these six, the five who showed considerable improvement had all been on the control, while the one who showed worsening had been on the drug. Surely the whole point of a controlled trial is that variables other than those being tested are assumed to be either eliminated or the same in each of the trial groups. Without arguing whether a patient's "life situation" can be satisfactorily assessed by the bare criterion of "changed" or "unchanged" during a three-week period, I think it would be generally considered an error of principle to "discard" cases that have successfully completed the trial. It is clear that if these six rejected cases are added to the results of table II the mean difference between the improvement score for the control and for the benactyzine group becomes unimpressive (7.8 against 9.4). Incidentally—though it is a small point—the mean improvement score for the control group in table II should clearly be 5.7 and not 5.6.

The authors draw the conclusion that their group of patients on benactyzine, as compared with the control group, showed a degree of improvement which could "reasonably" be attributed to the effect of the drug. We may pertinently ask why the authors calculate statistical probabilities if they are not going to accept the usual implications of a significance test. Surely the accepted conclusion from a finding that $P=0.08$ is that the results, although suggestive, might well be due to chance and that a larger series of cases must be studied before a firm opinion can be given.

The summation of a set of rating scores allotted to a range of symptoms is, I think, a questionable procedure. If the authors had reversed their rating scale and given 4 points for the absence of a symptom and 0 for its maximum severity, their results might well have been quite different—as I have found to my surprise in trials of my own. But, even accepting the principle of summation, we may question whether a gross score, obtained by adding together the scores for 13 symptoms, is any better an index than a simple "global" assessment; if, for example, a patient presented at the first interview with a troublesome gastro-intestinal disturbance from which he had recovered at the second interview his summed score might show an improvement even though his "anxious mood" had deteriorated from mild to grossly disabling.

When a group of patients on a treatment is compared with a group receiving another or no treatment, it is usually considered incumbent on the clinician to show that the two groups are comparable for sex, age, duration of illness, severity of symptoms, and other factors likely to influence the prognosis. This may not be very important where the allocation is random and the number of cases large; but where the groups are only of 12 and 14 cases, where no mention is made of sex, where the age may vary between 20 and 65, and the duration of illness from very recent to four years, I should have thought it essential for the authors to indicate that their groups were in fact well matched.

The authors dismiss the self-controlled trial as "providing no information on the course of the malady in comparable patients who do not receive the drug being investigated"; but, since all their own patients were given "known" benactyzine soon after completing the trial, they would seem to have deprived themselves of the only real advantage to be gained from using independent controls. The value of a self-controlled trial is that it eliminates the need for matched groups of cases. Its use depends, of course, on an assumption that the drug under test acts by suppressing symptoms rather than by causing any fundamental or lasting cure; but I should have thought that in the drug treatment of anxiety states this was a reasonable assumption.—I am, etc.,

Herpes Zoster and Chicken-pox

SIR,—My patient, a young married woman of 25 years, developed a small patch of herpes on the inner side of her left forearm on January 17, which rapidly subsided. On February 4 her small daughter, aged 6 months, developed a very severe attack of chicken-pox. So far as I can gather, neither had been in contact with any cases, and the child had not been out of the house since the beginning of January because of an attack of infantile eczema.—I am, etc.,

Bourne, Lincs.

GEORGE HOLLOWAY.

Dissecting Aneurysm and Physical Stress

SIR,—Mr. J. B. Cleland's speculations (*Journal*, February 2, p. 282) on the role of physical stress in producing dissecting aneurysm prompts me to record the following case.

A man, aged 36, was admitted to this hospital at 4.30 p.m. on January 10 last. He gave a very precise history. A few hours previously, just after lunch, while leaning over the table to play a shot at snooker, he experienced severe epigastric pain while, simultaneously, his right leg "failed under him" so that he had to clutch the table to save himself from falling. His opponent brought him a chair and massaged the leg—which was numb—without avail, and finally assisted him home. There he was seen by a doctor, who sent him into hospital at once as a possible case of poliomyelitis.

On admission he looked anxious and ill. He was shivering, his temperature was subnormal, and the tips of his ears were cyanosed, but, although his heart rate was only 50, his B.P. was 170/90. The abdomen did not move well on respiration, and there

was some tenderness and slight guarding in both upper quadrants. Bowel sounds were present. The leg in question, however, now appeared normal, the reflexes were present, and he could move it easily. Soon after admission he vomited several times, and this was followed later in the evening by severe and almost continuous diarrhoea producing a convincing picture of acute food poisoning. On the following day there was slight fever, but the diarrhoea was less and the pulse rate rose to normal. Epigastric pain was still present but not disproportionately severe. Thereafter the patient settled down fairly well. He was now constipated and his appetite was poor, but the pain was less and he was afebrile. On January 16, the pain was quite gone and he felt much more comfortable, though an aortic diastolic bruit was detected for the first time, and he still retained his expression of anxiety and strain. That afternoon, after he had taken his tea, he died suddenly.

At necropsy (Dr. W. F. Hamilton, of Ashford Hospital) the cause of death was found to be a rupture of the aorta through the anterior wall into the pericardial sac. In addition, on the posterior wall there was a small slit leading to a dissecting aneurysm which passed down through the abdominal aorta and into the right common iliac artery, about two-thirds of the way along which there was a second slit through which, presumably, the aneurysm had once again erupted into the main channel. The left common iliac artery was normal. There was some naked-eye evidence of atheroma in the abdominal aorta but none in the thoracic.

Clearly, the rupture into the pericardium was terminal. The dissecting aneurysm occurred presumably while he was bending over the snooker table, and, although at first sight it sounds absurd to speak of "physical stress" in this context, on reflection this may not be so. Frequently to reach an awkward ball without the rest a player may stretch violently over the table, leaning heavily against the side or corner, thus producing severe pressure in the abdomen generally and compressing one or other common iliac artery. In any event, it seems beyond doubt that this is what happened in the present instance, resulting in an accident which, to be sure, was sooner or later probably inevitable.—I am, etc.,

Isleworth, Middx.

G. E. BREEN.

Non-ulcer Dyspepsia

SIR,—In your leading article on the importance of non-ulcer dyspepsia (*Journal*, February 16, p. 391), you cite us¹—unfortunately in error—as having found that "patients with non-ulcerative dyspepsia are even more common in an urban general practice than are patients with peptic ulcer." What, in fact, our figures did show was that in a general practice, after careful and repeated screening of all cases of dyspepsia with the Gregersen slide test and x-ray follow-up—such as is normally impracticable in hospital—the prevalence of true ulcer dyspepsia was greater than non-ulcer dyspepsia.

There are two probable reasons why Wynn Williams and his colleagues (p. 372) were unable to find a cause for dyspepsia in over 60% of their cases. First, many patients with proved organic cause for their symptoms would not find their way to a hospital out-patient department. Secondly, many of the patients with dyspepsia are likely to have been previously investigated by the general practitioner to exclude the possibility of alimentary ulceration and would therefore have been referred only because no explanation of their symptoms had been found.

The non-ulcer dyspepsias are, as you say, a formidable challenge to physicians. The contrast between the ulcer/non-ulcer dyspepsia ratios in our general practice population and the ratios reported for such hospital series as those of Wynn Williams and his colleagues draws attention to the need for close and continuing co-operation between general practitioners and the hospitals in the further study of the natural history of dyspepsia and peptic ulcer.—We are, etc.,

Penetrating Ulcer of Tongue

SIR,—Dr. Gordon F. Cassie in his most interesting article on penetrating ulcer of the tongue (*Journal*, February 9, p. 325) describes a case in a man aged 63 years, edentulous, who had worn the same dentures for 20 years with no sign of any irritating factor on the dentures. The ulcer was in the centre of the tongue.

If the same dentures had been worn for 20 years it can in most cases be assumed that gross absorption of the alveolar ridges has taken place, resulting in a poor fit of the dentures, with little or no suction due to a lack of peripheral seal. When this means of retention fails, it becomes necessary for the cheek muscles, and more particularly the tongue, to keep the denture in place. When the incisors are used the tongue is thrust up into the palate of the denture in order to counter-balance the force of bite. After the food passes to the premolar and molar region for grinding, the tongue and cheek muscles grip the dentures on the palatal and labial surfaces of the denture base. If the denture base was constructed of vulcanite, which is most likely owing to their age, it can also be presumed that it was infected, as this material is porous. In this case there are therefore present the two necessary factors for producing a penetrating ulcer: (1) irritation due to the tongue thrusting up on to the palate of the denture in order to keep it in position, especially while eating, but also at rest; and (2) bacterial infection from the porous vulcanite base of the denture. It would be interesting to hear of any other cases of this type where a methyl methacrylate base has been used, as this material does not cause infection because it is non-porous and retains its polished surface better than vulcanite, and is also 25% lighter in weight—I am, etc.,

Exeter.

A. J. WALTERS.

Compound Aspirin and Steroid Tablets

SIR,—The recent annotation (*Journal*, February 16, p. 395) has suggested that a combination of corticosteroid and aspirin is of no advantage, and in fact may be disadvantageous in the treatment of rheumatoid arthritis. I have treated patients in my clinic since this combination has become available who have failed for years on aspirin. They have also been given corticosteroids with disappointing results, for one reason or another, but they responded very well to a combination of aspirin—5 gr. (0.3 g.)—and prednisolone (0.5 mg.), usually in doses of 10 to 12 tablets daily. There have been no unwanted side-effects.

This evidence is not without support. Spies *et al.*¹ have shown that combined therapy with salicylates and corticosteroids offered a more practical means than steroids alone for treating many arthritic patients when enough salicylate to produce a strong additive effect was given, so that less steroid was required to produce the desired result. Szucs *et al.*² treated 400 cases of various types of arthritis with this combination with notable improvement and a minimum of side-effects. Although I do not consider this combination to be preferable to steroids alone, nevertheless there are many cases which have benefited when all other recognized methods have failed. I am sure as experience is gained with this combination its place in the treatment of arthritic conditions will be assured—I am, etc.,

Birmingham.

Glycyrrhetic Acid

SIR,—I am sorry to have to encroach again upon your columns, but I cannot allow the rather personal comments made by Dr. R. D. Sweet (*Journal*, February 9, p. 340) to remain unanswered. First, if Dr. Sweet had taken the trouble to read and understand the large volume of chemical and scientific publications on this subject, as I have done, then I am sure he would not have felt blinded with science

or that this work had a "pseudo-scientific ring." Secondly, the fact that glycyrrhetic acid is "frightfully complex chemically" has not influenced me either for or against the drug. Thirdly, the difference between an active and an inactive isomer can easily be assessed by comparative trials. Fourthly, the expression "biosone G.A." side-chain is unfamiliar to me. Fifthly, I strongly object to the suggestion that I have repeated the commercial claims for any particular product. In this case the trade name was essential, due to the fact that all glycyrrhetic acid ointments available on the market do not have the same efficacy. In fact the editor of the *Lancet* commented that "the name of the substance . . . was included at our request, because we thought it an essential piece of information." I hope I have made my point of view clear, and any "experienced colleagues" who are "patently unconvinced" may care to visit me any week-end, by arrangement, when I could show them the medical files of the many patients successfully treated.

I note the comments of Drs. J. W. Cornforth and D. A. Long (p. 340). I was fully aware that they did not refer to glycyrrhetic acid in their patent, and in my letter I referred to "products which they obtained from liquorice root," which is in accordance with their patent specification. However, the resultant materials obtained by them by passing liquorice derivatives through an ion exchange column do not appear to have been chemically identified by the patentees. The results, however, in B.C.G.-infected guinea-pigs may in time be found to vary dependent upon different isomers or fractions of glycyrrhetic acid used. In conclusion, I can only agree with Dr. J. Sommerville (*Journal*, February 2, p. 282) "that any inference or statement that glycyrrhetic acid is an inactive substance is both misleading and wrong."—I am, etc.,

Hove.

Statistical Analysis in Progressive Disease

SIR,—In his article on a controlled trial of nicotinic alcohol tartrate (*Journal*, January 26, p. 207) Dr. R. O. Gillhespy states: "It should be noted that statistical analysis takes no account of the fact that this is a progressive disease and is therefore no substitute for clinical experience." A comparison of the number of patients who were worse at the end of the trial period in the treated and control series would show what influence the drug had in preventing progress of the disease. The usual statistical analysis would then take this into account, as well as the improvements due to the drug.—I am, etc.,

Sheffield.

D. KERRIDGE.

Chemotherapy in Primary Tuberculosis

SIR,—I was interested to read Dr. J. B. Ryder's article (*Journal*, February 9, p. 324) and to note his references to my previous work on this subject.¹ In my communication tuberculosis treated with antibiotics, who subsequently developed segmental lesions. I recalled that a number of children that we might be observing a larger incidence with this complication with our present methods. I said: "These figures are small, but they are disturbing." Dr. Ryder's contribution to this problem is interesting, but does it justify a conclusion that "there is no obvious increase in the natural frequency of segmental lesions as a result of antimicrobial treatment"? Particularly when dealing with small numbers, it would seem unwise to compare Eskimo and Indian children treated by antibiotics with children treated in the pre-antibiotic era in England.

We are making another study at High Wood of our recent groups of small children treated by antibiotics and comparing these with similar cases treated in the same hospital without these drugs, and it is hoped that this will elucidate the matter further. The numbers, however, may still be too

small to be conclusive. As I wrote previously, "A carefully planned trial is called for on a national scale to settle in this and in many other respects the proper place of antibiotic therapy in the treatment of tuberculosis in young people."—I am, etc.,

Brentwood, Essex.

Two New Human Genes

SIR,—Professor L. S. Penrose's letter (*Journal*, February 2, p. 282) seems to have conveyed the impression to some readers that the characters we have been investigating are not well differentiated. In fact, we have found that biochemical tests for the presence or absence of methyl mercaptan after eating asparagus are consistently either negative or positive on the same individual. With regard to the excretion of beet pigment, as we indicated in our original communication,¹ "Most positive subjects develop typical red urinary pigmentation whenever they eat beet-root; but in a minority the red pigment appears only intermittently, sometimes being replaced by a dark-brown pigment." Professor Penrose draws attention to the relatively small number of observations (219) which we included in our report. However, the technical difficulties are such that it is impossible to work on the scale customary in blood-grouping laboratories. We should be very pleased to see further family studies on both these characters, but additional data collected by us, which we intend to publish shortly, are entirely consistent with our original genetic hypothesis.

This is based upon more substantial evidence than Professor Penrose implies; even the findings originally published would occur by chance less than once in a million times. Professor Penrose's alternative hypothesis of "peculiarities of intestinal flora" must clearly be considered; experiments designed to introduce the precursor parenterally would presumably decide the point. Nevertheless, it is clear from our data that the appearance of the two characters in the same family is independent. On Professor Penrose's hypothesis, it would be necessary to postulate the simultaneous existence in the intestine of two groups of bacteria, the presence or absence of one of which simulates a recessive type of Mendelian inheritance, while the other appears in the ratios characteristic of a dominant type of inheritance. This does not seem to us to be the most economical hypothesis, and we suggest that it is simpler to postulate the existence of two pairs of genes ("As and "bt") operating in the way we described.—We are, etc.,

Tear-test for Glucose

SIR,—Glucose-oxidase has been shown to be useful in the detection of glucose in the urine and is commercially available as "clintix." It was decided to try clintix for the detection of glucose in lacrimal secretion. Clintix is either applied to the conjunctiva of the lower eyelid until the tip is moistened, or alternatively a tip moistened with water is applied for a few minutes. The results should be read after two to three minutes, preferably in daylight against a white background. If glucose is present a blue colour will develop. If, as in some cases, a momentary stinging in the eye occurs this can be minimized by moistening the stick with water, or by cutting the stick lengthwise to reduce its bulk. It has been found that in those with a blood sugar above 200 mg. a blue colour appears. The depth of the colour is roughly related to the blood sugar level. Where this value is over 300 mg. often a blue reaction quickly develops. It is suggested that this "tear-test" might be used to supplement existing orthodox tests, as illustrated by the following case. An undiscovered diabetic with long-standing symptoms was referred with gangrene. A tear-test was

strongly positive. Her urine showed 2% glycosuria and blood sugar was 307 mg.%. Following admission, her blood sugar dropped to below 175 mg., her tear-test was negative. The urine remained at 2%. It is possible that the test may be of value in certain circumstances, though it is not claimed to be quantitative. It might be specially useful to general practitioners suspecting diabetes but unable to obtain urine specimens. Diabetics with heavy glycosuria due to low renal threshold tend to give a weaker reaction than those with higher levels. Finally, as a bedside test it is possible that it could be an extra point of information in the differential diagnosis of coma in the diabetic.—I am, etc.,

London, N.W.3.

J. G. LEWIS.

Care of Discharged Mental Defectives

SIR,—In a recent letter (*Journal*, January 26, p. 226) Dr. J. Newcombe emphasizes the need for care and supervision of aments when the order under the Mental Deficiency Acts has been discharged. I agree with his suggestion. In this area discharged aments are kept under friendly observation by my mental health officers. We believe that unofficial observation is the best method of ensuring timely help and re-ascertainment if the need arises.—I am, etc.,

Halifax.

G. C. F. ROE.

Treatment of Acute Appendicitis

SIR,—Mr. Eric Coldrey's advocacy (*Journal*, December 22, 1956, p. 1458) of conservative treatment for acute appendicitis has received little support in your correspondence columns and indeed even less support from his own excellent figures for surgery—no deaths in 395 cases. There is one aspect of conservative treatment of the acute abdomen, in the matter of correct diagnosis, which receives little mention in all such articles. The conservative regime may be started for supposed acute appendicitis or perforated peptic ulcer; deterioration with subsequent laparotomy or necropsy may reveal gangrenous gut, ruptured spleen, or ectopic gestation, or a perforated diverticulum, and the corpse does not even have the honour of appearing in the statistics of the conservative treatment advocated. Any large series of acute abdominal cases must include a few such catastrophes, and to leave them out may be statistically correct, but is surgically misleading.—I am, etc.,

London, W.1.

G. QVIST.

SIR,—I wish to correct the inference in Dr. E. C. Atkinson's letter (*Journal*, February 16, p. 400) that the advice give to Captain R. S. Paton, of the *Tahsinia*, originated from a professional source. Whence that ill-conceived advice emanated, I do not know. As the surgeon who gave the advice *not* to operate, but to return to Ireland, I strongly advised against any attempt whatsoever to undertake operative measures, for very obvious reasons.

The hospital in Weston-super-Mare is unique, as far as I know, in that it is the only hospital in Great Britain which gives radio advice to ships at sea when illness occurs in the crew, and this is not the first occasion by any means when advice on conservative measures for acute appendicitis, even with peritonitis as in the case of the *Tahsinia*, has been given. In conclusion, may I add that we were informed a week ago that the patient had made an excellent recovery, the diagnosis having been confirmed?—I am, etc.,

Weston-super-Mare.

W. R. BLACK.

SIR,—I was most interested to read the letters in the *Journal* on the treatment of acute appendicitis. I entirely agree with Dr. E. C. Atkinson's observation (*Journal*, February 16, p. 400) that conservative treatment should be adopted when the "surgeon" is a layman, and in any case when facilities render surgical intervention hazardous. In my book¹ a case is described in which appendicectomy was performed during the late war by a laboratory technician in a submarine in enemy waters. The operation took 2½

hours, during which 5 lb. (2.3 kg.) of ether was administered by the communications officer.

My late chief James Sherren, of the London Hospital, a recognized authority on abdominal surgery, always emphasized that no case of acute appendicitis in an adult would prove fatal if treated by starvation and morphine. An abscess might develop, and if necessary be drained by means of a simple incision. Children are in a different category, as their resistance to infection is less than that of adults, and their short and flimsy omentum is not sufficiently developed to reach the right iliac fossa and so circumscribe the spread of inflammation. It is my conviction that conservative treatment of acute appendicitis in an adult is far safer, although less theatrical, than an improvised operation by an unqualified enthusiast, or even by a medical man with inadequate surgical experience.—I am, etc.,

London, W.1.

MCNEILL LOVE.

Viruses Made to Order

SIR,—Your leading article (*Journal*, February 16, p. 390) draws attention to an aspect of biological and medical research which may undoubtedly bring great benefits to mankind in due course. However, it may also lead to terrible suffering if such research is taken up by the bacteriological warfare departments of various nations. Once it has become possible to change the structure of a virus all previously acquired immunity to it would disappear, and one could imagine with horror a changed influenza virus let loose upon an unsuspecting country by an enemy who had carefully inoculated his own troops and population against it.

I understand that work is going on at present in Australia to change the myxomatosis virus in order to kill those rabbits which have become immune to the established virus. While this research appears useful to mankind, it would be terrible if it should become the prototype of other similar but more dangerous experiments.—I am, etc.,

London, W.C.1.

A. R. MICHAELIS,
Editor, *Discovery*.

Mongolism in Siblings

SIR,—More than one mongol in a family may not be as rare as is suggested by Dr. Freda M. Paul's letter (*Journal*, January 26, p. 212). In our practice of just over 3,000 patients, of five families with mongol children, one family has two; and one of us remembers another family of two.

A mother born in 1910 gave birth to a boy in 1944, who died at three weeks from convulsions. In 1947 and in January, 1950, she had normal girls, who are still thriving. In September, 1950, she had an early miscarriage, and in 1951 her first mongoloid child, a boy, was born. In February, 1952, there was a second miscarriage, and in December, 1952, a second boy mongol. Both mongols are in good health and free from other congenital abnormality.

This mother gave birth to mongolian children late in her reproductive life, but the usual long period of sterility preceding them both was absent. Rather might one suggest that the rapid succession of her pregnancies did not give time for preparation for normal maturation of gametes or ovum.—We are, etc.,

York.

MARGARET DUDLEY-BROWN.
L. JOAN LETTY.

Living with a Colostomy

SIR,—Your leading article on living with a colostomy (*Journal*, February 2, p. 274) should do much to enlighten the ignorance and indifference—still all too prevalent—of all concerned, be they patient, surgeon, physician, or nurse. May I, an active surgeon for some forty years, and by no means passive patient for three years, comment, suggest, and advise?

In the strict sense of the word, we have no methods of gaining control of the colostomy. The sphincterless colos-

tomy is impotent, uncontrollable, and incontinent, and will remain so until some ingenious surgeon devises an adequate and controllable sphincter such as is present at the normal exits of bladder and bowel. Restriction of roughage may result in vitamin deficiency with bowel looseness. This remote risk can be prevented or remedied by judicious intake of vegetable and "forbidden fruit" juice, yeast, etc. Other factors hitherto little appreciated deserve consideration—body build, previous bowel habit, mental make-up, climatic conditions, etc. Those of sthenic build possess a relatively shorter and more active colon than do their counterparts, the asthenic visceroptotics. The intestine, like other organs and tissues innervated by the autonomic system (well named sympathetic), is both sensitive and reactive to emotional states—worry, anxiety, trepidation, etc. A true sense of humour inhibits or minimizes both cause and effect, and enables one to face and cope with most situations with equanimity. Chilling should be avoided. The colostomite in these circumstances is more prone to suffer from diarrhoea.

I neither require nor use drugs of any kind, nor have I ever had a wash-out. Inhibitory drugs, I found, simply postpone the inevitable evacuation, which is likely to be more bulky or even a "gusher." Tea and coffee with lots of energizing sugar are well tolerated, so is whisky (with a little water), which diminishes the effects of emotional disturbances and helps to maintain morale. As a practical adjunct to the armamentarium of all colostomites I most strongly advocate the inclusion of an ordinary glass jam-jar, the use of which, I have found, ensures confidence and comfort and substantially reduces the amount and cost of dressings. After breakfast I go to the bathroom for shaving, etc. There, by a very simple adjustment of my belt, I fix the jam-jar over the colostomy, and with complete comfort and confidence proceed to do two things at once. A little gentle massage or squeezing over the terminal subcutaneous inch or two of the pelvic colon stimulates desirable activity. On my person I carry a spare dressing, and in my car the same, plus jam-jar. Thus all emergencies can be anticipated and in most circumstances circumvented.

I learned a lot as a patient in bed. I am convinced that ritual heavy-handed rubbing and scrubbing of bony prominences does more harm than good. Frequent change of posture and position, as is normally exercised and accomplished by the healthy and strong, is all that is necessary to prevent bed-sores, thrombosis, pulmonary oedema, etc. But so tightly was I tucked in that I could hardly move or breathe in freedom or comfort until I took evasive action. My bed was uncomfortable: it sagged so that I had no support between pelvis and heels. I demanded a soft pillow which when supine I placed under my thighs and when in a lateral position used as a very comfortable inter-knee pad. Somewhat to the chagrin, I suspect, of all concerned (to whom I am most grateful) I made a complication-free and rapid recovery.—I am, etc.,

"COLOSTOMY."

Distribution of Red Bone Marrow

SIR,—I had occasion recently to look up the accounts of the distribution of red bone marrow in long bones given in the common textbooks of anatomy used by students to-day. The results were surprising and exemplify the considerable delay which may occur before recent work of immediate use to the student is made readily available in his textbooks. Since much discussion centres round the teaching of anatomy, may I beg the hospitality of your columns to illustrate my point?

Gray's Anatomy, 1944.¹—Marrow is red "in the articular ends of long bones." *Gray's Anatomy*, 1954.²—"By the age of twenty the medullary cavities of the long bones, the spaces in the spongy substance of their extremities . . . are . . . occupied by yellow marrow." *Cunningham*, 1951.³—"At puberty the red marrow is found only in the spongy bone; and, as age advances, it is replaced by yellow marrow in the spongy bone of peripheral parts—distal ends of long bones and the lower part of the backbone." *Buchanan's*

Anatomy, 1937.⁴—" . . . red marrow occurs in (1) articular ends of long bones, (2) medullary spaces of cancellated bone . . ." *Buchanan's Anatomy*, 1946.⁵—"At the end of the period of later childhood fat has become apparent at the centre of the shaft and, as puberty approaches, smaller patches of fat make their appearance on the distal side of the central fatty area. These changes . . . are earlier in appearance and more marked . . . in the more distal bones and in the distal ends of individual bones. The change from red to yellow marrow is earlier in the foot and hand than in radius and ulna or tibia and fibula and these in turn earlier than in the humerus and femur." *Grant's Anatomy*, 1940.⁶—"Gives an account of some changes in childhood and continues, 'By the 14th year red marrow is almost entirely replaced by yellow in the limb bones.'" *Textbook of Human Anatomy*, 1956.⁷—"In the long bones the marrow in early childhood is red, but during late childhood and adolescence this is replaced by yellow marrow in most of its extent, though some red marrow may still be present at the ends."

Of these volumes, Cunningham³ refers to the excellent paper by Piney⁸ which appeared many years ago in your *Journal* and in which a good description of the regional variations in the appearance of marrow, based upon personal observation, is set out. At the end of Dr. Piney's paper, in a brief discussion of its contents, Dr. Graham remarked that medical students had as a rule no clear conception of the anatomy and physiology of bone marrow until they came to study pathology.—I am, etc.,

Fatal Hospital Falls

SIR,—I was interested to see in Dr. Gavin Thurston's paper (*Journal*, February 16, p. 396) that the incidence of fatal falls in hospitals is not much higher than the current suicide rate in the general population. This being so, I feel some concern at his suggestion that such precautions should be taken against this type of risk as virtually to transform hospitals into prisons—i.e., bars fitted to the windows, etc. Great efforts are being made to "humanize" hospitals, to allay as far as possible the patient's fears, and to preserve his sense of individuality. It would be a pity if, by emphasizing the possibility of legal liability, this desirable trend was reversed. I am naturally in full agreement with the other suggestions made by Dr. Thurston.—I am, etc.,

Cheam, Surrey.

WILLIAM N. ROGERS.

Treatment of Adrenocortical Deficiency States

SIR,—The problem of references in any article dealing with endocrinology, especially in the adrenal field, is becoming increasingly difficult and almost impossible. Further, medical history, as all history, is of practical importance only in regard to its influence in assessing modern situations. Nevertheless, such brevities as "The only treatment for adrenal deficiency prior to the advent of cortisone in 1949 lay in increasing the salt intake in the diet and in giving drugs to cause salt retention; deoxycortone was the most effective agent in this respect" (Dr. F. Dudley Hart, *Journal*, February 23, p. 417) do inadvertently miss out the very important 1930–1938 (even 1930–1950) era of cortical extracts, aqueous and lipid. I venture to draw attention to this because I was Fellow in Medicine at the Mayo Clinic in 1930 when L. G. Rowntree first used Swingle and Pfiffner's

extract with dramatic results in Addison's disease, which clinical results I was able to demonstrate to the Royal Society of Medicine in London a few months later; and I happen to be the first clinician to use deoxycortone, in 1938, supplied by Reichstein. Cortisone has undoubtedly superseded older methods of therapy; and as Dr. Dudley Hart (from whose excellent paper I quoted above) has shown in his remarkable series of adrenalectomy cases, as also in Addison's disease, 9 α -fluorohydrocortisone by mouth, in relatively minute doses (and intravenously if need be), will supersede deoxycortone. For those interested in the evolution of hormone therapy in adrenal insufficiency, the 1953 paper will give much relevant information, further brought up to date in a brief but excellent paper by Drs. R. N. Beck and D. A. D. Montgomery on the treatment of Addison's disease (*Journal*, October 20, 1956, p. 921).—I am, etc.,

London, W.1.

Primary Dislocation of Shoulder-joint

SIR,—Mr. R. Salisbury Woods's interesting account of primary dislocation of the left shoulder-joint in the boxing-ring (*Journal*, February 16, p. 387) reminds me that I witnessed an exactly similar incident in 1941 while acting as M.O. at an Army boxing contest. As far as I can remember, the conditions were exactly the same; the one boxer attempted a left hook, the arm being almost fully abducted, and this was parried by the right arm of the other, which struck the abducted arm from below upwards and laterally. There was no history of a previous dislocation. Reduction was performed at once and without difficulty.—I am, etc.,

Starcross, Devon.

FRANK BLAKE.

G. L. Alexander

SIR,—

Of Alexanders, G. L., please note there are two, In Bristol to boot, and in area 8. One, a ship's surgeon, writes oft to the press, On appendices hot; would long leaves advocate; And on broadcasting's failings would strongly lay stress. The other, a surgeon, from Auld Reekie came His craft neurosurgery here to perform. That the names are the same There is no one to blame. Such identical names are so far from the norm That confounded confusion is sure to arise; Which is why these few lines seem both timely and wise.

—I am, etc.,

Leigh Woods, Bristol.

G. L. ALEXANDER.

Smoking in the Wards

SIR,—In my practice I have been trying to discourage smoking among my patients as far as possible, after pointing out the harmful effects attributed to it. I was rather taken aback when one patient, who had recently been discharged from hospital, said, "Well, Doctor, I can't see why some doctors think smoking is harmful. Look at the notices in all the hospital wards stating the hours between which smoking is allowed." Surely hospitals should help in the campaign against smoking by discouraging this habit among patients under their care.—I am, etc.,

London, E.3.

BERNARD TAYLOR.

Abdominal Periarthritis Nodosa

SIR,—I would like to congratulate Mr. A. G. Norman and Dr. P. S. Wilkins for their memorandum on abdominal periarthritis nodosa (*Journal*, February 23, p. 445). This will be a much more valuable contribution if they can tell us what drugs—using the word in its broadest sense—this young

man consumed during the three weeks he had suffered from vague gastric upset, and what he was in the habit of taking for his asthma.

The more cases of polyarteritis nodosa one sees, the more common appears to be the association between many of these cases and a peculiar sensitivity to drugs. Although the question of drugs is usually implicated, particularly the sulphonamide group, I feel that those cases of malignant iodism which were reported years ago were really cases of this syndrome.—I am, etc.,

Sheffield, 10.

H. R. VICKERS.

Supply of Bodies for Dissection

SIR,—Dr. G. C. Milner's gruesome suggestion (*Journal*, January 12, p. 108), as quoted by Dr. E. N. Russell (*Journal*, February 9, p. 343), is quite unnecessary. Many people have a subconscious dread of being buried alive. And I have simply told them that such a misfortune would not be my lot, as I have given my solicitor the form supplied by the Ministry of Health, and have obtained the consent of my next of kin to have my body removed to a school of anatomy for the good of future students, and through them for the benefit of mankind.—I am, etc.,

Swindon

R. P. BEATTY.

Distinctive Tubes

SIR,—At the present time there is a large increase in the number of proprietary ointments being dispensed in tubes, and for some reason or other easily removable labels are being attached. This is probably a condescension to those practitioners who do not wish their patients to know what is being prescribed. Would it not be reasonable to suggest that the trade should adopt characteristic colours for their containers? It is a simple matter, particularly in hospital practice, for a tube of chloramphenicol and one of atropine to lose their respective labels and become indistinguishable, or even for their loosened labels to be incorrectly reattached by a conscientious nurse with, perhaps, disastrous results. Might I suggest that all atropine should be dispensed in red tubes, antibiotics in green, the sulphonamides in blue, cortisone in white, and, for those who still use it, ung. hydrarg. oxi. flav. in golden tubes, and so on?—I am, etc.,

Guernsey.

FRANK R. NEUBERT.

Medical Aspects of Boxing

SIR,—I congratulate Dr. Macdonald Critchley on his brilliant paper "Medical Aspects of Boxing" (*Journal*, February 16, p. 357). Your leading article (p. 392) also was timely. The horrors of boxing are well known, but it is surprising how this sport is going on without any adverse comment. As Dr. Critchley says, "One important distinction, however, distinguishes boxing from most other forms of athleticism. . . . In boxing the aim and object—explicit or implied—is to render the opponent *hors de combat*. Traumatata are therefore not so much regretted as regrettable."

The gradual decline of a boxer's career—from the height of glory to a life in a mental asylum (I have known a few)—is a fact which cannot be too strongly condemned. This sport should be banned, and I hope I shall have many colleagues who will agree with me.—I am, etc.,

Edinburgh.

A. K. CHATTERJEE.

Cancer of the Larynx in Women

SIR,—Dr. S. W. V. Davies (*Journal*, March 2, p. 519) refers to my suggestion (*Journal*, February 9, p. 299) of a possible connexion between defective diet and the high incidence of cancer of the larynx in women in rural areas, and asks if the consumption of white bread is greater in the country. There is no such statistical evidence, but this

suspicion rests upon a certain amount of basis which could not be stated fully in the paper to which he refers.

(1) The standard mortality ratio for cancer of the larynx in women in Wales (202) is twice that (100) for women in the whole of England and Wales.¹ (2) Stocks² has examined dietetic conditions in North Wales. "The statistical association between cancer and the amount of fresh milk and certain fresh vegetables in dietaries which was found some years ago by comparing the diets of 400 cancer patients with those of 400 control patients of the same ages from the same localities³ may help to provide a key to this. Fresh milk and vegetables seem to be very poorly represented in the diet of the bulk of the population of North Wales." (3) Visitors to Wales, who make no claim to have investigated the matter upon a statistical basis, may get the impression, from what they see in rural restaurants, that the big plate of white bread-and-butter and the teapot are the usual provision for a woman customer. (4) The Paterson-Kelly syndrome is more prevalent in Sweden than in any other country,⁴ and is thought there to be connected with defective diet.

Dr. Davies describes some occupational factors to which housewives are exposed, a subject to which more attention might very well be given. In an investigation carried out in the Pathology Department of St. Bartholomew's Hospital⁵ the carbon and ash were estimated in the lungs of (1) 26 males and 16 females dying in London, with and without bronchial carcinoma, and of (2) 4 males and 4 females of Iceland, without bronchial carcinoma (obtained through the kindness of Professor Niels Dungal, of Reykjavik). The Icelandic women showed mean and maximum figures for both carbon and ash higher than those of any of the London subjects. Professor Dungal writes of the woman giving the highest figure for ash, that she spent most of her life in the country on a farm. "If she has worked in one of our old-fashioned farm kitchens she will have inhaled a lot of smoke. These kitchens were small rooms with an open hearth, where a fire was kept burning day and night between two stones and the place was frequently full of smoke. There was no chimney. I have seen many of these kitchens in my young days; and as often as not they were full of smoke. In the lungs of this woman we found microscopically lots of black material, also in a lymphatic node from the neck. The fuel which was burned, and is still chiefly burned in the country, is peat. In spite of all the enormous amounts of peat smoke which must have been inhaled by our womenfolk in their old-time kitchens, cancer of the lung has been practically unknown among them."

The hearth in the living-room in the middle of the floor will be familiar to readers of the Icelandic and Heims-kringla sagas and can be seen in the reconstructed Viking house at Trelleborg in Denmark.⁶

Thus in the *Heimskringla Saga* of Snorre Sturlason (1178–1241) we read: ". . . there were many sea-kings who ruled over many people, but had no lands, and he might well be called a sea-king who never slept beneath sooty roof-timbers" (*Ynglinga Saga*), and King Sigurd "cast the book on the fire which was burning on the hall-floor . . ." (*The Sons of Magnas*).

There are perhaps racial differences in reaction to smoke from a domestic fire. Sheep farmers in New Zealand 100 years ago, my father and his brothers among them, left a hole in the wall when building their huts, to be filled by a chimney made, from lack of other suitable material, of turf. This structure, not very easy to build, had the defect that after prolonged wet weather it might collapse upon the hearth, giving the freest entry to wind and rain.—I am, etc.,

London, E.C.1.

Obituary

J. B. MENNELL, M.D.

Dr. J. B. Mennell, consulting physician in physical medicine to St. Thomas's Hospital and consulting physician to the British Red Cross Society's Physical Treatment Centre, Kensington, died at his home at Liss, Hampshire, on March 2. He was 77 years of age. Largely through his efforts the school of physiotherapy at St. Thomas's Hospital became one of the leading training schools in Britain.

James Beaver Mennell was born in London on January 31, 1880, the youngest son of Dr. Zebulon Mennell. From St. Paul's School he went on to Pembroke College, Cambridge, where he took the natural sciences tripos in 1902. Like his father, James Mennell was a student at St. Thomas's Hospital Medical School, which he entered in 1904. At this period the after-treatment of fractures had made little progress, and while still a dresser Mennell decided to try the effects of massage. After graduating M.B., B.Chir. in 1908 he continued his researches in an unofficial out-patient clinic for the after-treatment of fractures (which he had established himself). From 1908 to 1910 Mennell was casualty assistant, clinical assistant, physician to the exercise department, and house-surgeon at St. Thomas's Hospital. In 1910 he obtained his M.D., and from 1910 to 1911 was resident medical officer to St. Thomas's Home. He afterwards became medical officer to the physical therapy department at St. Thomas's Hospital, where he remained in charge until he retired in 1935. He was also a life governor of the hospital.

During the opening years of this century there were few hospital training schools for masseuses compared with to-day. They received their training in private schools, and relied for clinical experience on the out-patient departments of those hospitals which admitted masseuses. Mennell devoted a great deal of time and energy not only to building up the physiotherapy school at St. Thomas's Hospital, where he was lecturer, but to the welfare and recognition of properly qualified physiotherapists. He took an early interest in their Chartered Society, and actively inspired the establishment of provincial branches. When he resigned from the chairmanship of the council of the society in 1938 the members showed their appreciation of his services by making a presentation to him. He later became a vice-president and an honorary fellow of the society.

Mennell was at one time medical officer at a special military surgical hospital in Shepherd's Bush and formerly honorary consultant to the Royal West Sussex Hospital, Chichester. He was a past president of the section of physical medicine at the Royal Society of Medicine, and a past member of the council of the British Association of Physical Medicine. His fame was international and some of his publications were translated into several languages. He was president of the physiotherapy section at the Bilingual Congress of Radiology and Physiotherapy in 1922, and of the section of kinesitherapy at the International Congress of Physical Medicine in 1936. He became an honorary member of the Netherlands Society of Physiotherapy in 1945, and was awarded the golden key of the American Congress of Physical Medicine in 1940 and of the

American Physiotherapists Association in 1947. During the academic year 1947–8 he was visiting associate professor of physical medicine at the University of Southern California.

James Mennell's most important publications were *Treatment of Fractures by Mobilization and Massage* (1911); *Backache* (second edition, 1935); *Physical Treatment by Movement, Manipulation and Massage* (fifth edition, 1945); and *Science and Art of Joint Manipulation: Volume 1, The Extremities* (second edition, 1950), and Volume 2, *The Spinal Column* (1952).

The medical students who attended his department or clinical lectures at St. Thomas's found his views on diagnosis and treatment stimulating and useful, if sometimes outside their curriculum. Fortunately Mennell was able to continue to lecture at the physiotherapy school after his retirement from the hospital staff in 1935. Despite a very busy professional life he found time for his favourite recreations of walking and golf. He married Elisabeth Walton, youngest daughter of George W. Allen, of St. Louis, Missouri, in 1912, and had three sons.

H. S. STANNUS, C.B.E., M.D., Ph.D., F.R.C.P.
D.T.M.&H.

Dr. H. S. Stannus, consulting physician to the French Hospital, London, and an authority on tropical diseases and nutrition, died at his home in London on February 27. He was 79 years of age.

Hugh Stannus Stannus was born in London on June 18, 1877, the son of an architect, and received his medical training at St. Thomas's Hospital, qualifying M.R.C.S., L.R.C.P. in 1901. Two years later he graduated M.B. from the University of London, proceeding to the M.D. with gold medal in 1911. In 1912 he obtained the Cambridge D.T.M.&H. He took the London Ph.D. in 1926. Elected a Member of the Royal College of Physicians of London in 1920, he became a Fellow of the College in 1931. After qualification he held a number of appointments at St. Thomas's Hospital, and later the posts of clinical assistant at the East London Hospital for Children and resident medical officer at the Bethlem Royal Hospital. He was then appointed resident surgeon to the Hertford British Hospital, Paris. In 1905 he became medical officer to the King's African Rifles in British Central Africa. Here he found much to interest him. Not only did he investigate the endemic diseases of man and animals in the area, but he also engaged in ethnological studies. On the outbreak of the first world war in 1914 he became principal medical officer to the Nyasa-Rhodesian Forces operating in the south of German East Africa. He served throughout the campaign, and was three times mentioned in dispatches. On his return to England after the war Stannus had the opportunity of becoming director of medical services of the newly constituted Tanganyika Territory, but, on health grounds, he was advised to refuse the appointment. He became instead physician to the French Hospital, in London; a member of the associate staff of the Hospital for Tropical Diseases; and medical adviser to the Board of Inland Revenue. For some time he examined in tropical medicine for the University of Liverpool. His Lumleian Lectures delivered before the Royal College of Physicians of London on "Some Problems in Riboflavin and Allied Deficiencies" were printed in this *Journal* in 1944. He was awarded the Treacher Collins Prize by the Ophthalmological Society of the United Kingdom in

1948 for an essay on nutritional eye disease. During his period of service in Africa he wrote papers on a great variety of subjects, but in later years his published work was mainly on nutritional disorders, especially pellagra. He contributed the section on yaws to the *British Encyclopaedia of Medical Practice*.

During the second world war Stannus's services as an expert on nutritional disorders were utilized by the Ministry of Health, and he helped to initiate the rapid nutritional surveys which were carried out during the war. He was also specialist in tropical diseases to the Ministry of Pensions. For his work on tropical medicine he received the French award of Chevalier de l'Ordre de la Santé Publique; for his services to the French Hospital he was appointed a Chevalier of the Légion d'Honneur; and he was awarded the Médaille de la Reconnaissance Française for his work during the second world war. He was appointed C.B.E. in the Birthday Honours last year. He was a past-president of the section on tropical medicine of the Royal Society of Medicine; an original Fellow and a vice-president of the Royal Society of Tropical Medicine and Hygiene; and a Fellow of the Royal Anthropological Institute, the African Society, and the Society of Genealogists. A member of the British Medical Association for fifty-six years, he served as a vice-president of the Section of Nutrition when the Association held its Annual Meeting at Cambridge in 1948. A Freeman of the City of London, he was a Liveryman of the Worshipful Company of Founders, serving as Master of the Company in 1930-1 and again in 1953-4. He was unmarried.

WILLIAM STOBIE, O.B.E., M.D., F.R.C.P.

The sudden death of Dr. William Stobie at the age of 70 has removed from the life of Oxford an outstanding civic figure as well as one of its best-known medical practitioners.

William Stobie was born at Edinburgh on May 2, 1886, and was educated at George Watson's College and at Edinburgh University, where he graduated M.B., Ch.B. in 1908. In the following year he came to Oxford as house-physician to Sir William Osler, and ever since that time was closely connected with the Radcliffe Infirmary. From 1910 until he joined the Army he was medical officer to the Oxford Association for the Prevention of Tuberculosis. During the first world war he served in the R.A.M.C. as medical officer to the Oxford and Bucks Light Infantry; he was twice mentioned in dispatches and was appointed O.B.E. in 1919. After the war he returned to his medical work in Oxford, proceeding to the M.D. of Edinburgh in 1921 and becoming a member of the Royal College of Physicians of London in the following year. In 1926 he was appointed physician to the Osler Pavilion and in 1934 consultant for tuberculosis to Oxford City and Oxfordshire County. It was in this latter year that he was elected F.R.C.P. With the coming of the National Health Service in 1948 he was appointed consultant in diseases of the chest to the United Oxford Hospitals and clinical lecturer in the University of Oxford.

A member of the British Medical Association for some 40 years, Stobie was honorary secretary of the Oxford Division from 1923 to 1928 and of the Oxford and Reading Branch from 1924 to 1926; chairman of the Oxford Division in 1935-6 and again from 1940 to 1942; and president of the Berks, Bucks, and Oxford

Branch in 1938-9. At Headquarters he was a member of Council from 1933 to 1935, and served on a number of committees, including that on medical education (1933-5). At the Annual Meeting of the B.M.A. in 1936 at Oxford he held office as president of the Section of Tuberculosis.

In addition to his medical work Dr. Stobie was keenly interested in municipal affairs, becoming a councillor and subsequently an alderman on the Oxford City Council. He was appointed sheriff in 1927 and elected mayor in 1930. He was also a magistrate and a former chairman of the Oxford bench. Keenly interested in Rugby football, he became a very active supporter of the game at Oxford, and he was very proud of being the father of two Oxford University rugger blues. In his student days he played golf for Edinburgh University.

Dr. Stobie's work for the prevention and treatment of tuberculosis will be long remembered with gratitude, and his civic commitments showed what an active and full life he led in Oxford, where he will be greatly missed. Our sympathy is extended to his widow and family.—W. S. H.

W. C. MacFETRIDGE, M.D.

Mr. W. C. MacFetridge, surgeon emeritus to the Sussex Eye Hospital, Brighton, died at the Hereford General Hospital on February 23 at the age of 78.

William Christopher MacFetridge was born at Rushbrook, Co. Cork, on June 16, 1878, the son of the late Archdeacon of Ross, and was educated at Portora Royal School, Enniskillen, and at Trinity College, Dublin. He graduated M.B., B.Ch. from the University of Dublin in 1905, proceeding to the M.D. two years later. While at Trinity College he was a junior and senior exhibitioner, gaining first-class honours in classics and modern history. After graduation he held house appointments at Sir Patrick Dun's Hospital, Dublin, and at the Worcester General Infirmary. Later he was clinical assistant at the Royal Westminster Ophthalmic Hospital. From 1915 to 1919 he served as an ophthalmic specialist in the R.A.M.C. in Egypt with the 31st General Hospital and at the Military Hospital, Curragh.

After the war MacFetridge settled in practice in Dublin, where he became ophthalmic surgeon to Sir Patrick Dun's Hospital and to the Drumcondra Hospital and assistant ophthalmic surgeon to the Royal Victoria Eye and Ear Hospital. He was also an examiner in ophthalmic surgery for the University of Dublin. For a few years he acted as honorary secretary of the Irish Ophthalmological Society.

MacFetridge left Ireland in 1934 and lived at Cheltenham until he finally settled at Hove in 1936, becoming surgeon, and subsequently emeritus surgeon, to the Sussex Eye Hospital. He married Miss Louisa Carter in 1912, and had three sons and three daughters. Mrs. MacFetridge died in 1951.

J. P. S. W. writes: Many years ago an honorary surgeon at St. Thomas's Hospital said, "It is a great art to grow old gracefully." William Christopher MacFetridge undoubtedly had this art. Before coming to Brighton and Hove he had been an examiner and lecturer in ophthalmic surgery at Dublin University, and surgeon at the Royal Victoria Eye and Ear Hospital, and ophthalmic surgeon at Sir Patrick Dun's Hospital, Dublin. He came to Hove a few years before the second world war, and practised as a consultant in ophthalmology. During the war, when the honorary

Medico-Legal

E.C.T. FRACTURES

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

Mr. John Hector Bolam was admitted to Friern Hospital on April 29, 1954, as a voluntary patient. He had been a car salesman earning £1,000 a year in 1939 and had been commissioned in the Royal Engineers, but was discharged in 1942 suffering from serious nervous debility and depression. He had a series of jobs, but his mental condition became such by 1954 that during an attack of depression he had tried to take his own life.

After admission he had no treatment other than rest, and made good recovery. He was discharged on June 30, 1954, and went back to work, but depression returned and he was again admitted as a voluntary patient on August 16. On August 23, during the absence on holiday of Dr. J. de Bastarrechea, the consultant psychiatrist, he was given E.C.T. by the senior registrar, Dr. C. F. Allfrey. Dr. Allfrey found nothing in Mr. Bolam's history or on examination which suggested to him that a relaxant drug ought to be used, and the treatment was given with no restraint other than control of the shoulders, support for the jaw, and a pillow under the back.

As a result of the convulsion Mr. Bolam suffered from fractures shattering both acetabula, and would never walk properly again.

He subsequently brought an action for damages against the Friern Hospital Management Committee, alleging that the treatment given was negligent in that neither physical restraint through a restraining sheet nor manual pressure on shoulders and pelvis was used, nor was the alternative precaution of using relaxant drugs taken.

The action was tried before Mr. Justice McNair and a jury in the Queen's Bench Division.¹ Dr. J. B. Randell, consultant psychiatrist, called on behalf of Mr. Bolam, said that when relaxants were used the movement in convulsion was very slight and he knew of no case where a fracture had occurred. Relaxants were not commonly used in E.C.T. until 1946 or 1947, and the drugs then available were dangerous and unpredictable, and in 1954 they were not as commonly used as to-day. He knew that fractures did occur before the use of relaxants, but knew of the occurrence of only one among the cases under his supervision where a restraining sheet had been used. He would not in 1954 have carried out E.C.T. without any form of restraint, though he knew there was a school of medical thought which would do so. In cross-examination Dr. Randell agreed that there were real dangers in the use of relaxant drugs coupled with anaesthetics, which should be used in conjunction with them, but in the 6,000 to 10,000 cases of which he had experience in which they were used he had never had a death. He agreed that there existed to-day a large body of medical opinion which thought it wiser to give E.C.T. without the use of relaxant drugs, and which thought that the less restraint applied except to the chin the better. He had learnt with surprise that restraint was not used as often as he expected. It was a body of medical opinion which he would respect even though he did not agree with it.

Called for the defence, Dr. de Bastarrechea said that he was opposed to the use of relaxant drugs in E.C.T. owing to the mortality risk. He had been able to find no English statistics, but a United States survey covering the years 1948 to 1953 showed deaths at the rate of 1 in 370, and if the figures were broken down 1 in 2,000 would be acceptable. These figures confirmed his impression from the general theory of medicine of the danger involved in the use of anything which paralysed respiration. He used relaxant drugs only where the patient's life might be risked by straight E.C.T. Each case had to be considered from every aspect,

¹ *The Times*, February 21, 22, 23, 26, and 27.

staff of the Sussex Eye Hospital was reduced almost to vanishing point, he volunteered to act in any capacity. He assisted me in the out-patient department until the staff was once more completed by the return from the Forces of the younger consultants. This was no mean task for a man of his age, for the clinics would often last for 5½ to 6 hours. In order to mark our gratitude for his services the statutes of the Sussex Eye Hospital were specially altered so that he could be elected surgeon emeritus, a richly deserved honour. He was a handsome man and looked splendid in his white flannels on the lawn tennis court, at which game he excelled. The death of his wife a few years ago was a sad blow to him. His personal charm displayed the country of his origin, and he will be greatly missed by his patients and his colleagues alike, who extend to his children their sincere condolences.

Dr. D. A. DEWAR died at his home at Stanley, County Durham, on January 24 at the age of 86. Born at Portsmouth in 1870, David Alexander Dewar studied medicine at Glasgow and graduated M.B., Ch.B., with commendation, in 1893. After serving an assistantship at Low Fell he joined his brother-in-law, the late Dr. John Charles, in partnership in Stanley, where, except for some years in the Army in the first world war, he continued to practise until his own retirement fifty-three years later. Although of a reserved disposition, he soon won the confidence and affection of his patients, who appreciated his shrewd common sense, his innate kindness, and his high sense of duty. From his early training in Glasgow under Professor F. O. Bower he acquired an enthusiasm for botany which stayed with him all his life, so that no flower or plant grew in hedgerow or field to which he could not affix the name and order. This interest matched well with his own lifelong hobby of entomology, and in the countryside around his home he became a very familiar and well-loved figure. He leaves a widow and three sons, two of them in his own profession.

Lieutenant-Colonel H. ST. MAUR CARTER died at his home at Mortimer, near Reading, on February 10 at the age of 78, Herbert St. Maur Carter was born on May 7, 1878, of a military family, and was educated at Trinity College, Dublin, graduating M.B., B.Ch. from the University of Dublin in 1904 and proceeding to the M.D. in the same year. After holding the appointment of house-surgeon at the Adelaide Hospital, Dublin, he took out a regular commission in the R.A.M.C., in which he served until 1930.

A. S. W. writes: H. St. Maur Carter was one of the generation of officers before the first world war, when the prestige of the R.A.M.C. reached its highest peak; an era associated with the names of Bruce, Leishman, and many other officers who gained international fame. Colonel Carter's specialty was surgery, and he held important surgical appointments at the Cambridge Hospital, Aldershot, and elsewhere. In 1912-13 he was twice granted special leave to accompany Red Cross units to the Middle East, and for his services in Serbia was awarded the Order of St. Sava. He saw active service in France and Italy from 1914 to 1918. He was awarded the D.S.O. in 1915 and was three times mentioned in dispatches. He was the ideal Army doctor, being a keen soldier, but a doctor first and last. Cultured and well-informed, he possessed a kindly nature which endeared him to all his friends. With a keen sense of humour and a store of anecdotes and reminiscences derived from his service in various parts of the world, he was always the best of company. After retiring from the Service in 1930, he eventually settled in the village of Mortimer, where he took a great interest in people and in village affairs. During the second world war he undertook duties with the Civil Defence. In the last year of his life he bore a painful illness with the utmost courage.

and his technique was non-restraint. In cross-examination he said that six fractures during E.C.T. during the past seven years at Friern Hospital meant six in about 70,000 cases. Of the ten doctors giving E.C.T. in his hospital some always used relaxants, including one of his own juniors, some used them only in selected cases, but they had nearly all ceased using manual restraint at about the same time. The hospital records showed four deaths associated with E.C.T. using "scoline" (succinylcholine chloride) as a relaxant and two associated with straight E.C.T., in one of which the coroner's jury had found a verdict of death from natural causes.

Dr. Allfrey himself said that, though he had left neither the "non-relaxant" nor the "non-restraining" camp, he was now using relaxants to a greater extent than in 1954 because a new one, "brevdil," was considered safer. After the accident to Mr. Bolam he gave a relaxant in all cases of E.C.T. for the following seven days, because until he had become certain in his own mind that there had been nothing wrong with his technique he thought he ought to take no risk of further fractures till Dr. de Bastarrechea returned.

Dr. L. G. M. Page, deputy medical officer of the Three Counties Hospital, Bedfordshire, and Dr. A. A. Baker, consultant psychiatrist and deputy superintendent at Banstead Hospital, also gave evidence for the defence.

Summing up to the jury, Mr. Justice McNair said that a professional man was not guilty of negligence if he acted in accordance with a practice which was accepted by a competent body of professional men skilled in that particular art merely because there was a body of opinion which took the contrary view. They must not look through 1957 spectacles at what had happened in 1954.

The jury returned a verdict for the defendants, and judgment was entered accordingly.

MEDICAL NEGLIGENCE

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

Lord Nathan's express intention in writing this book¹ has been to give medical men and hospital administrators an idea of how they stand in law in the varying circumstances in which they may find themselves in the exercise of their profession. He was moved to write it because as chairman of the board of governors of the Westminster Hospital he had become very conscious of the effect upon them, and especially upon doctors of junior standing, of the apprehension of litigation.

Lord Nathan, with the collaboration of Mr. Anthony Barrowclough, has made a comprehensive examination of medical negligence. He has also explored a problem less widely canvassed but no less important—that of the legal implications of consent of the patient to treatment or operation. He points out that in this field there are few English decisions, and illustrates his argument and conclusions from United States and Commonwealth cases. If more of such cases come to be decided in England in future this will be very helpful. The fact that not many such cases have been reported in England so far is one of the few grains of relief from apprehension of litigation to be derived by doctors and hospital administrators from Lord Nathan's book. He cannot in the nature of things do more otherwise to relieve them than to explain that their legal duty to the patient is to take reasonable care for his safety, no more and no less, and to do so in the light of medical knowledge at the time when the treatment is given or operation performed. But the wide variety of cases cited by Lord Nathan in which this duty has been found to have been broken is a depressing reminder of medical fallibility.

While Lord Nathan amply succeeds in covering the many varying circumstances in which doctors and hospital administrators in the exercise of their profession may find

themselves in collision with the law, this is rather a lawyers' than a doctors' book. It will be an excellent source of lecture material for the medical school, making as it does a clear analysis of the legal relation between doctor and patient and its implications. But doctors may conclude it would have been safer to have gone to the Bar than take up medicine. Counsel, as Lord Nathan, being a solicitor, does not fail to observe in the opening paragraph of his preface, if not actually incapable of negligence, are at any rate immune from its consequences.

Medical Notes in Parliament

ROYAL COMMISSION ANNOUNCED

The PRIME MINISTER announced on February 28 the terms of reference of the Royal Commission on the remuneration of doctors in the Health Service. He said, in answer to questions by three members, the terms of reference will be as follows:

To consider:

- How the levels of professional remuneration from all sources now received by doctors and dentists taking any part in the National Health Service compare with the remuneration received by members of other professions, by other members of the medical and dental professions, and by people engaged in connected occupations;
- What, in the light of the foregoing, should be the proper current levels of remuneration of such doctors and dentists by the National Health Service;
- Whether, and if so what, arrangements should be made to keep that remuneration under review;

He said he would announce as soon as possible the names of the chairman and members. He could not fix a date by which the commission must report, but he would certainly urge the chairman to proceed without delay.

Mr. J. RANKIN (Glasgow, Govan, Lab.) asked if the Prime Minister was aware that a B.M.A. spokesman quoted in the press had said that his reference to an interim adjustment was extremely obscure, and that it might mean any of a number of things, some of which would be entirely unacceptable. Would the Prime Minister not make his attitude on the interim adjustment clear beyond a peradventure, or did he wish to give the tough boys in the B.M.A. the ammunition necessary to destroy the Health Service?

Mr. MACMILLAN: The sentence which I put into the letter means exactly what it says, and I do not wish to make any interpretation of it this afternoon. At the same time, we are always in touch with the leading members of the profession, and either the Minister of Health or I will be very willing to make any further explanation at an appropriate moment.

Mrs. E. HILL (Manchester, Wythenshawe, Con.): Is it not a fact that the Government are prepared to negotiate an immediate increase for junior hospital staff?

Mr. MACMILLAN: Yes.

Mr. F. BESWICK (Uxbridge, Lab.): Is the Prime Minister aware that if, as a result of any uncertainty as to the meaning of the phrase interim adjustment, any damage is done to the Health Service, the people of this country will not forgive him? Can he say why he cannot make it clear, both to allay apprehension on the part of doctors and also in fairness to those who may be invited to serve on this commission, that the commission is not now intended, as was originally the case, simply to dodge the issue, and does not preclude any interim negotiations on salary scales?

Mr. MACMILLAN said Mr. Beswick was very fond of making statements for which he had little ground; he preferred to rely rather on innuendo than fact. The commission was never intended for the purpose of dodging this issue. Members on both sides of the House knew the very difficult circumstances that surrounded some of these problems. "I am convinced that the commission will be able to act

rapidly and effectively, and I am very hopeful that we shall be able to reach a good point of view between all concerned in this matter."

Dr. EDITH SUMMERSKILL (Warrington, Lab.): Will not the Prime Minister say whether the terms of reference will enable the commission to take into account the conversations conducted at the inception of the Service between the Government and the doctors? Further, will he again consider interpreting this phrase, because the attitude of the profession during the next few months may be guided by what he says now?

Mr. MACMILLAN: On the first point, I have not the record of these conversations with me. Therefore if she pressed me on the matter I should have to ask for notice. I think it would be a matter for the commission itself to decide. With regard to the second point, I should prefer to leave the matter as it is at the moment. I feel quite certain we shall be able to make good progress in this affair.

Dr. DONALD JOHNSON (Carlisle, Con.), questioning the Prime Minister the previous day about the terms of reference, asked if he would extend them to include the examination of the method of payment by capitation fee, which had not always been satisfactory to either doctor or patient, and the substitution of another method of payment according to the nature of the service rendered to the individual.

Mr. MACMILLAN: I will consider that. We have not yet decided on the terms of reference, but I will be glad to consider what Dr. Johnson has said.

Mr. H. GAITSKELL, Leader of the Opposition: Is the Prime Minister aware that there is widespread anxiety that the Royal Commission will take a very long time before reaching its conclusions, and that while there may be a case for reviewing the whole question of the method of payments to doctors there is also a case surely for coming to some interim settlement on their claims?

Mr. MACMILLAN: If Mr. Gaitskell had read the letter that I wrote, which was published this morning, he would have seen that that was exactly the point I made.

Mr. GAITSKELL: The Prime Minister said nothing in the letter as to exactly how this interim settlement was to be arrived at. Is it to be left to the Royal Commission, or are the Government prepared to do their duty and reach an agreement?

Mr. MACMILLAN: I have nothing to add to the letter I wrote, which I think was explicit, clear, and helpful.

Leukaemia and Bomb Tests

Dr. BARNET STROSS (Stoke-on-Trent, Central, Lab.) asked the Prime Minister on February 28 whether his attention had been drawn to the rising incidence of leukaemia in many parts of the world where reliable statistics were available; and whether, in view of the increasing risks from this and other diseases which closely followed the explosion of nuclear weapons, he would suggest to Mr. Eisenhower and Marshal Bulganin that a meeting be called for further discussion on the abolition of the tests.

Mr. MACMILLAN stated that he was aware that there had been an increase in the death rate from leukaemia over at least the last 25 years, but he understood that, while it would be generally agreed that exposure to radiation was probably one factor causing this, the amount of external radiation due to fall-out from nuclear test explosions formed a very small proportion of the radiation to which man was exposed from all sources. Various proposals on nuclear and conventional disarmament would be considered when the Disarmament Subcommittee met on March 18.

Anthrax Investigation

Commander C. E. DONALDSON (Roxburgh, Selkirk, and Peebles, Con.), asked the Minister of Labour whether he proposed to review the operation of the Orders under the Anthrax Prevention Act, 1919.

Mr. IAIN MACLEOD announced on February 28 that he had received a number of representations which indicated the need for such a review. The last full-scale inquiry into the question of precautions against anthrax was made 40 years

ago, and he had decided, after consulting the Minister of Health, the President of the Board of Trade, and the Secretary of State for Scotland, and also the Medical Research Council, to appoint a committee of inquiry with the following terms of reference: "To consider the existing legal provisions concerning the importation of goods infected or likely to be infected with anthrax and the precautions to be taken in connexion with such imported goods for the protection of the health of persons and to make recommendations." Mr. R. F. Levy, Q.C., had agreed to act as chairman of the committee. He would announce shortly the names of the other members.

Lung Cancer Research

The firm intention of the Government to reveal the truth about the connexion between smoking and lung cancer as it came to light was declared by Mr. J. K. VAUGHAN-MORGAN, Parliamentary Secretary to the Ministry of Health, at the end of a short debate in the House of Commons on March 1. In the meantime, he said, they must avoid sensationalism.

Mr. M. LIPTON (Brixton, Lab.) opened the debate with a criticism of the Government for its failure to sponsor an anti-smoking campaign.

Mr. VAUGHAN-MORGAN asserted that the Government had not hesitated to announce any discovery as and when it became available. There had been very little advance since the Government statement in May, 1956. Carefully controlled inquiries had shown statistically that smokers had a significantly higher mortality rate from lung cancer than non-smokers.

There were many ways of interpreting the statistical evidence available. Without doubt the findings did constitute prima facie statistical evidence that smoking carried a risk of lung cancer. These mortality rates, and these risks, must be viewed with a due sense of proportion.

Lung cancer was not the only problem, nor must it be the only preoccupation. It continued to show a steady increase, which had varied from 5.7 to 8.7% over the past five years. The Medical Research Council was engaged in an extensive programme for the purpose of throwing more light on the exact nature of the relationship between smoking and lung cancer, the long-term aim being to identify those constituents of tobacco smoke which might be active in provoking cancer. Research was continuing also on far wider aspects than this. It could fairly be said that there was no promising line of investigation that was being neglected for lack of funds. The Government were spending £364,000 a year on cancer research of all kinds through the Medical Research Council alone. In addition, there was research in the hospitals and universities, and the voluntary associations were making large contributions. The M.R.C. were currently reviewing the existing evidence, and their considered views should be available before long. The Government would give these their full and urgent consideration, and he repeated the pledge that the public would be informed of all the evidence as it became available.

Periods of Hospital Treatment

The MINISTER OF HEALTH informed Mr. D. FREETH (Basingstoke, Con.) on March 1 that the average length of stay in hospital of in-patients who died or were discharged in 1955 was:—mental illness: treatment under Lunacy and Mental Treatment Acts, 552.1 days, others 103.9 days; mental deficiency 4,123.1 days; diseases of the chest 139.8 days; chronic sick 172.5 days; all others 15.7 days.

Interim Pay Adjustment

Mr. M. LIPTON (Brixton, Lab.) asked the Prime Minister on March 4 what communications he had received from medical organizations since his announcement of a Royal Commission on doctors' pay.

Mr. HAROLD MACMILLAN.—I have received a letter from the negotiating committee of the medical profession, which has been published together with a copy of my reply.

Mr. LIPTON.—If the Prime Minister has another look at his reply he will see that the English is bad and the meaning obscure. Will he say why he is so curiously unwilling to

¹ *Medical Negligence: Being the Law of Negligence in Relation to the Medical Profession and Hospitals.* By the Right Hon. Lord Nathan, P.C., with the collaboration of Anthony R. Barrowclough, B.A. (Pp. 218+xxxii; 35s.) London: Butterworth and Co. Ltd. 1957.

say whether this proposed interim adjustment may also apply to general practitioners?

Mr. MACMILLAN.—I am sorry about the English. I am always ready to take advice from a very expert source. I think the best thing I can do is to try and get the Commission started, and I hope, with great confidence, that we shall be able to clear up the other issues as we go on.

Mr. ERIC FLETCHER (Islington, East, Lab.) asked if the Prime Minister would not agree that, whatever might be the case for a Royal Commission to examine the overall question of doctors' pay, there was a strong case for some interim immediate adjustment of doctors' remuneration, and would he acknowledge that and remove all this misunderstanding by making his position clear? Mr. MACMILLAN said that it was for that reason he had made reference to it in his letter.

Mr. A. BLENKINSOP (Newcastle upon Tyne, East, Lab.).—Would the Prime Minister not agree that, since he has made this specific reference in his letter to the B.M.A., it is highly desirable that he should clarify it so that possibly some further dispute may be avoided?

Mr. MACMILLAN.—No. I think all these things will move along satisfactorily. The first thing to do is to get the Commission appointed, which, I am very hopeful, will be quite soon. Then, as I said in answer to supplementary questions, it will be made quite clear that the Minister of Health and I are very ready to take up these further questions with the negotiating committee.

Mr. BLENKINSOP asked the Minister of Health whether he would reopen negotiations with the medical profession for an interim settlement of their claim, pending the full review to be undertaken by a Royal Commission. Mr. D. VOSPER replied that the Government was prepared immediately to recommend the Management Side of the appropriate Whitley Council to offer to negotiate an interim increase in the remuneration of hospital medical and dental staff up to and including the grade of senior registrar. Beyond this he would refer the Member to the replies given by the Prime Minister on February 28.

Mr. BLENKINSOP said this was merely a stone-walling answer. When would the Minister give some information with regard to the interim negotiations in respect of general practitioners? Mr. VOSPER said it was not a stone-walling answer, because it related to the Government's decision to offer to negotiate immediately for junior hospital doctors. On that question he was still awaiting a reply from the negotiating committee. Beyond that, he had nothing to add to the Prime Minister's statement.

Prescription Costs

Mr. BLENKINSOP asked the Minister of Health what was the average cost per prescription under the National Health Service for the month of December, 1956; and how this compared with the average cost in December, 1955. Mr. VOSPER said it was approximately 5s. 6½d., which was about 11d. more than in December, 1955. Mr. BLENKINSOP said there had been a serious further increase in the cost since the new charges were imposed. Did not that show the grave danger of the advice to doctors to prescribe larger quantities per prescription? Mr. VOSPER pointed out that a great part of this increase occurred before the new prescription charge was introduced, and it was due in part to the increased chemists' remuneration and the release of new drugs. Only in part was it due to the new prescription charge. He would like to see the results for February and March before coming to a definite conclusion.

Mr. G. NICHOLSON (Farnham, Lab.) asked if the Ministry were doing anything to see that during their training doctors were made cost-conscious. Mr. VOSPER said "Yes."

Dr. EDITH SUMMERSKILL (Warrington, Lab.) said the high average cost of prescriptions was related to the high cost of proprietary drugs. What action was the Minister taking to keep this factor within reasonable limits? Mr. VOSPER told her the matter was under review. He could not say, on the figures for December, how much of the cost related to proprietary medicines.

Vital Statistics

Tetanus Deaths

Though deaths in England and Wales assigned to tetanus in 1954 numbered 37, a special examination of death certificates by the Registrar-General showed that in another 24 cases death was primarily due to tetanus.¹ Proportionately to population, twice as many occurred in the country as in towns. Among the causes of the tetanus were a few cases of the classical type of injury—"rusty iron spike penetrated foot," "wound from garden fork"—and several in which the source of infection was so inapparent as not to be traced. In between came some cases in which the injury was known but trivial and likely to be disregarded—for example, "grazed knee," "puncture wound in leg from splinter off park bench," "splinter in hand," "infection of ingrowing toenail." Four infections followed surgical operations—correction of foot deformity, hysterectomy for fibroids, gastrectomy for duodenal ulcer, and triple arthrodesis to correct foot deformity. Two cases of tetanus neonatorum occurred. Some noteworthy causes of the infection included: "associated with acute otitis media," "sprained ankle, developing osteomyelitis," "blister infected by fish manure," "abrasion of skin on removal of plaster strapping for fracture of humerus," and "infected epithelioma of scalp."

Industrial Accidents and Diseases

The number of workpeople (other than seamen) in the United Kingdom whose deaths from accidents in the course of their employment were reported in January was 85, compared with 116 in the previous month and 92 (revised figure) in January, 1956.

The numbers of cases of industrial diseases in the United Kingdom reported during January, 1957, were as follows: lead poisoning 4, aniline poisoning 1, epitheliomatous ulceration 10, chrome ulceration 4; total 19. There were no deaths.—*Ministry of Labour Gazette*, February, 1957.

Defective Poliomyelitis Vaccine

The Ministry of Health announced on February 27 that in the latest batch of poliomyelitis vaccine 47 vials were defective. They showed a change of pH towards acidity. These vials contain enough vaccine for 235 children, while the whole batch could vaccinate 200,000 children (with two doses). This change has not previously been encountered, but it is said not to be due to the presence of live virus, and probably not due to bacterial contamination. The cause of it is being investigated with the utmost speed, and meanwhile the rest of the batch is not being distributed.

A batch of vaccine takes about six months to prepare, and on the average the batches are now expected to emerge from production about two to four weeks apart. This batch was put into its final containers last November, since when it has been stored at 4°C. The material drawn off for testing had satisfactorily passed all the tests. These are biological in character, so that the material is used up by them. The material in the vials was divided into eight subdivisions, and the 47 faulty vials were in two of these subdivisions. The possibility of other vials developing this change is also being investigated.

Week Ending February 23

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 890, whooping-cough 3,190, diphtheria 2, measles 21,317, acute pneumonia 625, acute poliomyelitis 39, dysentery 1,296, paratyphoid fever 8, typhoid fever 1.

¹ The Registrar-General's Statistical Review for the year 1954, Part 3, Commentary. H.M.S.O. (8s.).

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases (deaths for influenza) of certain diseases notified weekly in England and Wales (great towns for influenza). Highest and lowest figures reported in each week during the years 1948-56 (influenza 1952-6) are shown thus -----, the figures for 1957 thus ————. Except for the curves showing notifications in 1957, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

Only small changes were recorded in the incidence of most infectious diseases in England and Wales during the week ending February 16. The only exception was an increase of 2,958 in the number of notifications of measles, from 16,752 to 19,710.

The largest rises in the incidence of measles were 466 in Lancashire, from 3,438 to 3,904, 277 in Middlesex, from 652 to 929, 266 in Yorkshire West Riding, from 930 to 1,196, 226 in Surrey, from 722 to 948, 211 in Yorkshire East Riding, from 367 to 578, 199 in Cheshire, from 586 to 785, 187 in Oxfordshire, from 159 to 346, 158 in Kent, from 291 to 449, and 155 in London, from 1,353 to 1,508; the only large exception to the general rise was a fall of 100 in Yorkshire North Riding, from 237 to 137. 830 cases of scarlet fever were notified, 39 fewer than in the preceding week, and only small changes were recorded in the local trends. 3,163 cases of whooping-cough were notified, being 15 more than in the preceding week. The largest fluctuations in the returns of whooping-cough were decreases of 51 in Essex, from 209 to 158, 47 in Lancashire, from 346 to 299, and an increase of 44 in Kent, from 160 to 204. Only 2 cases of diphtheria were notified, being 7 fewer than in the preceding week.

37 cases of acute poliomyelitis were notified during the week, and these were 10 more for paralytic and 7 fewer for non-paralytic cases than in the preceding week. The largest returns were 3 cases in Leicestershire and in Yorkshire West Riding (Barnsley C.B. 2).

The notifications of dysentery numbered 1,274 and were 16 fewer than in the preceding week. The largest variations in the local outbreaks were increases of 50 in Yorkshire West Riding, 48 in Warwickshire, and a decrease of 61 in Lancashire. The largest returns during the week were Lancashire 275 (Accrington M.B. 84, Stretford M.B. 58, Urmston U.D. 25, Tyldesley U.D. 14, Salford C.B. 10), Yorkshire West Riding 224 (York C.B. 46, Rotherham C.B. 34, Batley M.B. 31, Leeds C.B. 29, Sheffield C.B. 16, Dewsbury C.B. 14, Bradford C.B. 13, Colne Valley U.D. 11, Worsbrough U.D. 10), Warwickshire 123 (Coventry C.B. 66, Birmingham C.B. 47), London 92 (Hackney 16, Southwark 10, Wandsworth 10), Essex 67 (East Ham C.B. 55), Northumberland 63 (Blyth M.B. 30, Newcastle upon Tyne C.B. 19, Alnwick U.D. 14), Durham 61 (Gateshead C.B. 26, Blaydon U.D. 20), Middlesex 43 (Harrow M.B. 20), Nottinghamshire 43 (Arnold U.D. 14, Nottingham C.B. 11, Basford R.D. 10), Yorkshire East Riding 42 (Kingston upon Hull C.B. 33), Staffordshire 36 (Kidsgrove U.D. 15, Stoke on Trent C.B. 10), Surrey 30 (Surbiton M.B. 21), and Bedfordshire 20 (Luton M.B. 17).

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending February 16 (No. 7) and corresponding week 1956.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

Medical News

Rockefeller Grants.—In the last quarter of 1956 grants totalling over \$8 million were awarded by the Rockefeller Foundation. Medical education and public health, and biological and medical research, received between them \$2.2 million. The principal grant to Britain during the quarter was £10,000 towards the initial costs of the Institute of Statistics at Aberdeen, established recently by Aberdeen University and the Agricultural Research Council. The Institute offers postgraduate training in statistics (leading to a degree) and advises on the design of experiments. Although mainly concerned with agricultural problems, the Institute's staff also help other departments in the university. Other grants include \$9,500 to Sheffield University towards the cost of a study group in Holland arranged by the International Corresponding Club for Preventive and Social Medicine; \$5,000 for research equipment for the department of biochemistry at Glasgow; and a grant towards the expenses of a visit to surgical laboratories in the United States by Professor P. R. ALLISON, Nuffield professor of surgery at Oxford.

Chair of Chemical Pathology, Leeds.—Dr. G. H. LATHE, research biochemist at Queen Charlotte's Maternity Hospital, London, has been appointed professor of chemical pathology at Leeds University. He succeeds Professor F. S. FOW-WEATHER. Dr. Lathe, who is 43, graduated at McGill University in both science (1934) and medicine (1938). He also obtained the M.Sc. (1936) and later the Ph.D. (1947). After holding research appointments in physiology at McGill, Dr. Lathe was commissioned in the Royal Canadian Army Medical Corps in 1941, serving as an R.M.O. and later as biochemist. He was demobilized in 1945. Coming to England in 1946, Dr. Lathe went to Oxford with an I.C.I. research fellowship until 1948, when he moved to the Postgraduate Medical School of London. Here he continued his research. In 1949 he was appointed biochemist in the Bernhard Baron Research Laboratories at Queen Charlotte's. Dr. Lathe's main subjects of research have been alimentary absorption, the metabolic effects of wounds, and the bile pigments.

Medical Cinematography.—An international society dealing with "cine-endoscopy" and "cine-radiology" was officially inaugurated in Paris last December. It is the Société Médicale Internationale de Photo-cinématographie et Télévision Endoscopiques et de Radiocinématographie. Its headquarters are at Rheims, and the permanent honorary secretary is Dr. J. M. DUBOIS DE MONTREYNAUD, 4, Rue du Général Baratier, Rheims, Marne, France, from whom further information may be obtained. The society's first annual meeting will be held in New York on June 3 and 4, under the presidency of Dr. P. H. HOLINGER.

Clinics for Men with Sexual Problems.—The Family Planning Association now has six branches, in addition to its headquarters, where clinics for men are held. The latest to open is one at Birmingham. The commonest disabilities encountered in these clinics are impotence, infertility, and premature ejaculation. Doctors wishing for further information should apply to the Family Planning Association, 64, Sloane Street, London, S.W.1.

M.R.C.P. (Edinburgh).—The following were elected Members of the Royal College of Physicians of Edinburgh at the quarterly meeting of the college on February 5: R. F. Guymer, M. A. O'Halloran, M. M. Prasad, J. Allan, J. Wilkinson, B. Levin, S. Ahmed, Elaine H. McNeil-Smith, M. S. N. Pathy, S. S. Khandpur, R. D. Pasi, B. J. Baldachin, J. R. Roy, A. C. Gibson, P. S. Mukherji, Flora M. Bisset-Smith, J. P. F. Fogarty, N. Z. Sacks, T. B. Patel, A. Jain, J. H. Learmonth, K. A. Krishnamurthy, B. P. Mozoomdar, W. B. Hudson, and P. Dayal.

Otago University.—Dr. J. R. ROBINSON, of the department of experimental medicine, Cambridge, has been appointed associate professor in physiology at Otago University. Dr. Robinson is a fellow and assistant tutor of Emmanuel College, Cambridge, assistant director of research in the department of experimental medicine, and secretary to the faculty board of medicine. He is leaving for New Zealand in August.

London University.—Professor J. B. S. HALDANE, F.R.S., is resigning from the Weldon Chair of Biometry at University College on September 30. Professor J. L. D'SILVA, professor of physiology at the London Medical College, has been appointed a fellow of King's College.

University College of West Indies.—Dr. R. J. GOURLAY, assistant S.M.O. of the North-West Metropolitan Regional Hospital Board, has been appointed senior lecturer in preventive medicine at the College. He is expected to arrive in Jamaica early next month.

Birmingham University.—Mr. A. L. T. EASTON, F.R.C.S., has been appointed lecturer in obstetrics and gynaecology from March 1.

Leeds University.—Dr. J. M. ROBERTS has been appointed lecturer in the department of psychiatry. He was formerly tutor in psychiatry.

COMING EVENTS

Bradshaw Lecture.—Mr. A. LAWRENCE ABEL, F.R.C.S., will deliver the Bradshaw lecture on March 14 at 5 p.m. at the Royal College of Surgeons, Lincoln's Inn Fields, London, W.C.2. His subject will be "Diagnosis and Treatment of Diseases of the Large Intestine."

British Association of Physical Medicine.—Annual meeting at the Middlesex Hospital, London, W.1, April 5 and 6. Dinner at the Royal College of Surgeons on April 5 (tickets 30s.; apply before March 23). Further details from the secretary of the association, 45, Lincoln's Inn Fields, London, W.C.2.

Institute of Diseases of the Chest.—A discussion for general practitioners on hay fever and asthma, April 9 at 2.30 p.m. at the Institute. Details from the secretary of the Institute, Brompton, London, S.W.3.

Victor Horsley Memorial Lecture.—Sir GEOFFREY JEFFERSON will deliver the Victor Horsley Memorial Lecture on April 12 at 5.30 p.m. at B.M.A. House. His subject will be "Victor Horsley—His Life and Work."

Tuberculosis Educational Institute.—Intensive course for medical practitioners on "Chest Diseases and the Family Doctor," Norwich, April 13 and 14. Details from the Institute, Tavistock House North, Tavistock Square, London, W.C.1.

Society for General Microbiology.—Twenty-fourth general meeting, at the Royal Institution, Albemarle Street, London, W.1, April 15-17. Details from the Society, c/o Institute of Biology, 41, Queen's Gate, London, S.W.7.

Nutrition Society.—A symposium on "Clean Food" will be held by the Scottish Group in Aberdeen on April 20. Details from Dr. J. DAVIDSON, Rowett Research Institute, Bucksburn, Aberdeenshire.

Association of Surgeons of Great Britain and Ireland.—Annual meeting, April 25-27, at Newcastle upon Tyne. Registration before April 11. Details from the secretary of the association, 45, Lincoln's Inn Fields, London, W.C.2.

Welsh National School of Medicine.—Postgraduate course for general practitioners, April 29 to May 11. Details from the secretary of the school, 34, Newport Road, Cardiff.

Medical Exhibition at Glasgow.—The 1957 Regional Exhibition of the London Medical Exhibition will be held at the McLellan Galleries, Sauchiehall Street, Glasgow, April 29 to May 3. The exhibition will be open from 11 a.m. to 6.30 p.m. (8 p.m. on April 30).

British Diabetic Association.—The eleventh Banting Memorial meeting will be held on July 12 and 13 in Oxford. Professor H. A. KREBS, F.R.S., will deliver the memorial lecture. Early application for accommodation should be made to the British Diabetic Association, 152, Harley Street, London, W.1.

Universities Federation for Animal Welfare.—A symposium on "Humane Technique in the Laboratory" will be held on May 8 at Birkbeck College, Malet Street, London, W.C.1. Details from the secretary, Laboratory Animals Bureau, M.R.C. Laboratories, London, N.W.3.

NEW ISSUES

Archives of Disease in Childhood.—The new issue (Vol. 31, No. 160) is now available. The contents include:

THE ADOLESCENCE OF NUTRITION. L. Emmett Holt, jun.
THE DAY AND NIGHT OUTPUT OF URINE IN ENURESIS. David Vulliamy.
THE REBOUND PHENOMENON IN ACUTE RHEUMATIC FEVER. K. S. Holt.
PHENYLALANINE-RESTRICTED DIETS IN THE TREATMENT OF PHENYLKETONURIA. J. D. Blainey and R. Gulliford.
TUBERCLES OF THE CHOROID. R. S. Illingworth and J. Lorber.
ENCEPHALITIS AND THROMBOCYTOPENIC PURPURA AFTER RUBELLA. Emil Steen and K. H. Tord.
MASSIVE PULMONARY EMBOLISM IN A BOY AGED 9. Maureen Cashman.
SALIVARY ELECTROLYTES IN FIBROCYSTIC DISEASE OF THE PANCREAS. William H. Johnston.
THE INCIDENCE OF INFANTILE PYLORIC STENOSIS IN THE NORTH-EAST OF SCOTLAND. Muriel M. McLean.
THE POSSIBLE INFLUENCE OF HYPERADRENOCORTICISM ON THE FOETUS OF THE DIABETIC WOMAN. James W. Farquhar.
MESENTERIC LYMPHANGIOMA AS A CAUSE OF ACUTE ABDOMINAL SYMPTOMS. M. Levene, P. A. Walker, and T. A. White.
PROTEOLYTIC ACTIVITY OF THE PANCREAS. J. G. Bate and Ursula James.
ANURIA ASCRIBED TO ACUTE TUBULAR NECROSIS IN INFANCY AND EARLY CHILDHOOD. I. J. Carré and J. R. Squire.
THE EFFECT OF ORAL LACTULOSE ON FAECAL FLORA AND pH IN INFANTILE GASTRO-ENTERITIS. B. Zilberg.
BOOK REVIEWS.
INDEX TO VOLUME 31.

Issued six times a year; annual subscription £3 3s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

Journal of Neurology, Neurosurgery, and Psychiatry.—The new issue (Vol. 20, No. 1) is now available. The contents include:

ABNORMAL IMMUNOLOGICAL REACTIONS IN DISSEMINATED SCLEROSIS. Honor V. Smith, M. L. E. Espir, C. W. M. Whitty, and W. Ritchie Russell.
LOSS OF RECENT MEMORY AFTER BILATERAL HIPPOCAMPAL LESIONS. W. B. Scoville and Brenda Milner.
THE RECURRENCE OF INTRACRANIAL MENINGIOMAS AFTER SURGICAL TREATMENT. Donald Simpson.
A VARIETY OF PARAMYOTONIA CONGENITA. E. B. French and R. Kilpatrick.
A SIMPLIFIED NEUROSURGICAL TECHNIQUE FOR APPROACHING AND DAMAGING THE REGION OF THE GLOBUS PALLIDUS IN PARKINSON'S DISEASE. S. Obrador.
AN UNUSUAL FORM OF WIDESPREAD VASCULAR DISEASE OF THE BRAIN IN A YOUTH. C. S. Treip and R. J. Porter.
SOME RELATIONSHIPS BETWEEN PERIPHERAL VASOMOTOR AND E.E.G. CHANGES. Brian Ackner and G. Pampiglione.
CONDUCT DISORDERS IN EPILEPTIC CHILDREN. F. Grunberg and D. A. Pond.
PROCEEDINGS OF THE SOCIETY OF BRITISH NEUROLOGICAL SURGEONS.
BOOK REVIEWS.

Issued quarterly; annual subscription £2 2s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

British Journal of Ophthalmology.—The new issue (Vol. 41, No. 3) is now available. The contents include:

PROGNOSIS IN CASES OF STRABISMUS WITH SPECIAL REFERENCE TO ORTHOPTIC TREATMENT. T. Keith Lyle and Jill Foley.
KERATOCONJUNCTIVITIS SICCA DUE TO SARCOIDOSIS. Barrie R. Jones and C. J. Stevenson.
MENINGIOMA INVADING THE OPTIC NERVE. V. A. F. Martin and P. B. Schofield.
INTRA-EPITHELIAL EPITHELIOMA (BOWEN'S DISEASE). P. D. Trevor-Roper.
METHOD FOR THE DIRECT OBSERVATION OF RETINAL VESSELS IN THE EXPERIMENTAL ANIMAL. Christopher Pedler.
STUDIES ON DEVELOPING RETINAL VESSELS. IV. THE EFFECT OF IONIZING RADIATION. Christopher Pedler.
26 CASES OF EXTRA-CONJUNCTIVAL IMPLANTS. M. L. Nairac.
HEREDITY OF GREEN-BLINDNESS. W. M. Jablonski.
THE ZAGORA ROD TEST. Edward Zagora.
TAY-SACHS'S DISEASE (AMAUROTIC FAMILY IDIOCY). S. S. Manchanda, M. S. Nirankari, and M. C. Maudgal.
CORRESPONDENCE.
NOTES.

Issued monthly; annual subscription £4 4s.; single copy 8s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

into cortisone and related compounds in some 20 stages. The two latter methods are being employed in this country.

Corticotrophin is obtained from the pituitary glands of oxen, pigs, or sheep. The glands may be minced and extracted with acid, aqueous acetone, and a concentrate precipitated by addition of more acetone. Alternatively the glands, preserved in acetone or as an acetone-dried powder, may be extracted with acetic acid and the extract fractionated. The crude material is a mixture of active polypeptides of high molecular weight; homogeneous material—e.g., β -corticotrophin—is obtainable by fractionation using selective adsorption and distribution between solvents. In recent years the various methods which have been used have yielded crude protein, purified protein, and active products obtained after partial hydrolysis, particularly with pepsin, and there has been much confusion about the clinical response to be expected from a biological unit.¹

Mammary Hyperplasia in a Girl

Q.—A girl of 17 has a diffuse painless hyperplasia of her breasts, which reach almost to her umbilicus and are becoming difficult to control by a brassière. In all other respects she is normal. (1) Are her breasts likely to continue increasing in size? (2) Is it still true that hormone therapy has no beneficial effect? (3) What are the results of plastic operations to reduce the breasts?

A.—As the girl has reached the age of 17 it is unlikely that her breasts will increase in size, except as part of a progressively developing obesity.

Hormone therapy has no beneficial effect. Though in some cases androgens may relieve the pain and tenderness of premenstrual mastalgia, they never cause the breasts to shrink.

The results of plastic reduction are usually satisfactory, and this operation would seem indicated in this case.

Glutamic Acid and Mental Retardation

Q.—What place has glutamic acid in the treatment of mental retardation?

A.—There is no good evidence that glutamic acid has any place in the treatment of mental retardation. There is no rationale for its use. It is a component of any balanced diet and a considerable quantity is present in milk. Albert *et al.*¹ gave 8–10 gr. (0.52–0.65 g.) of glutamic acid per day and reported an "unmistakable" rise in mental level, and Zimmerman *et al.*² were similarly enthusiastic in regard to its effect both on epilepsy and on intelligence. However, subsequent carefully controlled work³ has failed to justify these conclusions.

Oral Test for Achlorhydria

Q.—What is the rationale of the oral test for achlorhydria which depends on a colour reaction in the urine? How reliable is this test?

A.—The test depends upon the combination of the hydrogen cation (H⁺) of the hydrochloric acid in gastric juice with a resin which is loaded with quinine. The hydrogen ion displaces the quinine which is absorbed from the gut and excreted in the urine, where it can be estimated by its fluorescence in ultra-violet light. Even in achlorhydric patients there is some small release of quinine in exchange for sodium and potassium, and in patients who have recently

been taking aluminium, magnesium, barium, etc., there may be further release of quinine.

Without knowing the purpose for which the test is to be used it is not possible to discuss the reliability of the method. The questioner should consult the excellent paper by Harkness and Durant.¹

NOTES AND COMMENTS

Varicose Eczema.—Dr. S. RIVLIN (London, W.1) writes: I doubt whether your correspondent's patients will derive a great deal of help from your reply ("Any Questions?" February 16, p. 415), for your expert would appear to be confusing varicose eczema with varicose ulceration. Whilst it is true that oedema is a *sine qua non* in the latter condition, it is certainly not so in the disease for which the questioner sought advice, and in any case occlusive compression bandaging does eczema far more harm than good. These patients produce their eczema themselves by scratching (who can blame them?) in response to intense irritation produced by dilating venules. Stop the itching and the eczema disappears. If the area is a small one, say the size of half the palm, then by all means use 1% hydrocortisone applied as a very thin film last thing at night (they usually scratch in bed), first thing in the morning, and once if necessary during the day. A local cotton bandage is all that is required. With a large area, soak the leg two or three times daily (10–15 minutes) in a 1:4,000 solution of potassium permanganate. Apply a thin film of Lassar's paste with 3% crude coal tar and cover lightly with a crêpe bandage in between the soaks. A bad eczema will clear in a fortnight, a dreadful one in three weeks. Do not operate upon the veins until the eczema is healed.

OUR EXPERT replies: One cannot but wonder what authority Dr. Rivlin has for his dogmatic opinions on this subject. I can assure him there was no confusion between varicose eczema and varicose ulceration in my reply. However, the term varicose eczema is not very satisfactory, and the condition is better called gravitational eczema or the American stasis eczema. The mere presence of eczema of the leg with varicose veins alone (and no signs of chronic venous insufficiency such as oedema and pigmentation) does not constitute varicose eczema. Frequently lichen simplex is found in this situation, the aetiology of which is quite different. It seems likely that Dr. Rivlin has himself confused the issue by failing to distinguish the two conditions. There is no evidence to support Dr. Rivlin's theory, stated as though it were a fact, that the itching of varicose eczema is produced by dilating venules. It is more likely to be caused by the presence of oedema, poor nutrition of the skin, and the accumulation of metabolites in a person prone to eczema.

Two Anencephalic Monsters.—Dr. J. H. S. GEGGIE (Quebec, Canada) writes: You were asked for an estimate of risk in a third pregnancy following the birth of two anencephalic monsters ("Any Questions?" January 5, p. 57). I have recently delivered a young woman of her second successive normal baby following two successive anencephalic monsters.

Books of "Any Questions?" and Refresher Course Articles.—The following books are available through booksellers or from the Publishing Manager, B.M.A. House, Prices include postage. *Any Questions?*, Volumes 2 and 3 (8s. each); *Refresher Course for General Practitioners*, Volumes 2 and 3 (26s. 6d. each inland, 26s. overseas); *Clinical Pathology in General Practice* (22s. 3d. inland, 21s. 9d. overseas).

Counting the cost...of living

It is estimated that over 50 per cent of the average practitioner's patients show some degree of anxiety neurosis. Such is the price exacted by the tempo of today. In this type of case MILTOWN meprobamate has far-reaching applications. MILTOWN is superior to other conventional sedatives and is remarkably free from side reactions. It acts safely and selectively to ease emotional and muscular tension without automatic effects. MILTOWN helps to 'unwind' the patient relieving his worry, agitation and anxiety. It induces true sedation by day and natural sleep without narcosis at night.

TABLETS

- — anti-inflammatory action 3 to 5 times that of cortisone or hydrocortisone.
- — gastro-duodenal side effects minimised by protective coating of individual hormone crystals.

PRESENTATION : Bottles of 30 tablets of 1 mg. or 5 mg.

NO PURCHASE TAX APPLICABLE ON HYDRODELTALONE TABLETS

Available under N.H.S. prescription (Form E.C.10.)

On local application, Hydrodeltalone has a rapid and powerful anti-inflammatory and anti-allergic effect.

In intra-articular and peri-articular injections, the anti-inflammatory effects of hydrocortisone are obtained with a smaller quantity of Hydrodeltalone.

HYDRODELTALONE

intra-articular injections

for local articular and peri-articular inflammatory conditions

PRESENTATION:

5 ml. vials containing 25 mg. of prednisolone acetate per ml. in saline suspension.

HYDRODELTALONE

skin ointment with neomycin

for infectious and non-infectious inflammatory and allergic disorders of the skin.

PRESENTATION:

tube containing 5 g. or 15 g.
Each gramme contains 5 mg. of prednisolone and 5 mg. of neomycin sulphate.

HYDRODELTALONE

ophthalmic preparation

for inflammatory and allergic disorders of the eye

PRESENTATION:

eye drops: 3 ml. bottle containing 2.5 mg. per ml. of prednisolone acetate suspended in saline solution.
eye ointment: 3 g. tube containing 2.5 mg. of prednisolone acetate per gramme.

Available under N.H.S. prescription (Form E.C.10)

WARD, CASSENNE LTD.,
116 Victoria Street, S.W.1.

The graph above is of an experiment to measure the effect of Transvasin on skin temperature on a subject. The red line plots the skin temperature before and at intervals after a single application of one inch of cream (0.924 grams) from a tube of Transvasin. The black line gives similar information with regard to the application of a plain vanishing cream used as a control. Skin temperatures were measured with an electro-thermo couple every five minutes for two hours. Photographs show the affected area before application; three minutes and thirty minutes later.

COMPOSITION OF TRANSVASIN

Salicylic acid tetrahydrofurfuryl-ester	..	..	14%
Nicotinic acid ethyl-ester	..	..	2%
Nicotinic acid n-hexyl-ester	..	..	2%
p-Aminobenzoic acid ethyl-ester	..	..	2%
Water-miscible base ad	..	..	100%

Transvasin

'Transvasin' is a registered trade mark of Lloyd-Hamol Ltd

IT is generally agreed that cases of soft-tissue rheumatism and of many types of arthritis benefit by hyperaemia of the affected tissues. Transvasin, which contains two quick-acting esters of nicotinic acid, induces such a deep and prolonged hyperaemia at the same time as it produces superficial erythema.

In addition to the esters of nicotinic acid, Transvasin contains the fat- and water-soluble esters of salicylic and p-aminobenzoic acids. Both these well-tried analgesic drugs are readily conveyed through the skin in therapeutic quantities and enable an effective concentration to be built up where they are needed.

Transvasin is now being widely prescribed, with successful clinical results. Since a very small quantity is sufficient for each application, the cost of treatment is extremely low.

Transvasin is available in 1 oz. tubes, basic N.H.S. price 2/6 plus P.T., and is not advertised to the public. Samples and literature will be gladly sent on application.

LLOYD-HAMOL LTD.

An assessment of Roter therapy in PEPTIC ULCER

"The treatment is ideal for general practice, where its simplicity appeals to both patient and doctor . . ."

Roter tablets contain a balanced content of recognised buffers with supportive carminative and mildly laxative agents.

FORMULA PER TABLET

Magnesium Carbonate (400 mg.), Bismuth Subnitrate (350 mg.), Sodium Bicarbonate (200 mg.), Rhizoma Calami (25 mg.), and Cortex Rhamni Frangulae (25 mg.).

F. A. I. R. LABORATORIES LTD., TWICKENHAM, MIDDLESEX.

Results

"The immediate clinical results were assessed after the first month's treatment in four main groups: (A) pronounced relief (symptom free); (B) definite relief (minor symptoms with no pain); (C) doubtful relief (symptoms persisting but improved); (D) no relief.

"Table II shows that 81% of cases became symptom-free—70% of them during the first week and 30% during the second week; a further 9% were relieved of the majority of their symptoms. Thus there was a satisfactory response in 90% of cases.

TABLE II

Group	Active Ulcers	Presumptive Ulcers	Totals
A	63 (79.6%)	17 (89.0%)	80 (81.7%)
B	8 (10.2%)	1 (5.5%)	9 (9.2%)
C	6 (7.6%)	1 (5.5%)	7 (7.1%)
D	2 (2.5%)	0 (—)	2 (2.0%)
TOTALS	79 (100%)	19 (100%)	98 (100%)

"Four of the nine cases in groups C and D have elected to go to surgery, and one of the remaining cases has a hiatus hernia as well as a duodenal ulcer. Experience of treating these 'Failures' over the past six years leads one to believe that no form of medical treatment will be effective and that surgery is the only hope of relieving their symptoms. In 75% of cases the patients were of the opinion that the tablets were superior to alkaline powders, and they found that they were able to take foods which they had avoided for years."

Extracts from the
BRITISH MEDICAL JOURNAL
1955, 2, 827

"SUMMARY: Seventy-nine cases of peptic ulcer and 19 of presumptive peptic ulcer have been treated with Roter tablets. Immediate clinical response was satisfactory in 90% of patients, with a relapse rate of 57% in the first year; a reduction in the average number of relapses was recorded in 15 cases kept on a maintenance dose for one year."

PACKINGS: Tins of 40, 120, 640, and dispensing size 720 (P.T. exempt). Basic N.H.S. price: 1/- for 10 tablets.

Roter Tablets are not advertised to the public, and may be prescribed on E.C.10 forms. Literature and samples on request.

HORMONAL INFLUENCE ON GROWTH*

BY

DOUGLAS HUBBLE, M.D., F.R.C.P.

Consultant Physician, Derbyshire Royal Infirmary and Derbyshire Hospital for Sick Children

Growth depends on the anabolism of protein, and its measurable *chemical* index is the retention of nitrogen and its measurable *clinical* index is the growth in length of the skeleton. If, for the sake of convenience and simplicity, we limit ourselves to the consideration of deviations of height as we discuss hormonal influences on growth we shall not forget that the growth of certain organs and certain cells is dependent on a specific stimulus, so that, for example, even in the presence of dwarfism due to athyroidism or hypothyroidism, enlargement of the anterior pituitary (Hubble, 1956), increased growth of hair (Perloff, 1955), and genital hyperplasia may all be observed (Hubble, 1955). Again, some growth occurs in all organs, even in the total absence of hormonal influences, for, while the hormones stimulate or inhibit growth processes, cellular growth is not entirely dependent on hormonal action.

The hormones which support growth are those which assist in the anabolism of protein, and those which inhibit growth are the hormones which are catabolic or anti-anabolic.

Childhood is the predominantly protein-anabolic phase, and the infant adds 10 in. (25 cm.) to its stature in the first year and 4 in. (10 cm.) in the second year;

in the second year 13%, and it falls to 3% in the thirteenth year, to rise again to 4.4% with the onset of puberty. This annual percentage increase in height offers us, disease and malnutrition apart, an approximate clinical index of the activity of the protein-anabolic hormones.

Protein Anabolism

What are the hormones which influence growth in man? The most powerful of the protein-anabolic hormones is the *growth hormone*—and it is unfortunate that we know less about its function in man than we do of any other hormone. No preparation of it which is potent in man has yet been produced, and, unlike all other pituitary hormones, it has no endocrine target-organ by whose function we might indirectly assess its activity. We can only assume its presence in man, and we have to be content with applying to man the considerable knowledge of its action in experimental animals. The experimental evidence is that growth hormone acts by directly stimulating tissue synthesis from amino-acids (Russell, 1951). It has also an effect on fat and carbohydrate metabolism, to which I refer later.

Thyroxine is necessary for the complete action of the growth hormone, and these two hormones have a synergistic action on protein anabolism—neither achieves its full effect without the help of the other. The effects of thyroxine-lack and thyroxine-excess on growth in both man and animals are so well documented that it is unnecessary to consider them further here.

Insulin also has a synergistic action with the growth hormone in its effect on protein anabolism in animals (Gaunt, 1954). Lawrence, Salter, and Best (1954) showed that insulin is a protein anabolizer in its own right and that growth in hypophysectomized animals can be maintained by insulin. In its action on protein anabolism, and therefore on growth, it is probably less important quantitatively than thyroxine and certainly less so than the growth hormone; but for our clinical purposes, and certainly until we have available chemical assays of these hormones, we should regard them as an integrated group of protein-anabolic hormones—growth hormone, thyroxine, and insulin. At puberty new and powerful protein anabolizers are introduced in the adrenal androgens in both girls and boys, and in boys by the testicular androgens. The effect of these androgens on protein anabolism and growth is well seen at puberty (the evidence has been reviewed by Tanner, 1955) and in diseases such as the adrenogenital syndrome, in

Fig. 1.—Average annual increments in height in boys, expressed as a percentage increase.

annual growth increments continue to occur at a diminished rate, expressed as a percentage increase of skeletal length, until the puberty growth spurt, when the rate temporarily increases, to fall away quickly until the time of epiphyseal closure occurs. In Fig. 1 these average annual increments in boys are shown as a percentage increase of height. In the first year it is 50%,

*Presidential address delivered to the Paediatric Section of the Royal Society of Medicine on October 26, 1956.

virilizing tumours of the adrenal and the ovary, and in interstitial-cell tumours of the testis. Except for one patient with congenital virilism I shall not refer again to this interesting group of children. In the estimation of the urinary 17-ketosteroids we have a well-established and sufficiently accurate method of assaying these androgens.

Protein Catabolism

In the group of protein anabolizers it has been necessary to include hormones from five organs: the anterior pituitary, the thyroid, the pancreas, the adrenal cortex, and the testis. For the protein catabolizers, the growth inhibitors, it is necessary to consider only the adrenal cortex, and for practical purposes we may regard this protein catabolism as the work of one hormone, cortisol (compound F). Its action is directly opposed to the action of the growth hormone, since it inhibits the incorporation of amino-acids into protein, particularly in connective and lymphoid tissue.

Cortisol and cortisone (compound E), prednisone and prednisolone, will inhibit, partially or completely, the growth of children, as you will see if you watch the growth of children who are having continued steroid therapy for diseases such as chronic asthma, nephrosis, rheumatoid arthritis, and collagen diseases. It is unusual for cortisone to depress the rate of growth if it is used in doses of less than 35 to 60 mg. per square metre of body surface (this is an average surface area for a child of 10 years) (Blodgett *et al.*, 1956). Sensitivity of children to this inhibition of growth by glucocorticoids shows, however, an individual variation. The amino-acids which are not being used for protein synthesis are then converted to glucose by the action of cortisol, a process known as gluconeogenesis. This is one of the homeostatic mechanisms by which the body corrects hypoglycaemia.

Protein Metabolism

I want now to introduce a concept which I have found useful in considering these problems of growth and protein metabolism; although it is not possible to provide proof for all the steps in this hypothesis it gives a ready explanation of well-established clinical facts, and I shall use it throughout this paper when dealing with various disorders of growth. Hypotheses, in medicine as in physics, should be regarded as valid for as long as they provide a useful explanation of the known facts.

Protein metabolism provides the site for a contest between the anabolic and the catabolic hormones. During the phases of active growth the anabolic hormones are in the ascendant. If you look again at Fig. 1, depicting the rapid growth of children in the first two years of life, you may correctly conclude that I assume either that children at this age are making a large amount of growth hormone or that their tissues are very sensitive to its action. This hypothesis is summarized as follows:

Competition for Protein in Childhood

A (Protein-Anabolizers)	K (Protein-Catabolizers)
G (Growth Hormones)	
+ T (Thyroxine)	C (Glucocorticoids)
+ I (Insulin)	

In normal growth the protein-anabolizers are more powerful than the protein-catabolizers. $A > K$.

In infancy the anabolic hormones (growth hormone, thyroid, and insulin) are much more powerful than the catabolic hormones from the adrenal cortex (the glucocorticoids), and rapid growth occurs. Growth hormone not only spares protein for growth, as I have already said, but it also inhibits the oxidation of carbohydrate. This means

that fat has to be used in large amounts by the growing child for its daily requirements of energy (Gaunt, 1954), and explains the clinical observation that ketosis is more common in young children than in older children and adults. Hypoglycaemia is difficult to deal with in young children and sometimes is disastrous in its consequences. This is explained by the fact that the action of the growth hormone allows little protein for gluconeogenesis and, in addition, it tends to suppress the utilization of carbohydrate by the tissues.

These are common clinical observations, but this formula also explains a rarer observation made by Blodgett *et al.* (1956): children with hypopituitarism are sensitive to the action of cortisone, so that as little as 5 to 20 mg. of cortisone per square metre of body surface daily will, in them, produce Cushing's syndrome and total cessation of growth. In hypopituitarism there is a disappearance of the protein-anabolic hormones (with the exception of insulin, which is itself reduced in amount since its output is regulated by the height of the blood sugar), so that when these contenders for protein are removed a small dose of cortisone is sufficient to claim all the protein in the metabolic pool.

These hormonal influences on the female skeleton are summarized as follows:

The Four Skeletal Ages of Woman

G + T + I	>C	Growth in infancy and childhood
G + T + I + A	>C	Growth in adolescence
g + T + I + A	≈C	Arrest or retardation of growth
g + T + I + a	<C	Post-menopausal osteoporosis

I have assumed that the quantitative effects of thyroid, insulin, and cortisol remain constant throughout life. In infancy the growth hormone (represented by a large G) captures the protein; in adolescence a diminishing amount of G is reinforced by the androgens (A); in adult life the anabolic hormones are in equilibrium—disease, disaster, and pregnancy apart—with the catabolic hormones, and the bones hold their protein; after the menopause the catabolism of decrecence arrives, with the protein anabolizers in decline (small g and small a) and the unhappy bones yield up their protein.

Disorders of Growth in Childhood

I will now consider some of the disorders of growth in children which illustrate this concept of growth as a competition for protein which is won by the anabolizers. The first two patients suffer from *primary hypopituitary dwarfism*, which can now be firmly differentiated from all other forms of dwarfism; the third child is a boy aged 8 years suffering from *Cushing's syndrome*, due to adrenocortical hyperplasia, with total arrest of growth; the fourth child is suffering from *congenital virilism*, despite her average growth and average bone-age; the fifth child suffers from *glycogen-storage disease* which induces catabolic consequences and defective growth; and the sixth child is an example of the catabolic phase with impaired growth which may occur in childhood in the course of a disease, *diabetes*, which is associated with a deficiency of one of the anabolic hormones, insulin.

Primary Hypopituitary Dwarfism

I have seen five examples of this constitutional disorder—which, let me emphasize, is quite unrelated to disease of the pituitary—three patients under my care and two by the courtesy of colleagues (Professor N. B. Capon and Dr. Cedric Harvey). Two are boys and three are girls. The appearances in all the cases are identical, so I will limit myself to the description of two of my own patients who have had a long follow-up and who have been carefully investigated by modern techniques.

P. T. B., aged 19½, weighed 7 lb. (3.2 kg.) at birth and his mother stated that his growth was normal up to the age of 2 years. I first knew him when he was 7½ years, but lost sight of him after six months; his height was then 39 in. (99 cm.). He

came under my care again at the age of 16½, when the photograph shown in Fig. 2 was taken and his height was 49 in. (124.5 cm.)—an average height increment without treatment of a little more than 1 in. (2.5 cm.) a year. At 19½ years his height was 56½ in. (143.5 cm.), an average annual increment of 2½ in. (6.3 cm.)—after much treatment—which gives him a height-age of 11 years; his bone-age is 14 to 15 years.

Fig. 2.—Primary hypopituitary dwarfism: P. T. B., aged 16½ years.

was first seen at the age of 7½ when his height was 36 in. (91.5 cm.) height-age 2 to 3 years) and his bone-age was 5 years. His birth weight was said to have been 7 lb. (3.2 kg.) and his growth was not thought to have been abnormal until he was 2 years old. The development of his facial bones was retarded, giving him a babyish appearance. He has had various treatments (see below). At 13½ years his height is 50 in. (127 cm.) (height-age about 7 years) and his bone-age 10 to 11 years. His maternal first-cousin, now aged 26, suffers from hypopituitary hypogonadism (Hubble, 1951) but has no deficiency of the growth hormone. After I published this description of the family hypopituitarism I discovered that his cousin had a double dose of the maternal grandfather's genes, for it was alleged that his grandfather was also his father.

The clinical criteria, then, in these cases are: normal birth weights, and growth that appears to have been normal for an indefinite period after birth; great retardation in height; a bone-age which although retarded is much less retarded than the height-age; a height increment, without treatment, of approximately 1 in. (2.5 cm.) a year; babyish facies; failure of sexual development as a rule; rarely, as in T. B., pituitary failure may be seen in another member of the family.

There is no clinical evidence of hypothyroidism, and the diagnosis of the "Tom Thumb" (proportionate) dwarf is easily excluded by the normal development of facial bones, by the average bone-age, and by a maturing personality which corresponds to the chronological age, all of which occur in the latter condition. Investigations have confirmed and extended the diagnosis of primary hypopituitarism in both these patients.

The *pituitary fossa* was of normal dimension in both boys. The *blood cholesterol* was high in both: in P. T. B. at the age of 16½–17 years the average of three values before treatment was 391 mg. per 100 ml., and in T. B., at the age of 7½ to 8 years, the average of three estimations before treatment was 270 mg. per 100 ml. The *insulin-sensitivity* test was normal in T. B., but in P. T. B., after 3.5 units intravenously, the fasting blood sugar of 78 mg. per 100 ml. fell to 11 mg. per 100 ml. in 30 minutes, but in a further half-hour had returned to 66 mg. per 100 ml. (increased insulin sensitivity but no hypoglycaemic unresponsiveness). The *response to water load* (Kepler 1) was normal in P. T. B.

Adrenocortical Urinary Assays.—17-Ketosteroids: In P. T. B. (aged 16–19 years) the average of four estimations was 2.7 mg./24 hours, and in T. B. (aged 10–13 years) 3.5 mg./24 hours. **17-Ketogenic steroids:** In P. T. B. (aged 16–19 years) the average of four estimations was 2.2 mg./24 hours and in T. B. (aged 10–13 years) 2.2 mg./24 hours. All these values are low, but the 17-ketogenic steroids are relatively much lower than the 17-ketosteroids (aged 6–10 years: average excretion of 17-ketosteroids 1–4 mg./24 hours and of 17-ketogenic steroids 2–8 mg./24 hours). **Response to intramuscular corticotrophin gel**, 20 units twice daily for four days (Fig. 3): the 17-ketogenic steroids per 24 hours in P. T. B. reached 36.4 mg. on the third day of treatment and in T. B. reached 27.8 mg. on the fourth day of treatment. This is a good response to corticotrophin, despite the low initial values. The basal metabolic rate in P. T. B. was +5%.

¹³¹I Uptake.

P. T. B. (aged 16½ and 19½ years) had a normal uptake curve over 48 hours, a normal plasma activity, and a normal response to T.S.H., 10 mg., given eight hours before the second uptake.

Gonadotrophins.—None present in P. T. B. (assayed five times between 16½ and 19½ years).

We may now add to the clinical criteria for primary hypopituitary dwarfism already cited the following metabolic and endocrinological data: hypercholesterolaemia of varying degree, increased insulin sensitivity (not invariable); normal thyroid function; reduced adrenocortical function responding normally to corticotrophin, and therefore itself dependent on deficient corticotrophin production by the pituitary.

If we now return to the formula for growth at puberty we see that these children with *primary hypopituitary dwarfism* lack G and A.

Competition for Protein in Primary Hypopituitary Dwarfism

G + T + I + A	>C	Normal adolescent growth
g + T + I + A	≈ or <C	Protein equilibrium in primary hypopituitary dwarfism

If G and A are absent there is a situation in which the protein anabolic hormones are represented by thyroid and insulin alone, and these are general rather than specific protein anabolizers. Cortisol should therefore be supreme—and the child would be in a state of Cushing-like catabolism were it not, as I have shown, that cortisol itself is also deficiently produced. It would have been possible to forecast from this formula that there must be reduced adrenocortical function in primary hypopituitary dwarfism, since these children do not present the picture of Cushing's syndrome.

Treatment of Primary Hypopituitary Dwarfism

These children are short of growth hormone and androgens so that treatment by methyltestosterone, combined with thyroid therapy, is reasonable. Nor, as I have shown, is much opposition to be expected from the glucocorticoids, whose urinary output has not been increased by androgen therapy. The results of treatment are good and one can achieve average annual height increments of 3 to 4%. The ultimate height depends, of course, on the age at which epiphyseal fusion occurs.

P. T. B. was 56½ in. (143.5 cm.) at 19½ years, and he had grown 2 in. (5 cm.) a year for the last three years. His bone-age was still no more than 15 years, so we may hope

Fig. 3.—Response of 17-ketogenic steroids to intramuscular corticotrophin (20 units twice daily for four days).

that his ultimate height will exceed 5 ft. (152.5 cm.), which is what I promised him when he started treatment three years ago, at 49 in. (124.5 cm.) (Fig. 4). The development of his personality has been just as striking as the development of his facial bones, the increase in his height and musculature, and the disappearance of his puppy-fat. The

FIG. 4.—P. T. B., aged 19½ years, after treatment.

absence of axillary hair and the growth of hair limited to the female escutcheon is dependent on the continued deficiency of adrenal androgens.

Treatment by testosterone and thyroid should be continued until the bone-age matches the chronological age; then thyroid treatment may be continued alone, but no addition to ultimate height can then be expected. An obvious enlargement of the clitoris in girls requires cessation of testosterone therapy, at least for a year or two; but no fear of inhibition of pituitary sex hormones should be allowed to interfere with therapy, for, once the diagnosis is established, hope of sexual development may be abandoned. There is, I believe, only one case reported in the literature (Hewer, 1944) in which failure of the growth hormone has not been accompanied by failure of the sex hormones.

I have used other reputed growth factors in treatment—anterior pituitary hormones, GF4, androstenediol, 19-nortestosterone (a weak androgen), and insulin—but none of these is to be recommended. Insulin is the only one of these in which I have been much interested, and I was able to show in T. B.'s case, in an eight-day nitrogen balance, that a good nitrogen retention was achieved. Obesity was the result of therapy, however, and not a gain in height (Fig. 5)—for his height curve flattened out and he gained 14 lb. (6.4 kg.) in three months—a tolerable adiposity.

My last remark about therapy is that the response to treatment provides a further diagnostic criterion between hypopituitary dwarfism and the primordial "Tom Thumb" dwarf.

M. B., aged 9 years, has a weight-age of 2 years and a height-age of 2½ years. His genital hyperplasia was caused by over-enthusiastic testosterone therapy between the ages of 2 and 3 years, and this was the only period during which his height increment paralleled the average height curve (Fig. 6). Otherwise the gap in both his height and weight curves is gradually widening. He has for the last three years been treated by a long-acting insulin without benefit. The very slow growth in the "Tom Thumb" dwarf resists all forms of therapy.

Catabolic or Anti-anabolic Mechanisms

Robert (Fig. 7), aged 9 years, is suffering from Cushing's syndrome. He had ruddy cheeks, great fat deposits, especially in his buffalo hump, and hirsuties. His father told me that there had been no growth in height in the preceding two years. The boy was 43½ in. (110.5 cm.) at 6½ years, and he was still 43½ in. when I saw him at the age of 8½ years. This arrest of growth never occurs in simple obesity, and it was not difficult, despite his youth and his sex, to make the diagnosis of Cushing's syndrome.

Up to 1950 there were 26 authentic reported cases of Cushing's syndrome in childhood under the age of 10 years, only four of them in boys (Lawson Wilkins, 1950). The usual investigations made it improbable that there was a tumour of the adrenal cortex, despite the fact that all the reported cases of Cushing's syndrome under the age of 10 years had been due to an adrenal tumour.

In Table I is set out the supporting evidence from urinary endocrine assays that Robert is indeed suffering from Cushing's syndrome, that a neoplasm of the adrenal cortex is highly improbable, and that the excessive output of the adrenocortical steroids is dependent on pituitary stimulation. In the third and fourth columns the 17-ketosteroid and 17-hydroxycorticosteroid urinary output in mg. a day are given. The 17-ketogenic steroids have been omitted,

FIG. 5.—Case T. B. Treatment by protamine zinc insulin (16 units daily for three months, from age 9½ to 10 years) flattened out his height curve and increased his weight by 14 lb. (6.4 kg.).

FIG. 6.—M. B., "Tom Thumb" dwarf. Treatment by testosterone from the age of 2 to 3 years produced an average height increment, but was discontinued on account of genital hyperplasia. Insulin used for three years has not accelerated either his weight or height gain.

FIG. 7.—Robert, aged 8½ years. Cushing's syndrome due to adrenocortical hyperplasia.

TABLE I.—Robert. Creatinine, 17-Ketosteroid, 17-Hydroxycorticosteroid in Urinary Assays per 24 Hours, Together with the Response to 9- α -Fluorohydrocortisone (Dr. J. K. Norymberski)

Day	Creatinine	17-KS	17-OH CS	Treatment by 9- α -Fluorohydrocortisone
1	0.51 g.	6.8 mg.	21.7 mg.	2 mg.
2	0.56 "	7.1 "	20.9 "	2 "
3	0.54 "	7.7 "	17.4 "	2 "
4	0.58 "	9.3 "	16.2 "	5 "
5	0.54 "	6.8 "	16.4 "	5 "
6	0.33 "	3.5 "	8.0 "	5 "
7	0.28 "	3.6 "	9.1 "	5 "

but their level, always a little less than the 17-hydroxycorticosteroids, followed closely their changes.

It will be seen that the 17-hydroxycorticosteroids are three to four times as high as would be expected in a boy of his age, and the 17-ketosteroid output is approximately doubled. In the last column of Table I is set out the administered dose of 9- α -fluorohydrocortisone. Now, 9- α -fluorohydrocortisone is a very effective depressant of corticotrophin in these small doses—compared with cortisone—and it has the added advantage that its degradation products do not interfere with the urinary assays of 17-ketogenic steroids and 17-hydroxycorticosteroids (Cope and Harrison, 1955). During this five-day course of 9- α -fluorohydrocortisone the output of 17-ketosteroids was halved and the output of 17-hydroxycorticosteroids was reduced by more than half. Neoplasms of the adrenal cortex are not as a rule pituitary-dependent, so that this result assists in the exclusion of a tumour.

It is assumed that in Cushing's syndrome the adrenal cortex is hypersensitive to corticotrophin stimulation. This was so in the case of Robert, in whom 30 units of intramuscular corticotrophin gel twice daily raised the 17-ketosteroid excretion to 30 mg./24 hours and the 17-hydroxycorticosteroid excretion to 189 mg./24 hours. The excess of adrenal glucocorticoids has been sufficient in Robert's case to prevent the allocation of any protein to skeletal growth. This protein wastage is nicely demonstrated by an unpremeditated observation in the second column of Table I. Urinary creatinine output is used in many laboratories as a rough check on the accuracy of the 24-hour urinary collections. It will be seen that when the 17-hydroxycorticosteroid output was reduced to normal levels the creatinine urinary output is halved—from 560 to 280 mg. daily. Ex-

cessive protein wastage has been arrested and the catabolic hormones are once more held in check by the anabolic hormones.

It will be recalled that the characteristic striae of Cushing's syndrome are less common in children suffering with this disease than in adults (Lawson Wilkins, 1950) and they are absent in Robert. Also, striae occur rarely in children treated by steroids. The explanation is not clear. Fuller Albright (that great master of metabolism) in the Harvey Lectures for 1942-3 provided the classical account of the changes in Cushing's syndrome—a brilliant contribution to medical thinking—and related the "thin skin" to the defect in protein synthesis. It is tempting to say that the anabolizers of protein—the growth hormone and possibly the adrenal androgens—may be adequate in Cushing's syndrome of childhood to prevent protein wastage in the skin. It would be impossible to advance this explanation in the face of the complete arrest of growth which occurred in Robert.

Professor Illingworth, of Sheffield, has generously allowed me to discuss the next patient. Helen was 2 years and 2 months old when the photograph (Fig. 8) was taken, and when I saw her she was 2 years and 8

months. The enlargement of the clitoris which can be seen in Fig. 8 was present at birth. Her height at the age of 2 years 2 months was 36 in. (91.5 cm.)—on the 50 percentile—and her growth in the subsequent eight months has been 1 in. (2.5 cm.). Growth in one year at this age, on the fifty percentile, is 2.8 in. (7.1 cm.), so that Helen's growth is now less than average. Her bone-age, on the other hand, is a little in advance of her chronological age—perhaps by 2 years. In Table II are set out the values for the urinary steroid metabolites—and for these estimations and for those in the last patient with Cushing's syndrome Professor Illingworth and I are indebted to Dr. J. K. Norymberski, of Sheffield.

In the second and third columns the values are approximately the same as for Robert, the boy with Cushing's syndrome, and yet Helen is obviously not suffering from Cushing's syndrome. The fifth column is headed 21-deoxyketols. The urine of normal men and women contains less than 0.5 mg. of 21-deoxyketols/24 hours (Norymberski), and therefore the excretion of these substances is greatly raised in Helen. This finding is now regarded as characteristic of virilizing adrenal hyperplasia, in which there is assumed to be a block in the formation of cortisol from progesterone which normally occurs in four stages: this arrest is held to occur at the second of the four stages by an enzymic defect which blocks the synthesis at 17- α -hydroxyprogesterone; this substance and some of its urinary metabolites, such as pregnanetriol, are 21-deoxyketols, and in congenital adrenal hyperplasia large quantities appear in the urine (Bongiovanni *et al.*, 1956). This girl may then be assumed to be suffering from congenital adrenocortical hyperplasia.

FIG. 8.—Helen, aged 2 years 2 months, suffering from congenital virilism but with normal height and bone-age. (Professor R. Illingworth's patient.)

TABLE II.—17-Ketosteroids, 17-Hydroxycorticosteroids, Iso-dehydroandrosterone, and 21-Deoxyketols in Urinary Assays per 24 Hours, Together with Response to 9- α -Fluorohydrocortisone (Dr. J. K. Norymberski)

Day	17-KS	17-OH CS	SDHA	21-Deoxyketols	Treatment by 9- α -fluoro-hydrocortisone
1	7.6	19.5	3.8	3.0	
2	7.0	19.3	2.2	2.4	
3	6.7	14.3	1.5	1.7	1 mg.
4	—	—	—	—	1 "
5	2.3	6.1	0.9	0.7	
6	3.8	11.1	1.6	2.1	
7	6.5	12.4	2.2	2.0	

Before considering still further difficulties let us take refuge, while looking at the last column, in some facts which are crystal clear. Helen was given 1 mg. of 9- α -fluorohydrocortisone daily for three days, and, with the consequent depression of corticotrophin output from the anterior pituitary, the output in the urinary steroids was reduced to one-third to one-quarter of their previous level. Therefore we may conclude, as in the case of Robert, that the excessive output of steroids is pituitary-dependent and the adrenal cortex in Helen is either exceptionally sensitive to corticotrophin or there is an excessive output of that hormone. The usual explanation of the elevated 17-ketosteroid excretion in congenital adrenocortical hyperplasia is that the production of cortisol is insufficient to hold in check the corticotropic activity of the pituitary; but in Helen the output of 17-hydroxycorticosteroids is high—let us say three to four times the average output. Dr. Norymberski tells me that the metabolites of 17- α -hydroxyprogesterone—both pregnanetriol and 21-deoxyketols—together with the metabolites of cortisol—both the dihydroxyacetones and the triols—contribute to the assay of the urinary 17-hydroxycorticosteroids.

The brilliant investigations of the steroid chemists have not yet fully explained the biological consequences of adrenocortical hyperplasia: it has not yet been established, for example, what is the androgenic substance circulating in excess, nor is it known whether 17- α -hydroxyprogesterone itself has any androgenic effect (Reifenstein, 1956). Without further analysis of the urinary steroids, can clinical observation and deduction make any contribution in the case of Helen? I believe they can. We may conclude from the enlargement of the clitoris, which has been present since birth, and from the moderate advancement of her epiphysal development, that there is excessive androgenic activity. Despite this excess of androgens there has been no acceleration of growth, and we may conclude from a consideration of the hormonal growth formula that the anabolic effect of the androgens has been held in check by the catabolic effect of a high output of cortisol. In fact, the struggle for protein in Helen is won by the anabolizers only in the same degree as in the normal child.

Why, then, does this high output of cortisol not suppress pituitary activity in the output of corticotrophin? This is still a problem in many cases of Cushing's syndrome, and I cannot debate it here (see Jailer *et al.*, 1956). I may advance, then, a final clinical conclusion that in Helen there are two separate abnormalities: (1) a partial but not a complete arrest at stage II in the formation of cortisol from progesterone, and (2) an unspecified derangement of the normal corticotrophin-cortisol homeostasis.

A full description of these two children, Robert and Helen, is to be published elsewhere (Hubble and Illingworth, 1957).

The Catabolic Mechanisms in Two Diseases

During the last ten years we have become accustomed, in dealing with acute illness, accidents, and operations, to the notion that in these stressful situations the catabolic side of the equation temporarily dominates the anabolic. There are two chronic diseases in childhood in which growth failure may occur because the competition for protein is lost by the anabolizers, and I will conclude this address

by a discussion of them. The first is glycogen-storage disease. Dwarfism is one of the features of glycogen-storage disease, and here the interference with growth is associated with the same metabolic effect on protein as is seen in Cushing's syndrome. The basic difficulty is the non-availability of hepatic glycogen, and the metabolic consequences of this were worked out in a classic paper by Bridge and Holt (1945).

D.W. was proved to be suffering from glycogen-storage disease by the failure of his blood sugar to rise after injections of adrenaline and glucagon, and by a liver biopsy which demonstrated an excess of glycogen in his liver. His height at 6 years was 4 in. (10 cm.) below the 10 percentile, and he was moderately obese, with a weight 10 lb. (4.5 kg.) above the average for his height. With the addition of protein to his diet, as recommended by Bridge and Holt (1945), he has grown 14 in. (35.5 cm.) in five years, so that his height has achieved the 50 percentile, as is shown in Fig. 9. His liver is smaller but still much enlarged. Gluconeogenesis from protein allows the correction of hypoglycaemia in this disorder, and the addition of protein, particularly at the night feed, gives enough substrate for the anabolic hormones to ensure normal growth.

The homeostatic correction of chronic hypoglycaemia by gluconeogenesis, presumably brought about by an increased secretion of corticotrophin, is one of the fundamental biological mechanisms (Long, 1952) and obviously in glycogen-storage disease it takes precedence of the growth hormone in the competition for protein.

Van Creveld (1952)—who, at the same time, but independently of Von Gierke, described glycogen-storage disease in 1928, and has therefore had the opportunity of watching his cases for 25 years—reported that two of his patients had not only achieved average growth but had exercised their reproductive functions. Having regard to the formula, this need not surprise us. As age advances there is a diminishing requirement of protein for growth, so that more protein is available for gluconeogenesis; and as the anabolic factors are increasingly counterbalanced by the catabolic hormones the conversion of protein to glucose is more easily achieved, with a correspondingly diminished dependence on hepatic glycogen and on the fat depots for the daily metabolic needs.

There is in diabetes a shortage of available carbohydrate, and the wastage of protein and fat which occurs in consequence in the untreated diabetic is well recognized. However, an interesting syndrome (Mauriac, 1930; Houet, 1949; Guest, 1953) which occurs in the imperfectly treated child diabetic has features in common both with Cushing's syndrome and with glycogen-storage disease. Its diagnostic features are dwarfism, obesity, florid facies, hypercholesterolaemia, greatly increased glycogen and fat deposit in the enlarged liver, and sexual retardation. Fig. 10 is a photograph of a child who died at the age of 15 years in consequence of this metabolic abnormality. Fig. 11 shows the progressive retardation of height from a 6-in. (15-cm.) to an 11-in. (28-cm.) deficiency in the space of four years. Fig. 10 shows the Cushing-like cheeks, the hepatomegaly sketched in, the obesity, and the absence of sexual development. At necropsy greatly increased glycogen and fat deposits in the liver were demonstrated.

FIG. 9.—Better-than-average height increments in D.W., a boy with glycogen-storage disease given additional protein.

FIG. 10.—Mauriac syndrome in a diabetic aged 15 years. The shading shows the area of hepatomegaly.

FIG. 11.—Progressive retardation of growth in patient shown in Fig. 10.

the excretion of 11-oxysteroids in their urine was three times the average amounts. These children are insulin-sensitive and run easily into hypoglycaemia; McArthur and her colleagues (1952) showed that there was a greatly increased corticosteroid excretion in a diabetic male mongol aged 19 years who had frequent daily insulin reactions. Children with the Mauriac syndrome have long periods of ketosis, and it has been shown that in diabetic ketosis increased adrenocortical activity occurs (Stowers, 1951; McArthur *et al.*, 1952). All the features of this syndrome—the moon-face, the obesity, the glycogen and fat deposits in the liver, and the failure of growth and of sexual development—are adequately explained by a deficiency of insulin and by an excess of cortisol.

Competition for Protein in the Mauriac Syndrome (Childhood Diabetes)

G + T + I > C Normal growth
G + T + i $\equiv$ or < C Arrest or retardation of growth

Summary and Conclusions

In childhood there is a competition for protein which is won by the protein anabolizers, and normal growth results.

The protein anabolizers are the growth hormone, thyroxine, insulin, and the androgens; the protein catabolizers are the glucocorticoids, of which the chief is cortisol.

To the classical picture of primary hypopituitary dwarfism these features are added—hypercholesterolaemia, adrenal hypocorticism, and deficient production of corticotrophin.

The treatment of primary hypopituitary dwarfism by methyltestosterone and thyroid is described, and its differentiation from primordial dwarfism is indicated.

Two examples of adrenocortical hyperplasia in childhood are described. In the first, a boy with Cushing's syndrome, arrest of growth resulted; and in the second, a girl with congenital virilism, average growth has occurred.

Two examples of catabolic diseases are discussed—glycogen-storage disease and the Mauriac syndrome in child diabetes.

The construction of a simple hormonal formula for growth explains many features of endocrine and metabolic disease in childhood.

My debt to the laboratories and those that work in them is heavy—and I acknowledge with gratitude the help I have had from Dr. A. Jordan and Mr. M. J. Level, M.Sc., of the Sheffield Royal Infirmary; from Dr. J. K. Norymberski, of the Rheumatic Centre, Sheffield; from Dr. C. G. Payne and Dr. F. L. Mitchell, of the Jessop Hospital for Women, Sheffield; and from Dr. G. R. Osborn, Mr. D. Watson, M.Sc., and Miss A. Matthews, B.Sc., of the Derbyshire Royal Infirmary.

TREATMENT OF POLYARTERITIS NODOSA WITH CORTISONE: RESULTS AFTER ONE YEAR

REPORT TO THE MEDICAL RESEARCH
COUNCIL BY THE COLLAGEN DISEASES
AND HYPERSENSITIVITY PANEL*

The purpose of this study was to learn whether cortisone improves the expectation of life of patients suffering from polyarteritis nodosa, and whether it improves their well-being. The generally accepted method of answering such questions is the controlled therapeutic trial, in which a series of patients selected on well-defined criteria is divided at random into treated and control groups, and the results are compared. Unfortunately, in this case, three factors made the use of such a method both ethically undesirable and impracticable. First, untreated polyarteritis nodosa is a disease of grave prognosis; but published reports on cortisone therapy have been very favourable—for example, Rose *et al.* (1950) and Shick *et al.* (1951). Second, it is a rare disease, and for any one centre to obtain enough patients for the two groups seemed unlikely. Third, it seemed probable that any trial would have to be completed before enough cortisone became generally available. It was therefore decided that in this instance there was no practicable alternative to giving an agreed form of cortisone treatment to all cases fulfilling the criteria for diagnosis, and comparing their fates with those of patients selected retrospectively on the same criteria. If this report does nothing else, it serves to illustrate some of the limitations of retrospective control.

Selection of Patients

The manifestations of polyarteritis nodosa are often described as "protean." While certain combinations of symptoms and signs are so characteristic as to be diagnostic, no physician of wide experience is unfamiliar with the case in which a seemingly probable diagnosis of polyarteritis nodosa has been disproved at necropsy. It was therefore decided that before a patient could be admitted to the series the presence of polyarteritis must be proved histologically by biopsy. To minimize observer error, histological sections were submitted to a panel of pathologists: Professor G. Payling Wright, Professor C. V. Harrison, Dr. A. H. T. Robb-Smith, and Dr. H. Spencer. Dr. Spencer saw all sections and referred doubtful ones to the whole panel. We would like here gratefully to acknowledge his unstinted help. The following histological definition of polyarteritis was laid down:

"(a) Necrosis of the artery with local inflammatory response, or (b) evidence of previous necrotizing arteritis, as shown by medial scarring and interruption of the internal elastic lamina; but excluding (i) cases where the arteritis is in an area of tissue damage (infection or infarction) and might be secondary to such damage; (ii) cases with evidence of bacterial or mycotic infection spreading from within the lumen and producing the arteritis; (iii) giant-cell arteritis (temporal arteritis)."

*Members of the Panel: Professor G. W. Pickering, Dr. E. G. L. Bywaters, Professor J. F. Danielli, Dr. P. G. Gell, Professor J. H. Kellgren, Dr. D. A. Long, Dr. A. Neuberger, Dr. H. Nicholson, Professor F. T. G. Prunty, Dr. A. H. T. Robb-Smith, Professor G. Payling Wright, Dr. J. J. R. Duthie, Dr. E. T. Conybeare.

Schedule of Treatment with Cortisone

Before the introduction of cortisone and corticotrophin, polyarteritis nodosa was ultimately fatal in most cases. Death was sometimes due not to active polyarteritis but to the late effects of lesions in patients in whom active disease had ceased. This applied particularly to patients in whom renal involvement had led to the development of hypertension. For these reasons it was decided when planning the present trial to recommend the use in each patient of sufficient cortisone to maintain complete suppression of the disease, the dose being limited only by the need to avoid intolerable side-effects. Cortisone for patients in the trial was supplied by the Medical Research Council. The following regime was recommended to the various physicians who took part in the trial:

"(1) Treatment should be started as soon as a positive biopsy has been obtained; in seriously ill patients, however, it may be started as soon as a biopsy has been taken, without awaiting its result. The initial dose of cortisone should be 200 mg. daily by mouth for one week. If at the end of the first week symptoms and signs are not suppressed, the daily dose should be raised by 100 mg. each week until full suppression has been achieved or until intolerable side-effects appear.

"(2) If symptoms and signs are suppressed by 200 mg. daily for one week, an attempt should be made to reduce the dose as follows: 2nd week, 150 mg. daily; 3rd week, 100 mg. daily; 4th week, 50 mg. daily; 5th week, 25 mg. daily; and 6th week, 0. If symptoms or signs recur during or after this process of withdrawal, cortisone should at once be given in a dose which is judged to be sufficient to suppress the signs and symptoms without serious side-effects, and thereafter cortisone treatment should be continuous.

"(3) In cases requiring continuous therapy the maintenance dose should be the minimum required to suppress all symptoms and signs of the disease without intolerable side-effects.

"(4) In cases with blood urea over 60 mg. per 100 ml. or a diastolic blood pressure over 110 mm. Hg, special care should be used and the dose adjusted daily where necessary."

Records of treatment and of the clinical and laboratory findings were made daily for one week after the start of treatment, weekly for the next five weeks, and thereafter monthly. It is proposed, where possible, to continue the follow-up of all patients either to death or for a period of five years.

The Treated Group

It was at first hoped that members of the Panel might in their own clinics collect enough cases for this group. It was soon apparent that this could not be done, and an appeal was made to a wider group, particularly those handling cortisone for the Ministry of Health.

Up to the time of writing, 25 patients have been admitted to the trial. Four are excluded from the present analysis because they have not yet completed 12 months in the trial. Three others are excluded because the biopsy sections, although suggestive, were considered on review to be inconclusive. One patient is excluded because he removed from the district and no follow-up was possible. His withdrawal from the series occurred six weeks after starting cortisone, at which time there was still evidence of active polyarteritis in the skin. The present analysis is based on the remaining 17 patients.

Cases were admitted provisionally to the trial as soon as the physician in charge reported a positive biopsy, and treatment was started immediately afterwards in all but three patients. The exceptions were: (1) In Case 24 cortisone was started immediately after the taking of a biopsy, which subsequently proved to be negative. A positive biopsy was obtained in an exacerbation of the disease four months later; at this time the patient was receiving 150 mg. of cortisone daily. (2) Case 5 had received a very short course of cortisone two months before biopsy. (3) Case 8 had received a short course of corticotrophin one year before biopsy. Two patients were first given a short course of corticotrophin before being transferred to the standard cortisone regime described above.

The Untreated Group

To obtain a retrospective control, it was decided to search the diagnostic indices (both clinical and pathological) of the hospitals providing most of the treated cases, and to collect all cases proved by biopsy in the period from 1946 until the introduction of cortisone therapy in 1950. The Medical Research Council appointed Dr. G. A. Rose to do this work, and to him also we record our thanks. To obtain sufficient cases, it became necessary to extend his inquiry to cover the period from 1941, and also to include a total of 13 teaching hospitals, to whose administrative, clinical, and pathological staffs we also wish to express gratitude for generous co-operation.

In the treated series the disease began in 1950 or later in all cases except one which began in 1947 but was not diagnosed until 1950. The untreated control series consisted of all the cases found in the records in which the disease had started between 1941 and early 1950, and which had been proved by biopsy. The same panel of pathologists verified the biopsy sections from both series.

Comparison of the Two Groups at Time of Diagnosis by Biopsy

Table I compares the chief features shown by the control and treated groups at the time of biopsy.

TABLE I.—Comparison of Treated and Untreated Cases of Polyarteritis Nodosa up to the Time of Obtaining a Positive Biopsy

	Untreated		Treated

2-5 months	10	53	10	58
6-11	4	21	2	12
12-23	3	16	4	24
24+	0	0	1	6
Mean	6.0	—	16.4	—
Mean, excluding treated Case 4	6.0	—	7.6	—

The treated group included a slightly higher proportion of older subjects. The severity of the constitutional illness appeared to be similar in the two groups. Loss of weight was recorded in all but four of the untreated patients and in all but three of the treated. The latter tended to show slightly higher fever, and high values for the erythrocyte sedimentation rate (E.S.R.) were more frequent.

There were few important differences in the incidence of polyarteritis in the various organs, but the treated group included slightly fewer patients in whom there was no evidence at all of polyarteritis in major viscera. This difference would tend to weight the prognosis of this group adversely, and would hence tend to lessen the apparent benefit, if any, derived from cortisone.

The duration of the disease from onset to biopsy was of comparable distribution in the two groups, except that the treated group included one patient in whom this interval was 13 years. This patient had had three previous episodes of polyarteritis, each of which had remitted spontaneously. The fourth episode had lasted one month when the patient entered the trial. At this time he was suffering from a severe constitutional illness and extensive involvement of the kidneys, skin, joints, and alimentary tract. Despite the long total duration of the disease, the prognosis at the time of entry into the trial appeared poor. Hence it is unlikely that the inclusion of this case has produced undue bias in favour of cortisone.

The chief difference was in the incidence of hypertension. This has been defined as being present (a) if the systolic arterial pressure exceeded by 30 mm. Hg or more the expected pressure for subjects of the same age and sex (the expected pressure being taken from the data of Hamilton, Pickering, Roberts, and Sowry, 1954); or (b) if the diastolic pressure exceeded its expected level by 20 mm. Hg or more. Using this definition, it was found that 8 (42%) of the untreated group had hypertension at the time of biopsy, but only 1 (6%) of the treated group. This difference is statistically significant (χ^2 corrected for continuity = 4.495; $P < 0.05$). Hypertension is one of the most serious complications of polyarteritis nodosa, and in fact all the eight hypertensive patients in the untreated group died within a year of biopsy. In the analysis below, results are therefore given separately (1) for all patients, and (2) for cases with normal blood pressure at the time of biopsy.

This large difference in the incidence of hypertension might be due to a change in the natural history of the disease over the two periods in question, or to a difference in the clinical features which were regarded by physicians as an indication for taking a biopsy. It could not be ascribed to any general tendency towards earlier diagnosis (Table I).

Comparison of the Two Groups One Year After Biopsy

The results of this comparison are shown in Table II. One year after biopsy only 7 of the 19 untreated cases were still alive, as compared with 14 of the 17 treated cases;

TABLE II.—Comparison of the 17 Treated and 19 Untreated Cases 12 Months After Biopsy

	Untreated		Treated	
	No.	%	No.	%
All cases: alive	7	37	14	82
Excluding cases with hypertension at time of biopsy:				
Alive	7	64	13	81
Clinically remitted	2	18	4	25

if patients with hypertension at the time of biopsy are excluded these figures become 7 out of 11 and 13 out of 16 respectively. At the end of the period active polyarteritis appeared to have ceased in two untreated survivors and in four treated survivors. One of the latter was still receiving 75 mg. of cortisone daily, but there was no recurrence of activity when this was stopped three months later.

In the fatal untreated cases the interval from biopsy to death ranged from 1 week to 7 months, with a mean of 3.0 months; in the fatal treated cases it ranged from 1 to 11 months, with a mean of 6.7 months. If cases with initial hypertension are excluded, the mean duration in the untreated group becomes 3.75 months; the other figures are unchanged.

Detailed Analysis of the Treated Group

The trial was undertaken not only to learn the effects of cortisone on survival, but also to gain experience in the practical problems of this method of treatment. The collection and assessment of this type of information was, however, made difficult by the number of hospitals and

physicians involved. Some details of the management of these patients and the results achieved are presented in Table III.

TABLE III.—Progress of Patients in the Cortisone-treated Group

Period (months) from start of cortisone	1-2	3-4	5-6	7-8	9-10	11-12

" survivors	16	16	16	15	15	14

Initial Effects of Cortisone Treatment

In patients with a severe constitutional illness the initial effects of cortisone were always definite, and often they were dramatic. Within two or three days fever abated, appetite and well-being improved, and joint and muscle pains decreased. Early weight gain was usually noted (perhaps due to a combination of fluid retention and re-synthesis of wasted tissues).

Degree of Suppression Achieved

An ideal result—that is, suppression of all clinical evidence of active disease and maintenance of a normal E.S.R.—was achieved consistently in only a few patients. Even at the end of six months' treatment complete control (assessed over the next two months) was maintained in only 3 of the 15 survivors. Failure of control was sometimes only temporary, following a tentative attempt at dose reduction. But in 10 of the 15 patients a normal E.S.R. was not achieved even once during this two-months period; and in nine patients there was evidence of active renal lesions during the period. Similar results were observed during the remainder of the first year's treatment.

Included in Table III are the values for the mean daily cortisone dosage, calculated for all patients, and for those in whom full suppression of active disease was not being achieved. The results show that on average the dose used to treat the uncontrolled cases was not particularly high. In only one patient had it been considered necessary to limit cortisone dosage because of "intolerable side-effects." This patient had sustained a perforated gastric ulcer, following which no more cortisone was given.

It may thus be considered doubtful whether the dosage was in fact large enough to secure complete suppression of the disease; cortisone seems to have been used rather to control the more severe manifestations. The short-term results of this policy were often reasonably good; for example, despite microscopical haematuria and a high E.S.R., some patients had only trivial symptoms.

By contrast, at some other centres rigorous attempts were made to achieve complete suppression. The impression was gained at these centres that complete suppression is usually attainable, but that it not infrequently requires a sustained dosage of 300 to 500 mg. daily. The supervision of these patients was troublesome and time-consuming.

Side-effects of Cortisone Treatment

The commonest side-effect was oedema, which was noted in six patients. In three patients this was associated with

the general appearance of moderate or gross Cushing's syndrome. There was a good deal of individual variation in the relation between cortisone dosage and the development of these features. But, broadly speaking, it appeared that sustained doses of 150-200 mg. daily usually led, despite salt restriction, to the development of a "moon face" and often to ankle oedema; and that doses of 350 mg. daily or more produced gross features of Cushing's syndrome, including deposition of fat and skin atrophy with striae.

Glycosuria appeared during cortisone treatment in three patients, but was slight and inconstant. In one patient, in whom diabetes mellitus was already present, the daily insulin requirement was 30 units before the start of treatment, but rose to 60 units when she was receiving 300-400 mg. of cortisone daily.

Supplementary potassium was given to most patients who were receiving a sustained dosage of more than 150 mg. of cortisone daily. Potassium deficiency was recorded only once. In this patient the plasma potassium fell to 2.3 mEq/l., despite a regular daily dose of 4 g. of potassium chloride; there were no relevant symptoms. The cortisone dose at the time was 350 mg. daily.

As mentioned above, one patient developed perforation of a gastric ulcer; cortisone, which was being given at the time in a dose of 75 mg. daily, was discontinued. Another patient developed the symptoms and radiological appearances of duodenal ulcer whilst receiving 300 mg. of cortisone daily, but healing was achieved by medical treatment without any decrease in cortisone dosage. The same patient developed an ulcer of the leg during a phase of active cutaneous polyarteritis. Subsequently, complete suppression of active polyarteritis was achieved by 300 to 450 mg. of cortisone daily; nevertheless, the ulcer showed no tendency to heal, and over the next six months it slowly enlarged to a diameter of 7 cm. It was thought very possible that this failure to heal was attributable to cortisone.

Of the 14 patients still alive 12 months after starting cortisone, 4 had developed hypertension (defined, for this purpose, as a rise over the pre-cortisone level of either 30 mm. Hg or more in the systolic pressure or 20 mm. Hg or more in the diastolic pressure). The increase in the systolic pressures in these patients ranged from 10 to 80 mm. Hg (mean 36 mm.) and in the diastolic pressures from 20 to 40 mm. Hg (mean 31 mm.). In addition, the patient with hypertension initially showed a further rise in pressure; and another whose initial pressure was normal died with malignant hypertension 11 months after the start of treatment. Of these six patients whose blood pressures rose significantly during the period of treatment, four had definite urinary evidence of renal polyarteritis or glomerulitis, and in one other the record of urine examination was inadequate. No conclusions can therefore be drawn at this stage about the relative importance of specific renal lesions and of cortisone in causing the rise in pressure.

One patient developed bilateral pulmonary infiltrations and cavities, and was transferred to a tuberculosis sanatorium. Examination of the sputum for tubercle bacilli was, however, repeatedly negative, and there is little doubt that these were in fact the lung lesions of polyarteritis nodosa (Rose and Spencer, in press).

Deaths

Three deaths occurred during the first year of treatment:

In Case 10 death occurred two weeks after the start of treatment, as a result of acute cerebral polyarteritis. At the end of the patient's first week of treatment the E.S.R. was still 56 mm. in one hour, and the urine contained protein and red blood cells. According to the standard regime for the trial, the dose of cortisone should then have been increased from 200 to 300 mg. daily, since the disease was uncontrolled. Instead, however, it was decreased to 150 mg. daily, because the patient was looking and feeling so much better.

In Case 13 cortisone was discontinued because of a perforated gastric ulcer. For the next four weeks the patient progressed satisfactorily, and he was then discharged from hospital at his own request. A week later he deteriorated rapidly. He was readmitted with cachexia, peripheral nerve lesions, and gangrene of the fingers and toes, and died shortly afterwards.

Clearly this was a difficult case to manage. It is pure conjecture whether the risk of restarting cortisone would or would not have been greater than the risk of leaving active polyarteritis untreated.

In Case 14 the patient died with malignant hypertension 11 months after the start of treatment. Cortisone, which was originally started at the standard dosage of 200 mg. daily, had been decreased after four days because of the dramatic improvement in the patient's general condition. Thereafter the patient received only from 37.5 to 75 mg. daily, except for a terminal increase to 100 mg. Throughout this period there was persistent evidence of active polyarteritis in the skin and joints, and the E.S.R. (Westergren) ranged from 35 to 100 mm. in one hour. This level of cortisone dosage cannot be held directly responsible for the development of malignant hypertension, which was probably due to renal involvement by polyarteritis.

Discussion

This paper illustrates very clearly the difficulties of using retrospective controls. We tried to minimize the factors responsible for differences between treated and control series by choosing consecutive periods and drawing cases mainly from the same hospitals. The two series, as shown in Table II, are closely comparable except in one feature—namely, the incidence of hypertension, which is much higher in the control than in the treated group. Unfortunately, this is an important difference, since analysis of other cases shows hypertension to be one of the most important factors influencing prognosis. When the cases with hypertension are included, the results seem better in the treated than in the control series; when these cases are omitted, the differences are small, though still in favour of the treated series. But since the numbers are so small, and the series are dissimilar in an important respect, comparing them does not justify conclusions about the effect of cortisone on expectation of life in polyarteritis nodosa; though it is to be said that our results are consistent with the idea that cortisone may prolong life.

In view of the importance of the question asked, we felt a moral obligation to try to answer it; but, for the reasons explained earlier, the method of retrospective control seemed the only one possible. The uncertain meaning of the results obtained makes us wonder whether the labour was worth while. Its chief importance is perhaps to emphasize that the assessment of therapeutic activity by the use of retrospective controls is an inherently fallacious method and no substitute for the strictly controlled clinical trial (Hill, 1951).

Those who have used cortisone therapy in polyarteritis nodosa agree that nearly always it improves symptoms conspicuously and suppresses the major manifestations of active disease. To maintain suppression of symptoms may require doses of cortisone which provoke troublesome and occasionally dangerous side-effects. Whether the treatment is better or worse than the disease is a matter on which we have no unequivocal evidence to present.

Summary

Survival rates at the end of one year are recorded in a series of 17 cases of polyarteritis nodosa proved by biopsy and in a retrospective control series of 19 cases proved in the same way.

The results illustrate the fallacies of retrospective controls; at the time of diagnosis the incidence of hypertension, which materially affects prognosis, was greatly

different in the two groups. Differences in survival rate may thus be due to variations over these periods in such factors as the indications for biopsy or the course of the disease.

Cortisone treatment usually produces quick relief of symptoms and suppression of signs. To secure sustained suppression of outward manifestations may require large doses producing troublesome side-effects.

The panel is greatly indebted to Dr. G. A. Rose for compiling the data contained in this report.

The following hospitals co-operated by permitting access to their case material for the collection of information on the retrospective untreated group: Canadian Red Cross Memorial Hospital, Taplow (Special Unit for Juvenile Rheumatism); Guy's Hospital; London Hospital; Middlesex Hospital; Radcliffe Infirmary, Oxford; Royal Infirmary, Edinburgh, and hospitals served by the Edinburgh University Department of Pathology; Royal Infirmary, Manchester; Royal Victoria Infirmary, Newcastle upon Tyne; St. Bartholomew's Hospital; St. Mary's Hospital; St. Thomas's Hospital; University College Hospital; Westminster Hospital.

The following hospitals are co-operating in the clinical trial of cortisone treatment: Canadian Red Cross Memorial Hospital, Taplow (Special Unit for Juvenile Rheumatism); Hammersmith Hospital; Kingston Hospital; Norfolk and Norwich Hospital; Northern General Hospital, Edinburgh; Paddington Hospital; Royal Infirmary, Manchester; Royal Sussex Hospital; St. Mary's Hospital; St. Thomas's Hospital; University College Hospital.

PERINATAL DEATH FROM FOETAL EXSANGUINATION*

BY

A. P. B. MITCHELL, M.B., M.R.C.O.G.
Senior Registrar in Obstetrics and Gynaecology

G. S. ANDERSON, M.B.
Lecturer in Pathology

J. K. RUSSELL, M.D., M.R.C.O.G.
Senior Lecturer in Obstetrics and Gynaecology

King's College, University of Durham, and the Princess Mary Maternity Hospital, Newcastle upon Tyne

Foetal exsanguination may not be a frequent cause of perinatal death, but it is a risk to the child's life that can be treated successfully if recognized early, and may on occasion be prevented. For these reasons we record the experience we have had of foetal exsanguination during the years 1951 to 1956. We have previously drawn attention to blood loss from the foetal circulation incurred at caesarean section (Neligan and Russell, 1954, 1955). This paper is concerned mainly with foetal blood loss as it may occur during vaginal delivery and with a method of detecting the foetal source of such bleeding with rapidity and certainty.

Foetal Blood Loss Associated with Vaginal Delivery

In the past five years we have noted at least nine cases where foetal blood has been lost before delivery of the

*This article is based on a symposium presented to the Edinburgh Obstetric Society on December 12, 1956.

baby. Seven of the nine babies lost their lives. In three cases blood was lost from ruptured vasa praevia, and in three others the ruptured vessels lay at a distance from the cervical os and were associated with a velamentous insertion of the cord or a succenturiate lobe of the placenta. In one case there was a circumvallate placenta, but no damage to foetal vessels could be demonstrated. In a further case the mechanism of foetal blood loss remains uncertain, for placenta and cord appeared normal in all respects. The most unusual case was one in which a large foetal vessel, in a normally situated placenta, was damaged at the time of induction of labour with a Drew Smythe catheter.

Brief clinical details of nine cases follow.

Case 1.—A gravida-3 aged 25 was admitted to hospital at term. During the 12 hours before admission there had been slight intermittent vaginal bleeding. The foetal heart was not heard on admission and a few hours later spontaneous delivery occurred of a fresh stillborn child; weight 8 lb. 6 oz. (3.8 kg.). Examination of the placenta revealed ruptured vasa praevia.

Case 2.—A gravida-2 aged 35 was admitted to a private nursing-home at term, following a sudden small vaginal haemorrhage. A slight ooze was noted once or twice during the next 24 hours and the patient was then transferred to our hospital; the foetal heart at this time was quite regular. Over the next few hours a trickle of blood was noted on one or two occasions, but the foetal heart remained regular. Suddenly, eight hours after admission, there was a short brisk vaginal loss and the foetal heart sounds disappeared. A stillborn child weighing 6 lb. 7 oz. (2.9 kg.) was delivered spontaneously two hours later and examination of the placenta showed ruptured vasa praevia.

Case 3.—A primigravida aged 24 was admitted to hospital at 38 weeks, having had a small haemorrhage a few hours previously. The foetal heart was noted to be regular. Four hours after admission a further loss was reported, but this soon ceased. Eight hours later there was a trickle of blood from the vagina, but again this quickly settled. Eleven hours later labour began with rupture of the membranes and the passage of blood-stained liquor. Without warning the foetal heart sounds disappeared. A vaginal examination at this stage revealed a cord-like structure running in the membranes. A fresh stillborn child weighing 5 lb. 14 oz. (2.7 kg.) was delivered spontaneously a few hours later. The placenta showed ruptured vasa praevia.

Case 4.—A primigravida aged 35 was admitted to hospital in labour at term. The foetal heart was regular. Labour progressed normally until the second stage was reached, when the foetal heart sounds suddenly disappeared. Ten minutes later the foetal head appeared at the vulva and was accompanied by a small gush of blood. A fresh stillborn child weighing 7 lb. 14 oz. (3.6 kg.) was delivered; the child was noted to be very pale. Examination of the placenta showed a velamentous insertion of the cord, and one large foetal vessel had ruptured.

Case 5.—A primigravida aged 20 had a surgical induction of labour at the 36th week of pregnancy because of pre-eclampsia associated with twin pregnancy. Twin babies were subsequently delivered spontaneously; neither before nor during labour was any haemorrhage observed. The second twin showed marked pallor at birth and the haemoglobin was 73%. There was a velamentous insertion of the cord and two foetal vessels were seen to be torn across. A blood transfusion was given and the baby recovered.

Case 6.—A gravida-5 aged 37 was admitted to hospital at term because four days previously there had been a small haemorrhage followed by intermittent staining. Vaginal examination in the theatre revealed a type I placenta praevia. The membranes were ruptured with a catheter and labour began shortly afterwards. The foetal heart was regular. At the end of the first stage of labour there was further small loss of blood and the foetal heart was not heard. The baby was stillborn and weighed 7 lb. 8 oz. (3.4 kg.). The praevia portion of the placenta was noted to be a succenturiate lobe

and one of the vessels joining it to the main placenta had ruptured.

Case 7.—A gravida-10 aged 30 was admitted to hospital at term in labour. Two hours before admission she had had a small vaginal haemorrhage. One hour after admission there was a further slight loss and the foetal heart became irregular. The patient was examined under anaesthesia; no placental tissue was felt and the membranes were ruptured. A baby weighing 6 lb. 4 oz. (2.8 kg.) was subsequently delivered by forceps and was noticed to be pale at birth. The haemoglobin was 95% and fell in one hour to 75%. A blood transfusion was given and the baby made good progress. The placenta was circumvallate, but no damage to foetal vessels was found.

Case 8.—A primigravida aged 32 was admitted to hospital at term in labour. When the cervix was 4 fingerbreadths dilated there was a loss of 2 to 3 oz. (60-90 ml.) of fresh blood and the foetal heart became irregular. A precipitate delivery occurred 15 minutes later. The baby was pale and died 45 minutes later. Post-mortem examination revealed marked exsanguination of all foetal organs. Examination of placenta and cord failed to show any injury to the foetal circulation.

Case 9.—A gravida-5 aged 29 had a surgical induction of labour at the 38th week of pregnancy because of pre-eclampsia. No placenta was felt, but a "blood-stained tap" was obtained with a Drew Smythe catheter. For the next 28 hours there was an intermittent slight ooze of blood from the vagina and then the foetal heart suddenly became irregular. The baby was delivered by caesarean section and was noted to be pale at birth. The baby's haemoglobin was 70% and a transfusion was given. The baby improved but died 52 hours later. Examination of the placenta revealed a puncture hole in a large foetal vessel and this area was surrounded by blood clot.

Comment on the Cases

It will be noted that in eight of these cases small antepartum or intra-partum haemorrhages occurred. The origin of the blood loss, however, was not appreciated until after delivery, and this drew our attention to the need for a simple and reliable test to differentiate foetal from maternal blood. In order to ascertain whether the application of such a test would be of practical value it was first of all necessary to determine the time interval between the onset of vaginal bleeding and the delivery or intrauterine death of the foetus. We believe that the test described below would have been of value in Cases 2, 3, 7, and 9 (Table I). The test might also

TABLE I.—Time Intervals in Hours Between Onset of Vaginal Bleeding and Delivery or Intrauterine Death of Foetus

Case No.	Intra-partum Death	Born Alive but Died	Recovery Following Blood Transfusion
2	32 hours		
3	25 "		
7		29 hours	
9			34 hours

have been of value in Case 1, but we cannot be sure, for we do not know when the foetal heart sounds disappeared in relation to the repeated small vaginal haemorrhages. In Case 4 the foetal heart sounds disappeared before there was any bleeding, and in Case 5 no vaginal bleeding was noted. We are uncertain about Case 6; for the first bleeding, four days before delivery, may well have been due to partial separation of the succenturiate placental lobe.

Detection of Foetal Bleeding before Delivery

Adult and foetal blood differ in several respects (Lancet, 1954), and, though methods for distinguishing the two types of blood on the basis of different properties are available, most of them, at present, are not suitable as a diagnostic test. Williamson (1912) suggested that foetal bleeding might

be detected in a vaginal blood loss by recognition of nucleated red blood cells, but this test is impracticable.

In our attempts to find a practicable and reliable diagnostic test for the detection of foetal bleeding use has been made of the fact that foetal haemoglobin is much more resistant to denaturation by alkali than is the adult haemoglobin. In the human foetus traces of adult haemoglobin first appear by the tenth week and the amount slowly increases so that, at term, on average, 20% of the total haemoglobin is of adult type. After birth the percentage of foetal haemoglobin decreases, and by the age of 4 months 90% is of adult type; in the normal adult foetal-type haemoglobin is present, but in minute amounts.

Singer, Chernoff, and Singer (1951) devised a method using the alkali-denaturation technique for the detection of foetal haemoglobin, but in its original form it is not suited to the needs of routine obstetrical practice. Clearly the test would have to be done in all cases of ante-partum and intra-partum haemorrhage in order to detect the few cases where the blood was of foetal origin: speed and simplicity are essential, for the clinician himself must usually do the test and act upon the result.

Rapid Modification of Singer Test

The following test, which is a modification of Singer, Chernoff, and Singer's method, was accordingly devised by one of us (G. S. A.) to meet the necessary requirements: the test takes between five and ten minutes.

Principle.—A sample of blood is allowed to react with an alkali for a set period of time. The reaction is then stopped by an acid solution which also precipitates non-haemoglobin chromogens. The mixture is filtered immediately and the filtrate examined by the naked eye and in a colorimeter.

Reagents.—Alkali: N/12 NaOH or N/12 KOH.* Acid-precipitating solution: 800 ml. of 50% saturated $(\text{NH}_4)_2\text{SO}_4$ plus 2 ml. of 10 N HCl. Blood:—The sample is either pure blood or a mixture of blood and other contaminants issuing from the vagina. It should be collected in a clean heparinized bottle. If collected in an oxalated tube or by means of a siliconed syringe there is a danger of "foetal results" being obtained from adult blood.

Technique.—The haemoglobin level of the blood sample is first determined. To 2 ml. of alkali, 0.1 ml. of blood is added and the mixture is shaken. The reaction is allowed to proceed for one minute at room temperature, when 4 ml. of acid-precipitating solution is added and the mixture again thoroughly shaken. It is then filtered through a No. 1 Whatman filter paper and the filtrate collected.

Results of Test

The results are usually obvious by naked-eye examination. With adult type haemoglobin the filtrate is either clear and colourless or a faint brown-amber colour. With foetal type haemoglobin it varies from a faint pink to a distinct cherry red, depending on the amount of haemoglobin in the sample.

Readings on the colorimeter have been determined, first, so that foetal blood might be detected even when mixed with blood; and, second, to lessen the danger of a mistaken result that might be possible on naked-eye examination alone. The readings obtained by us on an E.E.L. colorimeter, using a green Chance glass filter OGRI with the filtrate in small-bore tubes ($3\frac{1}{4}$ by $\frac{1}{4}$ in.—8 by 0.6 cm.), are presented in Table II. It will be seen that the haemoglobin level of the sample makes an appreciable difference in foetal blood (12 or more units) and a slight difference in adult blood (4 units), but that a range of readings for both types of blood at different haemoglobin levels has been established. It will also be noted that the range for adult blood of 50% haemoglobin (7.4 g.) and above approaches the range for foetal blood of 50% (8.5 g.) and under—that is, samples of

*Singer *et al.* specify N/12 KOH at exactly pH 12.7. It has been found that the concentrated volumetric solutions of NaOH (B.D.H.) can be used to make a satisfactory N/12 solution when one ampoule is dissolved in 600 ml. of distilled water.

TABLE II

Adult Blood		Foetal Blood	
Haemoglobin		Haemoglobin	
Above 50%	Below 50%	Above 50%	Below 50%
46 samples. Highest reading 10	40 samples. Highest reading 6	44 samples. Lowest reading 22	36 samples. Lowest reading 10

In all estimations of haemoglobin the M.R.C. grey-wedge photometer has been used.

foetal and adult blood may give a reading of 10 units, depending on the haemoglobin level. There seemed to be no advantage in making a more complicated division than the one adopted (50% haemoglobin level), for the reading of 10 units obtained with foetal blood was on one specimen only and this had been diluted to 16% (2.72 g.); all other samples gave readings well above 10 units. With adult specimens, only two gave readings of 10 units; four more gave readings above 7 units, but the remainder were below this figure.

There may be a failure to detect foetal blood when the sample contains very little haemoglobin—for example, below 15% (2.55 g.). The colour change under these circumstances may be so slight that the photometer reading falls into the adult range. This circumstance may arise when faintly blood-stained liquor is obtained at surgical induction of labour. With such a sample too little haemoglobin will be contained in 0.1 ml. to give either a clear visual change after alkali treatment or a reliable colorimeter reading after the rapid alkali denaturation test. The difficulty can be overcome by using a larger quantity of the blood-stained liquor. Into each of two test-tubes about 4 ml. of sanguineous liquor is placed and to one, the control, an equal amount of water is added. To the other an equal amount of N/12 alkali is added and the mixture shaken. With adult blood a colour change will be observed at five minutes, when the colour becomes greenish amber. Foetal blood does not show any changes at five minutes, but a colour change does begin at about 30 minutes, to be completed in several hours.

Meconium-stained liquor provides a complicating factor in that heavily contaminated liquor, if put through the rapid alkali denaturation test, will give a reading of 2 or 3 units. Pure meconium can give a reading of 10 units. Fortunately the occurrence of ante-partum haemorrhage with the escape of meconium-stained liquor is rare.

Mixtures of Adult and Foetal Blood
