Safe symptomatic relief for the anxious patient

OBLIVON-C is a new, long-acting derivative of Oblivon in tablet form, with the same wide margin of safety and freedom from side effects. In the treatment of anxiety states OBLIVON-C gives day-long freedom from tension and creates a climate of confidence in which simple reassurance can be accepted.

PRESENTATION :

OBLIVON-C is presented as Ovets, each containing 100 mg. of methylpentynol carbamate. Containers of 100.

DOSE:

1-2 100 mg. Ovets three times a day and 2-4 Ovets at bedtime.

TOWARDS A SOLUTION OF THE TOBACCO-CANCER PROBLEM

BY

E. L. WYNDER, M.D.

From the Section of Epidemiology, Division of Preventive Medicine, Sloan-Kettering Institute, New York

Human Evidence

Statistical and epidemiological evidence linking smoking to cancer of the lung and also to cancer of other sites of the upper respiratory tract is so extensive that it hardly needs to be recited for the physician and the scientist who have followed these data. Sixteen separate investigations from seven different countries, studying smoking habits of over 6,000 patients with lung cancer, are all in agreement that lung-cancer patients smoke significantly more than any group of controls and that the relative risk of developing lung cancer rises in proportion with the amount of tobacco and particularly of cigarettes consumed. Two prospective studies, carried out in England and in the United States, that followed population groups whose smoking habits were known, also showed that the heavy cigarette smoker has a far greater chance of developing lung cancer than the non-smoker. In fact, the study by Hammond and Horn (1954 and personal communication) indicated that for a person smoking 40 cigarettes a day this chance was 70 times greater than for a non-smoker. To account for such magnitude of difference on the basis of statistical errors would require errors of equal magnitude. Such errors have so far not been demonstrated.

The belief that smoking is a major cause of lung cancer is not only based upon statistical evidence but it also is supported by the general epidemiological pattern of lung cancer. In countries, such as Great Britain and the United States, with a high cigarette consumption already 30 years ago, the present lung-cancer rates are high, while in countries, such as Iceland, where the cigarette consumption was low, the current rate of lung cancer is low. Among males in every country lung cancer is more common than among women. This fact has always presented a particular challenge. Any factor found to be significant statistically has to account, at least in part, for this sex difference. In a recent study we have shown that the present sex ratio of lung cancer is quite consistent with the long-term smoking habits of the two sexes. For instance, while some 20% of American males over the age of 50 smoke in excess of one packet a day, only 2% of the women in this age group smoke this amount. This study also showed that, among women who had smoked, the risk of developing epidermoid cancer of the lung or its undifferentiated types is about the same as that for men (Wynder *et al.*, 1956).

To consider smoking as a major cause of lung cancer does not mean that it is the only cause of this disease. Obviously there is the factor of internal predisposition

which must exist, since not everyone who smokes develops lung cancer. Obviously, too, there are other exogenous factors that may produce cancer of the lung. Among these are a number of occupational exposures. There is also evidence that general air pollution and/or motor exhaust fumes may be a contributing factor (Stocks and Campbell, 1955; C. Mills, personal communication). However, with the possible exception of a few isolated cities, such as Liverpool, air pollution is at best only a secondary factor. This belief is based on the fact that among non-smokers lung cancer occurs but rarely, that the incidence of lung cancer among women, who are also exposed to city air, is low, and that the age distribution of epidermoid lung cancer with its peak in the fifth to sixth decade and its subsequent decline is more compatible with an exogenous factor to which only a certain population group was exposed some 30 to 40 years ago rather than with air pollution, which would expose an entire population group at the same time (Levin, 1953).

While most students of the problem of the aetiology of lung cancer admit to an association between smoking and lung cancer, some question whether this association also represents causation. Until proved otherwise, an association means at least a contribution toward if not a causation of a disease. For any given patient it matters little whether a factor has contributed to or caused a disease. In either case the elimination of this factor will lead to reduction of the disease. In this sense, smoking, and especially cigarette smoking, is to be regarded as an important factor in the development of lung cancer. In fact, among the exogenous factors that influence the development of this disease it represents the most important one. Present incidence data indicate that some 80% of all lung-cancer cases occurring in males to-day would not have occurred were it not for tobacco smoking, and that about 10% of males over the age of 25 who smoke in excess of 20 cigarettes daily will develop lung cancer by the age of 75.

In view of these data, which gain significance because lung cancer represents the most common cause of cancer death among males in many countries, it becomes paramount to ask what we can do about solving this problem. Ideally this problem could be largely overcome by abolishing the use of tobacco. It is evident, however, that because of economic factors and because of firmly entrenched habits such advice is not likely to be heeded, regardless of how strong the evidence. For this reason we became interested in experiments that might lead to a reduction of carcinogens in tobacco and its products.

Animal Evidence

Experimental work is not carried out to prove that smoking causes cancer in man. Such proof can come only from human statistical and epidemiological studies. The purpose of an animal experiment is to define the mechanism by which a given agent produces cancer and to determine the specific substances responsible for this activity. In a series of experiments with different strains of mice we have demonstrated that condensed cigarette tar obtained in a manner simulating human smoking habits will produce skin cancers in a significant number of animals, varying from 10 to 44%, depending upon the strain of mice used (Wynder, Graham, and Croninger, 1953, 1955; Wynder, Lubberger, and Grener, 1956). Preliminary data show that some 20% of rabbits whose ears have been painted with tobacco tar for more than five years also develop cancer (Graham, Croninger, and Wynder, unpublished data). Thus carcinogenic activity of cigarette tar has been demonstrated in two species of animal and in several strains of mice. By itself, this observation might be only of academic significance, but taken together with the human evidence already at hand it gains practical significance.

Among the well-established principles of carcinogenesis is the relationship of dose to the latent period and number of tumours that may be obtained. The fulfilment of this principle is one of the reasons smoking is regarded as a cause of lung cancer in man. The risk of developing lung cancer rises in proportion to the amount of tobacco smoked. It has been of interest to determine whether with tobacco this principle could also be established for the experimental animal. Preliminary work leaves no doubt that this is the case (Wynder, Kopf, and Ziegler, unpublished data). When tar was applied to the back of Swiss mice twice a week, instead of three times weekly as is standardly followed in our laboratory, only 10% of 40 mice developed papillomas and 3% cancers at the end of 17 months. Of the animals painted three times a week for the same interval, 58% had developed papillomas and 26% cancers. The first papilloma in the group painted twice a week occurred two months later than in the group of animals painted three times a week. 40 mice painted once a week for 17 months developed only one papilloma.

A comparable reduction in tumour formation and lengthening of latent periods is also noted when one decreases the amount of tar applied. A 33% solution produced about 20% fewer cancers and increased the latent period by three months over that obtained with a 50% solution.

In still another way we can demonstrate the dose-response principle by stopping the painting after a given period of months. Painting animals three times a week for only three months and then stopping produced no tumours after 16 months of observation; painting 50 mice for six months produced two papillomas which subsequently regressed; nine months' painting produced a significant number of papillomas and cancers, but this was exceeded if animals were painted for one year.

Thus, animal experimentation has demonstrated a definite relationship between the amount and duration of tar applied to an animal and the total number of tumours and the duration of the latent period observed. The importance of this demonstration serves not so much as an example for those investigators who report negative results after painting animals with insufficient amounts of tar or over a too short time period, but serves chiefly to re-emphasize the existence of a threshold value for tobacco tar below which tumours will not or but infrequently occur after a long latent period. Here again human and animal data confirm one another. The realization of this principle has practical aspects that are discussed below.

Tobacco Carcinogens

Having established the carcinogenic activity of cigarette tar, one needs to determine the nature of the carcinogens responsible for this activity. The benzpyrene content of

cigarette tar is not more than 2 p.p.m., which, according to our experiments, is not sufficient to produce the type of activity noted in our animals painted with tobacco tar (Wright and Wynder, 1955, 1956). The arsenic content of our tar sample is about 35 p.p.m. Again this is not sufficient to induce the number of skin cancers produced. Cooper and Lindsey (1955) have found traces of 1:2-benzpyrene, and G. L. Wright (unpublished data) observed spectrographic evidence of traces of 2 methyl,3:4-benzphenanthrene. At present there is no evidence of a known carcinogen in tobacco tar in quantities large enough to account for the observed animal activity. A summation effect of the substances just mentioned or perhaps a co-carcinogenic effect of other substances remains to be ruled out. It seems more likely, however, that there are carcinogenic substances in tobacco tar which are as yet unestablished.

Most, though not all, of the carcinogenic activity of the cigarette tar lies in the neutral fraction (Wynder and Wright, 1956). Within the neutral fraction the carcinogenic components are those that are eluted by hexane and particularly by carbon tetrachloride or solvents of similar polarity. Both of these fractions proved highly active for the rabbit, and the latter particularly potent for the mouse (Wynder and Wright, 1956). The benzpyrene content of both fractions is low. In the concentration as applied to the animals it was not more than 2 p.p.m. In these fractions there is spectrographic evidence of other higher aromatic hydrocarbons which are present in 50 times the concentration of benzpyrene. We are currently engaged in various separation schemes trying to isolate these substances.

Formation of the Tobacco Carcinogens

Present evidence suggests that the majority, though not all, of the carcinogens in tobacco are formed during pyrolysis. Human statistics comparing the risk of cancer among tobacco chewers with that of tobacco smokers, and our own experimental work comparing the activity of cigarette tar obtained by extracting cigarettes with methanol and hexane with that of condensed cigarette smoke, indicate far greater activity for the latter in each case (Wynder and Wright, 1956). Thus there is good reason to believe that the majority of the carcinogens are formed during combustion. In fact, ever since the classical work of Kennaway (1925) and his associates showing that under pyrolytic conditions by which they are formed the pyrolysis of isoprene and that of acetylene in turn form potent carcinogens, it has been apparent that higher aromatic hydrocarbons can be formed by the pyrolysis of saturated or terpinoid aliphatic hydrocarbons. Most recently this was again demonstrated by Lam (1956a, 1956b), who obtained such substances upon pyrolysis of dicetyl as well as of aliphatic tobacco hydrocarbons. In this respect one recalls Kennaway's recent remark (personal communication) that in view of the high temperatures associated with smoking he was surprised that tobacco smoke was not more carcinogenic than present evidence indicates.

It is our working hypothesis that a major proportion of the tobacco-tar carcinogens are formed through pyrolysis of substances naturally occurring in tobacco, which thus serve as precursors to tobacco-tar carcinogens. The practical aspects of research in this field must be directed towards reducing the exposure to and the formation of carcinogens in tobacco tar.

Practical Aspects

Practical aspects of solving the tobacco-cancer problem centre in the following suggestions and research programmes.

1. *Moderation of Smoking Habits.*—All a physician can do is to present the facts to the public. In general, of course, the public is unable to evaluate the present facts fully, in part because of the confusion that special interests in some countries have added to this situation. In the final instance it must become the function of the public health services of different countries to evaluate the data at hand, and, if convinced by the evidence that tobacco plays a part in the development of lung cancer, decide whether lives are more

important than economic considerations. In view of the apparent difficulty that may be foreseen in arriving at a decision on this issue, research must be carried forward that may give a practical solution to the problem at hand.

2. *Effective Filtration.*—During recent years filtered cigarettes have become increasingly popular, initially because of "supposed health protection" and to-day because of a combination of factors, which include large advertising campaigns, the perhaps more pleasant feeling of a filtered tip, and a somewhat "milder smoke." According to present knowledge, filtration to remove specific components from tobacco smoke to pass, a minimum of tobacco smoke to pass, a satisfactory pressure drop and tobacco taste. In the United States some tobacco companies have taken advantage of the public's desire for filtered cigarettes and its equal wish for good tobacco flavour by marketing increasingly ineffective filters. Since both human and animal evidence indicates that the risk of developing cancer is directly related to the amount of tar exposure, it stands to reason that a given filter which will permit x milligrams of tar to pass is more effective than one which will permit the passing of 3x milligrams of tar. Sooner or later, regulations must be passed that establish criteria for the amount of tar which may pass through a given filter and that will make it a requirement for the manufacturer to state the effectiveness of a given filter. Present work indicates that it is entirely possible to develop a filtered cigarette with a good pressure drop and satisfactory tobacco taste which will remove about 40% of nicotine and tar from a given cigarette. Uniform acceptance of a filter in this range will be a partial answer to the present problem, provided, of course, that the smoker does not decide to smoke twice as many cigarettes, and provided, too, that the tobacco selection, cut, or packing is not altered in such a way as to yield increasingly more tar.

3. *Removal of Precursors.* If the hydrocarbons naturally occurring in tobacco represent one of the major precursors of tobacco-tar carcinogens, a reduction of such substances occurring in tobacco, a reduction of such substances may have a direct effect in reducing the carcinogens. Most of the aliphatic hydrocarbons are in the waxes that cover the tobacco leaf. Terpenes are also present. It may be practicable to remove all or part of these substances from tobacco by washing it with eluents such as hexane. Experiments testing this hypothesis are now in progress.

4. *Modification of Pyrolysis.*—Since pyrolysis plays an important part in the formation of carcinogens, modifications of pyrolysis may affect the formation of carcinogens. This problem can be studied from the point of view of all those factors that affect the process of pyrolysis of tobacco. This includes the amount of oxygen supply, the temperature levels reached and maintained, the catalysis available, the cut of the tobacco leaf as such, the length to which a cigarette is smoked, and even the cigarette paper used. Experiments are now in progress for studying the interrelation of these factors so as to determine how a modification of the factors might lead to a reduction of the carcinogens formed during pyrolysis.

In this respect recent work of Lam (1956a, 1956b) is of particular interest. Pyrolysing aliphatic tobacco hydrocarbons, he found smaller amounts of aromatic compounds formed at 700° C. than at 800° C. At the latter temperature Lam found 3,4-benzpyrene to account for 1.3% of the total aromatic compounds and at 700° C. for 0.5%. The respective figures in parts per million were 340 and 30. At 600° C. Lam was unable to find evidence of aromatic substances, but studies by Wright indicate that some polynuclear aromatics are found even at lower temperatures (G. Wright, unpublished data).

Conclusion

The practical aspects outlined above may not individually lead to a tobacco tar that will have less tumorigenic activity, but a combination of these factors may be effective.

This discussion has dealt only with the problem of carcinogens and not with the equally important problems of nicotine and its apparent effect on the cardiovascular system. Jointly with work carried out toward reducing the carcinogens in tobacco tar to a subthreshold level, work should also be carried out on nicotine effects to determine whether it can also be brought to a subthreshold level so far as its effects on man are concerned.

A final point concerns a comparison of human and animal data referred to in the beginning of this discussion. It was there stated that the proof that smoking is the cause of cancer in man rests entirely upon human statistical and epidemiological data. Animal data chiefly serve to indicate the nature of the carcinogens in tobacco tar. Obviously they can only indicate the nature of a carcinogen to a specific animal strain, species, and tissue. This truism applies not only to this specific instance but to all phases of cancer research. In cancer chemotherapy, as in carcinogenesis, many similarities and also many differences are known to exist between human and animal data. On having identified the specific carcinogens in tobacco tar as they apply to the experimental animal, one can only assume that these carcinogens are also responsible for the human cancer problem. If an agent has been found to be carcinogenic to a variety of animals, and human epidemiological data are not inconsistent with this finding, then the burden of proof lies upon those who claim that these substances are not carcinogenic to man. For that reason we should try to establish measures, if at all practicable, that can reduce established carcinogens from tobacco tar and apply these to the manufacturing of smoking products and the smoking habits of the population. This problem, as any other problem in life, cannot be solved by ignoring its existence or depreciating its importance. It can only be solved by facing it directly. In view of the work already completed and the investigations in progress now, a satisfactory solution should be attainable. The lives of people everywhere who will in years to come die from cancer of the lung and cancer of the upper respiratory tract demand that we give this problem our fullest attention.

Reporting to the Waikato Hospital Board, Hamilton, North Island, on the shortage of house-surgeons in New Zealand, the medical superintendent of the Waikato Hospital, Mr. R. S. A. GRAHAM, said that early marriage or projected marriage was one of the three predominant causes of the early loss of senior house-surgeons from the hospital service to better-paid positions in private practice. Mr. Graham said he understood that the marriage rate among medical students was increasing rather than diminishing. In 1956 nearly 30% of final-year students at the University of Otago would have married by the end of the year, as against 10 to 12% in previous years. Of the two other main causes for the loss of senior house-surgeons, one was the desire to get overseas—or at least to take a locum to accumulate funds for overseas work, he said.

THE MILD ENDOGENOUS DEPRESSION*

BY

C. A. H. WATTS, M.D., D.Obst.R.C.O.G.
General Practitioner

In a recent paper on endogenous depression (Watts, 1956) it was suggested that not more than one-quarter of the cases occurring reached the psychiatrist, and that the disease was essentially one of general practice. It is probably one of the most common misdiagnoses, frequently being labelled either an anxiety state or an organic illness. The typical mental-hospital type of endogenous depression is easy to identify. To wait for this severe state of affairs to be reached in order to clinch the diagnosis is like waiting for cavity formation before deciding that a case is one of tuberculosis. There is one big difference between these two diseases. Tuberculosis is a chronic progressive condition which will in time compel recognition, whereas endogenous depression is a self-limiting disease which in 85% of cases remits after a few months or years, and once the patient has recovered the problem of diagnosis is forgotten. Only about one case in every six is a classical deep depression. The other five are milder types, and more difficult to diagnose. Twenty years ago, at the very end of a list of possible aetiologies, one found "hysteria." This clause should be amended to "anxiety states, endogenous depression, and other psychiatric disorders."

The first step in making the diagnosis is to realize the possibility. The mild depression has to be sought for. The presenting symptoms in 100 cases are shown in Table I.

TABLE I.—Presenting Symptoms in 100 Cases

Depression	9	Muscular pains	2
Cough	8	Injury	2
Run down	7	Strange behaviour	2
Insomnia	7	Palpitations	1
Headache	6	Tinnitus	1
Vague complaints	4	Globus hystericus	1
Dyspepsia	4	Urticaria	1
Nervousness	4	Tremor	1
Tight feeling in chest	4	Tonsillitis	1
Giddiness	4	Pseudocyesis	1
Pain in chest	4	Bad smell in nose	1
" " back	3	Plles	1
Belching of wind	3	Diarrhoea	1
Pregnancy	3	Constipation	1
Attempted suicide	3	Haematemesis	1
Vaginal bleeding	3	Collapse	1
Dysuria	2	Dysphagia	1
Fainting	2		

If all the cases with symptoms that could possibly be called neuro-psychiatric are collected together, the total number of the cases will amount to 60% of the whole (Table II). In other words, two-fifths of the cases present as a possible organic disease.

TABLE II

Nervous and psychiatric symptoms	60
Respiratory system	12
Gastro-intestinal system	12
Urogenital system	9
Muscular	8
Ear, nose, and throat system	5
Injury	3
Skin diseases	2

	100

To approach the problem of diagnosis another way, it is suggested that mild endogenous depressions appear in four ways. (1) Some of the patients exhibit overt evidence of a depressive disorder, and the problem is to

*This article and its predecessor (Watts, 1956) were the substance of the Sir Charles Hastings Prize essay for 1955.

decide whether the case is endogenous or reactive. (2) Some present as cases of psychiatric disorder, but the depression is heavily disguised. (3) Some present as a "depressive equivalent"; that is to say, the case simulates an organic illness, and the latter has to be excluded before the diagnosis can be made. (4) The depression may be grafted on to genuine organic illness. To illustrate these points, typical cases in the various categories are described.

1. Overt Depression

This kind of case is often presented in general practice as the respectable good patient who suddenly goes "neurotic" and becomes really troublesome. For weeks or months he is a constant attender at the surgery with vague complaints which have no adequate physical basis. He tends to exchange one set of symptoms for another and his outlook is irrational. Then just as suddenly as he started his trips to the surgery, they cease, and once again he becomes the perfect patient, requiring no attention.

A man of 50 presented himself in an apologetic way. He wasn't really ill; he just felt queer. He had never been like it before and just could not understand himself. He could not read as he used to, found it very difficult to make up his mind about things, was restless, and could not sleep, having difficulty in dropping off. There was no obvious reason for any anxiety or depression. Testosterone was ineffective, but he found great help from quinalbarbitone on retiring and dexamphetamine in the mornings. He was unable to work for four weeks, and when better admitted he had had ideas of poverty he had never spoken about. When seen six months later he had quite recovered.

A woman in her forties was very prone to this condition. She usually came to the surgery with some fairly trivial complaint, but if given a sympathetic ear she was prepared to pour out her troubles. "Doctor, I don't know what is the matter with me. I have a good husband, a nice home, and three lovely children. I have everything that a woman can want and yet I'm utterly miserable."

A married woman aged 44 came to see me because of dizzy bouts. She said she could not understand herself, as the least thing upset her. Some days she felt on top of the world, and the next useless. She kept waking up in the early hours of the morning and what sleep she had was broken with bad dreams. She could not concentrate, and found her memory was going. She could not settle to do jobs which at one time gave her great satisfaction. There was no wish to be dead, but she was given to weeping bouts.

2. Depression Disguised as an Anxiety State

The following case illustrates the difficulty in making a diagnosis. While three doctors were agreed on the psychogenic nature of the problem it was not until psychotherapy was started that the case was shown to be one of endogenous depression.

A man of 31 was passed on to me as a psychiatric case by one of my partners. He had already been seen at the hospital out-patient department, where the diagnosis was considered to be "psychogenic." His story was that in June, 1955, while working a crane, a giddy feeling came over him and he had palpitations. He felt very frightened and thought he might drop dead. He had been sleeping badly for some time before this attack. When seen by me in February, 1956, he was complaining of headaches and vertigo, and my first diagnosis was one of anxiety state. Financial worry seemed to offer some explanation for his troubles, but he had no insight into his condition and he was unresponsive to psychotherapy. Attention was then turned to probe for depressive feelings. Inquiry showed that he was in very low spirits and often wished he was dead. He felt it was all his own fault that he had allowed himself to slip, and he had distinct ideas of guilt. Powers of concentration had gone, he could no longer read books,

and noise upset him. He found the children a problem and the wireless unbearable. The world, he said, looked different, a less pleasant place than it had been. He was referred to a psychiatrist, who agreed with the diagnosis, and he entered a mental hospital as a voluntary patient.

3. The Depressive Equivalent

The type of case in which the depression simulates an organic illness was called by Kraines (1943) a depressive equivalent. A selection of these cases is given to illustrate how deceptive the disease can be, and not because equivalents are more numerous than other types of depression.

Simulating Gastric Carcinoma.—A man aged 52 sent for me in August, 1946, because he had had a haematemesis. I did not see the blood, but he was obviously very ill. He was pale but not exsanguinated. He had a marked anorexia, was very thin, but had no pain whatsoever. I could find no physical signs in his abdomen, but I suspected carcinoma of the stomach. As soon as he was fit enough he was sent for x-ray examination, with negative results. In November he was a living skeleton. He could not sleep, and felt he was a living skeleton. He was morose and could not bring himself to speak to his family. He admitted he was very depressed, and when I asked him if he wished he was dead he replied, "I have indeed, but I would never have told you had you not asked me." He stated he still could eat nothing before dinner, but felt better by evening. At bed-time he felt much better, but could not get off to sleep. This morning depression and evening vigour is fairly common in melancholics. A week later he was very depressed and admitted that but for his family responsibilities he would get out of it. I persuaded him to see a psychiatrist, who reported as follows: "This patient has, as you say, a typical involuntional depression of something like 12 months' duration. He should have E.C.T., but refused to go to a mental hospital. His haemorrhage is indeed difficult to account for, though it did follow vomiting. Did the strain of retching rupture a vessel?" The patient was very satisfied with this second opinion, although he poured scorn on the idea of a mental hospital. By July, 1947, he had recovered enough to go back to work.

This man presented a typical picture of gastric neoplasia: but he proved to be a case of depression.

Simulating Asthma.—An old man of 84 sent for me because he was having attacks of nocturnal dyspnoea. I found him setting potatoes in his garden, so he was by no means an invalid. He actually lived alone and cared for means an invalid. He actually lived alone and cared for himself. His story was that at 2 a.m. he awakened short of breath. He had to get out of bed and open the window, and there was no more sleep. I thought he probably had cardiac asthma, but there was no evidence of either heart or kidney disease. Linctus and cough medicines were ineffective in helping his dyspnoea. He pressed me to let him know the worst, and all his family felt it was the end. The early waking and his deep concern over himself made me suspect depression. I gave him a barbiturate hypnotic each night, and once his sleep had returned to normal he greatly improved. He never had a return of his symptoms and he lived to the ripe old age of 92.

I have called this incident a depression. It was certainly no organic or progressive disease. There was no history of asthma, and I never found any evidence of bronchospasm. He had a very fine health record. My view is that this was a very mild depression which fortunately came and went fairly quickly, lasting in all about two months.

Simulating Rectal Growth.—A man aged 45 came to see me in February, 1947, complaining of diarrhoea. His stools were running from him in the surgery, so that I had to send him home and go there to examine him. There was a history of alternating diarrhoea and constipation with marked loss of weight. Nothing was found on physical examination either per rectum or per abdomen. He was referred to hospital, where investigations were again negative, but later, when his diarrhoea had ceased, he complained of diffi-

culty in falling off to sleep, bad dreams, and awaking unrefreshed. He said he felt awful in the mornings and had done so for at least three months. Everything was too much trouble; but he denied being depressed. He was irritable at home and his sexual desires had gone. I returned him to hospital with the suggestion that he was depressed. This view was confirmed by the physician. By April he was worse, neither eating nor sleeping. In May his wife came to see me. She was very worried about him and was sure he was suicidal. She agreed to his going to a mental hospital, but we could not persuade him to go. Fortunately he began to improve, and by July was back at work, having been "on the club" for five months.

Simulating Intestinal Obstruction.—A woman aged 57 came to see me in April, 1947, complaining of abdominal pain. Physical examination revealed that her abdomen was distended, and she presented a picture of subacute obstruction. I sent her to see a surgeon privately, and he admitted her to hospital at once and performed a laparotomy, to find nothing abnormal. I saw her again in May, when she came out of hospital. All her abdominal symptoms had gone and she complained of insomnia, early waking in character. She was depressed and lacrimose, but admitted no death wish. Her memory was bad and she could not stand noise. She told me she had been very depressed 27 years previously, after the death of a child. She had visited the grave twice daily and once filled a tub in which to drown herself. A week after this interview she was somewhat better, having good days and bad days. The depression gradually lifted, and in October, 1947, she said she would not come again as she was quite well, and her recovery appears to have been maintained for the past nine years.

This case is of interest because the depression did not become obvious until after the laparotomy; but it must have given rise to the obstructive signs and symptoms. Autonomic upsets are not infrequent in depressive illness, as shown by sweating, tremors, fainting, and even ague.

4. Depressive Grafts

In my opinion few chronic sick are more cheerful in adversity than the victims of severe forms of rheumatism.

A man of 27 had been confined to his bed for seven years with a poker back and ankylosing arthritis of both his hips. He was usually cheerful and contented in spite of his crippling and sometimes painful complaint. He seemed to have accepted the bad prognosis and adjusted himself to the limited little world in which he was compelled to live. He revelled in the praise he got from his family and friends for his uncomplaining attitude. His bedside became a social centre. But periodically a cloud descended and he lost his tranquil frame of mind. He grew restless and demanded further investigation of his condition or a new treatment. He became complaining, morose, and difficult to live with. He felt his life in his deplorable state was not worth living, and suicidal ideas were not far away. He was broody and had difficulty in sleeping. He refused to eat, was depressed, and at times lacrimose. He was full of symptoms, and each new pain had an ominous significance. His whole attitude to his suffering became illogical and quite the reverse of his usual fortitude.

I saw this man in only one of his attacks, but my partner, who had been looking after him ever since his illness began, said he had had three or four similar attacks. These usually lasted for about a month, and then the cloud lifts and he becomes his old self again, seemingly adjusted to his physical limitations.

A man of 64 had very severe chronic bronchitis and marked emphysema. Only on his best days could he walk very slowly along the village street. Most of his life was spent in his chair in the kitchen. He was a man of character. Starting life as a collier, he had continued at that work until his chest had stopped him five years previously. But besides his mining he had saved money and bought property. He was a fine gardener and owned a sizable poultry farm. He was always an interesting man to visit, although he was

so short of breath that even speech was difficult at times. He was philosophical about his illness, and usually said little about it. He preferred to talk about gardening or hens. When I called to see him in March, 1946, he had left his place in the kitchen and was sitting in a chair in his downstairs bedroom. He looked thoroughly miserable and depressed. He felt his end had come, and, although he had no ideas of suicide, he wished he could die. Life was a burden to him and he could see no future. His sleep was bad, as he was given to early waking. He made a good response to phenobarbitone and amphetamine, and in about three weeks the depression had passed. He came back to the kitchen and was his old cheerful self until he died in an emphysematous crisis some eight months later.

A married woman of exceptional personality and ability lived alone and did all her own housework at the age of 82. In August, 1947, I was called out to see her in the night as she had an attack of renal colic. I gave her morphine, and the next day she was much better. I noticed she had auricular fibrillation and a fast pulse, so I kept her in bed for a few days. She developed oedema and became seriously ill. Her son took her to his home, and there she became very depressed. She did not weep, but felt she was finished, and actually asked me to put her away. She could neither eat nor sleep, and it was difficult to control her oedema. Slowly she improved, but she remained profoundly depressed. In ordinary times she knitted, did the *Daily Telegraph* crossword puzzle every day, and enjoyed jigsaw puzzles, but she could settle to none of these things. She even lost interest in her own home, and she had always been of a very independent nature. Just after Christmas she was persuaded to go to her other son in a distant town for a few weeks. She hated every minute of the change and must have been a very difficult guest. The doctor who looked after her wrote and told me that, while her fibrillation was under control, she was very much a "cracked pot." She came back in February, and an improvement soon became obvious. She had started knitting and listening to the wireless. By Easter she was well enough to go home and take up her own life again, including her crossword puzzles. She kept remarkably well for two years and then had a stroke and died in two days.

Symptomatology

The severe depression is expressed in the triad of symptoms—namely, difficulty in thinking, depression, and psychomotor retardation. In the profound case these are often obvious at a glance, but with mild cases they have to be sought for.

Difficulty in Thinking

This is expressed in the patient with mild depression in two different ways. First, as a feeling of tiredness and exhaustion. The "reading test" is quite a useful measure of its magnitude. The reader of books finds he cannot concentrate enough to enjoy a book, but he can read the newspaper. Patients with more severe depression cannot even take an interest in the newspaper. One collier who could raise enough interest at midday to drink his beer and make a bet, could not by nightfall raise the interest to look at the results in the evening paper.

The second way in which this basic symptom is expressed is an illogical approach to the problem. As Robert Burton (1628) put it 300 years ago, "Reason as well as imagination is at fault." One man blamed a quarrel with the foreman for his troubles. Argument could not convince him that this explanation was phony, but a week later he decided that the real cause of his trouble was he needed glasses. The quarrel was forgotten. Often there is an element of self-blame in these phony explanations. An engineer blamed worry over a haulage cable which he had not tested to his satisfaction, but there was no real evidence that his fear about the cable was valid. He could never forgive himself if it ever broke. The mind of the anxious patient is rational and he can follow with interest a logical argument. That of the depressed patient is irrational. His thoughts and ideas are repetitive. He will say the same thing over again, and

ask the same questions; he makes no progress with superficial psychotherapy.

Depression

The victim of a mild depression does not look depressed, but he will readily admit he feels in low spirits. The colour has gone out of life, and the future, if not black, is at least grey. The sense of humour goes. He "is not himself" in a very real way, and he feels isolated and misunderstood. The tolerance of noise drops in depression, and, as wireless is an almost universal noisemaker, the patient's reaction to it is significant. The patient who used to work to a background of wireless programmes now switches the set off. The row made by his children upsets him in a way it never used to.

1. *Suicidal Ideas*.—These ideas are an expression of this symptom. In a depressive with suicidal feelings the depression is not mild, but even in the mild cases the seeds of the suicidal urge may be evident. This is expressed first as a fear of dying. The patient feels he has some mortal illness such as cancer or tuberculosis, or he is going to have a stroke. This same feeling may be expressed not as a fear of any disease, but as a feeling of apprehension as if something terrible is going to happen. "Every time a car stops outside, I think they are bringing my husband back from the mine," or, "Every time the 'phone rings I feel it is bad news." As the depression deepens, the patient expresses not so much a fear of death as a wish to be dead. This is still not the same as a true suicidal urge which occurs in the worst types of depression. If a true suicidal urge is suspected the patient should be sent to a mental hospital for treatment. Occasionally even the apparently mild depressive may be more suicidal than one thinks.

2. *Phobias and Obsessions*.—Just as the suicidal urge has forerunners in such symptoms as a fear of impending disaster, a fear of death, or a wish to be dead, so the frank delusions of the profound depressive may start as simple phobias or obsessions. A fear of venereal disease is a not uncommon symptom of depression.

One of the village fathers, a venerable man of 65, came to ask me for a tonic, as he was run down. His symptoms were all very vague and indefinite. During this first consultation he confided in me that as a young man he had had gonorrhoea. He concluded by saying, "I have never told anyone about that before. I have been wondering lately what my children would say if they knew, or what my friends and their wives would think of me." This was in fact the beginning of a depression which lasted for about three months. Soon after recovery he had a coronary thrombosis which ultimately killed him, but during the physical illness he was never morbid or depressed, and no mention was ever made of venereal disease.

The phobia which persists may become an obsession, so that the patient can think of nothing else. The obsession may be about disease, as in a case of cancerphobia, or it may be about some misdeed, as in the case of a mother who felt she had killed her child. Phobias are common among mild depressives, but if the patient becomes obsessed the depression is getting deeper, and it is as well to get the advice of a psychiatrist, as such cases often need E.C.T.

3. *Insomnia*.—This in one form or another is an essential feature of endogenous depression. While the most common form of sleeplessness is that the patient awakens in the early hours, this is by no means always true. When a series of 100 cases was analysed early-waking insomnia was evident in only 44% of the patients. A more general form of insomnia is not uncommon. The patient finds difficulty in getting off to sleep, and, once asleep, sleeps only fitfully, to wake in the morning more exhausted than when he went to bed. A further 22% had difficulty in dropping off to sleep, but then slept reasonably well. Most patients with endogenous depression awaken with a heavy head and they feel useless for several hours. Bad dreams occurred in 21% of the cases, and in two the dreams were so awful as to account for the insomnia. "I dream of terrible and shameful things," "I never had such dreams in my life," or, "I am always

dreaming of death and dead people," are examples of how such dreams are described. Two patients could not sleep because of their bad coughs, and another woman, who was suffering from pseudocyesis, was unable to sleep because of the "movements inside her."

Psychomotor Retardation

In the case of mild depression psychomotor retardation may be expressed by minor habit changes. This symptom is a most subtle measure of depression. It happens for a variety of reasons. Sometimes the habit change is because there is a falling off of powers of concentration and application. The pianist never opens her piano, and the keen gardener lets his weeds grow unheeded. The tidy person tends to neglect personal hygiene and look unkempt, but with mild depression this is not likely to be marked.

The social habits of the patient are very prone to alter. The normally affable person tends to stay at home because people are apt to ask questions about his health or pass remarks about him which only make him more depressed. The music-hall and the cinema no longer amuse him, and his inability to laugh with others only underlines his troubles. On the other hand, some timid normal unsociable types begin to seek company. They are so fearful of their own thoughts that they prefer and feel safer with other people.

Bizarre forms occasionally arise. One depressed woman who was obsessed with the idea of a growth in her back used to wear holes in all her clothing by rubbing the affected part against suitable articles of furniture. The habit was noticed long before the depression was diagnosed or the reason for the back-rubbing was elucidated. Another reason for habit changes is that the patient is always on the look-out for an explanation for his symptoms, and, like the drowning man, he will clutch at a straw. If he happens to blame the habit of a lifetime for his symptoms, it is dropped. One man of 56 ceased to take his ritual purge on Sundays in case that was upsetting him. The regular drinker may in case that was upsetting him. The regular drinker may in case that was upsetting him. The regular drinker may in case that was upsetting him. One thoroughly reliable and normally abstemious patient developed delirium tremens, as he took to relying on alcohol to get him off to sleep.

The Feel of the Case

The classical melancholic oozes depression, so that the observer feels depressed himself, in much the same way as the merry "drunk" readily transmits his cheerful state of mind to responsive company. There is no aura of depression about mild cases, and yet they have a definite quality of their own. Their attitude of mind is one of injured bewilderment. "Why am I like this"; "I have never been like this before in my life"; "I don't know what has come over me"—all these are the patient's ways of describing his feelings. He is pained and worried by his change of outlook. He seems to want reassurance, but does not appear to accept it at the time, as with monotonous regularity he goes over his symptoms again and again. He is in fact assisted by reassurance.

A man of 56 appeared to have a mild depression. After a full history and careful examination he was reassured, and the disease was explained to him. He was told that in a few weeks, or perhaps months, his troubles would all disappear. He was seen weekly for some time and then six months later he came down to the surgery. He had quite recovered, but was still able to give a vivid description of his depressive feelings. He had felt hopeless, and the doctor's reassurance, although viewed with considerable doubt and misgiving when it was given, had helped. In fact, now that he was well he was prepared to admit that all forecasts of recovery, disbelieved at the time, had been fulfilled, and he was grateful for such reassurance.

The depressed mind, besides being somewhat rigid, appears to work in an illogical manner. The melancholic is unimpressed by a reasoned explanation of his feelings. He may, in fact, feel worse if told too much. On the other hand, a perfectly intelligent depressive will ascribe his state

to quite absurd possibilities. An innocent pimple has fearful significance, some distant peccadillo is now bringing retribution, and so on. In spite of this rather difficult frame of mind, the patient is at heart grateful for all attention and sympathy. One woman who has in eight years had five severe but short-lived depressions come along or sends to the doctor if she feels an attack coming on. She must know by now that no medicine the doctor can give her will help. She evidently feels that his knowledge of her suffering and his understanding in some way helps to make the burden lighter. Even if the recurrent case knows it may lead him back to a mental hospital, he usually comes back to his doctor when he feels the clouds are descending on him.

Treatment of the Mild Depression

The factors which should make the general practitioner pass a depressive case on to the psychiatrist are twofold. First, if he can detect a suicidal urge, or symptoms such as agitation or delusions are emerging, then the depression is no longer mild, and E.C.T. is probably indicated. Secondly, if the illness lasts more than three months, further advice should be sought, to confirm the diagnosis and to consider physical treatment. If these two points are borne in mind the treatment of the mild types of depression is safe and simple and within the scope of general practice.

The most important factor in treatment is to establish a good rapport. The patient is so often spurned and misunderstood, especially by well-meaning relatives, that it is a great relief for him to find a sympathetic ear. His feelings of guilt, if not overt, are latent, and he tends to feel a very inferior creature and thoroughly ashamed of his symptoms. The doctor who can assure him he is suffering from a common and well-understood disease makes him feel less lonely. If added to this the practitioner can show real interest and encourage him to come again once or twice each week, the patient is greatly relieved. He expects to feel he is a burden, a waster of the doctor's time. Have not his family told him that only he himself can help himself? He comes to the surgery expecting to be snubbed and feeling that the busy doctor will have no time for cases such as his. To find himself the centre of interest and understanding is a pleasant surprise in the grey world of depression.

Symptomatic Treatment

Insomnia is the most obvious symptom to treat. Barbiturates have a wide range of action. For the early-waking types butobarbitone, 3-6 gr. (0.2-0.4 g.), is indicated. Barbitone sodium, 7½-10 gr. (0.5-0.65 g.), is very useful, but it is so prolonged in its action that it tends to cause a hang-over the following day. For those who have difficulty in dropping off to sleep the quick-acting barbiturates such as quinalbarbitone, 1½-4 gr. (0.1-0.3 g.), should be given. The general insomnia or fitful sleep needs a mixture of both, such as quinalbarbitone, 1½ gr. (0.1 g.), and barbitone sodium, 7½ gr. (0.5 g.). Hypnotics should be looked on as a temporary measure, and if a habit is being formed the patient should be switched to the safer and less appetizing chloral hydrate, 30 gr. (2 g.). All hypnotics should ideally be given to a relative, who should administer them to the patient and see that he takes them, as the capsules and tablets are such an easy method for the would-be suicide. This is a council of perfection. It should be applied to the moderate and severe cases, but the patient with mild depression rarely brings a relative: the ritual of bringing the next of kin, and giving him a private session to discuss the patient's symptoms, and so on, only tend to increase the patient's apprehension about his troubles. In a series of 289 cases of endogenous depression four actually did use the barbiturates with suicidal intent. Only one patient was seriously ill and eventually died. On the other hand, it must be admitted that three of the four cases were viewed before this episode as cases of mild depression. In the early stages, when the patient is being seen twice weekly, the drugs need only be prescribed in small quantities to last three or four days.

As euphorants and dispellers of the morning headache the amphetamine group of drugs are still the most useful. In a small proportion of cases, probably not more than one in ten, they work like a charm, and yet in others serve no useful purpose. They can be used in combination with barbiturates or aspirin in certain cases.

Malleson (1953) recommends the use of small doses of natural oestrone, ethisterone, and methyltestosterone in cases of premenstrual and menopausal depressions. If one hormone fails to work another is tried, or two are tried alternately. No adequate series has so far been established, but a few most gratifying results have been recorded, and further work on the subject is certainly indicated. There are many drugs on the market which claim to be useful in cases of depression, such as rauwolfia, chlorpromazine hydrochloride, pipradrol hydrochloride, benactyzine, and methyl phenidate hydrochloride, but again none have been given an adequate trial so far in the mild depressions of general practice.

Light work or work devoid of responsibility is to be encouraged, but the patient should not be physically exhausted by his labours, or weighed down by an overactive sense of duty. If work is a burden, it should be abandoned for a while. A change of scenery or company may help those with a mild depression, whereas it is definitely contraindicated in those with the severe type, who need to be kept under constant observation. Very few housewives, who form a big proportion of these cases, ever allow themselves to be put off work altogether.

Summary

The mild endogenous depression accounts for 60% of the cases which occur. The symptoms are usually so mild that the patient is not likely to get past his general practitioner into the hands of a psychiatrist. It is essentially a disease of general practice. The condition is frequently disguised, and is often misdiagnosed either as an anxiety state or as an organic illness. It can also occur as a graft on to established organic disease, and if such a patient is to receive adequate treatment the depression must have due recognition. These disguised forms of endogenous depression are illustrated by typical cases. The severe mental-hospital type of depression, with the classical triad of symptoms, is easy to diagnose. The case of mild depression has to be sought out. Difficulty in thinking, depression, and psychomotor retardation are all evident in an early and modified form. The evolution of such symptoms as suicidal ideas and delusions is observed in the various grades of depression. The mild depression has a distinct "feel" of its own. The patient presents a picture of "injured bewilderment."

Most of these mild cases can be treated at general-practice level. If a suicidal urge emerges, or the patient becomes agitated or deluded, a psychiatrist should be called in. It is as well to pass even a mild uncomplicated case on to a specialist if the depression shows no signs of improvement after three months' observation.

Symptomatic treatment is described, but the most potent weapon in the hands of the general practitioner is a good rapport with his patient. The sympathetic understanding of the doctor goes a long way to tide him over the dreary and painful weeks or months of depression. This is confirmed by the way in which patients with recurrent depression come back as soon as they feel the clouds descending.

TRIAL OF RESERPINE IN TREATMENT OF SCHIZOPHRENIA

BY

J. N. P. MOORE, M.D., F.R.C.P.I., D.P.M.

Medical Superintendent, St. Patrick's Hospital, Dublin

AND

E. A. MARTIN, M.B., M.R.C.P., M.R.C.P.I.

Physician in Charge of Clinical Research, St. Patrick's Hospital, Dublin; Assistant Physician, Adelaide Hospital, Dublin

This is a report on the immediate results of a clinical trial of the use of reserpine in the treatment of 119 cases of schizophrenia. The study covers a period of 18 months. An assessment of the cases was made on December 31, 1955. Only patients whose response to the drug was regarded as decisive by this date were included. The follow-up period ranges from a few weeks to ten months.

Inquiry into the efficacy of a new treatment in psychiatry is notoriously difficult. A controlled investigation satisfactory to statisticians is difficult to obtain, especially with a drug which has marked side-effects. Psychiatric diagnosis is inexact, and descriptive terms may have widely different meanings for different psychiatrists. The natural illness is often fluctuating and subject to remission. Enthusiasm for a new treatment, a new interest in the patient, and a favourable change in the environment can all react markedly on the patient, and influence results.

We have divided our cases into five groups, and the order in which we report on them reflects the history of our attitude to the drug. Thus the first group consists of chronic deteriorated patients who were long since regarded as past any hope of improvement. Results with this group encouraged us to treat a group of cases which had failed to respond satisfactorily to other better-tried methods of treatment. Later, we used the drug as the first line of treatment in cases considered unlikely to respond to these better-known methods. Finally, we report the results in two groups of acute cases in which the immediate prognosis with other methods had been thought likely to be good.

Regime of Treatment

The preparation of reserpine used throughout the trial is marketed under the trade name "serpasil."

When we began to use reserpine it was available only in tablet form, and in group I the dosage varied from 2 to 8 mg. daily by mouth. In the other groups we were guided by Kline's scale of dosage (Kline and Stanley, 1955; Barsa and Kline, 1955), and the following amounts were used: 3 mg. orally daily throughout; 5 mg. intramuscularly on the first evening; and 10 mg. intramuscularly nightly for three to seven weeks, reducing this to 5 mg. on alternate nights for two weeks, and finally 2.5 mg. on alternate nights before discontinuing the injections. If side-effects were troublesome the dosage was reduced earlier. In the most severely and chronically ill the intramuscular dosage was continued as a maintenance dose on every second or third night indefinitely. The giving of the injections at night minimizes absenteeism, due to side-effects, from occupational therapy classes and recreational and social events. Each case must be treated individually, and dosage modified according to the side-effects and the mental

state. Our present tendency is to decrease the dosage rather more slowly than at first, and to keep the patient on an oral maintenance dose for many months after symptoms have disappeared. All discharged patients are encouraged to attend the out-patient department regularly, and, if they live at a distance, to keep under the care of their local doctor and to report to us by letter. Sometimes a patient should untoward symptoms arise. Sometimes a patient who has improved relapses when the drug is reduced, and a return to bigger doses is indicated. A number of patients who subsequently did well showed this tendency to relapse, from the fourth to the seventh week.

The drug was the focal point of the treatment of these patients. They were interviewed at least once weekly and their symptoms elicited. Usually the patient was told directly that he was mentally ill, and simple explanations were given of paranoid ideas, delusions, and hallucinations, with their mode of development. A full programme of occupational therapy, games, work parties in the open, and social events was provided. As soon as possible week-end parole was given.

Effects of the Drug

Often in the first few days, and almost always in the first week, there is evidence of a tranquillizing effect. The patients are more relaxed and sociable, and less preoccupied with their symptoms. Disturbed behaviour is lessened. In some a mild elation replaces confusion and preoccupation. By the end of the first week previously withdrawn or suspicious patients may be anxious to talk to the doctor about themselves and their symptoms. It is often easier to elicit symptoms. Patients who had previously been evasive or secretive about their condition may discuss their abnormal ideas quite freely. Sometimes from then onwards there is a progressive lessening of delusions and hallucinations, and a gain in insight. The patients may for the first time accept explanation and reassurance about the nature of their symptoms. The course varies widely, and, as with other treatments, the most recent symptoms disappear first, and the oldest ones last.

In many patients in the acute schizophrenic group, satisfactory improvement with good insight had been achieved by the 21st day, whereas similar improvement in patients of the chronic group might take 60 days, and occasionally much longer. Sometimes insight appears to be gained as a result of patient and persistent explanation; in others there may be a sudden change for the better, symptoms subside, and patients appear to gain insight overnight, almost as if some crisis had been passed. Several chronic patients said spontaneously that they had suddenly realized for the first time that they were mentally ill. One patient who had written scores of paranoid abusive letters, over years, wrote a letter in the alleged illegal detention, over years, wrote a letter in the third month of treatment saying that he had just realized that what had been done was in his best interests, and that he would like to change his status to that of a voluntary patient for the remainder of his treatment. The patient, a paranoid schizophrenic of seven years' duration, has achieved a very good remission, and has been symptom-free for more than nine months.

A highly intelligent woman with a three-years schizophrenic history was convinced of the reality of her "voice," and admitted it without reserve. After a month's treatment she flushed angrily when it was suggested that the voice was a hallucination, and com-

plained in a letter to her husband that the doctors suggested she was "mental." She had then achieved sufficient insight to wish to avoid discussion of her symptom. A month later she could discuss her symptom objectively, admit that it was a product of her illness, expressed pleasure at the fact that it sometimes went away altogether, and inquire anxiously when it was likely to go away permanently.

A number of patients expressed fear that their "voices" would come back again when they stopped taking reserpine, and for this reason were loath to give up taking it.

Side-effects

In the first few days of treatment flushing, tremor, nasal stuffiness, and drowsiness occur. Sometimes there is dizziness and vomiting. In a few patients short periods of elation occur, but more often there are periods of tension and depression. These may coincide with the drowsiness which tends to come on from one to three hours after an intramuscular dose of the drug. After about seven to nine days restlessness appears, and within a few days, in varying degrees, the other side-effects—pains in the calves and forearms, pains in the lumbar region and neck, loss of natural mobility of the face and arms with increase of salivation—appear. These latter may progress to a well-developed picture of Parkinsonism.

Rigidity may be so marked that spoon-feeding is required within two weeks of the beginning of treatment. Often sleep is disturbed, and early waking may be a troublesome feature, even in patients who are not depressed. A curious combination of drowsiness and restlessness appears. Drowsiness makes the patient want to lie down on his bed, while the restlessness impels him to pace up and down the ward. Those of a phlegmatic temperament bear it grimly, while the more volatile clamour for attention and relief. Nasal stuffiness may result in nose-bleeding, and we have seen sinus infections in two cases. Breathlessness and, rarely, a sensation of smothering may occur. Rarely, too, a patient may feel weak to a degree he interprets as "paralysis." Frequency of micturition and nocturnal incontinence are fairly common. Delay in initiating micturition, subjective impairment of accommodation, and unexplained oedema of the face and ankles have been noted. We have had no difficulty from postural hypotension. If for any reason electroplexy is given, adequate relaxants and preliminary atropine are necessary. Otherwise excessive salivation and possibly nose-bleeding might cause difficulty in maintaining the airway. We have, however, had no worry from any of these.

One patient, after discharge from hospital on a daily dosage of 2 mg. orally, had an attack which may have been epileptic. This is our only experience of that complication, which is described by Barsa and Kline (1955). We have given reserpine to several epileptics, not included in this series, without any increase in their attacks.

One patient, not in this series, died while on reserpine. She was suffering from schizophrenia and thyrotoxicosis. The cause of death was a thyroid crisis, which may have been precipitated by a maxillary sinusitis due to reserpine.

Appetite is often increased, and some patients get up in the middle of the night to appease their hunger. When side-effects become marked, reduction in appetite and difficulty in swallowing may lead to loss of weight. In a few cases diarrhoea has occurred.

Provided explanation and encouragement are given, the side-effects present no great problem in the average case. An antazoline-naphazoline nitrate ("antistin-privine") nebulizer is useful when nasal symptoms are severe; too great restlessness is usually relieved by one of the short-acting barbiturates or chlorpromazine hydrochloride ("largactil"). Tincture of belladonna is a help in lessening the salivation of Parkinsonism. All the side-effects lessen if the dose is reduced. Indeed, these side-effects, although

troublesome, appear to have their value; they create a bond between the patient and his fellows; they provide a topic of conversation, and many seem almost relieved to complain of physical rather than mental symptoms. In some cases they seem to distract the patient from preoccupation with his fantasies and delusions. Patients turn to the doctor to ask for relief of their physical symptoms, and sometimes this is the beginning of a more satisfactory doctor-patient relationship.

Barsa and Kline (1955) have described a turbulent phase of variable duration following on a sedative phase in the first week. In this, they state, the patients become more deluded, hallucinated, and disturbed. We have not been able to confirm this observation. In our experience the turbulent phase, except in the rare patient, is one of physical disturbance rather than mental turbulence. It is due to the side-effects of the drug—in particular, restlessness—rather than any increase in the psychotic process. In a few patients who appeared to have a low tolerance for tension the physical restlessness led to impulsive behaviour, such as breaking cups or a window. These few patients described sensations of something about to snap in their heads.

Trouble from side-effects varies widely, but is generally more pronounced in patients with neurotic or psychopathic personality traits. Some leucotomized patients seemed to be very tolerant of the side-effects of the drug.

Depression

The most serious complication of the treatment is the development of severe depression. This has been noted by physicians treating hypertension with—by our standards—small doses of the drug (Freis, 1954; Doyle and Smirk, 1955; Smirk and McQueen, 1955). Transient depression may come on a few hours after an injection, but in most cases it passes off again. In our experience, persistent deep depression has developed as early as the 27th day and as late as five months after treatment has started. A number of those who developed depression after a long period on the drug did so when the dose had been substantially reduced—sometimes when an oral dosage only was being given.

The picture is usually characteristic of the endogenous type of depression—early wakening, a sense of hopelessness, often a sense of guilt, with suicidal preoccupation. Although there is a retardation and deep dejection, the patient is usually able to express his thoughts, and admits to thoughts of suicide. Sometimes there is a fear of giving way to a suicidal impulse rather than a desire to be dead.

When depression occurs we feel that reserpine should be discontinued and sedatives given for relief of tension and insomnia. In a few cases symptoms have subsided within a week or two; in others a course of electroplexy has been given with success. A few patients proved resistant and required several courses of electroplexy before the depression finally cleared up.

Two of our patients in this series made determined suicidal attempts after discharge from hospital and while on maintenance dosage of 2 mg. daily. Fortunately neither suffered serious injury. Both were depressed, but neither showed any return of the schizophrenic symptoms for which the treatment had been given originally. It may be significant that the pre-psychotic personality make-up of both these patients showed definite evidence of immaturity and instability. The attempt was an impulsive desire to be rid of an intolerable feeling of tension and depression; it was not premeditated, nor was it the result of delusional thinking or in response to a hallucination.

It seems probable that the risk of suicide in this reserpine-induced depression is greatest in personalities with a poor tolerance for tension. *It must be emphasized that this is a very serious complication of the treatment. It is quite unsafe to prescribe the drug unless the patient can be seen regularly by a doctor aware of the dangers involved.* Some out-patients may require admission to hospital.

Group 1. Chronic Deteriorated Schizophrenics

Our first group of cases were chosen from a small ward of chronic deteriorated patients who had been in hospital for many years. Twenty-two patients were included (11 male and 11 female). Their average age was 45 years and their average stay in hospital 13.5 years. The shortest stay was one year, but in her case there was evidence that she had been ill for ten years. The patients were chosen because of one or more undesirable features in their behaviour, such as resistiveness, aggressiveness, noisiness, or destructiveness. Only with three could one establish contact or make conversation. Some were having maintenance electroplexy to control their disturbed behaviour. Some had been on chlorpromazine hydrochloride, and in all cases the usual sedative drugs had been tried over the years.

Regime.—Reserpine was given orally in dosage of 2–8 mg. daily for an average period of 75 days. The initial dosage was 2 mg., but if there was no beneficial effect this was increased. Following this, control tablets were substituted without the knowledge of the medical staff—with the exception of the physician in charge of the clinical trial. The control tablets were given for an average period of 45 days, when reserpine was resumed in all the patients and dosage adjusted within the limits of 2–8 mg. to obtain the best response. Otherwise the routine of the patients was unchanged, except that any fresh interest in occupational therapy or social events was encouraged.

Side-effects were comparatively mild. Increased appetite and weight gain were frequent. Twelve of these very chronic patients improved on the drug, a few strikingly. Ten of them relapsed on controls, and two of these failed to regain improvement on a second course of reserpine. Most of those who improved did so in the first two weeks of treatment. A sedative effect, sometimes with drowsiness, was noted, beginning most usually from the second to the seventh day. Those in whom drowsiness was well marked did best.

These figures give an indication of the results, but cannot really convey the general improvement of the group in morale, in hygiene, in the standard of occupational therapy, and in the general happiness of both patients and staff in this section of the hospital.

There is general agreement in the published literature that reserpine is of value as a sedative in some patients of this type (Kline, 1954; Glynn, 1955; Noce *et al.*, 1955).

Group 2. Chronic Treated Schizophrenics

For the intensive treatment we chose first a group of patients whose illness was more recent than that of Group 1 but none the less chronic. None was ill for less than two years; the average duration of symptoms was 7.5 years (range 2–29 years). The average age was 35.5 years (range 18–52 years). In every case one or more of the physical methods of treatment had been tried and had failed to produce a sustained remission. The average duration of reserpine treatment was 193 days (range 53–470 days).

TABLE I.—Treatments Previously Given to the 38 Patients (23 Male, 15 Female) in Group 2

Previous treatment	No. of Cases
E.C.T.	37
Insulin	27
Leucotomy	19
Intravenous acetylcholine	12
Leucotomy was planned for 9 patients if reserpine failed to produce remission.	

Table I shows the treatment previously given to the 38 patients in this group. In none had a sustained remission been produced. Leucotomy was projected in nine cases because of the continued failure to respond to treatment. All patients were classifiable as chronic hospital invalids or likely to fall into this class if projected leucotomy did not produce a remission. Twenty patients presented serious nursing problems because, under the influence of their delusions or their "voices," they became aggressive or negativistic.

All but four of these cases had been under our own observation in hospital for at least a year, many for much longer periods. Of the four patients treated in other hospitals, one had been leucotomized and three had had insulin and electroplexy combined. These patients were known intimately by the staff of the hospital, and every effort had previously been made, without success, to achieve a sustained remission. Thus this group of patients could act as their own controls. In none of these cases was the diagnosis in any doubt—all showed active schizophrenic process symptoms. Seventeen of the patients admitted to auditory hallucinations when reserpine treatment started; 31 were deluded, without insight; 24 had ideas of reference or influence; 22 showed marked affective blunting or incongruity.

In assessing results we tried to make our criteria as objective as possible. A clinical impression that the patient had improved was not regarded as valid unless it could be shown that specific psychotic symptoms had disappeared. The term "recovered" was deliberately avoided, in view of the short-term nature of the results. We classified the results into three groups: much improved, improved, and no improvement. These terms are defined in the legend below Table II.

Of the 17 patients who were hearing voices when the treatment started, 11 lost their hallucinations, but in two they returned. Of the 24 who had clear-cut ideas of reference or influence, 11 lost them. Of the 31 who had frank delusions, 15 lost them or showed considerable diminution in delusional ideas. Ten gained fairly good or good insight.

This group was a most instructive one because the case material was so well known to us, the symptomatology so clear-cut, and, since no other physical method of treatment was used once reserpine therapy started, improvement when it occurred could be attributed with reasonable certainty to the drug. The statistical details of this group are given in Tables II, III, and IV. One patient became depressed.

TABLE II.—Response of Patients in Group 2

	Much Improved	Improved	No Improvement	Total
Whole group	17	10	11*	38
Leucotomy	7	6	6	19
Insulin—E.C.T.—Leucotomy projected	4	6	3	13
Leucotomy	7	2	—	9

* Includes one case of depression.
Much improved = Free of all psychotic symptoms—that is, delusions, hallucinations, ideas of reference or influence, thought disorder, affective incongruity, or marked blunting; some insight.
Improved = Better, but with some residual symptoms, chiefly emotional flattening or incongruity.

TABLE III.—Response of Patients in Group 2 Related to Age at Time of Treatment

Age	Much Improved	Improved	No Improvement	Total
30 and under	6	6	4	16
31–40	9	4	3*	16
41 plus	2	—	4*	6

Average age, 35.5 years. Range, 18–52 years.
* Includes one case of depression.

TABLE IV.—Response of Patients in Group 2 Related to Duration of Symptoms

Duration of Illness	Much Improved	Improved	No Improvement	Total
Less than 5 years	5	4	2	11
5–10 years	11	6	4*	21
More than 10 years	1	—	5*	6

Average age, 7.5 years. Range, 2–29 years.
* Includes one case of depression.

Group 3. Chronic Untreated Schizophrenia of Insidious Onset

The third group of cases also could act to some extent as their own controls. The group consisted of recent admissions who were regarded as unsuitable for insulin treatment

by reason of long history, insidious onset, or lack of florid features. It comprised 17 patients (14 male, 3 female), 16 of whom had never been in hospital before and none had been ill for less than two years. One had been in hospital for 22 years but had never been treated by any of the physical methods because permission was refused by relatives.

In this group the average age was 29.4 years, ranging from 17 to 56 years. The length of illness ranged from 2 to 22 years, with an average of 6 years.

Five of the group had been given electroplexy since admission to hospital. In such chronic cases this was not given in the hope of any long-term benefit, but in order to obtain initial sedation or co-operation. Five patients had auditory hallucinations and nine had persecutory delusions. Nine showed apathy, withdrawal, lack of initiative, and marked affective blunting. Six cases might be termed "simple schizophrenia."

The dosage and general regime was the same as in Group 2, and the criteria used in assessing results were also the same. Nine patients were regarded as much improved and six as improved. Twelve have been discharged, and nine are known to be back at work. Details are given in Table V.

TABLE V.—Response of Patients in Group 3

	Much Improved	Improved	Not Improved	Total
Whole group	9	6	2*	17

* Much improved and "improved" as defined in Table II.
* Includes one case of depression.

The results here are in some respects more unexpected than those in group 2, because the symptomatology was less florid, the pre-morbid personalities were less good, and the onset was more insidious. Although none had been thoroughly treated by the physical therapies, they had all been rated as unlikely to respond to these methods when reviewed by the staff at case conferences.

Group 4. Acute Schizo-affective Psychosis

The fourth group in this series were diagnosed as suffering from schizo-affective psychosis. It consisted of 21 patients (7 male, 14 female) who presented predominantly manic (7 cases) or depressive (14 cases) features. In addition, all cases showed some schizophrenic features such as auditory hallucinations or paranoid delusions. Seven depressed and five manic patients had had previous psychotic episodes, either with electroplexy (7) or electroplexy combined with insulin coma therapy (5). All but one had been treated in St. Patrick's Hospital. All the patients in this group were thought to have a good prognosis for the present episode. With two exceptions, patients were given reserpine because the expected remission did not follow one or more courses of electroplexy—the patient either did not improve or relapsed within a few weeks of treatment. All had been ill for less than one year. The average age was 39 years (range 18–61 years).

The two patients who went straight on reserpine therapy were recent admissions, but both had had previous episodes, one having achieved a remission following electroplexy and insulin, and the other having achieved a remission on reserpine given a year previously in an American hospital. Both these patients improved with reserpine alone, and they are both out of hospital and back at their work.

Because the illnesses reported in this group were of much shorter duration, a more rigid standard of assessment was used. The term "recovered" was again discarded, in view of the lack of follow-up period. Cases were classified as much improved only if free of all psychotic symptoms and if their pre-psychotic personality had been restored as judged by clinical observation. Cases regarded as improved were

better but had some residual symptoms or personality defects. The results are shown in Table VI.

TABLE VI.—Response of Patients in Group 4

	Much Improved	Improved	Not Improved (All Depressed)	Total
Depressed Manic	1	1	8	14
			1	7

Much improved=Free of all psychotic symptoms; pre-psychotic personality restored.
Improved=Better, but with some residual symptoms.

It is instructive to note that the incidence of depression was much higher in this group. This observation, if confirmed in larger series, would seem to indicate that this serious complication may occur chiefly, if not entirely, in those constitutionally predisposed to endogenous depression.

Group 5. Acute Schizophrenia

The last group under review consisted of 21 acute schizophrenics (5 male, 16 female). All had a history of under one year. Patients with marked manic or depressive features, and who might thus be regarded as suffering from a schizo-affective psychosis, were excluded. All showed active process symptoms. All had been ill for less than one year. Average age was 30 years (range 19-52 years).

In general the immediate prognosis in this group was regarded as very good. Six of the group had suffered from previous schizophrenic episodes (one or more). Five of them had remitted following insulin coma therapy, and one following electroplexy. Five other patients had recently completed full courses of insulin coma therapy without sustained improvement. In two cases a course of insulin treatment had been stopped—one because of hypersensitivity to insulin, and one because of her violent behaviour during sopor. Three were not given insulin because of a history of pulmonary tuberculosis, and one because she was considered too old. The remaining five patients were given reserpine as a first choice.

All patients in this group had been given a course of electroplexy on admission to hospital to control acute symptoms. They were given reserpine only when clear-cut schizophrenic symptoms persisted after electroplexy.

TABLE VII.—Response of Patients in Group 5

Much Improved	Improved	Not Improved	Depressed	Total
18	3	—	—	21

"Much improved" and "improved" as for Table VI.

The results were assessed by the same criteria as in group 4 and are shown in Table VII. The average duration of treatment in this group was 80 days. On the completion of treatment, 18 of the 21 patients were regarded as much improved and 3 as improved. Twenty of these patients have been discharged from hospital, and 15 are known to be back at their former occupations.

Since December 31, 1955, when the table was drawn up, two patients placed in the much improved group have been readmitted—one was brought back by her relatives in a state of deep depression, the other was noted to be rather depressed on a routine follow-up visit and was readmitted for observation. There has been no return of schizophrenic symptoms in either case.

Discussion

The results we have had are encouraging and justify the continued use of the treatment. Not only have some schizophrenics with all the characteristics associated with chronicity lost their process symptoms, but in many cases they have gained a surprising degree of insight.

A woman civil servant aged 35 was referred for inefficiency and absenteeism in 1952. She had the delusion that she was hypnotized by a strange man whom she had met some years previously, and his voice dominated her life. In 1952 a full course of insulin coma therapy (60 comas) made her less withdrawn and more sociable. She never lost her hallucination or gained insight. She has been seen by one of us (J.N.P.M.) periodically as an out-patient since then, but the picture has remained unchanged. In October, 1955, she was given a last chance by her employers and told that if she was late or absent again she would be dismissed from the service. She was readmitted to hospital and started on intensive reserpine therapy. After 10 weeks she spontaneously said in a shamefaced way—"Whether it is a good thing or not, at last I believe you when you say I am mentally ill." "Thank goodness the voice goes away sometimes—do you think I can get rid of it altogether?"

In this type of case the drug does not merely act as a sedative. Sometimes the psychotic process remits after reserpine therapy. Such a remission of symptoms occurred in a convincing number of cases. It occurred to patients, such as those in group 2, who had resisted other standard treatments, and in a regime unchanged except for the addition of the drug. We can offer no explanation of how this remission is achieved, but we would suggest that the drug has a central effect on schizophrenic patients. These become less influenced by their delusions and hallucinations. Fresh delusions and hallucinations cease to form. They can view their symptoms more objectively, and psychotherapy can play a part in bringing them into true perspective. They are more able to take interest in their surroundings, and active rehabilitation therapy is more likely to be successful.

Enthusiasm for a treatment in psychiatry always has a favourable influence on the patient. This factor plays much less a part when one has been dealing with psychotics, as we have in this study. Lavish enthusiasm and a placebo could not have produced the changes, often striking, which are reflected in our results. This is particularly true of patients in group 2 who were resistant to all other forms of treatment. The fact that this drug will in some patients produce a typical endogenous depression indicates that it has an action on some centre of fundamental importance in the development of mental illness. The associated effects on the pulse, blood pressure, and pupil, with the production of Parkinsonism, suggest that this may be in the region of the hypothalamus and basal ganglia. Experimental work tends to confirm this (Plummer *et al.*, 1954; Winsor, 1954).

A most impressive feature of the use of the drug is the quality of the remission. Insight into their morbid ideas, friendliness towards staff and fellow-patients, and a healthy interest in occupational and social activities is a usual rather than exceptional result of the treatment. This insight is reflected in the readiness with which patients agree to report for follow-up talks after leaving hospital. Appointments have been kept punctiliously, even though in some cases it meant a long journey by train or car. Liberal parole was granted as soon as improvement began and when side-effects permitted, and only a few have not returned to hospital.

Besides using the drug in the intensive way described in this series, we have given smaller oral dosage to a number of chronic schizophrenics. We are not reporting in a detailed way on these cases here. A number of well-preserved chronic hospital patients, as well as a number of ex-patients who attend our out-patient department for general advice and supervision, have benefited greatly by small doses of the drug—for example, from 1-4 mg. daily. A few have improved dramatically. Some have been able to remain out of hospital when otherwise admission seemed inevitable.

Another problem for the future, therefore, is to decide whether or not the large doses prescribed by Kline and Stanley (1955) and Barsa and Kline (1955), and followed in this work, are necessary. Our present impression is that where an active progressive schizophrenic process is present the intensive dosage may be necessary. It seems, too, that length of history may be an important factor in deciding both the length and the intensity of the treatment required.

For example, the average length of treatment in the acute group was 80 days, whereas in the chronic treated group it was 195 days.

Apart from the treatment of schizophrenia, we have used reserpine in a number of other psychiatric conditions. In general the results have not been so dramatic. Patients with endogenous depression are not improved (and may be made worse). We noted in the early stages of this trial (before we became aware of the danger of depression as a side-effect) that some patients who were restless, unsettled, and discontented after a course of electroplexy did become more settled on 1-3 mg. daily. It seems wiser, however, never to use the drug in cases of endogenous depression or in those with a past history of depression. Cases of anxiety neurosis were given the drug mainly by mouth on an out-patient basis. Rarely do they get any immediate subjective relief of their symptoms, and many are put off by the side-effects, such as nasal stuffiness or drowsiness, and stop the drug. Patients with chronic anxiety states who are underweight seem most helped by the drug. They may put on weight, and this is accompanied by a feeling of well-being and reduction in tension rather similar to the improvement one gets with modified insulin. Classical cases of anorexia nervosa appear to respond very well to the drug. Seven patients who showed the characteristic mixture of hysterical and obsessional traits in their personalities, with anorexia, amenorrhoea, emaciation, and restlessness, lost their symptoms and put on weight. Details of this group will be published elsewhere.

Apart from the statistical results given in the tables and mentioned in the text, the introduction of reserpine treatment has greatly changed the character of the hospital. Negativistic or impulsive behaviour has been much diminished, and the general morale of the wards has been correspondingly improved. Maintenance electroplexy is now seldom used.

Although patients do not like the treatment because of the irritating side-effects and the numerous injections involved, little difficulty is experienced in encouraging them to carry on with it. It does not arouse the fear and antagonism sometimes evoked by electroplexy and insulin treatment.

The restlessness induced by reserpine must be helped not only by sedation but by organized activity. Many more patients than formerly are well enough to take an active part in occupational, recreational, and social therapy. Classes of all kinds have had to be greatly increased. Physical training classes, relaxation classes, and organized games are particularly helpful in combating reserpine-induced restlessness. In the same way, outdoor work parties, digging, cutting grass, sawing logs, etc., are beneficial and mostly welcome activities, except where the patient is heavily under the influence of the drug.

With awakening insight, patients are in particular need of psychotherapeutic interviews, and the work of the medical staff in this respect has been greatly increased by the treatment. The fact that memory is not disturbed makes explanation and reassurance more rewarding as well as more necessary. Although we have not used group therapy in any formal way, it seems probable that, in future, only by this means can the medical staff cope adequately with the patient's needs.

It must be stressed that the results given here are the immediate results. Few cases have been in a state of remission for more than six months. We have satisfied ourselves that the drug can favourably influence a schizophrenic process, at least temporarily. Only a long-term follow-up can decide the drug's eventual place in the treatment of schizophrenia.

Summary

Reserpine given orally may benefit deteriorated chronic hospitalized schizophrenics with troublesome symptoms.

Chronic schizophrenics who have failed to achieve a sustained remission following E.C.T., insulin coma, or leucotomy may improve remarkably with intensive reserpine therapy. As a result of our experience we have made it a rule that no schizophrenic should be leucotomized without first having a prolonged trial on reserpine.

Patients with schizophrenia of insidious onset but without florid symptoms or gross personality deterioration may respond favourably to intensive reserpine therapy. It is probably necessary to continue on an oral maintenance dose for a prolonged period.

Immediate results of reserpine therapy in acute schizophrenics are impressive. Observation over a prolonged period alone can determine whether in these early cases it is a better therapeutic agent than insulin coma therapy.

Severe depression of the endogenous type with characteristic early morning waking and suicidal pre-occupation is the most serious complication of the treatment. The incidence of this complication was greatest in the schizo-affective type of psychosis. A past history of endogenous depression is a contraindication to the use of the drug.

Some chronic schizophrenics improve on oral dosage only. Intensive and prolonged treatment seems necessary in most cases of progressive schizophrenia.

Some patients with chronic anxiety states, especially if underweight, may benefit from oral reserpine. The results in most cases are not so dramatic as in schizophrenia.

Most patients on reserpine eat better and put on weight. Cases of anorexia nervosa may improve rapidly on the drug.

The extensive use of reserpine alters the character of a psychiatric unit considerably. Negativistic, aggressive behaviour is greatly diminished. Patients can enjoy more freedom and take a more active part in the hospital routine. It places an increased demand on hospital staff for individual psychotherapy.

We are indebted to Ciba Laboratories Ltd. for liberal supplies of reserpine in the form of "serpasil" and for supplies of "antistin-privine."

ADDENDUM

A follow-up of the 109 cases described above was undertaken from November 1, 1956. About half of these patients were interviewed either by one of us or by other members of the medical staff of St. Patrick's Hospital. Information about the remainder was obtained by letter from the patients, their relatives, or their family doctor. The results for groups 1 to 5 are shown in Tables Ia, IIa, IIIa, and IVa. The assessment criteria are the same as in the main paper.

TABLE Ia.—Response of Patients of Group 2—Chronic Treated Schizophrenia

Much Improved	Improved	No Improvement or Relapsed	Untraced	Total
16*	2	19	1	38

* One relapsed and was given a second course of reserpine.

TABLE IIa.—Response of Patients of Group 3—Chronic Untreated Schizophrenia of Insidious Onset

Much Improved	Improved	No Improvement or Relapsed	Untraced	Total
9	4*	2	2	17

* Three relapsed and were given a second course of reserpine.

TABLE IIIa.—Response of Patients in Group 4—Schizo-affective Psychosis

Case Type	Much Improved	Improved	No Improvement or Relapsed	Untraced	Total
Depressed	2	0	11	1	14
Manic	5*	0	2	—	7

* One relapsed and was given a second course of reserpine.

TABLE IVa.—Response of Patients of Group 5—Acute Schizophrenia

Much Improved	Improved	Relapsed	Untraced	Total
15*	2*	4	—	21

* One relapsed and was given a further course of reserpine.

It will be seen that the results confirm in a general way the trends of the initial assessment and encourage us to continue trial of this method of treatment.

A further year's experience suggests that smaller doses may give similar results with less distressing side-effects. At present an intramuscular dosage of 10 mg. daily is the exception rather than the rule. Our usual maximum dosage is 3 mg. orally and 5 mg. intramuscularly daily.

We hope to publish a further paper on a larger series with a detailed analysis of the factors influencing good or bad response, the relapse rate, and the incidence of depression.

IDIOPATHIC OR HYPERCATABOLIC HYPOPROTEINAEMIA

CASE EXAMINED BY ¹³¹I-LABELLED ALBUMIN

BY

MICHAEL SCHWARTZ, M.D.

Physician, Bispebjerg Hospital, Copenhagen

AND

BAGGER THOMSEN, Cand. Med.

Physician, Silkeborg County Hospital, Silkeborg, Denmark

Hypoproteinaemia is not an uncommon clinical finding, and is nearly always caused by an external loss of protein—for example, proteinuria, skin disease, bleeding—or a reduced protein synthesis (hepatic or intestinal disease, starvation, etc.).

In a few exceptional cases such low serum protein has been entirely inexplicable—idiopathic. A critical review of the literature shows that the reported cases which can be designated idiopathic hypoproteinaemia do not amount to more than 25.^{1 2 4 6-18 21 22} Despite this small number of cases the syndrome appears to be well defined.

The main sign of this disease is oedema formation caused by and varying with the hypoproteinaemia, which (nearly) always affects the albumin and globulin fractions equally. In most instances the disease has persisted for months and often for years. Practically all the reported cases of idiopathic hypoproteinaemia have been particularly well studied. In addition to the low serum

protein some of them have exhibited eosinophilia (4 out of 10 cases so examined) and several have been allergic, but all other tests have failed to show abnormalities.

Attempts at raising the serum protein level by oral administration of protein in large amounts have proved ineffective, although a highly positive nitrogen balance may be obtained thereby.⁷

Most authors have merely concluded that in idiopathic hypoproteinaemia protein synthesis is impaired. It has been suggested that this reduced protein synthesis is due to hepatic disease, but what kind of hepatic disease is not quite clear, as no patient with genuine idiopathic hypoproteinaemia has shown other signs of hepatic involvement.

The Degradation Theory

As no external loss of protein can be demonstrated and as there is no obvious cause why the production of protein should be reduced, the reason for the low serum protein might theoretically be imagined to be an internal loss—an increased degradation of protein.

Only a few authors have dwelt on this idea. As early as 1935, however Cope and Goadby⁷ stated: "The possibility that unduly rapid breakdown of plasma protein was occurring could not be excluded, but was considered to be improbable."

In recent years, however, reports on four patients with idiopathic hypoproteinaemia indicate that in these patients there has been a question of increased breakdown of protein. In 1949 Albright, Bartter, and Forbes¹ (1 patient) and in 1955 Hennemann and Albright¹¹ (2 patients) studied the fate of intravenously administered albumin. These extremely difficult and painstaking investigations will not be described in detail here: suffice it to mention that during the experiment the patients received 52 g. of serum albumin intravenously every day for more than two weeks.

The results of these balance experiments unequivocally showed that, compared with normal persons, the patients retained only a small proportion of the administered albumin during the experimental period, whereas an excessive amount must have been burned or converted into protoplasm. These authors conclude¹ that "the disorder in albumin metabolism was not a decreased rate of synthesis, but an increased rate of destruction."

Kinsell *et al.*¹⁴ studied the fate of intravenously administered ³⁵S-labelled methionine in some patients, including one with idiopathic hypoproteinaemia. This study also failed to show any signs of reduced plasma protein synthesis—rather the opposite. The rate at which ³⁵S disappeared from plasma protein by far exceeded that in normal people. Similarly, the urinary excretion of ³⁵S was increased compared with normal persons. Kinsell *et al.* sum up that "the basic defect is one of hypercatabolism."

Against the studies of Albright *et al.* it may be objected that intravenous administration of 50 g. of albumin daily for 16 days is rather an unphysiological procedure, and against the technique of Kinsell *et al.* that it may be difficult to assess the results of experiments with labelled amino-acids because of the possibility of their re-utilization. As patients with idiopathic hypoproteinaemia present special possibilities of elucidating the largely unknown mechanism which regulates serum proteins, it seemed to us of great interest to study the serum protein turnover, using directly labelled

protein. By this method only a few milligrams of protein are administered, and re-utilization is of no importance.

Such a study was carried out in the case reported below.

Case Report

A 25-year-old woman was first admitted to the Central Hospital, Silkeborg, on June 13, 1955, because of oedema of the legs. Her family history was negative. She had possibly had "jaundice" in childhood, but was otherwise in good health. Menstruation was normal. From the age of 17 she had been suffering from swelling of the ankles and lower legs, gradually ascending to the knees. The swelling had been most pronounced in the right foot and lower leg, but during recent years it had also involved the left hand. Facial oedema had never been observed. Apart from these swellings, there were no complaints. At another hospital the serum protein level was found to be 5.5% (albumin 3.7%, globulin 1.8%), when she was 20 years of age. At 22 she was treated in a surgical department for crural oedema by paste bandage. Phlebography as well as oscillometry showed normal findings.

The patient had spent a total of 113 days at the Central Hospital, Silkeborg, during which the condition had remained entirely unchanged, characterized by moderate but persistent oedema of the feet and lower legs. Upon bed rest they subsided slightly. Apart from the oedema nothing abnormal was found: development and nutrition were normal. Radiological examination of the stomach and small intestine gave normal findings. Chest radiography and E.C.G. were normal. X-ray films of sella turcica: small, measuring 10 by 7 mm. Ophthalmological examination normal.

Laboratory Tests.—Height, 154 cm.; weight, 48.9 kg. Haemoglobin, 90%; R.B.C., 4,560,000; colour index, 0.96; E.S.R., 1 and 2 mm./hour; W.B.C., 8,690 (staff cells 17%, polymorphonuclears 59%, eosinophils 8%, lymphocytes 13%, monocytes 3%). Sternal marrow: slight eosinophilia, no other definite abnormality. Urine: no albumin (several tests) or sugar. Blood urea: 20, 28, and 18 mg. per 100 ml.; blood urea clearance, 75% of normal. Serum bicarbonate, 27.6 mEq; serum chloride, 105–102 mEq; serum phosphorus, 6.6–6.8 mg. per 100 ml.; serum calcium, 9.3–8.6 mg. per 100 ml.; serum potassium, 16.7 mg. per 100 ml.; serum cholesterol, 122, 105, and 180 mg. per 100 ml.; total lipid in serum, 690 mg. per 100 ml.; alkaline phosphatases in serum, 2.5–3.0 units (Buch). Icterus index, 3. The bromsulphthalein, thymol turbidity, and Takata-Ara tests were negative. Faeces: no blood; excretion of fat normal. Adrenal cortical hormones in urine: 24-hour excretion of 17-ketosteroids, 6.2 mg.; reducing corticoids, 1.07 mg. (normal). Thorn's test with adrenaline, 50% decrease in eosinophils, with corticotrophin 25%, decrease (?). Skin tests with various allergens, all negative. Histamine test meal, free acid present. Glucose tolerance, normal curve. Serum protein: 4% (albumin 2.6%, globulin 1.4%). Paper electrophoresis: total protein 4.1% (albumin 53%, alpha₁ 7.3%, alpha₂ 13.6%, beta 13.1%, gamma 13.1%). Fibrinogen 650 mg. per 100 ml. (normal 200–400 mg.). Oedema fluid 0.2% (albumin).

Thus the essential result of the numerous laboratory tests was a marked decrease in serum proteins, a decrease which affected all fractions equally. In addition there was slight eosinophilia, whereas no other tests showed definitely abnormal values.

The patient had been tentatively treated with a high-protein diet for two weeks, with testosterone for three weeks and with corticotrophin for 18 days without the slightest effect. During the observation period the serum protein values have remained about 4% and there have been no changes in the individual fractions.

Serum Albumin Turnover

For this study we used human serum albumin prepared at the State Serum Institute by the method of Cohn (more than

99% pure albumin), and labelled with ¹³¹I by the method of Veall *et al.*²⁰ The finished iodinated albumin contains 5 atoms of iodine per molecule of protein; upon paper electrophoresis it is indistinguishable from non-iodinated albumin. The non-protein-bound radioactivity was <0.5%. Studies of the albumin turnover by ¹³¹I-labelled albumin have been described on several occasions.^{5 19} The rationale of this method is that the labelled albumin will be dealt with by the organism just as its own albumin. When the labelled albumin has mixed with the subject's native albumin the plasma radioactivity will act as an indicator of the albumin's rate of degradation, which will also be reflected by the urinary excretion of ¹³¹I.

Since the turnover rate of iodine-labelled proteins is more rapid than that of biologically labelled proteins, and since it may also vary within certain limits, presumably because, in spite of everything, proteins change slightly during iodination, the determination is relative rather than absolute. Each batch of labelled protein must therefore be tested on a number of normal persons in addition to the patients being investigated.

In our study the albumin turnover was determined in three normal persons as well as the hypoproteinaemic patient. All four subjects were hospitalized, given ordinary diet, and permitted moderate activity. In order to secure a rapid excretion of iodine and inhibit thyroid uptake of ¹³¹I, we administered a 3% solution of potassium iodide, 30 g. daily.

The labelled albumin was injected intravenously (30 mg. of albumin with an amount of radioactivity of about 90 microcuries), and heparinized blood samples were drawn every day or every other day for more than two weeks, the first sample being obtained 10 minutes after the injection.

FIG. 1.—Plasma disappearance curve of ¹³¹I-labelled albumin in two normal subjects.FIG. 2.—Plasma disappearance curve of ¹³¹I-labelled albumin in patient with idiopathic hypoproteinaemia.

The plasma radioactivity was determined on 0.4-ml. samples dried in aluminium dishes and counted with a Geiger counter and a Brüel and Kjær scaler. No correction was made for self-absorption (all specimens from the same subject were of the same weight).

The measurements of radioactivity (counts per minute) were corrected for decay if necessary, and converted to percentages of the 10-minute sample, which was also used to determine the plasma volume.

Fig. 1 gives the disappearance curve for the labelled albumin in a semilogarithmic scale for two of the three normal subjects, and Fig. 2 for the patient with idiopathic hypoproteinaemia. The curve consists of two parts: a curved portion extending over the first five to six days, corresponding to the mixing of the labelled albumin with the native albumin—that is, the “albumin phase”—and a straight line representing the degradation of the injected iodinated albumin (or the rate at which labelled albumin is replaced by unlabelled albumin).

The slope of the straight line indicates the rate of albumin turnover—the steeper the curve the quicker the turnover. The half-time ($T_{1/2}$) of the administered albumin may be determined graphically as seen from the figures, and from the equation representing exponential decay the decay constant (λ) may be calculated.

On the basis of the values shown on the curve and the serum albumin percentage it is now easy to compute the total amount of albumin in the body as well as its distribution into intravascular and extravascular sites (cf., for example, Sterling¹⁹).

The Table sets out these values for the three normal subjects and for the patient with idiopathic hypoproteinaemia.

Data Pertaining to Distribution and Degradation of ¹³¹I-labelled Serum Albumin in Three Normal Persons and Patient with Idiopathic Hypoproteinaemia

	Persons Studied			
	Normal			Idiopathic Hypoproteinaemia
	M.	F.	F.	
Age (years)	26	40	47	25
Weight (kg.)	83	70	53	50
Plasma volume (ml.)	3,970	3,460	2,780	2,200
Serum protein (%)	7.1	7.4	6.8	4.3
“ albumin (%)	5.47	5.03	4.50	3.01
Total exchangeable albumin (g.)	440	407	308	190
Intravascular albumin (g.)	217	174	125	65
Extravascular	223	233	183	125
Albumin turnover half-time (T _{1/2}) in days	21.3	22.7	23.9	7.2
Albumin degradation %/day	3.26	3.06	2.90	9.64
“ “ g./day	14.3	12.4	8.94	18.3
“ “ g./day kg.	0.172	0.177	0.169	0.366
Total renal excretion of injected dose ¹³¹ I in first 14 days following injection of labelled albumin			50%	91.9%

The result of the study is unequivocal. The patient with idiopathic hypoproteinaemia has a greatly increased albumin turnover. In our case the degradation rate for albumin was more than three times that in the normal subjects. Despite the greatly reduced amount of protein at her disposal the patient with idiopathic hypoproteinaemia degraded and synthesized over twice the amount of albumin per kilogram of body weight formed by normal persons. That the albumin is not merely removed, but also broken down, is shown from the fact that in our patient the renal excretion of iodine was about twice that in the normal subjects.

Discussion

The result—that idiopathic hypoproteinaemia is associated with marked protein catabolism—is in keeping with previous findings by Albright *et al.* as well as by Kinsell *et al.* The technique used by us cannot in any way affect the albumin metabolism as such. Only 30 mg. of albumin is administered, and the label substance (¹³¹I) is not re-utilized, but

excreted. The entire picture reminds one of that found by the same technique in nephrotic patients, apart from the fact that in the latter the lost protein is recovered in the urine. The old designation of idiopathic hypoproteinaemia “nephrosis without nephrosis” is in fact not out of place, although a linguistic monstrosity.

Now, three different methods of studying the protein turnover in a total of five patients with the rare disease idiopathic hypoproteinaemia have given the same result. It seems reasonable, therefore, to postulate that it is increased protein catabolism and not reduced synthesis which is the basal defect in all cases of this disease. A better name would therefore perhaps be “hypercatabolic hypoproteinaemia.” Still, this result does not solve the mystery of idiopathic hypoproteinaemia, but it must alter the approach of future studies. The mechanism which regulates the protein concentration of the blood is largely obscure. Perhaps the hormones of the adrenal cortex are operative, but we do not know how such regulation is effected. Messinger’s¹⁸ patient was apparently cured after having become pregnant, and Messinger interpreted this as a sign that the disease was due to temporary disturbance of anterior pituitary function (the patient had previously suffered from mild thyrotoxicosis).

A defect in the regulation of, at any rate, serum albumin may be seen from the fact that serum albumin remains low in these patients.

Balance at a low but not at a high albumin level must be interpreted on the supposition that the albumin level *per se* influences the catabolism, which must fall with a decreasing albumin concentration, or—presupposing a uniformly high albumin degradation regardless of the albumin concentration—that albumin synthesis increases with decreasing albumin concentration.

It is of particular interest that among the proteins of the body the plasma proteins appear to be affected selectively by the rapid degradation. The haemoglobin turnover, for instance, appears to take place at the usual rate, and experience from paediatric practice does not indicate a reduced rate of growth in children with idiopathic hypoproteinaemia. It must be mentioned also that these patients may well acquire a positive nitrogen balance. This would be difficult to explain if the protein catabolism in all tissues were increased to several times the normal.

Serum-protein hypercatabolism may remind one to a certain extent of the conditions in haemolytic anaemia, and this raises the question of how much serum protein the organism can produce. The present experiments determined only the albumin turnover. Kinsell *et al.* determined the total plasma protein turnover, so it is not yet known whether the rate of globulin turnover is increased as well. Since the present method utilizing ¹³¹I-labelled albumin must be presumed to afford a relative rather than an absolute measure of the albumin turnover rate, this question must await investigations using biologically labelled proteins.

Summary

Until recently it was believed that the low serum protein level in the rare disease idiopathic hypoproteinaemia was due to reduced protein synthesis.

Recent studies comprising a total of four patients indicate, however, that the basic defect is one of hypercatabolism.

A typical case of idiopathic hypoproteinaemia of eight years’ duration is reported. In this patient, too, a study of the albumin turnover with ¹³¹I-labelled serum albumin showed a greatly increased catabolism of albumin. We therefore suggest that the disease be called hypercatabolic hypoproteinaemia.

The investigation was aided by a grant from Statens Videnskabsfond, University of Copenhagen.

ORAL ADMINISTRATION OF PENICILLIN

WITH A NOTE ON METHODS OF ASSAY

BY

L. HENRY, M.B., Ch.B.
Senior House Officer

G. WHITE, M.B., Ch.B.
Senior House Officer

AND

M. J. MEYNELL, M.D., M.R.C.P.
Clinical Pathologist

From the Department of Clinical Pathology,
General Hospital, Birmingham

It has been noted that all preparations of penicillin, when given by mouth, are unstable in the acid medium of the stomach and are poorly absorbed from the gastrointestinal tract. Oral penicillin therapy has thus been of value only in children, in whom the gastric acidity is lower (Cathie and MacFarlane, 1953).

In 1940 it was established that by the addition of various chemicals to the medium in which the mould was grown a variety of penicillins could be obtained, differing widely in their physical and antibacterial properties. Behrens *et al.* (1948), by using N-(2-hydroxyethyl)-phenoxymethyl penicillin. However, the *in vitro* isolated phenoxymethyl penicillin. The effect of this differed only slightly from that of penicillin G, and it was not until Brandt *et al.* (1953) demonstrated its acid stability that its use as an oral penicillin was realized. Several articles appeared on the Con-
tinent confirming its value (Giovannini, 1954; Sjöberg *et al.*, 1955; Spitz, 1955), and the preparation was marketed under the name of “distaquaine V.” The recent work in America (Jones and Finland, 1955; Martin *et al.*, 1955; Wright *et al.*, 1955) has been the subject of two leading articles (*B.M.J.*, 1956; *Lancet*, 1956), and we have already reported a preliminary survey of the serum levels obtainable (Henry and Meynell, 1956). Most papers have demonstrated that adequate and reliable absorption can be obtained with distaquaine V, but comparison is usually made with oral crystalline penicillin G. The latter is known to be

inadequately absorbed, the amount recoverable in the urine being in the region of 12% (Wright *et al.*, 1955). It was thus felt that injected penicillin would give a better basis for comparison.

The object of this paper is to compare the serum levels and urinary excretion rates obtained with phenoxymethyl penicillin (distaquaine V) and benzathine penicillin (“penidural”) given orally, with crystalline penicillin G, and procaine penicillin (“avloprocil”) given by intramuscular injection. In addition, the accuracy of the two standard methods of assay has been compared—the serial broth dilution method using *Staphylococcus aureus* (Oxford strain) and the plate method using *Sarcina lutea*.

Method

Six subjects were given 200,000 units of each preparation in turn, and thus acted as their own controls. The dose was given before meals and blood withdrawn at $\frac{1}{2}$, 1, 2, 3, and 4 hours, except in the case of procaine penicillin, when the intervals were $\frac{1}{2}$, 1, 2, 6, and 24 hours.

The bladder was emptied before the administration of the penicillin, and thereafter a 24 hour specimen of urine was collected; the volume was measured and an aliquot retained for assay. Serum levels were estimated on the same day by both methods, but in the case of the urine assays the *Staph. aureus* method was found to be unsuitable and the *Sarcina lutea* method only was used.

Staph. Aureus Method.—Serial dilutions of the serum are made in 1% glucose broth, containing Andrade’s indicator, and to each tube is added one drop of an overnight culture of the Oxford strain of *Staph. aureus* (sensitive to 0.02 unit of penicillin per ml.). Readings are taken after 18 hours’ incubation at 37° C. and the end-point is read according to colour change in the medium and visible growth, both being compared with a control estimation, using normal serum containing a known amount of penicillin. The end-point is sometimes difficult to judge, and it may be necessary to subculture the tubes on to a solid medium.

Sarcina Lutea Method.—Two media are used—a “base” layer with a “flood” layer superimposed. The base layer is made up of 1.5 g. of “lemco,” 3 g. of “bacto” yeast, 6 g. of bacto peptone, and 15 g. of agar, suspended in 1 litre of water.

The flood layer is the same as the base layer with the addition of 1 g. of dextrose. The organism used is *Sarcina lutea* CPI—1001 (N.C.T.C. 8340). This is grown on slopes of flood layer agar, and after 18 hours’ incubation is washed off with normal saline and the opacity is adjusted to that of a No. 8 Burroughs Wellcome opacity tube. If a standard Petri dish is used, base medium is poured in 10-ml. amounts and allowed to set. The flood medium is brought to 50° C. and is inoculated with the *sarcina* suspension, 2 ml. per 50 ml. of flood layer medium. Immediately after inoculation 4 ml. amounts of the medium are poured on to each plate containing the base medium. The plates are allowed to set and four holes punched in each, a No. 5 cork-borer being used, although the method is actually independent of the size of the hole.

Assay Procedure

Three plates are used for each assay. A standard solution of penicillin containing 0.1 unit per ml. is prepared, and the serum to be assayed is diluted to approximately the same strength with pH 7.5 phosphate buffer. Both these solutions are then diluted further (usually twice) with buffer, and four drops of a given dilution are introduced into the four holes on each plate, using a pipette delivering 70 drops per ml.

The plates are incubated at 26° C. for 18 hours, when the diameters of the clear areas are measured with a millimetre steel rule, and the average of the readings on the three plates is used in the calculation.

Calculation

The concentration of penicillin which diffuses through the agar diminishes exponentially with increasing distance from the punched hole. Since all four readings are on the same plate and are taken at the same time, the size of punched hole can be eliminated.

This leads to a formula of the type:

$$T_2 = S_2 \lambda \frac{(R_2 - r_2)(R_1 - r_1)[(R_2 - R_1) + (r_2 - r_1)]}{(r_2 - r_1)(R_2 - R_1)[(R_2 - r_2) + (R_1 - r_1)]}$$

which, on taking logs, becomes

$$\log_{10} T_2 = \log_{10} S_2 + \left[\frac{(R_2 - r_2)(R_1 - r_1)[(R_2 - R_1) + (r_2 - r_1)]}{(r_2 - r_1)(R_2 - R_1)[(R_2 - r_2) + (R_1 - r_1)]} \right] \log_{10} \lambda$$

However, if $\lambda=2$ and the diameters are similar, a simpler formula may be used, thus:

$$\log_{10} T_2 = \log_{10} S_2 + \left[\frac{(R_2 - r_2) + (R_1 - r_1)}{(R_2 - R_1) + (r_2 - r_1)} \right] \log_{10} \lambda$$

where T_2 is concentration of test solution; S_2 is concentration of standard solution; λ is the dilution ratio used; r_2 is radius of clear area using solution S_2 ; r_1 is radius of clear area using diluted solution S_2/λ ; R_2 is radius of clear area using solution T_2 ; R_1 is radius of clear area using diluted solution T_2/λ . The diameters can be used in place of the radii without any alteration in the formula.

Results

The serum levels and urinary excretion rates for each preparation are given in Tables I-IV. The figures obtained with the *Sarcina lutea* method are given first, the corresponding levels for the *Staph. aureus* method being given in parentheses.

Side-effects were not noted in any subject.

Discussion

From the tables it is clear that parenteral penicillin is well absorbed from the site of injection, whether in the crystalline form or as a depot preparation. In the former a

See footnote to Table I.

high level is reached after half an hour, falling below the therapeutic concentration of 0.1 unit per ml. after three hours; in the latter the levels are lower, but the effect lasts for over six hours. In both, approximately 75% of the injected penicillin (in terms of biological activity) can be recovered in the urine.

In contrast, oral penicillin is affected by a number of variable factors. These include the gastric acidity, the rate of stomach emptying, and the absorptivity of the intestinal mucosa. With phenoxymethyl penicillin this was reflected by the demonstration of only 30% of the ingested penicillin in the urine. The serum levels were correspondingly lower, but were still adequate, and remained above the therapeutic level (0.1 unit per ml.) for over three hours, although the rate of absorption varied in individual subjects.

With benzathine penicillin the results were much less satisfactory. Only 5-10% of the ingested dose was recoverable in the urine, and even when a therapeutic level was reached this was in no case sustained for over one hour. The levels obtained were in no way comparable with those of injected penicillin or phenoxymethyl penicillin.

Note on Methods of Assay.—The method using *Sarcina lutea* is reliable and has an accuracy within 5%, but it is laborious to carry out and requires an incubator set to 26° C. The *Staph. aureus* method is much simpler and requires no special equipment, but, being a serial dilution method, has an inherent accuracy of only 50% in that the actual concentration of penicillin lies somewhere between the end-point tube and the tube containing the next highest dilution. In no case should the level obtained with the *sarcina* method be lower than that with the *Staph. aureus* method. However, on comparing the results of both methods, in 44 out of 120 readings the *Staph. aureus* method failed to give levels even within this wide range of accuracy, and can thus be discounted as a method of assay when the absolute concentration of penicillin is to be determined. However, its simplicity renders it the method of choice when the sensitivity of an infecting organism is known, and assays are carried out

to ensure that a certain minimum concentration of penicillin is being obtained, the actual level being unimportant provided it is above the therapeutic one for the organism concerned.

Owing to the possible contamination of the urine, the *Staph. aureus* method is unsuitable for urine penicillin assays and the *Sarcina lutea* method must be used.

Summary and Conclusions

Serum penicillin levels and urine excretion rates were measured in six subjects, using two intramuscular and two oral preparations of penicillin. The two standard methods of assay are described in some detail, and the results obtained with both methods are compared.

The results obtained clearly indicate that oral penicillin is no substitute for parenteral therapy when consistently high levels are required. Where oral therapy is indicated phenoxymethyl penicillin gives adequate and reliable blood levels. Benzathine penicillin appears to give disappointing results in adults, and it is probably of more value in children.

The *Sarcina lutea* assays were performed throughout by Miss M. A. Butcher, working under a grant from the Endowment Fund of the Birmingham United Hospitals, and we would like to thank Messrs. Glaxo Ltd. for instruction and advice in this method. Mr. J. P. Henry, M.Sc., for invaluable help with the mathematics, and Miss M. N. Ellis for secretarial assistance. Miss B. J. Burden, Miss P. J. Dickens, and Mr. A. L. Tapparo kindly acted as subjects for the survey.

RAPID INTRAVENOUS TRANSFUSIONS
IN CHILDREN

BY

Hospital, London

Bayliss and Starling (1894) showed that rapid injections of crystalloid solutions and blood caused a rise in venous pressure in dogs. Previous cord transections at the level of T I had increased the capacity of their vascular system by one-quarter. In 1918 Starling pointed out that transfusions in anaemic patients caused the heart to behave as an overloaded heart-lung preparation, giving further rise to an already elevated venous pressure. This resulted in a fall of cardiac output and pulmonary oedema. Cabot (1926), Ellis and Faulkner (1939), and Sharpey-Schafer (1944) found the cardiac silhouette enlarged on radiological examination, electrocardiographic changes, and increased cardiac weight at necropsy in

anaemic patients. Sharpey-Schafer and Wallace (1942b) found increased cardiac diastolic size and electrocardiographic changes after transfusions in normal patients. In fatal cases necropsy has shown pulmonary oedema and cardiac dilatation (Plummer, 1936; Fishberg, 1937; Drummond, 1943). According to Riddell (1939) the commonest cause of fatality following blood transfusion is circulatory failure secondary to overloading.

This paper is a report on three anaemic children to whom 16 very rapid transfusions—35-50 ml. a minute—were given under general anaesthesia. There were no ill effects.

Case Reports

Case 1.—A boy aged 6, weighing 2 st. 1 lb. (13.2 kg.) and 3 ft. 8 in. (112 cm.) in height, with congenital hypoplastic anaemia, had a systolic murmur most clearly audible in the pulmonary area, and a liver enlarged to three fingerbreadths below the right costal margin. By May, 1955, he had received a total of 51 transfusions. Initially these consisted of 50 ml. of whole blood, but later he was being transfused with the packed cells from 1 pint (570 ml.) of blood. These earlier infusions were administered under basal narcosis—rectal thiopentone, 1 g. per 50 lb. (22.5 kg.) body weight—given in 20-30 minutes. Splenectomy in March, 1955, brought no improvement. Since June, 1955, he has received nine rapid transfusions under general anaesthesia, each consisting of the fresh packed cells from 2 pints (1,140 ml.) of blood. Blood-volume estimations were performed on three occasions.

Case 2.—The patient was a boy aged 7 weighing 3 st. 11 lb. (25 kg.) and 3 ft. 6 in. (107 cm.) in height, with congenital hypoplastic anaemia, probably of the Fanconi (1927) type—that is, with small head and pigmentation, though this latter may have been due to early haemochromatosis. The heart and respiratory systems appeared normal, but the liver was enlarged to two fingerbreadths below the right costal margin. By June, 1955, he had received a total of 93 intravenous blood infusions consisting of 50 ml. of whole blood, and later the packed cells from 1 pint (570 ml.) of blood. The operation was conducted under basal narcosis—rectal thiopentone, 1 g. per 50 lb. (22.5 kg.) body weight—and completed in 20-30 minutes. Splenectomy in May, 1953, produced no improvement. Since June, 1954, six very rapid transfusions have been given under general anaesthesia, each consisting of the fresh packed cells from 2 pints (1,140 ml.) of blood. On three occasions blood-volume estimations were performed and venous pressure changes were recorded manometrically once.

Case 3.—A girl aged 4, weighing 2 st. (12.7 kg.) and 3 ft. 3 in. (99 cm.) in height, had a neuroblastoma of the left adrenal gland. The cardiac and respiratory systems were normal. She had received two previous slow transfusions each consisting of 1 pint (570 ml.) of whole blood. We transfused her rapidly once under general anaesthesia with 1 pint (570 ml.) of whole blood.

Method

Each child was given a fat-free diet for 18 hours before transfusion. Pentobarbitone sodium, 0.6 gr. per stone (6 mg. per kg.), was given one hour before operation, and atropine, 1/100 gr. (0.65 mg.) hypodermically, half an hour pre-operatively. A quiet induction of anaesthesia was achieved with nitrous oxide, oxygen (30%), and trichlorethylene, and maintenance was with nitrous oxide, oxygen (30%), and ether. A Dinsdale (1954) respirator was used in order to assure minimal resistance to respiration. A high flow of gases was maintained in order to prevent accumulation of carbon dioxide.

The apparatus for transfusion was of a modified scalp vein type with Luer-Lock fittings (see Fig.) (Black et al., 1951; Mollison, 1951). The packed cells were usually

given into the back of the hand. On one occasion (Case 1) the blood was given direct into the internal jugular vein.

Blood-volume estimations were performed, using 1% Evans blue (T.1834)—16 mg. diluted to 10 ml. with distilled water. A baseline specimen of blood was collected, after which the dye was injected. A second specimen of blood was taken after 10 minutes to allow adequate mixing (Gibson and Evans, 1937). The child was then transfused and three further blood specimens were taken, preferably from the opposite arm at intervals of 7, 15, and 30 minutes. The plasma volumes were calculated photoelectrically (Harington *et al.*, 1940) using a wavelength of 620 and a red filter. The average plasma volume at 10 minutes after transfusion was obtained by plotting a time/concentration graph. From

these results and estimations of packed cell volume the total blood-volume changes were determined. Blood-volume estimations were also performed in Cases 1 and 2 without transfusion, to show that rapid excretion of the Evans blue dye via the reticulo-endothelial system and biliary tract (Gibson and Gregersen, 1935) occurred neither during mixing nor for 30 minutes afterwards (Crooke and Morris, 1942). The plasma volume at zero time had to be assumed to be the same as that at 10 minutes after injection of the dye. This implies a calculated error of less than 2% (Russell, 1949).

Results

The results of the investigation are shown in Table I. During the first three transfusions in Cases 1 and 2 continuous electrocardiographic recordings showed no change apart from slight slowing of pulse on two occasions. Before transfusion the jugular venous pressure was not elevated, but this was probably because the haemoglobin was seldom allowed to fall below 45%. An increased venous filling became

obvious after anaesthesia had been induced. After the transfusion the jugular veins looked fuller, but, as the children were anaesthetized and lying supine, no accurate assessments of the jugular venous pressure were made. Direct manometric readings in a peripheral vein showed no change in venous pressure. In Case 1 the pulmonary systolic murmur was much less audible after the transfusion.

Discussion

The children with congenital hypoplastic anaemia were losing one week's schooling in six in order to be transfused. Under the method described above they could be in and out of hospital and return to school in 24–48 hours.

Anaesthesia

We considered preliminary anaesthesia essential because of the marked apprehension resulting from regular six-weekly transfusions. Anaesthesia also made venepuncture easier owing to the increased venous filling. The supine position, however, was not ideal, as there is evidence that the propped-up position lowers the right auricular pressure (Sharpey-Schafer, 1945; Paul Wood, 1950). Ether is the anaesthetic agent of choice. Changes in the central venous pressure in adults are said to be negligible with thiopentone and nitrous-oxide-oxygen sequence (Fieldman *et al.*, 1955). A thiopentone induction, however, is impracticable in small, feeble children. Fletcher and Pender (1954), reporting on studies of venous pressure in adults, under ether anaesthesia, state that the venous pressure remained significantly raised during a three-hour period. This has not been our experience during ether anaesthesia in children. The impression that transfusions are particularly dangerous while the patient is anaesthetized does not seem justified. There is only the minimal danger of incompatibility (Wiener, 1943).

Total Blood Volume Changes

McMichael *et al.* (1943) found a reduced blood volume in chronically anaemic adults. Sharpey-Schafer (1944) confirmed this and found that right auricular pressure, cardiac output, and percentage utilization of available oxygen were increased. Patients with the highest venous pressure had the lowest haemoglobin and a reduced blood volume. One case, however, with the highest venous pressure and cardiac output and lowest haemoglobin, had a blood volume which was not as low as in some cases. Four days after transfusion, in this particular instance, the blood volume was lower still, although the patient had improved as judged by a falling venous pressure. In chronic anaemia the cardiac output is maintained by greater minute output secondary to an increased venous filling on the right side of the heart, and a tachycardia. Barcroft *et al.* (1944) thought the increased right auricular pressure must be at the expense of the

capillary and venous systems. Their findings were based on observations on the pulse, skin circulation, and total peripheral resistance following acute haemorrhage. Altschule and Gilligan (1938) noted skin flushing and a bounding pulse after transfusions in adults, and Russell (1947) observed skin flushing and local heat without venous engorgement after giving blood to children at the rate of 5 ml. a minute.

Sharpey-Schafer and Wallace (1942b), however, had produced evidence to show that the peripheral and pulmonary capillaries and veins dilate to accommodate the increased blood volume. The reason for administering venous transfusion slowly to anaemic patients is to enable the slow adjustment of venous filling pressure to the extra volume given (Sharpey-Schafer, 1945). We believe that ether anaesthesia may lower venous vasomotor tone in children so that the venous side can not only accommodate the blood much more quickly but is probably adjusted to receive it before the transfusion is given. Furthermore Fieldman *et al.* (1955), in a study of 11 adult cases, found a decrease in blood volume on induction of anaesthesia—calculated from the Stewart (1921) formula. A further significant decrease in blood volume occurred on deepening the anaesthesia. There was no significant increase in blood volume on emergence from deep anaesthesia.

The decrease in blood volume in chronic anaemia is an active process by which available haemoglobin is concentrated. This increases the availability of oxygen (Sharpey-Schafer, 1944), allowing the minimum necessary minute-volume cardiac output. Our results showed that in the anaemic phase in children the blood volume was approximately average or actually increased compared with the heights and weights of normal control children (Russell, 1949) (see Table II). Russell's figures and those of Bakwin and Rivkin (1924), however, show a wide range of normality in healthy children.

TABLE II

Case No.	Weight	Height	Average Blood Vol. for Patient's Weight	Average Blood Vol. for Patient's Height	Lowest Blood Vol. Pre-transfusion
1	13.2 kg.	112 cm.	1,100 ml.	1,600 ml.	1,316 ml.
2	25 "	107 "	2,100 "	1,400 "	1,959 "

Russell (1949) thought that the blood volume related to height was more valuable than when related to weight, as when the volume is increased owing to congestive failure the weight would rise automatically. Russell (1947), using the weight would rise automatically. Russell (1947), using a concentrated corpuscle-haemoglobin method for determining blood volumes (Hill, 1941; McMichael *et al.*, 1943), found that blood transfusion to an anaemic child with an initial low blood volume for its height and weight resulted in an increased total circulating volume. In another anaemic child with a high initial blood volume, transfusion resulted in a shift of fluid to the tissues. In our Cases 1 and 2, where the initial blood volume was average or high, transfusion resulted in an increase in the total circulating volume. The percentage increase in volume (Table I) was higher than expected from the quantity of blood given (on all occasions except one in Case 2). A low blood volume does not occur in chronically anaemic children as it does in adults. If the haemoglobin is allowed to fall below 25%, the blood volume may then follow the adult pattern. It can be argued that if the blood volume is reduced before transfusion then the infusion will give a relatively big increase in circulating fluid; if, however, the blood volume is normal or high to begin with, the proportional increase in volume will be less and so the risk of overloading diminished.

Plasma Changes

Sharpey-Schafer and Wallace (1942a) have shown that when blood volume is at a normal level transfused serum leaves the circulation in from one to two hours. Where the initial blood volume is reduced the transfused serum is retained in the circulation. Marriott and Kekwick (1936)

found that where whole blood is transfused in patients with chronic anaemia the added plasma may disappear even during the transfusion, and particularly if it is given slowly. Following our transfusions of packed cells the plasma volume was always increased ten minutes after the termination of the infusion. Russell (1947) suggests this increase in volume may be partly due to differences in the plasma protein levels of the blood of the donor and recipient. Mellett (1944) found that, in dogs, if the blood of the donor has a higher protein content than that of the recipient, fluid is likely to be withdrawn from the tissues to equalize the osmotic pressure. Conversely, transfused blood of lower osmotic pressure would tend to cause a shift of fluid to the tissues.

Sharpey-Schafer and Wallace (1942a) showed that the rate of disappearance of injected serum depended upon the initial blood volume and not on its protein content. Boycott and Oakley (1934), using cats, and Hayward and Jordan (1942), using human subjects, showed that movement of plasma proteins probably occurs simultaneously with the fluid shift. There is no plasma protein change during haemodilution following acute haemorrhage (Wallace and Sharpey-Schafer, 1941). As we used packed cells the plasma protein content is probably not the main cause of the extra fluid shift from tissues to circulation. Furthermore, there is no substantial loss of injected red blood cells for the first two days after blood transfusions, any volume change being one of plasma (Boycott and Oakley, 1934). The extra plasma could not have come from the spleen in Cases 1 and 2 as they had been splenectomized. Splanchnic or hepatic blood (both cases had large livers) is a possible source. It is unlikely to come from the venous side because of the reduced vasomotor venous tone resulting from the ether anaesthesia.

Quantity and Rate of Transfusion

The signs of an overloaded circulation are an elevated jugular venous pressure (Lewis, 1937) and basal rales (Drummond, 1943). DeBaKey (1938), in over 5,000 transfusions, never once observed the so-called phenomenon of speed shock (Hyman and Hirschfeld, 1931), and not infrequently 650 ml. was transfused in three minutes. In normal hearts Caughey (1935) found that 1,500 ml. of saline at 50 ml. a minute gives no venous pressure rise, but Altschule and Gilligan (1938) found that when more than 500–1,500 ml. of fluid is injected at greater than 26 ml. a minute the venous pressure, cardiac output, and blood volume increased. The faster the rate and the larger the quantity of fluid given, the higher was the venous pressure. Beattie and Collard (1942) found no changes of venous pressure by direct measurement in cases of diabetic coma and post-operative shock receiving similar large transfusions. Sharpey-Schafer and Wallace (1942b) found that 2,000 ml. of saline, serum, or blood can be given to normal hearts at 160 ml. a minute, but again with some rise in venous pressure. Previous reduction of blood volume by venesection prevented this rise. Marriott and Kekwick (1940) advised 1 ml. per 1 lb. (450 g.) body weight per hour to severely anaemic patients (haemoglobin less than 25%), uncomplicated by acute haemorrhage, and did not think it was safe to increase the rate if packed cells instead of whole blood were used. Sharpey-Schafer (1945) showed that 500 ml. at moderate rates (18 ml. a minute) may overload the anaemic heart.

We have found in three cases that 500 ml. could be safely given under general anaesthesia to children in approximately 10–15 minutes—that is, 35–50 ml. a minute. On one occasion this quantity was given direct into the internal jugular vein in ten minutes. This involves infusing two to four times faster than that thought likely to overload the chronically anaemic adult heart. We would not entertain such a rapid transfusion in proved pathologically abnormal hearts—for example, a case of pernicious anaemia—where rapid transfusions under any circumstances would be dangerous. Anginal symptoms may occur in severe anaemia even in normal hearts (Pickering and Wayne, 1934). Hunter (1946) found that, after correction of chronic anaemia,

cardiac pain and enlargement and electrocardiographic changes may persist and be almost identical to the signs of organic heart disease. Thus in chronic anaemia, even when the heart appears normal, ischaemic changes may already have occurred. This, however, seems unlikely to be the case in children.

Summary and Conclusions

A method is described of rapid intravenous transfusions to children. The procedure is regarded as safe in children with clinically normal hearts. It may be particularly indicated where regular transfusions are required during the child's life.

In children with chronic anaemia the blood volume does not fall as in adults. The relative volume increase after transfusion is thus small.

More blood can be given and at a faster rate owing to a reduced blood volume resulting directly from other anaesthesia, and probably a release of venous vasomotor tone.

The young chronically anaemic heart can withstand fast transfusions better than adult hearts. In selected children transfusions can be given with safety two to four times faster than the rate causing a falling cardiac output in chronically anaemic adults.

The blood volume soon after transfusions is greater than can be accounted for by the volume of blood given: the extra volume may come from the splanchnic or hepatic pools.

We wish to thank Dr. C. Pinckney and Dr. G. Edwards for their encouragement and advice, and Mr. J. G. Davis, Miss S. Fry, and Mr. L. G. Jones for technical assistance. The blood-volume estimations were done by Dr. C. B. Cameron.

GREAT AURICULAR NEUROTOMY FOR TIC DOULOUREUX

A CONTROLLED CLINICAL TRIAL

BY

JOHN PENMAN, M.B., M.R.C.P.

Neurologist, the Royal Marsden Hospital, London

AND

L. S. WALSH, M.B., F.R.C.S.

Research Assistant to the Department of Neurosurgery,
St. George's Hospital, London

Tic douloureux can at present be cured by any of several methods, all of which depend on interruption of those pain-conducting nerve fibres which pass from the ganglion of the trigeminal to the nucleus of its descending tract. All therefore cause some lifelong trigeminal sensory loss, which in most cases entails lifelong facial dysaesthesiae, and each has at least one of these further drawbacks: a more than negligible death rate, an insufficiently high success rate, and a risk of neuromyolytic keratitis or of lesions of other cranial nerves besides the fifth. For many years there has been a search for a cure—or even a means of prolonged relief—without such drawbacks, the two latest operations, which are both still unproved, being trigeminal “decompression” and compression.

Wyburn-Mason (1953) reported that he had treated about 56 patients suffering from tic douloureux by interruption of the great auricular nerve. Each of them first received an alcohol block of that nerve, and about half were completely relieved, “provided the tongue was not involved. . . . The treatment does not relieve the pain in the tongue.” Regarding the periods of complete relief thus obtained, he wrote: “In cases treated by alcohol block alone the pain may return after 6 to 18 months.” When the pain had returned, or if it had not been initially relieved, he treated it in some cases by a further alcohol block and in others by surgical section of the nerve.

Twenty-five of his patients received this surgical treatment, of whom two, at the time when he wrote, had had some return of pain, one two and a half years and the other three and a half years after nerve section. His follow-up was for as long as five years, which presumably means that five years was the maximum, but he did not state the minimum period.

Here, one might think, is the long-sought remedy without serious drawbacks, except for its failure to relieve pain in the tongue. Of the two ways of interrupting the great auricular nerve, Wyburn-Mason evidently prefers surgical section, and we agree with him, for with only a little more trouble than alcohol injection it produces a more certain interruption and a permanent one. Anything which it fails to do, injection likewise will fail to do. We have therefore subjected great auricular neurotomy to a controlled clinical trial on the lines recommended by Hill (1951).

Present Trial

Definitions.—Throughout the remainder of this paper neurotomy means great auricular neurotomy, and injection means alcohol injection of the trigeminal sensory root. Entry-injection interval means the interval between the date of a given patient's entry into the trial and the date of his injection.

Purpose of Trial.—The trial was primarily designed to answer the following question. Suppose that a patient with tic douloureux (1) after hearing the pros and cons of injection,

decides for himself when to undergo it, and (2) agrees to try neurotomy while awaiting or considering injection. What difference will neurotomy make to the entry-injection interval?

Collection of Patients

Out-patients with “trigeminal neuralgia” were referred to one of us (J.P.) for injection, but only those who fulfilled five diagnostic criteria (Penman, 1950) were accepted as having tic douloureux. To each of them an explanation of injection and its results was given, with emphasis on three points: that permanent cure was probable, that it would mean permanent and uncomfortable numbness of the affected side of the face, and that there would be a small risk of temporary trouble with the eye on that side. Each patient was then asked: “At present, are you sure you want injection, or sure you don't want it, or not sure either way?” Not infrequently he tried to make the doctor, or the relative or friend whom he had with him, decide this question for him, but he was told that he must decide for himself, since no one else could judge how severe his pain was. His answer having been recorded, he was asked: “Suppose you were suitable for another, milder treatment, which is certainly harmless, but which is still unproved and may turn out to be useless; would you be interested in that?” If he answered yes, an explanation of neurotomy was given to him, but it was stressed that this treatment, being unproved, could not be given to everyone who wanted it. If he said that he would be willing to try it he thereby entered the clinical trial. Whether in fact he was to be neurotomy or not was determined randomly, by the method described below under the headings “classification” and “treatment groups,” and he was immediately told the result of this random determination.

Fifty-one patients were thus collected, and eight more in the following different way. At the beginning of the trial there were eight patients who had previously been given the same explanation of injection, had said that they definitely wanted it, and were already waiting for it. To be brought into strict conformity with the other 51 they would have had to be interviewed again and specifically offered the opportunity of entering the trial; instead, their acceptance of it was assumed, and a date soon after the beginning of the trial was taken as the date of entry for all eight. When their treatment was randomly determined, all eight, when their treatment was randomly determined, were offered it in the five proved to be for neurotomy, and underwent the same terms as the other 51, accepted it, and underwent it; the remaining three were not neurotomy.

To this second method of collection it can be objected that any of the three unneurotomy patients, if specifically

offered entry into the trial, might perhaps have declined it. However, these eight cases gave results so similar to the rest that we think it justifiable to include them.

During the period of collection one patient was seen who had tic douloureux limited to the tongue, and was therefore excluded. Eighteen patients were included who had pain in the tongue as well as in other structures.

Classification

One of these 59 patients had bilateral tic douloureux which was almost equally severe on the two sides, and each side of his face was regarded as a separate case. In many places, therefore, we shall refer to our 60 cases instead of our 59 patients.

The cases were analysed at entry into the trial with regard to six features which might be held to influence the course of the disease (see Table I, part 1).

Severity of Pain at Time of Entry.—By their responses to the offer of injection the patients divided themselves into three classes, which finally contained the following numbers: class 1, certainly wanting injection (38 patients, 39 cases; class 2A, uncertain (18 patients); class 2B, certainly not wanting injection (3 patients). In randomly allocating treatment by neurotomy we preserved this division into three classes, but for all other purposes we have combined class 2B, since it was so small, with class 2A to make a single class 2.

Sex.—There were 34 women and 25 men.

Age on Date of Entry.—The patients were divided into those below the age of 60 years, who numbered 25, and those aged 60 years or over, who numbered 34.

Side of Face Needing Treatment.—Forty patients needed treatment on the right side, 18 on the left, and 1, already mentioned, on both.

Duration of Tic Douloureux at Time of Entry.—The cases were divided into those of less than four years' duration, which numbered 28, and those of four years' duration or more, which numbered 32.

Previous Attempts at Radical Treatment.—The cases were divided into those in which one or more attempts at injection, trigeminal sensory rhizotomy, or other forms of trigeminal surgery had already been made, which numbered 12, and those in which none had been made, which numbered 48.

In Table I, part 2, the features of patients in more severe pain (class 1) are compared with the features of those in less severe pain (class 2). Even with these small numbers it

TABLE I.—Classification, Treatment Groups, and Results

Features Possibly Influencing Results	Primary Groups	All Cases	Part 1		Part 2		Part 3		Part 4				Part 5. Results

	Total	60	39	21	35	25	23	16	12	9	22	1	14	2	7	5	3	6		

is worth noting that of the patients who were sure that they wanted injection, practically one-half were men, but of those who were uncertain or against injection only one-third were men. Also the shorter histories of tic douloureux were associated with a greater tendency to want injection. (The men did not tend to have shorter histories than the women.) In other respects the two classes did not differ.

Treatment Groups

Classification of the cases in relation to all the six features listed in Table I leads to 96 subgroups. Though some of these subgroups were bound to remain empty, 96 lists were prepared, each with spaces for ten names. Opposite each space, before the trial began, was written either A, signifying treatment, or C for control, the order of A's and C's on each list being determined by random sampling numbers. As soon as each case had been classified, the patient's name was written in the first vacant space on the appropriate list, and the presence of A or C opposite it determined whether neurotomy should be carried out or not. The resulting distribution of cases is shown in Table I, part 3. The aim of this method of determination of treatment was to obtain neurotized and unneurotized groups that were equivalent in their main features, and it was achieved except as regards previous treatment (and as regards the very small class 2B). Even for classes 1 and 2 separately there was a reasonable equivalence between the neurotized and unneurotized groups (see Table I, part 4). In order simultaneously to achieve equal numbers of neurotized and unneurotized cases, a larger total than 60 would have been needed.

The patient needing bilateral treatment proved to have his right side among the neurotized cases and his left among the unneurotized.

Of the 18 patients with pain in the tongue as well as in other structures, 12 were neurotized and 6 unneurotized.

Neurotomy

As soon as it had been determined that a given patient was to be neurotized, his name was put on a list, and the neurotomies were carried out in the order in which the names had been listed. The names of all patients in class 1 and of some in class 2 had on the day of entry into the trial been put also on a second waiting-list, for admission to hospital and injection. Whenever this second list was short—and it was seldom long—there was a danger that a patient's injection might have to be delayed in order to find time for his neurotomy. To reduce this danger, most neurotomies were carried out within five days of entry, some one day after it, and a few on the day of entry; but, even so, there were some cases in which injection was thus delayed for a short while. Such delays could only weight the results slightly in favour of neurotomy.

Just before each neurotomy we applied pressure, as recommended by Wyburn-Mason, to the great auricular nerve of the affected side through the intact skin. A few patients, all of whom had been having paroxysms of tic douloureux just before this pressure, had them also just after it, but none was relieved of pain by it.

All 35 neurotomies were carried out by one of us (L.S.W.) and nearly all were witnessed throughout by the other. Only local analgesia was used, and Wyburn-Mason's directions were strictly followed. The great auricular nerve was identified where it crossed the posterior border of the sternomastoid muscle, freed from neighbouring structures, and traced as far centrally as possible. In 31 cases the most central portion of the nerve that could be reached was squeezed and tugged with a forceps; 4 of these 31 patients felt nothing, doubtless because of the preliminary infiltration of the operative field with local analgesic; 25 felt painful or other sensations in the ear; two felt them only in the neck; but none felt any sensation in the trigeminal area. (In the remaining four cases of neurotomy we inadvertently did not record whether this stimulation of the nerve was carried out or not.)

A length of at least 1 cm. of the nerve was excised and sent for microscopy, which in each of the 35 cases confirmed that it was a portion of a peripheral nerve. A few patients felt the same sensations during the cutting of the nerve as they had felt during the squeezing and tugging of it, and in the same areas. One patient, when re-examined just before injection, had no sensory loss on the ear; presumably the great auricular nerve was either exceptionally small and had a correspondingly small territory, or else proximally to the site of operation it had already divided into two or more branches, of which only one was found and cut. In all other cases there was permanent analgesia or anaesthesia in the lobe of the ear and in immediately adjacent areas, but in none was there any sensory loss within the trigeminal area.

Thus the great auricular nerve was stimulated in 31 cases and completely cut in either 34 or 35 cases, but no support was found for Wyburn-Mason's view that it must partly innervate the trigeminal area.

Follow-up

Patients whose names were on the waiting-list for injection were told that if by the time they were sent for they no longer wanted it they would be welcome to postpone it. Those whose names were not on the waiting-list were told that whenever they wanted injection they might send word, and their names would at once go on the list. Both these instructions were given whether neurotomy had been carried out or not, but in addition the neurotized patients were told that if they really wanted injection they should not postpone it because of the neurotomy. However, the inclination to wait a little longer and give the neurotomy "time to work" must have been strong in some cases, and it is doubtful whether our instruction entirely counteracted it. One patient to our knowledge was persuaded by his general practitioner to postpone injection for that reason, and others may have been similarly persuaded. This is a second inevitable factor which tended to weight results somewhat in favour of neurotomy, especially in class 2.

Injections were carried out in the order of the waiting-list. So far as was possible, all uninjected patients were followed up every two calendar months from the date of entry, on the first two occasions by interview and thenceforth by letter. On five occasions we had to be content with a letter instead of an interview, and on three with a telephone message instead of either. Twice we lost touch with patients temporarily, but none defaulted entirely, and a few had extra interviews at their own request. The first entry was on August 16, 1954, the last on May 4, 1955, and the follow-up was closed on August 16, 1955.

Results

One criterion of failure or success with the 35 neurotomies is the subsequent need or absence of need for injection, as compared with the same need or absence of it in the 25 unneurotized cases. In injected cases another criterion is the entry-injection interval, and in uninjected cases the period for which each patient was followed up without needing injection.

Injection had to be carried out in 36 of 39 cases, or 92.3%, in class 1, but in only 10 of 21 cases, or 47.6%, in class 2, and all results must therefore be considered separately for these two classes.

In class 1 there were 23 neurotized cases, 22 of which had to be injected, and 16 unneurotized cases, 14 of which had to be injected. In class 2 there were 12 neurotized patients, seven of whom had to be injected, and nine unneurotized patients, three of whom had to be injected. For details see Table I, part 5. The maximum, average, and minimum entry-injection intervals are given in Table II, which shows that in class 1 the average intervals for neurotized and unneurotized cases differed by less than one day. In class 2 the average entry-injection interval was 75 days longer for the neurotized than for

TABLE II.—Injected Cases: Number of Days Elapsing Between Entry into Trial and Injection

		Class 1		Class 2	
		Neurotized	Unneurotized	Neurotized	Unneurotized
No. of cases	Entry-injection interval (days)	22	14	7	3
	Maximum	85	148	204	25
	Average	21.4	22.1	93	18
	Minimum	4	0	12	16

the unneurotized, but here the total of 21 patients, injected and uninjected, was too small for this comparison to be very significant.

Uninjected cases numbered 14. In class 1 they represent one "success" out of a possible 23 for neurotomy and two "successes" out of a possible 16 for doing nothing; in class 2, five "successes" out of a possible 12 for neurotomy and six out of a possible nine for doing nothing. The follow-up periods, for what little they are worth with so few cases, can be compared in Table III; the three

TABLE III.—Uninjected Cases: Length of Follow-up

		Class 1		Class 2	
		Neurotized	Unneurotized	Neurotized	Unneurotized
No. of cases	Individuals	1	2	5	6
	Length of follow-up (days)	250	321	—	—
	Maximum	—	322	314	271
	Average	—	—	256	184
	Minimum	—	—	189	125

patients in class 1 all happened to enter the trial before any of the 11 in class 2, which is the only reason why they were followed up longer.

The patient needing bilateral treatment said when first interviewed, and again on the day of his right-sided neurotomy, that the left side needed treatment rather more than the right, so that it was for left-sided injection, as we thought, that he was admitted to hospital. He then said, however, that the right-sided pain had become worse than the left, and asked for a right-sided injection, which was given. About three and a half months later he began to have a bout of severe left-sided pain, which continued for two to three weeks and then abated. During that bout he asked for left-sided injection, but changed his mind before it could be given. Thereafter until his latest follow-up, 322 days after entry, his left-sided pain was not severe enough to make him want injection.

In all of those 12 cases in which the pain had both affected the tongue and been treated by neurotomy, it continued not only in the tongue but also in other structures, and in 10 out of the 12 cases injection was carried out.

A few neurotized patients found the numbness in and round the ear unpleasant, especially when lying in bed with the affected area in contact with a pillow. The 29 neurotized patients who required injection nearly all said in effect that neurotomy had been worth trying, but had made no difference whatever to their pain.

Comment

Controls apart, it would be hard to praise any treatment for tic douloureux which in 22 out of 23 severe cases left the patient in need of injection within 85 days.

The search for a cure without trigeminal sensory loss must continue, but each proposed new remedy ought, in the very first cases in which it is used, to be subjected to a controlled clinical trial. This precaution is especially necessary in any disease which is so chronic and remittent as tic douloureux. The two features of the present inquiry which we have found most valuable are (1) preliminary classification of the severity of each case by the patient himself, through his response to a standard offer of radical treatment, and (2) assessment of the efficacy of the method

under trial by the patient himself, through his decision when to undergo radical treatment. By these means, and with an adequate supply of patients, reliable results can be obtained within 12 months.

Summary

Between August, 1954, and May, 1955, 23 severe cases of tic douloureux, strictly diagnosed, were treated by great auricular neurotomy, and 16 other severe cases, comparable in all essentials with the first 23, were left untreated. In each of these 39 severe cases the patient when first interviewed had his name put on a waiting-list for trigeminal injection, which he was left free to postpone if his pain had abated enough. In 22 of the 23 neurotized cases (95.7%) trigeminal injection had to be carried out at most 85 days later, and in 14 of the 16 unneurotized (87.5%) it had to be carried out at most 148 days later. The average interval between entry into this clinical trial and injection was 21.4 days in the 22 neurotized and 22.1 days in the 14 unneurotized cases. One severe neurotized case and one equally severe unneurotized case, instructively, were on the right and left sides of a single patient. Twenty-one other patients with milder tic douloureux were similarly divided into 12 neurotized and 9 unneurotized and left to decide when they must undergo trigeminal injection, with similar results. Great auricular neurotomy, to judge from this trial, has no effect on tic douloureux.

We thank Mr. Wylie McKissock for encouraging us to do this work in his department, Professor A. Bradford Hill for valuable guidance and criticism, Professor T. Crawford and Dr. N. F. C. Gowing for microscopy of the excised portions of nerves, Miss Audrey Gear for her skill and patience in organizing the case records and the follow-up, and members of the almoners' department of the Royal South Hampshire Hospital for their prompt efficiency in tracing a psychiatrically ill patient who would otherwise have defaulted.

HAEMOGLOBIN C DISEASE AND TRAIT REPORT OF A FAMILY IN ENGLAND WITH HAEMOGLOBIN C

BY

H. M. RICE, M.D.

Director, Department of Pathology, General Hospital,
Nottingham

Abnormal, genetically determined haemoglobins are being recognized with increasing frequency as the cause of certain anaemias, generally of the haemolytic type. Their discovery has followed the application of electrophoretic techniques to the study of sickle-cell haemoglobin (S) by Pauling, Itano, Singer, and Wells (1949). The other human haemoglobins so far described are A (adult), C, D, E, F (foetal), G, H, I, and J; and the list is doubtless incomplete. The hereditary haemoglobinopathies occur almost exclusively in people of non-European descent, and principally in negroes.

Haemoglobin C was described by Itano and Neel (1950). Their cases were North American negroes, and the haemoglobin C was in the heterozygous state, with A or S. Homozygous haemoglobin C (haemoglobin C disease) was reported, again in North American negroes,

cases of aneurysm of the heart, of which four were in natives. Zuidema (1941) stated that cases are seen in Europeans, Indo-Europeans, and Chinese, but rarely in natives of Java, although hypertension and arteriosclerosis are common. He reported the cases of two Javanese, one of whom was a doctor. An extensive review of heart disease in Thailand was made by Bisal (1938). He analysed 530 cases admitted to Siraraj Hospital in Bangkok, of which 4.5% were described as arteriosclerotic in type. Although this group was further broken down the diagnosis of cardiac infarction was not mentioned.

Sengupta (1940) collected the cases seen at the Medical College Hospital, Calcutta, from 1931 to 1936. The total in this period was only 21, which was 2.1% of all cardiac cases. From correspondence I have had with Indian physicians I find the condition is not regarded as rare to-day, and Vakil (1949) has published a series of cases. In Ceylon the disease also seems fairly common now, Jayewardene and Jayasekera (1954) having collected 270 cases from the General Hospital, Colombo, during 1952 and 1953.

Scope of Investigation

This investigation covers the four years 1952-5. During this time all patients attending the Penang General Hospital who were found to have suffered from cardiac infarction were studied. Those with an old infarction diagnosed for the first time as well as those seen during an attack are included. The hospital is the main medical centre in the Settlement of Penang and Province Wellesley, which is situated in the north of the Malay Peninsula. Accommodation is graded into first, second, and third class. For third-class accommodation a small charge may be made, but most of the patients are treated free. The general medical beds of the hospital are divided into two medical units, each of which has 60 third-class beds and further beds in the better-class wards as required. Nearly all the cases were inpatients, but a few out-patients were seen in consultation. The diagnosis of cardiac infarction was based on definite changes in the QRS complex of the electrocardiogram, and a series of tracings was taken from each patient when that was possible. The customary twelve leads, occasionally more, were usually recorded at each examination. Post-mortem examinations are rarely permitted, and in only 4 of the 18 deaths was necropsy performed, and in these the diagnosis was confirmed.

In the four years 89 cases of cardiac infarction were diagnosed, an average of only 22 a year. During the same period a yearly average of 562 E.C.G.s were taken. The population of the Settlement from which these patients were drawn was 527,770 (estimation for 1954) and the average yearly admissions to the hospital were 9,396. The figure of 89 cases in four years is probably a little less than it should be, as fewer cases were diagnosed in the earlier part of the investigation. This may be attributed to shortage of staff and difficulties with the electrocardiograph, resulting in rather fewer recordings being taken.

Distribution by Sex, Age, Social Class, and Race

Of the 89 patients only 13 were women. Although this low figure for women may be partly due to the fact that fewer women than men are admitted to hospital, this explanation is quite inadequate, and the difference can be attributed to the different sex incidence for the disease. The ages of the men, by decades, are given in Table I.

TABLE I.—Age Incidence of 76 Male Patients

Age	No. of Cases	Age	No. of Cases
20-29 years	2	50-59 years	30
30-39 "	7	60-69 "	13
40-49 "	20	70+ "	4

The average age of the men was 52 and of the women 57. The youngest patient was an Indian Moslem aged 25 who worked as a boatman, and the oldest an Indian cowherd who gave his age as 81. The average age of the men by nationality was: Chinese, 55 years; Indians, 51; Malays, 50; and Europeans and Eurasians, 52. Thirty-two of the patients were admitted to first-class wards, nine to second-class wards, and 48 to third-class wards. The total admissions by class are not recorded in the hospital, but it is estimated that there are at least four times as many third-class admissions as first and second in the medical units.

The great diversity of races in Malaya gives an opportunity of comparing the incidence of cardiac infarction among them. Table II shows the estimated population of each

TABLE II

Race	Population of Penang and Province Wellesley (1954)	Average Yearly Admission	No. of Cases in 4 Years	Yearly Rate per 10,000 Admissions
Chinese	291,252	4,971	24	12
Indians	70,845	2,721	44	40
Malays	157,873	1,141	8	17.5
Europeans and Eurasians	5,226	454	11	60.5
Others	2,574	107	2	
Total	527,770	9,396	89	

race for 1954. As these races do not make comparable use of the hospital facilities the average yearly admissions by race are also given. The significance of the figures in Table II are discussed below. It should be pointed out that nearly all the Chinese originally came from South China, those from the Fukien Province being the commonest. Some of the Chinese patients were born in Malaya and most of the others have spent many years there. The Indians are mostly from South India, and include both Hindus and Moslems. Although the habits of these two religious groups differ it is not possible with such small numbers to make any subdivision. Like the Chinese, most have spent many years in Malaya.

Symptoms

A comparatively large number of patients in whom sound electrocardiographic evidence of infarction was found were unable to give a history of any definite episode to indicate the attack (Table III). Of those included under "typical

TABLE III

Class	Typical Episode	No Episode
First	30	2
Second	9	0
Third	26	22
Total	65	24

episode," two collapsed suddenly and died within three days, and one became unconscious but recovered. A fourth collapsed a week after childbirth, and the F.C.G. demonstrated infarction. Soon after this she suffered from hemiplegia. Practically all these patients had electrocardiographic tracings which indicated a recent infarction. A few gave a history of chest pain some time before coming to hospital. On the other hand, among the 24 without a history of an acute episode most of the tracings suggested old infarctions. This group usually presented with symptoms of cardiac failure, but one presented with a hemiplegia, one with cirrhosis of the liver and heart failure, and one with a vague history of weakness and oedema.

Two factors that are related to atheroma and so to cardiac infarction are diabetes and hypertension. Both these conditions are common in Malaya, but I do not know of any

significant figures regarding their incidence. Of the 89 patients with cardiac infarction, 11 were noted to have glycosuria, and consisted of six Indians, four Chinese, and one Eurasian. It is not so easy to assess the incidence of hypertension in the series, as many cases were on the borderline. If the diagnosis is based on the blood-pressure readings and E.C.G. tracings taken after an attack, there were only 15 with clear evidence of hypertension. This number is probably too small, and little weight can be attached to it.

Cases Outside the Hospital Practice

During the inquiry into cardiac infarction it became evident that the total number of patients with the disease was small and that the incidence seemed particularly low among the Chinese. It was therefore decided to seek further information on the subject from the 54 private practitioners of the Settlement. A simple questionnaire was sent to each asking for the number and nationality of patients with cardiac infarction that they had seen in the previous twelve months, excluding all who had been referred to the hospital. Answers were obtained from 44. Twenty-six had no cases, but the other 18 had seen 48—38 Chinese, 7 Indians, 2 Malays, and 1 other.

A further source of information was in the coroner's cases investigated by the Government pathologist. The only figures available were for a period of two years. In this time there were 16 cases—6 in Chinese, 4 in Indians, 5 in Malays, and 1 in Europeans.

When these figures are added to the hospital figures of Table II a more complete picture can be obtained (Table IV).

TABLE IV

	Population	No. of Cases per Year	No. of Cases per 100,000 of Population per Year
Chinese	291,252	47	16
Indians	70,845	20	28
Malays	157,873	6.5	4
Europeans and Eurasians	5,226	2.75	55

Discussion

The number of patients found suffering from cardiac infarction is not large or complete enough to allow of any dogmatic statements about the incidence of the disease among the peoples of Malaya. Other factors influence the value of some of the figures, and these are mentioned below. It is, however, interesting to note that the same trends for age, sex, and social status appear in Malaya as elsewhere. The distribution of hospital patients according to class shows that those of higher social classes are more often sufferers. There were nearly as many patients in the first- and second-class wards as in the third-class wards, in spite of the great difference in numbers admitted to these respective wards. About a third of those admitted to the third-class wards were engaged in the less strenuous or better-fed occupations such as coffee-shop keepers, clerks, etc. It should be added, however, that in some cases age or early heart failure may have driven them from manual work. More patients were treated by private doctors than were admitted to hospital, and this fact supports the opinion that the rich are more likely than the poor to be affected.

Is the disease less common in Malaya than in the United Kingdom? In comparing figures for these two countries a correction must be made for age because cardiac infarction is a disease of older people. In the last Malayan Census Report (1947) the number of the population aged 40 years and over is given as 219 per 1,000. This is only a little over one-half of the corresponding figure for England and Wales as given in the report of the Ministry of Health for 1953. My estimate for the Settlement of Penang and Province Wellesley is 78 cases in a population of 527,770. If an increase is allowed for the age distribution one has an inci-

dence of about 30 per 100,000 to compare with any United Kingdom figures. Unfortunately it is not easy to find in the literature suitable statistics for comparison. However, through the courtesy of Dr. G. M. Fyfe, who is studying coronary sclerosis in a Scottish county, I can make use of some of his observations. In a total population of 219,502 there were 429 cases in one year. This incidence is six to seven times greater than that which I have found in Malaya. Dr. Fyfe's figures were, however, obtained by a special scheme of notification by the medical practitioners of the area and should be more accurate and more complete than mine. They also include angina pectoris in the 429 cases. The difference, therefore, is probably less than the figures indicate.

The comparison of hospital figures is most difficult. The Penang General Hospital admits patients suffering from pulmonary tuberculosis, infectious diseases, and tropical diseases as well as those with general medical and surgical complaints. In two small hospitals in Scotland the average yearly admission for coronary sclerosis (mostly cardiac infarction) was 110 out of a total admission of 1,840. The Penang figures were 22 out of a total admission of 9,396. This difference is very great, but probably can be taken as little more than evidence of the different use that is made of the hospitals in these countries.

A further point of interest is the racial incidence. The impression gained in hospital work was that it was commoner among the Indians than among the Chinese. Further considerations modify this opinion and demonstrate how many fallacies there may be in attempting to analyse statistics in such a country as Malaya. For example, tuberculosis was one of the common causes for admission to hospital, the figures by nationality being available. In 1954 there were 491 Chinese admissions to 98 Indian. Whatever the cause of this difference it means that for other diseases the Chinese were even more reluctant to use the hospital than the figures in Table II indicate. Furthermore, the age incidence in hospital for these two races also differs, there being comparatively fewer Chinese in the middle group of 30-49 years. Out of 500 Chinese admissions, 196 were over 39 years of age and 124 over 49. The corresponding figures for Indians were 203 and 93. The number of patients reported by the general practitioners was dependent upon memory and cannot be accepted as more than approximately accurate. As nearly all the doctors work in the municipal area of Penang, and as the percentage of Chinese in this area is higher than in the Settlement as a whole, the figures have limited value in demonstrating incidence. The figures shown in Table IV, based on total population, indicate that the incidence among the Indians is nearly twice as high as among the Chinese, but this apparent higher susceptibility of the Indian must remain only a suspicion, as the evidence collected here is not good enough to offer statistical support.

In proportion to their numbers the Malays use the hospital less than the other races. It is certain, too, that they make little use of the services of the general practitioners. The figures available can be accepted only as evidence that infarction does occur in this race. The majority of Malays living a traditional country life as farmers or fishermen have little representation in the figures given in this paper.

One would like to give particulars of the diets and the people concerned. Some figures are available for the poorer section of the community, and these indicate that the intake of fat is low; but among the middle and upper classes the intake is probably quite high. Financially Malaya is more prosperous than most other Asian countries and the diet therefore correspondingly richer. So far as racial incidence is concerned it is of no value, however, to add inadequate diet figures to my own inconclusive incidence figures.

Lastly, it is of interest to consider the difference in symptoms as shown by the large number of patients who did not give a history of an acute episode. Parkinson and Bedford as long ago as 1928 described the type with dyspnoea and

heart failure without pain. In two recent papers (Papp, 1952; Roseman, 1954) on painless cardiac infarction the incidence is given as 4.6% (7 out of 150) and 4.5% (10 out of 220). In the present series it was 27% (24 out of 89), and this painless infarction was much commoner in the patients in the third-class wards; while Hunter (1946), in the U.S.A., found painless infarction commoner in the poor negro than in the poor white patient. The cause for this high proportion of painless infarctions must be conjectural. Perhaps some patients had forgotten the pain. To the educated man of to-day a pain in the chest is alarming, but to one who has never heard of coronary thrombosis and in whose life there have been many pains and hardships it may, unless very severe, be passed over as of little importance. One of the patients included here as a typical case came to hospital complaining of dyspnoea and swelling of the feet. It was only when the history was fully taken that it was learnt that he had had a pain in the chest two weeks earlier. It may be, too, that the pain in the poorer man is actually less severe; that just as the disease is less common, each attack may also be on the average less acute. Possibly the explanation is a combination of both suggestions. Whatever the reason may be, it is evident that the painless cardiac infarction is one of the causes of the not infrequent cases of heart failure of obscure aetiology found in the poor Asian patient.

Summary

The literature on cardiac infarction in South-East Asia is reviewed.

A series of cases in a Malayan hospital is described and further figures of patients seen by private practitioners are also given.

The difficulties in comparing the incidence either between Malaya and the United Kingdom or among the races of Malaya are discussed.

The figures that are given show that the disease is not a rarity in Malaya, but suggest that it may be less common than in the United Kingdom.

Among the different races of Malaya the figures available for Malays are too few for comparison. There is a suspicion that the incidence is higher among the Indians than among the Chinese.

In the symptomatology a high incidence of painless infarction is noted.

I wish to thank Dr. H. A. Reid, who has allowed me to include all his cases and has given other help; all the doctors of the Settlement who so kindly replied to my questionnaire; Dr. J. T. Boyd, of the London School of Hygiene and Tropical Medicine, for advice on statistics; Dr. G. M. Fyfe for figures of incidence in the U.K.; Dr. H. I. Williams for necropsy figures; and the following for answering other inquiries: Drs. F. R. Dieuaide, H. S. Gear, C. Gopalan, E. W. Graham, C. K. Menon, R. Subramaniam, and I. Simpson. I am indebted to Dr. R. E. Anderson, Director of Medical Services, Federation of Malaya, for permission to publish.

Medical Memoranda

Toxic Psychosis Caused by "Preludin"

"Preludin," a new drug for controlling the appetite, is, I believe, gaining popularity among those who for a number of different reasons try to slim. It was discovered in 1953 and first marketed in Germany in 1954. It has been on sale in this country for about twelve months. Below is reported the case of a young woman who took Preludin in large doses for its central stimulant effect, and as a result developed a toxic psychosis. This was at first thought to be a schizophrenic illness. I have not seen this danger reported before.

CASE REPORT

The patient, aged 29, was an assistant matron at an infants' boarding school run by her mother. She suddenly began to complain that the floor was magnetized and her jewellery electrified. In an attempt to insulate herself she had cut up her hot-water bottle. Her family looked after her at home until her admission to hospital three days later. On admission she was dishevelled, tense, depressed, and emotional, but otherwise there were no abnormal findings. Formal psychometric testing showed no confusion, no clouding of consciousness, and no disorder of perception. She was co-operative and expressed remorse for all the trouble she had caused. Chlorpromazine was given, and within a few days she calmed down.

On her third day in hospital her father telephoned to say that he had found amongst her belongings at home a large number of empty Preludin tablet containers. He estimated that she must have taken at least 1,400 tablets during the previous 12 weeks. He said that three months previously he had discovered she was taking dexamphetamine sulphate ("dexedrine") tablets, and had asked the near-by chemist shops to stop supplying her with this drug. The patient, when asked about the Preludin, admitted that her father was quite right. She had taken Preludin tablets in order to forget everything and to be able to go off and enjoy herself with her friends. She had needed about a dozen Preludin tablets to get the same effect as a few dexamphetamine tablets gave her.

A review of her behaviour over the three months before she had startled her family with her complaints that the floor was magnetized and her jewellery electrified revealed that she had been very irritable and suspicious. Her fiancé had commented that she seemed to "babble" at times. It had been noticed that she had seemed restless at night and unduly fearful of burglars. In fact, she had gone to the trouble of putting talcum powder on her window-sill so that fingerprints of any intruder would be readily available, and had placed small articles against the inside of her bedroom door in order to have warning if it was being opened.

Her previous personality was that of an unstable erratic girl who from childhood had been unreliable. Her personal history showed that thread of instability, lack of conscience, and disregard for others in her behaviour so characteristic of a psychopathic personality.

COMMENT

Preludin is claimed to produce early satiety of the appetite without disturbing side-effects. Any central effect is said to be only that of a very mild elation. Its chemical formula shows that it is an oxazine derivation of ephedrine, which is more closely related to caffeine than amphetamine. However, it is known that a toxic psychosis may occur when excessive quantities of either of these drugs are taken.

The toxicity of Preludin has been studied in mice by Thomä and Wick (1954), who found that, compared with amphetamines, the lethal dose of Preludin by the oral route is nearly five times as great. They also found that to produce the same degree of excitement in unanaesthetized dogs the amount of Preludin needed was six times that of

amphetamine. These last findings were confirmed in the human by my patient. As stated above, she needed many more Preludin tablets to obtain the same stimulant effect as a few of dexamphetamine gave her.

Preludin has been used in the treatment of psychiatric conditions. Spiegelberg (1954) has reported favourably on its use for "psychiatric conditions, psychopathic reactions, and endogenous depressive states." There are also reports on Preludin in the treatment of obesity by Berneike (1954) and Rostalski (1954) from Germany and by Gelvin, McGavack, and Kenigsberg (1956) from the U.S.A. In none of these series of cases are toxic manifestations reported.

Amphetamines were placed on the Schedule I list of poisonous drugs a few months ago. The occurrence of a toxic psychosis as a result of taking excessive doses of toxic Preludin—which is without some of the protective unpleasant side-effects of amphetamine—shows that the latest "slimming drug" is not without hazard and should also be placed on the Schedule I list.

Haemorrhage from Primary Carcinoma of the Liver Complicating Pregnancy

Primary carcinoma of the liver is a rare neoplasm. Of even greater rarity is sudden haemorrhage from such a growth complicating a pregnancy.

CASE REPORT

A Chinese woman aged 43, in the 30th week of her 13th pregnancy, was admitted to the Kandang Kerbau Hospital, Singapore, on June 23, 1956, complaining of abdominal pain, dyspnoea, and general malaise. Nothing abnormal was known of her previous medical and obstetrical history.

On examination her general condition was poor and she looked anaemic. There was some oedema of the feet and ankles. The heart sounds were normal and the blood pressure 140/80 mm. Hg. Several spider angiomas were present over the shoulders. On abdominal examination the size of the uterus corresponded to the period of amenorrhoea. A single foetus was presenting by the head, and the foetal heart was heard. No definite diagnosis was made.

Two days later her dyspnoea increased and engorgement of the neck veins was noted. The liver was thought to be of the neck veins was noted. The liver was thought to be palpable to a distance of two fingerbreadths below the costal margin. Some crepitations could be heard at the lung bases. Her temperature was 102.2° F. (39° C.). A provisional diagnosis of incipient cardiac failure was made and appropriate treatment instituted, including systemic penicillin.

The next day jaundice developed. Her haemoglobin was 42% (Sahli) and the total white-cell count 10,200 per c.mm. The urine contained albumin. Urobilin and urobilinogen were present. The icteric index was 40 and she had a direct triphasic van den Bergh reaction. A physician thought the condition was basically a lung infection with a superimposed infective hepatitis and mild cardiac failure due to her liver.

For the next four days her condition remained much the same. To counteract her anaemia a transfusion of packed red blood cells was given, and by July 6 she seemed rather better, although the jaundice had remained constant. A week later she became quite drowsy and complained of pain in the right hypochondrium. Her temperature was still raised. The liver was still palpable below the costal margin and tender. The possibility of amoebic hepatitis was considered. X-ray examination of her chest confirmed an upward enlargement of the liver as judged by an elevation of the right dome of the diaphragm.

On July 20 she developed severe upper abdominal pain, and a very tender mass was palpable in the right hypochondrium. The blood pressure fell and her pulse rate started to rise. The clinical picture suggested an "acute abdomen," and it was decided to perform a laparotomy. On opening the abdomen free blood and clots were found. The uterus looked normal. To facilitate the search for the source of the haemorrhage a classical caesarean section was performed and a live female infant, weighing 3 lb. 12 oz. (1,800 g.), was delivered. The bleeding was found to be coming from the liver. This organ was much enlarged and cirrhotic, and its capsular surface was covered with large clots of blood. It was obvious that nothing surgical could be done for the condition. A small portion of liver was removed for histological examination and the abdomen closed. The patient's condition was now grave and she died 14 hours later. Permission for a post-mortem examination was refused.

The pathologist's report on the biopsy specimen was: "The normal architecture of the liver columns is lost in many areas and the cells are many layers deep, with much mitotic activity. Areas of haemorrhage are also seen. Diagnosis: hepatoma."

COMMENT

All investigators are agreed on the comparative rarity of primary carcinoma of the liver. In a review of 76,776 necropsies performed in the United States of America, Blatchford (1952) found only 183 cases. Tull (1932) found 134 cases in a total of 17,664 necropsies performed in Singapore—an incidence of 0.76%. The disease appears to be less common in races living under the conditions of Western civilization and to be more common among tropical and Eastern peoples—for example, the Bantus of Africa, the Japanese, the inhabitants of South China, the Philippine Islands, and the Malay States (Webb, 1945).

It has long been recognized that primary carcinoma of the liver arises, almost invariably, in livers which are already cirrhotic. Muir (1908) pointed out that it is particularly prone to develop in that type of hepatic fibrosis characterized by conspicuous nodular hyperplasia. The racial and geographical incidence of the condition does suggest that primary carcinoma of the liver and "tropical cirrhosis" are associated, and the latter is now generally believed to result from a diet deficient in protein. There is good reason to suspect that this patient's diet, in common with that of many others in this part of the world, was deficient in protein, although containing enough carbohydrate to prevent marked wasting. In searching for aetiological factors attempts have been made to implicate infestations with intestinal parasites such as *Entamoeba histolytica*, *Schistosoma*, and *Clonorchis sinensis* as precursors of primary carcinoma of the liver, but no convincing evidence is available (Trevathan, 1954).

Haemorrhage from rupture of the liver in pregnancy has been reported in the literature in a number of cases, but the complication has usually been the result of the hepatic lesions of eclampsia. Rupture of the normal liver from direct trauma, unless of severe degree, is said to be unlikely. In the abnormal liver even minor trauma might precipitate a break in a capsule weakened by disease (Schnabel, 1935). Therefore, in any case of known disease of the liver, rupture of the organ should be thought of in the presence of a picture simulating a sudden acute surgical condition in the abdomen.

I thank Professor B. H. Sheares for permission to publish this case report.

Reviews

ROYAL NAVAL WAR MEDICINE

Medical History of the Second World War: Royal Naval Medical Services. Volume II—Operations. Edited by Surgeon Captain J. L. S. Coulter, D.S.C., R.N. (Pp. 543+xvii; illustrated. 57s. 6d.) London: H.M. Stationery Office. 1956.

"History," as Lord Acton said, "is better written from letters than from histories." And here the editor has followed that dictum, selecting from the wealth of detailed reports available among official records not only those which called for comment or prominence because of their special naval medical significance but also those which, in proper sequence and with due emphasis, gave rise to a balanced and just account of the work of the Royal Naval Medical Services in the second world war. Essentially it is the record of the doctor's work at sea in wartime, for that was the lot of most naval doctors, and this is portrayed by reproducing his own account of his experiences. Thus a graphic and accurate picture of the stress and hazards of the naval warfare of the time, and of the medical lessons to be learnt from them, is set forth quite simply in the log of a doctor in a cruiser guarding a Russian convoy. The medical consequences of submarine attack, of aerial bombardment, of bitter cold weather, and of the strain of prolonged action are thereby illustrated.

The war in the Mediterranean and in the Far East is treated similarly, and one may select some items of outstanding interest. These include accounts of specialized medical units ashore; of the fate of prisoners in Japanese hands as viewed by the medical officers who shared their captivity; and, perhaps most important of all, the account of what happened to a group of 48 men shipwrecked on a tropical island. Without a doctor and without an elementary knowledge of hygiene, these men suffered from much preventable disease, from apathy and loss of morale, and 20 of them died in a period of 14 weeks. How vitally important is the instruction of all naval personnel in the simple rules of preventive medicine! A wonderful story, too, is that of the Royal Naval Hospital at Hong Kong, which was overrun when that colony was captured by the Japanese. It is a record of quiet fortitude, unrelenting work, and brilliant improvisation under appalling conditions. And from defeat the story changes to the medical preparations for the landings on the Normandy coast, and so it goes on as the war ran its course.

This is the most readable official history I have encountered, and it is as far removed from historiography as could be imagined. It is to be recommended not only to those concerned with the Royal Navy and with medicine but also to everyone interested in a stirring chapter in our country's history.

W. D. W. BROOKS.

ANALYSIS OF PERCEPTION

Analysis of Perception. By J. R. Smythies, M.A., M.D., M.Sc., D.P.M. Preface by Sir Russell Brain, Bt., D.M., LL.D., D.C.L., P.R.C.P. (Pp. 170+xiii. 21s.) London: Routledge and Kegan Paul. 1956.

This is a rather short book dealing with a very complex topic. The author points out that the study of perception has been carried out by specialists in many different fields, such as philosophy, neural physiology, neurology, and experimental psychology. He adds, with some show of justification, that there has been little liaison between these various endeavours. He is concerned about the fact that most neurologists and neural biologists with philosophical interests adhere to a representational theory of perception which is rejected by most contemporary philosophers. In this book he has attempted to make the representational theory more acceptable to professional philosophers, and he illustrates his account with experimental data from mesca-line intoxication work and from experiments with the stroboscope.

The book will probably be of interest to philosophers rather than to scientists, who may occasionally wonder precisely what Smythies is trying to prove. His style is excessively abrupt and curtailed, making his presentation very uneven and difficult to follow. Whole chapters, such as Chapter 6, are included without any obvious reason, and might have been left out without altering the argument. On the other hand, certain important definitions are presented without sufficient discussion to make it very easy for the reader to see the rationale for the writer's choice, nor does he give a detailed discussion of the relevant psychological evidence. Thus take, for instance, his definition of "sense-datum": "If the boundary J of the after-sensation (hereafter y) can be observed to describe a Jordan curve in the total field composed of x and y such that it divides this total field into one *inside* and one *outside*, then x is a sense-datum." The writer nowhere makes clear why he chooses this definition rather than another; he never explains what a Jordan curve is (how many neurologists will be familiar with the *Cours d'Analyse*?); and he never touches on the difficulties raised for his definition by such phenomena as "Bidwell's ghost." Altogether an interesting but excessively undisciplined book, which may with advantage be read by the expert philosopher but will give little to the experimentalist.

H. J. EYSENCK.

THE RECOVERY ROOM

The Recovery Room—Immediate Postoperative Management. By Max S. Sadove, M.D., and James H. Cross, M.D. Contributions by 24 authorities. (Pp. 597+xxi; illustrated. 84s.) London: W. B. Saunders Company Ltd. 1956.

Writing the first chapter in this book, an administrator suggests that the intensive therapy unit, which is the natural progeny of the post-operative recovery room, is capable of three things: it improves nursing care, utilizes equipment and personnel more effectively, and assures the patient and his family that everything humanly possible is being done. The writer maintains, too, that such a service results in the lowest morbidity and mortality rates at lowest cost to the patient and hospital. Nothing in the way of figures is adduced in the text to substantiate this claim.

The joint editors have organized several recovery rooms; the large amount of information they have so gathered has, they humorously say in the preface, prevailed over their better judgment and impelled them to present it in this volume. In this enterprise they have been assisted by 24 authors representing some dozen specialties; nearly all are associated with the University of Illinois, Chicago. The management of patients in a recovery room is considered in detail. The control of pain and infection, of shock and nutrition, are first dealt with. There follow chapters dealing specifically with the post-operative management of patients in all specialties. Indeed, the book provides a manual of post-operative care. There is an additional chapter on the treatment of medical emergencies. The contributions are of variable quality and there is of necessity much repetition. Views differ on which patients should go to the recovery room. Some hold that every patient after even small procedures should be so treated; others that the service should be used only for complicated cases. Among the instructions given, the recommendations for the use of intravenous therapy and of antibiotics will seem to many over-elaborate; some drugs are difficult for British readers to identify from the trade names freely used.

There is a need for careful study of the principle presented by this book, in which much useful material has been assembled.

C. J. LONGLAND.

Brompton Hospital Reports, Vol. XXIII, 1954, contains 20 papers selected from among those published during the year by members of the staffs of the Hospitals for Diseases of the Chest and of the Institute of Diseases of the Chest. It also includes an index to all the previous volumes, and can be obtained from the hospital, price 15s.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY JANUARY 5 1957

PREPARATION FOR ACTION

The Negotiating Committee, under the joint chairmanship of Sir Russell Brain and Dr. A. B. Davies (acting for Dr. A. Talbot Rogers), is meeting the Minister of Health and the Secretary of State for Scotland on Friday of this week. This is nearly a year after the B.M.A. informed the Minister that the profession intended to make a claim for more pay in view of the increase in the cost of living since March, 1951. Since February last year the two sides have exchanged several letters, the Ministers have met the profession's negotiators on one occasion only, and the profession has backed up its insistence that the Government has a moral obligation to continue acting on the Spens recommendations by sending the Ministers a carefully argued legal statement of the case. But the Ministers have refused to acknowledge that the translation of the Spens recommendations into the changing post-war value of money was to be a continuing operation. In fact they have followed the example of a succession of Ministers who since 1948 have tried to ignore what is implicit in the reports of two interdepartmental committees, the recommendations of which were accepted by both Government and profession, and which persuaded a reluctant body of medical men and women to take part in the National Health Service in 1948. Doctors are united in considering that the Government, by its apparent repudiation of the Spens reports, has broken faith with the profession. The employees have lost all trust and confidence in their monopoly employer. One sign of the present discontent with the Government's attitude and the conditions of the N.H.S. is the fact that in recent months the number of doctors inquiring at B.M.A. House about possibilities of practice in the Dominions and elsewhere has increased from an average of three a week to about five a day.

This *Journal* went to press in advance of the meeting with the Ministers this Friday. In view of their attitude during the past year we shall be surprised if they do anything more than find another formula for saying "No!" Our negotiators have shown exemplary patience and great persistence, but, unless the

omens are brighter this Friday than anticipated, it may soon be time to admit that negotiations have failed to make any impression on the Ministers. The Negotiating Committee's powers are, of course, limited to negotiation on an increase in pay in terms of the Spens recommendations. If the Ministers bring these negotiations to a halt, then the organized profession as a whole will have to decide what its policy should be and what action it should advise. At the moment the important thing is to take the machinery for action out of moth balls. The recent meeting of the Council of the B.M.A. was followed by a meeting of the Trustees of the British Medical Guild, the membership of the latter being almost identical with that of the former. Both the Council and the Guild Trustees considered preparation for action to be urgent, and the Secretary of the Guild, Dr. A. Macrae, has invited doctors in different parts of the country to set up local committees of the Guild with membership representing all branches of the profession. It is proposed, too, that these local committees, when formed, should appoint local conveners or group organizers. The area covered by a Guild committee corresponds with the area of a local division of the B.M.A.

The Guild was established in 1949 to do those things which by its constitution the B.M.A. is prohibited from doing. The B.M.A. cannot undertake what would be held to be trade-union activities. The Guild can. The Guild cannot determine policy. The B.M.A. can and does. The Guild is an instrument for action, for carrying out legally policies decided by others. If, for example, the Representative Body of the Association decided to advise withdrawal from the National Health Service it would be the Guild which would organize and finance such action and compensate any member suffering serious financial hardship as a consequence. The money for this comes from the Trust Funds of the three main branches of the profession. It should be stressed that the activating of the Guild machinery is a precautionary measure—an obvious measure to neglect which would expose those responsible to justifiable criticism. If the profession is forced by the Government's failure to honour its word to consider withdrawing from the National Health Service—eventually, as some have suggested, to work in a new and better form of service—then the mechanism must be geared for action and well lubricated. This is what is being done now, no more and no less. No decision to act has been taken. When the Council of the B.M.A. meets at the end of January it will then know the outcome of this week's meeting with the Minister and the views of the Negotiating Committee on it. The profession may well be on the eve of a severe

conflict with the State, its present employer. That this has become possible is in itself an indictment of the N.H.S. To find the right answer to this and many other defects of the Service will call for an "agonizing reappraisal," and none are in a better position to do this than those who work in the Service. To find the right answers will require ripe wisdom, far-sighted statesmanship, and a determination to stick to principles in the face of possible sources of disagreement. In a conflict the Minister of Health, who by the nature of his office is first and foremost a politician, will undoubtedly take advantage of any division of opinion within the profession, a profession whose strong sense of individualism makes this at times seem easy. But a profession really united on the things that matter will win the day, however long the struggle.

ABNORMAL HAEMOGLOBINS

It has been known for more than 90 years that the haemoglobin of newborn infants differs from that of adults.^{1,2} Körber reported in his inaugural lecture at Dorpat University that placental haemoglobin differs from that of the adult in being resistant to denaturation by alkaline reagents. At birth more than half of the haemoglobin is of the "alkali resistant" type; from then on the concentration falls steadily, and usually none can be found after 4-6 months. The production of foetal haemoglobin is under a different genetical control from that of adult haemoglobin; it does not cause a disease, but its presence after the age of 6 months indicates that there is some interference with the production of normal adult haemoglobin. The inherited haemoglobinopathies cause anaemia within a few months of birth, and in cases of sickle-cell anaemia³ and thalassaemia¹ foetal haemoglobin is almost invariably found. It is present in some children with spherocytic anaemia, leukaemia, or even malnutritional anaemia of early onset.^{3,4,5} The haem is the same in both haemoglobins, but the globin moiety is different. Until recently no other human haemoglobins were known.

Then in 1948 H. Hörlein and G. Weber⁶ described a family with hereditary methaemoglobinaemia in which the behaviour of the globin was abnormal. On separating the globin from the haem and on reuniting them with those from normal persons it was seen that the patients' globin was incapable of forming a haemoglobin with the iron in the reduced form. In 1949 L. Pauling and his colleagues made the fundamental discovery that sickle-cell anaemia is caused by an abnormal haemoglobin.⁷

In 1910 J. B. Herrick⁸ noted that some negroes suffered from an anaemia which was associated with "peculiar elongated and sickle-shaped red corpuscles." It was then found that some healthy negroes had red cells which were normal *in vivo* but which became sickle cells on incubation *in vitro*.^{9,10} The sickling phenomenon was found to be familial and to be inherited as a single Mendelian dominant.^{11,12} At first it was assumed that the same gene produced in some persons an asymptomatic condition, the sickling trait, and in others a severe disorder, sickle-cell anaemia. J. V. Neel first suggested in 1947¹³ that there might be an alternative hypothesis, according to which the first was the heterozygous and the second the homozygous condition. In 1949 he presented convincing evidence,¹⁴ and simultaneously and independently the same hypothesis was advanced by E. A. Beet.¹⁵ Pauling's discovery of the sickle-cell haemoglobin fully supported the genetical theory. Carriers of the sickle-cell trait possess both the normal and the new abnormal haemoglobin, but in patients with sickle-cell anaemia only sickle-cell haemoglobin and no normal adult haemoglobin was found. The method by which sickle-cell haemoglobin was discovered was electrophoresis. In this technique proteins are dissolved in a buffer solution and an electric current is passed. The charge of the protein and therefore the speed at which it will migrate towards the anode or the cathode will depend on the difference between the pH of the buffer and the pH at which the protein is iso-electric. Normal haemoglobin is iso-electric at pH 6.9 and sickle-cell haemoglobin at pH 7.1; hence on electrophoresis in

an alkaline buffer normal haemoglobin migrates towards the anode faster than sickle-cell haemoglobin. The application of electrophoresis to haemoglobin has led to the discovery of seven, possibly eight or even nine, further haemoglobin variants. Fortunately at an early stage rules for their nomenclature were adopted. Normal adult haemoglobin is named haemoglobin A; sickle-cell haemoglobin, which was at first called B or b, is haemoglobin S; and foetal haemoglobin is designated by the letter F. All other haemoglobins are assigned letters of the alphabet in order of their discovery beginning with the letter C (since B or b had at one time been used for the sickle-cell haemoglobin) unless as in the case of the first three haemoglobins there is a letter with a special mnemonic association. Haemoglobins C, D, E, G, H, I, J, and possibly K and M (for the methaemoglobin of Hörlein and Weber) have been recognized. Apart from S and D they all differ in their electrophoretic properties. S and D cannot be told apart by electrophoresis, but the first causes sickling and the second does not. Not all these variants have been examined with equal thoroughness; some have been seen in only one or two families. It seems that they all are inherited as simple Mendelian characters, though H may not be present in the phenotype of the AH genotype unless formation of haemoglobin A is partly suppressed by additional thalassaemia.¹⁶ The haem is the same in all the haemoglobins; only for M has a specific difference been claimed in the visible spectrum, and only F has a specific spectrum in the ultra-violet region; no differences have been found in either the visible or invisible spectra. Haemoglobin S differs from all the others by its low solubility in the reduced form,¹⁷ but otherwise only very minor chemical and physical differences have been described. V. M. Ingram¹⁸ has recently compared the polypeptide chains—some thirty in number—which make up the haemoglobin A and S molecules. One chain from haemoglobin S differed in its electrophoretic and chromatographic properties from its counterpart in haemoglobin A. The difference between the two molecules seems to lie therefore not in the folding of the polypeptide chains but in the amino-acid sequence in one part of one of these chains. This is of genetical interest, because the formation of S must be due to the mutation of a single gene, and we may visualize gene action as directly affecting this aspect of haemoglobin synthesis.

Red cells which do not contain any haemoglobin A seem to be thinner than normal cells, with the exception of those of the one homozygote for G described so far.¹⁹ All the other homozygotes for abnormal

haemoglobins suffer from a haemolytic anaemia. Target cells are prominent in the blood smear, and Dr. H. M. Rice describes in this issue of the *Journal* (p. 25) a patient in whom this phenomenon led him to an examination for abnormal haemoglobin. The anaemia may be compensated in some instances. H. Lehmann and his colleagues²⁰ described recently two Burmese who were presumed to be homozygous for haemoglobin E. Though the mean corpuscular haemoglobin was greatly reduced, a compensating polycythaemia had restored the haemoglobin level to nearly normal. Dr. Rice's patient turned out to be homozygous for haemoglobin C, but once her anaemia of pregnancy was successfully treated her haemoglobin level rose to 14.7 g. per 100 ml., yet the proportion of target cells remained unaltered. Heterozygotes are usually quite unaffected, unless the single gene for haemoglobin A cannot find its full expression because of the presence of an additional thalassaemia gene. In thalassaemia no abnormal haemoglobin is found, but formation of haemoglobin A is suppressed. A severe haemoglobinopathy results in the thalassaemia homozygote—thalassaemia major—but even the heterozygote may present with anaemia of varying degree—thalassaemia minor.

Patients with haemoglobin S suffer pathological changes due to intravascular sickling in addition to the haemolytic anaemia. The crises and other thrombotic and infarctive events are restricted to the sickling homozygote or to sickling heterozygotes in whom the proportion of haemoglobin S is high; this is frequently the case in heterozygotes for S and C (sickle-cell-haemoglobin-C disease) and in AS heterozygotes with an additional thalassaemia trait (microdrepanocytic disease). Heterozygotes for S and D also suffer from a modified sickle-cell anaemia with sickle-cell crises. Cases have recently been reported of splenic infarcts even in simple AS heterozygotes who were exposed to anoxia as it occurs in high flying,²¹ and both sickle-cell homozygotes and heterozygotes are often unable to produce a concentrated urine,²² presumably because of intravascular sickling in the kidneys.

The geographical distribution of the abnormal haemoglobins suggests that mutations for a new haemoglobin gene must be rare. Haemoglobin C, the subject of Dr. Rice's paper, is found at high frequency in West Africa, and it has been found wherever West Africans have been brought. It is therefore seen in American negroes, in North Africa, and in South Africa, but not in East Africa.²³⁻²⁵ Haemoglobin S is found both in East and in West Africa and wherever African slaves have been brought

in the past. In Asia haemoglobin S is also found in some of the older populations of Arabia and India.²⁶ This has led to the suggestion that haemoglobin S arose in the Middle East in prehistoric times and that it found its way from there into Africa and India. Haemoglobin D is present in low frequency in India,^{27 27} and haemoglobin E is found further east in Siam,²⁸ Burma,²⁰ Malaya,²⁹ and Indonesia,³⁰ as well as in Ceylon, Bengal, and Cambodia. The influx of West Indians into Britain, as well as the presence of visitors of many races, makes it necessary to look for abnormal haemoglobins in likely patients with an obscure anaemia. Numerous target cells in the blood smear are in Britain usually associated with cirrhosis of the liver; as Dr. Rice's article shows, they may also be the first indication of a haemoglobinopathy.

SMEGMA AS CARCINOGEN

From time to time the suspicion has been canvassed that human smegma is carcinogenic. A preliminary report has recently appeared on a series of well-controlled experiments designed to throw light on this problem.¹ Human smegma was collected in sterile saline and centrifuged; the deposit was ground into a paste and stored in the refrigerator. This material was applied directly by specially devised instruments to the upper vagina and cervix of female mice of different ages and belonging to a special strain. In one group of mice one dose only of smegma was used; this was retained permanently by suturing the vaginal orifice. Two other groups received weekly and bi-weekly injections respectively. In yet other groups some of these procedures were supplemented by injection of oestrogen. In parallel experiments, the contents of human dermoid ovarian cysts, which closely resemble smegma in physical and chemical constitution, were used instead of smegma. Two groups of mice received bi-weekly vaginal injections of methylcholanthrene, a known carcinogen. Out of twelve mice receiving bi-weekly injections of smegma for an average period of 19½ months, four had frank invasive carcinomas, one had early carcinoma with borderline invasion, and two had changes identical with intra-epithelial carcinoma. The remaining six showed epithelial hyperplasia. A similar

change but without definite invasion was produced in eleven of twenty-six mice receiving weekly injections for an average period of 15½ months. A single injection of smegma with vaginal ligature also gave a few positive results, including one carcinoma, one possibly malignant papilloma, and two sarcomas. Oestrogen appeared to inhibit the action of smegma. A comparable number of positive results was obtained with the contents of ovarian dermoid cysts and by methylcholanthrene. The gross and microscopical features of the lesions produced are comparable to those found in the human cervix. These experiments show that human smegma has a carcinogenic effect on the squamous epithelium of the vagina and cervix of the mouse. The possibility that it may be a factor in causing cancer of the penis and of the cervix uteri in the human subject must therefore be seriously considered. It has been suggested that certain bacteria—for example, *Mycobacterium smegmatis*—may act upon cholesterol (a lipid found in smegma) and convert smegma into a carcinogen. Experiments along these lines are not yet completed. I. Hieger and S. F. D. Orr² have reported the occurrence of sarcomata in mice following injection of commercial and purified cholesterol, after a long latent period.

The effect of circumcision on the subsequent development of carcinoma of the penis is well known. F. Homburger and W. H. Fishman³ give the incidence as follows: In Jews, in whom circumcision is performed during the first eight days of life, 0%; in Mohammedans, in whom circumcision is practised between the ages of 3 and 14 years, 1.5 to 2.1%; in the Chinese, non-circumcised, 15% of all cancers. In contrast, the rate in Europeans is considered to be less than 5%. E. L. Kennaway,⁴ after an extensive inquiry, reached similar conclusions, and stated that the difference in susceptibility between the Jews and Moslems was due to the fact that "the train of events leading to the malignant growth is set going early in life, and that removal of the cause does not then avert the development of cancer at a much later date." He does not consider that the protection given by the Jewish operation is due to the removal of the cancer-bearing area but that "the influence of phimosis in predisposing to cancer of the penis suggests that the carcinogenic agent is formed in material between the prepuce and glans." Homburger and Fishman suggest that a long period of contact between the penis and the carcinogen contained in the smegma of the penis is necessary to foster the susceptibility of the penile tissue to undergo cancerous transformation at a later date. It has also been suggested that circumcision may be an important factor in the prevention of carcinoma of the cervix uteri. The rarity of this condition among Jewish women has been noted by several authors, and F. Gagnon,⁵ and later J. E. Towne,⁶ have described a low incidence in nuns. W. Sampson Handley⁷ found that in the Fijian Islanders cervical carcinoma was eight times commoner among a group of Indian immigrants not practising circumcision than among the natives who do. On the other hand, recent statistics collected by J. M. Montpellier⁸ in Algiers showed that cancer of the cervix is not rarer in

the Jewish and Mohammedan women than in the European, and figures quoted from Constantine showed a similar trend.

In a recent review of the aetiology of cervical carcinoma W. L. Williams and C. C. Erickson⁹ discuss three possible causative factors— inflammation, pregnancy, and hormones. Cervicitis is prevalent among women and is often associated with cervical laceration and erosions following childbirth. The long-continued irritation in consequence of the inflammation may increase the susceptibility to the development of cancer. The importance of pregnancy is indicated by the fact that carcinoma of the cervix is much more frequent in women who have borne children than in nulliparae. Some authorities hold that oestrogen may play a part in the production of carcinoma of the uterus in humans, not only of the body but also of the cervix, but further work is required on the subject. W. U. Gardner and his associates,^{10 11} however, have reported the appearance of metastasizing cancer of the cervix in mice following injections of oestrogens. These considerations suggest that a carcinogenic action of human smegma in relation to carcinoma of the cervix uteri would appear to be less direct and more remote than in the case of carcinoma of the penis.

OCCUPATIONAL MORTALITY IN SCOTLAND

No regular relation between social class and general death rates is to be seen in the figures for Scotland covering the years 1949–53. The latest Annual Report of the Registrar-General for Scotland,¹ which includes a section on occupational mortality based on the 1951 census population, shows that the comparative mortality for adults aged 20–64 for social classes 1 to 5 was 107.9, 86.2, 102.5, 90.3, and 112.6 respectively (in comparison with 100 for the whole of this population). Within the social classes there was considerable variation between occupations; in social class 3, for instance, mineworkers and clerical workers had a mortality above the average with rates of 137.9 and 124.9, while agricultural workers in class 4 had the low rate of 71.9. The high rate for clerical workers was largely due to the heavy mortality from respiratory tuberculosis and from coronary thrombosis, with rates of 123 and 143. Mineworkers had a very high rate from accidents, 203, while clerical workers had a very low rate, 58. Other high comparative mortality rates for violence, for males aged 15–64, were 209 for water transport workers and 200 for fishermen. Social class 1 had the high comparative mortality of 113 from accidents at ages 15 and over; this is rather surprising, since this class has little occupational risk. The rates for accidents for social classes 2 to 5 were 85, 94, 110, and 124.

The comparative mortality for males aged 15 and over from tuberculosis was over twice as high in the lowest social class as in the top classes, the rates for social classes 1 to 5 being 61, 59, 102, 90, and 143. The rate

for tuberculosis varied widely in the various occupational groups, from 39 for agricultural workers to 187 for unskilled workers. Other high tuberculosis rates were 159 for tanners and leather-goods makers and 145 for those professionally engaged in entertainment and sport; low rates were 46 for persons in administrative occupations and 65 for professional occupations. The mortality from coronary thrombosis declined continually with descending social class from 167 in social class 1 to 79 in social class 5, and within the social classes the sedentary occupations had the largest rates. The mortality from vascular lesions showed a similar trend, falling from 128 in social class 1 to 95 in social class 5. The trend was reversed for bronchitis and pneumonia, the rate rising from 63 in social class 1 to 135 in social class 5; the highest rates were found among unskilled workers, 174, and the lowest were those of fishermen, 51, and agricultural workers, 52. Cancer was not related to social class. The rates were 104, 93, 109, 96, and 106 for social classes 1 to 5, respectively, and ranged from 88 to 167 within the main occupational groups.

HEALTH OF SCHOOLCHILDREN

Twenty-five years ago a medical officer examining the children in an elementary school in an industrial area might have expected to find about 5% of them suffering from malnutrition and about 25% in need of medical or surgical treatment.¹ Since then the change for the better in the health of children has been as remarkable as it has been gratifying, and the Chief Medical Officer of the Ministry of Education is now able to report² that in 1955 "the physical condition of the great majority of the children was found by school doctors to be satisfactory, only 1.45% being regarded . . . as unsatisfactory." Not only are the average heights and weights of children still increasing, but in Liverpool, for instance, the average weights of 8- and 12-year-old boys and girls considered to be in good health in 1925–7 were less than those of boys and girls of similar age but judged to be in poor physical condition in 1953–5. There is now some evidence that the number of children who are grossly over-weight is increasing.

So far as respiratory diseases are concerned, asthma and bronchitis are still easily the commonest disorders found at medical inspections, and about 1,000 children with asthma are in schools for delicate children. The decreasing prevalence of juvenile rheumatism is reflected in the reduction in the number of children with rheumatic heart disease in special schools. Even so, the Chief Medical Officer estimates that there are probably about 2,000 new cases a year in England and Wales, though only a small minority of the children are left with a damaged heart. Tuberculosis has also greatly declined as a killing disease of children: between 1938 and 1955 deaths fell from 973 to 54. Education authorities

should now be well aware of the possible danger of children contracting tuberculosis from their teachers, and in 1955 about 1,000 teachers (out of 250,000) were under supervision because of pulmonary tuberculosis. From the mortality figures it might be thought that diphtheria is becoming an insignificant disease, only 5 deaths being reported in 1955, compared with 1,733 in 1938. But towards the end of 1955 there were three small outbreaks of the disease, one of them occurring in a residential school for 80 educationally subnormal boys. In this outbreak there were 19 cases, and 18 carriers were found. Only 40% of the boys had been immunized. This should serve as a warning of what might happen if the proportion of children immunized against diphtheria became dangerously low.

About a quarter of a million children are still found with verminous heads, and in some schools the percentage of verminous children is as high as 15. High infestation rates occur for the most part in areas where the housing is poor and overcrowding at home is common. In contrast to some of the other infections of childhood, both food-poisoning and dysentery are tending to increase rather than decrease. There were 60 outbreaks of food-poisoning in schools in 1955, and in more than half of these the cause was not discovered. At one school there were two outbreaks of food-poisoning due to *Cl. welchii* in five days. On both occasions meat was cooked 24 hours or more before being eaten cold, and an important factor in both outbreaks was a faulty refrigerator.

Urging close and friendly co-operation between the school health service and the family doctor, the Chief Medical Officer recommends that a précis of a child's school medical history should be sent to the family doctor when the child is about to leave school: this, he writes, "should be a permanent feature of the school health service everywhere."

TRIBUTE TO A CARDIOLOGIST

The British Cardiac Society has paid Professor Crichton Bramwell an unusual compliment by dedicating to him the fourth issue of the *British Heart Journal* in 1956 (vol. 18, No. 4), on the occasion of his election to honorary membership of the society. In an introductory note, Dr. Maurice Campbell, the editor of the *British Heart Journal*, describes Professor Crichton Bramwell's services to the society and mentions some of his more important contributions to cardiology. He became a member of the Cardiac Club, the predecessor of the Cardiac Society, in 1923, the year after the club came into existence. From 1928 to 1932 he was secretary of the club, and in 1937 he presided at a special meeting at which the decision was taken to launch the larger Cardiac Society. Shortly after this the society asked the B.M.A. to publish a journal that would meet its special needs, and, the Association having agreed, the first number of the *British Heart Journal* appeared early in 1939, with Professor Crichton Bramwell as one of the original members of the editorial board. It is fitting

that the first four articles in the issue dedicated to him should come from the department of cardiology at Manchester, of which he was the distinguished chief until his retirement in 1955.

NEW YEAR HONOURS

Four medical men received knighthoods in the New Year Honours List—Professor G. L. Brown, F.R.S.; General W. A. D. Drummond; Mr. C. D. Read; and Sir Arthur Porritt—and Dr. Janet Vaughan is made a D.B.E.

Professor Brown succeeded Sir Charles Lovatt Evans as Jodrell Professor of Physiology at University College, London, in 1949, and a year ago was elected biological secretary of the Royal Society on the retirement of Sir Edward Salisbury. During the last war he brought to the study of the efficiency of naval personnel a deep experience of neurophysiology gained during the 1930's at the National Institute for Medical Research, partly in Sir Henry Dale's laboratory. He has been a member of the Medical Research Council since 1951 and chairman of its Royal Naval Personnel Research Committee, and his interests have naturally been centred on studying the transmission of nervous impulses. General Drummond was appointed Director-General of Army Medical Services just over a year ago. Commissioned into the R.A.M.C. in 1925 (in the last batch of candidates to be put through a special entrance examination), Drummond early took a special interest in E.N.T. surgery, becoming adviser to the Army in otolaryngology during 1946–51. In the second world war he served in the Middle East, and in addition to British distinctions received a Polish Order for many services to the Polish Army, under General Anders, both in Perthshire and in the Middle East. He was appointed Deputy Director-General in 1954. Sir Arthur Porritt, who received the K.C.M.G. in 1950, is now made a K.C.V.O., an additional honour that will evoke a ready welcome among his innumerable friends throughout the British Commonwealth, and indeed in many countries beyond it, for his travels have been extensive, whether to lecture on surgery or to give advice on sporting affairs. Sir Arthur holds the appointment of Sergeant-Surgeon to the Queen. Mr. C. D. Read was elected President of the Royal College of Obstetricians and Gynaecologists in 1955. Since 1950 he has been Director of the Institute of Obstetrics and Gynaecology at the Postgraduate Medical School, London, a post created on the retirement of Professor James Young from the professorial chair. Like Sir Arthur Porritt, Mr. Read is a New Zealander. Dr. Janet Vaughan has been Principal of Somerville College, Oxford, since 1945. She carried out many studies of blood diseases at the Postgraduate Medical School in the 1930's, and during the war played a leading part in organizing the country's blood transfusion services. Latterly her researches have been mainly into the experimental absorption, deposition, and excretion of radioactive strontium and yttrium. This recognition of her great gifts, both academic and administrative, will be widely acclaimed.

COMMON INFECTIOUS DISEASES IN GENERAL PRACTICE: CLINICAL*

BY

G. I. WATSON, M.D.

Infection is a reminder that our existence in this world is constantly challenged by our microscopic neighbours. They came first, and our capacity to resist them is a prime condition of our survival. Consideration of this may help us to keep in focus the nature of parasitic invasion and the importance of the body's response to infection. The better we understand, the more useful we can be to sick people during these not infrequent episodes of their lives. In my practice in January, 1955, infectious diseases accounted for 70% of 113 new visits—50% in children and 20% in adults. Even in July they accounted for 50% of 90 new calls—40% in children but only 10% in adults.

The prevalence of these different infections has varied throughout history. In this country infectious diseases fall broadly into two main groups, those due to viruses and others due to bacteria. Some of protozoal origin, which remain common in tropical countries, are to-day rarely encountered here. Those variations reflect the barrier that we have successfully put up between ourselves and the insect parasites since the time when malaria, plague, and typhus were frequently seen in English homes.

In more recent years another barrier has been created—namely, chemotherapy and the antibiotics. These selective weapons have brought us temporary respite from most of the pathogenic bacteria—for how long we cannot yet clearly foresee. Against what are possibly man's older enemies, the viruses, we still have only our natural resistance to rely on. The responses of the body to parasitic invasion and the damage done by the invaders together make up the varied clinical picture of infectious illness.

Identification over the Centuries

Over the course of centuries first one and then another of these common patterns have been identified and described (Osler, 1912; Encyclopaedia, 1952; Walker, 1954). Plague, (Osler, 1912; Encyclopaedia, 1952; Walker, 1954). Plague, leprosy, malaria, phthisis, and probably cholera had all been mentioned or described before 500 B.C. Tapeworm infection was known to the Jews of the Captivity, and the diphtheria with paralysis of the palate is referred to in the Talmud. Pneumonia with pleurisy, and mumps with its orchitis, were described by Hippocrates 300 years B.C. The association of rabies in dogs with hydrophobia in man was known to Celsus 100 years B.C. On the other hand, although smallpox has been recognized as affecting an Egyptian mummy of about 1000 B.C. (Osler, 1912), the first extant clinical description of it dates only from about A.D. 900 by Rhazes, of Basra. He also first described measles, but as a mild form of smallpox, not as a separate disease. It was Sydenham, in 1675, who first showed that these two were distinct, who also named scarlatina and mentioned its variations in virulence. Just before his time three other common diseases had been first identified—syphilis in 1493, chickenpox in 1553, and whooping-cough in 1578. After Sydenham there was another lull until German measles was described in 1752. The early nineteenth century saw several more diseases separated from the general welter of infection

*Opening paper in the Section of General Practice at the Annual Meeting of the British Medical Association, Brighton, 1956.

—cerebrospinal fever in 1805, typhoid in 1813 and 1829, herpes zoster in 1831, and infantile paralysis in 1840.

All these descriptions were based on man's unaided senses, but during the second half of last century microscopy helped to quicken the pace, and provided doctors with a means of detecting hitherto invisible differences between one man's illness and another's. Then with the discovery of filterable or ultramicroscopic forms of parasitic life a new chapter was opened, written in a language difficult to read. We in our lifetime are at long last seeing what is known about viruses translated into practical help for the clinician, by means of serology linked with modern tissue culture.

While the discovery of antibiotics has opened the way for the virtual elimination of bacterial diseases as a major cause of human suffering, viral infections—which so far remain largely outside the control of antibiotics—have assumed a fresh importance (Andrewes, 1953). The clinician has once more been thrown back upon his own resources, and must needs study these infections minutely as of old in order to see if he can detect any further differences between the clinical patterns of many undiagnosable epidemics. An accurate description of such a pattern still remains an important duty of every family doctor; the encouragement and collection of these reports is a main objective of the Epidemic Observation Unit of the College of General Practitioners.

Evidence of Infection

First let us consider how we decide that a patient's illness is due to an infectious agent. Evidence falls into two broad categories—that from the patient and that from his associates. In the patient we find first a general reaction—fever and its symptoms. I hold the opinion that we should aim at teaching someone in every household to read a thermometer and to record their measurements on paper for us. I transfer such figures on to a usefully small pocket chart, which covers four weeks. The pattern of fever can be of diagnostic value and may guide us, too, in the duration of our treatment. Speaking of charts, I also encourage my patients with pertussis to keep "cough charts" for me, showing the total number of coughs, whoops, or vomits which occur each day. Such records occupy the children and give a good visual guide to their progress and to the value of one's treatment.

In our patient we next look for evidence of local tissue changes and their symptoms. The meaning of some physical signs is not yet fully understood—for example, painless enlargement of the posterior cervical lymph nodes. A pilot survey among children carried out at his surgery by Dr. J. R. Robertson showed that palpable enlargement of the post-cervical lymph nodes was seldom found in infants, became increasingly common in children of 5–8 years, and was less frequent again in the "teens." This subject is now being further studied in the S.E. England Faculty of the College of General Practitioners, with the help of Dr. I. M. MacDougall, County Medical Officer of Health for Hampshire.

The old physicians examined their cases with the greatest care, discovering, for example, the friction rub of pleurisy, the sweet taste of glycosuria, and Koplik's spots, which are still taken on trust by some of us. The importance of searching for physical signs can be exemplified if we consider how difficult it would be, even now, to distinguish measles without its rash. We need to study the non-exanthematous viral diseases more closely, looking and feeling for fresh abnormal signs. Blood examinations, including serology in the acute and convalescent stages, throat swabs, or throat washings of the patient and his immediate contacts, the collection of sputum for bacteriology or of faecal specimens for both bacteriology and sometimes for virus isolation—these can all on occasion be important laboratory aids, but not short cuts, to diagnosis. Nothing can take the place of regular and frequent examination of our puzzling cases of infectious disease, for it is at the bedside that we will detect our first glimpse of a new syndrome.

A Fruitful Field

Another fruitful field for inquiry and research in general practice is the evidence which we can gain from our patient's associates. Contacts, incubation periods, and quarantine are the stock-in-trade of our young patients and their parents, both in term-time and in holidays. But what a lot we still have to learn. For example, just how long before or after the rash of measles and chicken-pox or the swelling in mumps is a patient really infectious? Does the duration of contact matter? Does it differ indoors from out-of-doors? I make a plea for the publication of every good example of a single short contact before or after the primary illness which leads to infection of the secondary cases. I have seen measles spread by a 10-minute contact out-of-doors on the day before the rash. Such records would help to fill in many gaps. For example, are we sure yet that the incubation period of glandular fever is short—5 to 12 days, as is usually stated (Price, 1946)—rather than a much longer one, as in mumps or hepatitis? In this respect we should take care to use the term "serial interval," rather than incubation period, when we measure, for example, from rash to rash, rather than from contact to the onset of illness.

Infectivity seems to vary from one outbreak to another, especially in mumps. I am familiar with the family contacts of this disease going down one by one throughout the summer holidays. An epidemic in my practice went through 11 generations of infection. I have heard, too, of a family in Mauritius, with 12 children and many servants, who were in quarantine for mumps for more than a year. Once, however, I had a schoolboy return with mumps into a large family, none of whom had had the disease. My usual forecast was confounded when his mother and her five other children all developed mumps on the same day, the day they were moving house. They all went by ambulance.

As regards quarantine, is it not time that our profession challenged the schoolmasters, or rather mistresses, particularly over the question of German measles? I would like to encourage "German measles tea parties" to which an infected girl might invite her non-immune school friends, or a holiday camp run by the Medical Research Council, where an attempt could be made to keep a culture of the disease going by constant replenishment among the young volunteer visitors.

Seasonal Prevalence

Consider, now, another aspect of the differential diagnosis of infections of unknown origins—namely, the value of learning the seasonal prevalence of some of the diseases that are less well known. Winter vomiting disease is coming to be recognized for what it is—a common disease among our patients. It appears to occur sporadically throughout the year, becoming epidemic in the autumn, perhaps decreasing in the coldest weather, and increasing somewhat again in the spring. The spread of winter vomiting disease has been traced by collective reports from 158 family doctors, each of whom saw a few cases for only a few days or weeks. The reports gave details, not of patients, but of the presence or absence of an outbreak in the district.

The season for Coxsackie virus infections is not yet well established. In several years, about April, I have seen little groups of cases of sudden dry pleurisy that may have been Bornholm disease. During the late summer and autumn I have followed an outbreak of Coxsackie virus infection from Oxford to Shere, through seven generations of infection. None of these cases really looked like non-paralytic poliomyelitis: the onset of high fever was very sudden—one boy took ill while on a swing; the children neither felt nor looked as ill as their temperatures suggested; many of them had unduly pink-looking eyes but no photophobia; there was headache but no dorsal spasm; the fever ceased without drugs in 24–48 hours; and convalescence was rapid (College of General Practitioners, 1954).

A.P.C. Group of Viruses

In June, 1955, I was privileged by their medical officers to visit two public schools where outbreaks due to viruses of the adenoidal-pharyngeal-conjunctival group, recently identified in America (Huebner *et al.*, 1954; *Lancet*, 1955), were occurring. Serological tests in a family in my own practice then showed that an outbreak of conjunctivitis among them just previously had also been due to a similar virus. We have no idea yet how prevalent these A.P.C. virus infections really are. In the following September and October an epidemic among schoolchildren at another village in my practice, associated with high fever, headache, mild sore throat, abdominal pain, and glandular enlargement, was proved almost certainly to be due to a virus of this same group; and in May, 1956, a boy with "pink eye" and high fever was also found to be positive. Here, then, were three such outbreaks in one practice within a year.

I had a chance to make use of my clinical observations about the autumn epidemic which I saw. During it one of the schoolboys, not yet affected, broke his leg and was admitted to hospital. I phoned the house-surgeon later and warned him that if the boy suddenly developed a temperature of 104° F. (40° C.) there might be no need for alarm. He duly did so, and it was in fact from him that we obtained serological proof of the nature of his infection. The first boy to take ill in this epidemic was admitted to hospital and had his appendix removed, being afterwards labelled as acute non-specific mesenteric lymphadenitis. On the day after he was taken ill several more of his schoolmates went down, and it was clear that we were dealing with an epidemic. Perhaps we should test future cases of mesenteric lymphadenitis serologically for evidence of recent infection by A.P.C. viruses.

Before leaving the subject of differential diagnosis of infections of unknown origins, I would like to emphasize this reddening of the conjunctivae. It is a feature of several virus diseases; measles, of course, is the best-known example, but the reddening of the eyes in some patients with A.P.C. virus infection is even more striking. Injection of the conjunctivae in a feverish child should put us on guard that we may be dealing with a viral rather than a bacterial infection.

I now raise the subject of the comparative severity of viral illnesses in primary and secondary cases, and in children of different ages. For some years I have had the impression that secondary cases of chicken-pox are more severely affected than the primary, if all are in the same house. This factor of house contact seems to override the factor of age in determining severity, especially in chicken-pox, and may be due to a heavier infection contracted over a longer period; otherwise both in chicken-pox and in measles I observe that the younger children suffer a lighter attack, while teenagers and adults are usually more severely ill (Watson, 1954).

Problems in Treatment

A mother often first recognizes that her child is feverish between tea-time and going to bed, or because he cannot get to sleep. It follows that in general practice a doctor frequently starts his treatment of infectious disease towards nightfall. What can he do to help? When I diagnose a bacterial infection likely to respond to an antibiotic—for example, acute sore throat or otitis media—I consider that immediate treatment should be given, whenever possible, with penicillin by injection. I prefer this to a sulphonamide because of its rapid action without the risk that vomiting may delay the start of effective therapy. The pain of early acute otitis media may cease within three hours after an injection of 500,000 units of penicillin G without any other drugs being given. Later doses of penicillin can be given orally. If, however, the diagnosis is in doubt, or where I suspect I am dealing with a viral infection, I prefer to see what the morrow brings. During the summer or autumn I tend particularly to avoid parenteral penicillin

in a child with fever until the need for it is clear; at that season I prefer to give penicillin in liquid or tablet form rather than by injection, especially if poliomyelitis is prevalent locally.

At my first visit, before leaving I shall be asked for "something for the night." Until recently I was as content as anyone to prescribe aspirin for this purpose in a feverish patient, but three years ago a case "went wrong," which made me stop to think. We are all familiar with the similarity between aspirin and cortisone in suppressing the inflammatory reaction of the body in rheumatic disease. Cortisone also suppresses the body's reaction against all parasitic infection, and, for example, may liberate a latent tuberculous focus. Has aspirin this danger too? I believe that recovery from influenza may be delayed by aspirin, and that a sore throat can become more extensively affected. Some of the prostration in those who have dosed themselves with aspirin compounds before asking for our help is due, I believe, to their reduced resistance. This is a problem, however, which needs much more clinical and laboratory investigation. For example, is aspirin dangerous in poliomyelitis? Can it, like cortisone, increase the susceptibility of healthy rhesus monkeys to infection by poliomyelitis virus? Can it influence the amount of paralysis resulting from invasion by this virus? Should we warn our patients against their ready use of aspirin for fever and headache, especially during the summer and autumn?

I try now to avoid prescribing aspirin at night except in hyperpyrexia, and am looking for a good sedative and analgesic for children which is not antipyretic.

While on the subject of symptomatic treatment, there is a use of antihistamine drugs to which I would like to draw attention. For several years I have been using full doses of mepyramine maleate in children with chicken-pox for the irritation which characteristically accompanies the rash (Watson, 1954). In children who were expecting an attack and who have been able to start taking their tablets as soon as the rash appeared I have found that the eruption is as the rash appeared in two respects: first, a smaller proportion of the spots go on to form blisters by the fourth day, and, secondly, around each blister the ring of erythema is smaller. In one family the mother was kind enough to attempt a measurement of the first difference for me on her two boys. The elder was not treated with mepyramine, as I was away; on his front he had 154 spots, of which 45 blistered (29%), and on his back 211, of which 39 blistered (18%). His younger brother had a heavier crop of spots, (or 18%). His younger brother had a heavier crop of spots, as I expected, being the secondary case, and fever to 102° F. (38.9° C.) for four days. But of his 286 spots in front only 31 (or 11%) blistered and only 28 (9%) out of 314 on his back (see Table).

Effect of Mepyramine Maleate on Blistering in Chicken-pox

	Age	Number of Spots			
		Front		Back	
		Total	Blistered	Total	Blistered
D.C.	9	154	45 (29%)	211	39 (18%)
P.C.	7	286	31 (11%)	314	28 (9%)

College of General Practitioners' Report

On the subject of treatment, I want finally to refer to the prophylactic use of sulphonamides and antibiotics, particularly in measles. Three years ago about 130 of us in general practice agreed to keep records about our cases of measles in a way that could subsequently be analysed. We hoped to measure some of the influences which affect the likelihood of complications arising in any particular child, to see how these could be prevented. The results of this investigation, based on 4,728 records, have been published by the College of General Practitioners (1956).

In children who were healthy at the onset of their measles we found that it was the severity of the measles itself which mainly determined the incidence of complications. Among

mild cases the rate was only about 4%, among the average cases it rose to about three times, and among severe cases it was ten times this figure. There were proportionately more mild cases of measles among infants and young children than among those of school age. In children under 5, the proportion of mild cases was slightly but significantly higher among those who were breast-fed than among those who were not. If complications did arise in young children they were more likely to affect the chest than the ear; among previously healthy children, acute otitis media was not seen under the age of 2. For each grade of severity the incidence of complications scarcely varied in different types of practice—urban, mixed, or rural; but gross overcrowding in any house nearly doubled the incidence of complications compared with an ordinary house. If instead of being healthy the child showed at the first visit physical signs that were not normal in measles, the incidence of complications rose from 4% to about 20% in mild cases, to about 40% in an ordinary attack, and to 66% if the measles was severe. Even a past history of infections of the ear or chest increased the complications rate, particularly when the measles itself was mild; this was also true if the child was one whom we would call "catarrhal." These differences, however, were less striking among the average cases and not noticeable where measles was severe.

Instead of lowering the total incidence of complications in measles, the use of sulphonamides as routine, without reference to any of these factors, raised it slightly in all types of practice and for all grades of severity. In measles of average severity, however, the incidence of acute otitis media and other aural complications was lowered by the routine use of sulphonamides, though only at the cost of doubling the rate for pulmonary complications. The routine use of oral penicillin or other antibiotics lowered the total incidence of complications slightly. It had least effect upon the rate for otitis media in the ordinary case and most upon the rate for pulmonary complications in severe measles.

To sum up, the routine use of antibacterial drugs confers little or no benefit on a healthy child undergoing an ordinary attack of measles, and indeed it may do harm. If, however, the child is not healthy; if its attack of measles is judged to be severe; particularly if there are already abnormal signs present in its ears or chest; then antibacterial treatment will probably be required. In deciding the most suitable drug to use for any such child we must bear in mind that the action will be curative, not strictly prophylactic. We should therefore wait for clear indications of the need for such treatment, rather than embark upon an expensive and sometimes harmful routine. These drugs can help us to resist the challenge of our bacterial neighbours, but only when appropriately used.

Summary

Infectious diseases may account for more than 50% of new visits in an English country practice. Since before 500 B.C. descriptions of epidemics based on man's unaided senses have survived, but in the last century microscopy provided a new means of differentiating between one infection and another. The control of bacterial diseases by antibiotics has brought viral infections into fresh prominence. A description of epidemic diseases of unknown origin based on careful examination still remains an important duty of every family doctor.

Much work remains to be done in the biometrics of infectious diseases. Useful records of temperature and progress charts in whooping-cough can be kept in many homes. Some physical signs need revaluation—for example, enlargement of the posterior cervical lymph nodes.

In general practice, treatment of infectious disease often starts towards nightfall, and some possible arguments against the widespread use of aspirin are given.

The report of the College of General Practitioners on the complications of measles is summarized, and the need for clear indications for antibacterial drugs is emphasized.

MEDICAL NEW YEAR HONOURS

The names of the following members of the medical profession were included in the New Year Honours List published in the *London Gazette* on January 1.

K.C.V.O.

Sir ARTHUR ESPIE PORRITT, K.C.M.G., C.B.E., LL.D., M.Ch., F.R.C.S. Sergeant-Surgeon to the Queen. Honorary Consulting Surgeon to the Army

K.B.E. (Military Division)

WILLIAM ALEXANDER DUNCAN DRUMMOND, C.B., C.B.E., F.R.C.S., D.L.O. Lieutenant-General, late R.A.M.C. Director-General, Army Medical Services.

D.B.E. (Civil Division)

JANET MARIA VAUGHAN (Mrs. Gourlay), O.B.E., D.M., F.R.C.P. Principal, Somerville College, Oxford.

Knighthood

GEORGE LINDOR BROWN, C.B.E., M.Sc., M.B., Ch.B., F.R.S. Jodrell Professor of Physiology, University College, London.

CHARLES DAVID READ, M.B., Ch.B., F.R.C.S., F.R.C.S.Ed., F.R.A.C.S. President of the Royal College of Obstetricians and Gynaecologists.

C.B. (Military Division)

ALFRED EDWARD CAMPBELL, M.D., D.P.H. Major-General, late R.A.M.C. Honorary Physician to the Queen. Director of Army Health.

JOHN CONRAD NEELY, C.B.E., D.M., D.O., D.O.M.S. Air Vice-Marshal, R.A.F. Honorary Surgeon to the Queen. Consultant in Ophthalmology, R.A.F.

C.B. (Civil Division)

Sir WELDON DALRYMPLE-CHAMPNEYS, D.M., F.R.C.P., D.P.H. Lately Deputy Chief Medical Officer, Ministry of Health.

C.M.G.

JOHN GEORGE HUNTER, M.B., Ch.M. General Secretary of the Federal Council of the British Medical Association in the Commonwealth of Australia

C.B.E. (Military Division)

DAVID HERBERT KERNOHAN, M.B., B.Ch. Surgeon Captain, R.N. (retired).

LIONEL LOCKWOOD, M.V.O., D.S.C., M.D. Surgeon Rear-Admiral, Royal Australian Navy.

C.B.E. (Civil Division)

HAROLD MAURICE COHEN, M.D., D.P.H. Principal School Medical Officer for the City of Birmingham.

HUMPHREY FRANCIS HUMPHREYS, O.B.E., M.C., T.D., M.B., Ch.B., F.D.S. R.C.S. Formerly Vice-Chancellor of the University

of Birmingham and Emeritus Professor of Dental Surgery in the University. For services to dental surgery.

JOHN McQUEEN JOHNSTON, M.D., F.R.C.S.Ed., M.R.C.P.Ed. Principal Medical Officer and Pharmacologist to the Department of Health for Scotland.

RONALD EPEY LANE, M.D., F.R.C.P. Nuffield Professor of Occupational Health in the University of Manchester. Member of Industrial Health Advisory Committee.

JOSEPH ANTOINE RENÉ LAVOPIERRE, M.D., D.P.H., D.T.M. Director of Medical Services, Mauritius.

JOHN FREEMAN LOUTIT, D.M., F.R.C.P. Director, Radiobiological Research Unit, Harwell.

GEORGE WILLIAM JOHN MACKAY, M.B., Ch.B., D.P.M. Medical Superintendent, Rampton Hospital, near Retford, Nottinghamshire.

WILLIAM NORMAN PICKLES, M.D., D.Sc., F.R.C.P.Ed., M.R.C.P. Lately President of the College of General Practitioners.

RALPH WHISHAW, M.B., Ch.M., F.R.A.C.P., F.R.C.P. A prominent physician in Hobart, Tasmania.

CHARLES FRANCIS WHITE, O.B.E., M.D., D.P.H., D.T.M. Lately Medical Officer of Health for the City of London. Recently President of the Society of Medical Officers of Health.

O.B.E. (Military Division)

JOHN GEOFFREY WAUGH, L.R.C.P.&S.Ed. Lieutenant-Colonel, R.A.M.C., T.A., now Territorial Army Reserve of Officers.

O.B.E. (Civil Division)

LESLIE WILSON BANKS, M.B., Ch.B. Senior Medical Officer (Clinical), Western Region, Nigeria.

WILLIAM JOSEPH BRANDAY, M.R.C.S., L.R.C.P. Superintending Medical Officer (Specialist), Trinidad.

WILLIAM MICHAEL COURT BROWN, M.B., Ch.B., F.F.R. Director, Group for Research on General Effects of Radiation, Medical Research Council.

ARTHUR BARRETT CARDEW, M.C., M.B., B.S., F.R.C.S.Ed. Commissioner, St. John Ambulance Brigade, Gloucestershire.

WILLIAM RICHARD SHABOE DOLL, M.D., M.R.C.P. Senior Member, Statistical Research Unit, Medical Research Council.

HENRY JOHN CHADWICK HANRAHAN, M.B., B.S. A medical practitioner of Albany, Western Australia. For services to the community.

RICHARD WILLIAM DAVID MAXWELL, M.B., Ch.B. Lately Deputy Director of Medical Services, Fiji.

SYDENHAM FREDERICK MOORE, B.M., B.Ch. British subject lately resident in Egypt.

HAYDN JONES MORRIS, M.R.C.S., L.R.C.P. For public services in the Federation of Rhodesia and Nyasaland.

ERIC PARRY, M.B.E., M.B., Ch.B., F.R.C.S., F.R.C.S.Ed. Chief Medical Officer to the Kuwait Government.

WALTER LAING MACDONALD PERRY, M.D. Director, Department of Biological Standards, National Institute for Medical Research.

JOHN CHARLES ROBB, M.D., M.Ch. Consulting Surgeon, Downe Hospital, Downpatrick, Co. Down.

GEORGE SIMPSON, M.B., B.S., F.R.C.O.G., M.R.C.P., of Ivanhoe, Victoria. For services to the Flying Doctor Service of Australia.

WILLIAM ARTHUR LEIGH TUCKER, F.R.C.S.Ed., F.R.F.P.S. Surgeon Specialist, Aden.

M.B.E. (Military Division)

JOHN VAUGHAN-BRADLEY, T.D., M.B., B.Chir., F.R.C.S.Ed. Major, R.A.M.C., T.A.

M.B.E. (Civil Division)

OLIVE GUMPRICH, M.B., Ch.B. For social welfare services in Southern Rhodesia.

SYDNEY DOUGLAS GUN-MUNRO, M.B., B.S., D.O. Resident Surgeon, Colonial Hospital, St. Vincent, Windward Islands.

SEBASTIAN BYEKWASO KYEWALYANGA. For medical services in Uganda.

ALEXANDER DAVID BAIN MACKIE, M.B., Ch.B. Chairman, Birmingham "Stirling" Sea Cadet Corps Unit.

GEORGE DAVIS McLEAN, M.R.C.S., L.R.C.P., D.T.M.&H. Medical Officer, St. Kitts, Leeward Islands.

ROBERT CUTHBERT OGG, M.B., Ch.B. Formerly a Medical Officer in Basutoland.

FRANK BLACKLOCK THOMSON, M.B., Ch.B. Deputy Chairman, Dundee National Service Medical Board.

Correspondence

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

Cholesterol and Vascular Disease

SIR,—I was glad to read Sir John McNee's letter (*Journal*, November 17, 1956, p. 1172) on this subject. By the time this reaches you others will doubtless have pointed out that cholesterol feeding (or stuffing) can produce vascular lesions in other animals than the rabbit—e.g., in chicks, dogs, and under certain experimental conditions, the rat and the monkey. But these are slim pickings in return for years of work on this subject, and, if I read correctly between the lines of Sir John McNee's letter, I suspect that he is as weary as I am of the dreary and uninspired feeding of what must now amount to many tons of cholesterol to many thousands of assorted birds, beasts, and, it may be, fishes during the past few years. And as regards the serum cholesterol levels of the South African Bantu—heavens! There will soon be as many nutritionists out there as Bantus.

Over here in the States a remarkable situation has developed since President Eisenhower's attack of coronary thrombosis. It is now easy—too easy—to get vast sums of money for the support of research on vascular disease. Now there is nothing wrong with this except that these funds tend to be given to a small number of ringmasters who are fanatically conducting large cholesterol circuses to the exclusion of other studies that would appear at least as worthy of attention. I know of one department—that previously had a fine and diverse record of work in experimental nutrition—which now, alas, has become a cholesterol circus. How this came about is simple: an enormous grant was awarded for vascular studies, and that was the finish of those sturdy individualists who flatly refused either to add cholesterol to their experimental diets or, alternatively, to study serum cholesterol levels in their experimental animals. It is interesting to speculate what might happen if a future President were to die of gastric cancer—one suspects that the study of possible, and impossible, dietary carcinogens would boom alarmingly, and that this would have a disastrous effect on other equally promising lines of attack.—I am, etc.,

Hyperparathyroidism and Steatorrhea

SIR,—In a letter by Drs. Russell Fraser and B. E. C. Nordin (*Journal*, December 8, p. 1363), they query, quite rightly, the report of a low urinary calcium excretion associated with a serum calcium level of 11.4 mg. per 100 ml. in the presence of a normal blood urea. They suggest that an error in the serum calcium estimation or possibly a raised protein-bound calcium fraction might explain the discrepancy. We recently had a similar experience in the laboratory of the Courtauld Institute of Biochemistry, and, unable to reconcile the serum and urinary calcium figures, we repeated both determinations only to obtain comparable figures.

It was suspected that in this case it was the urinary calcium figure which was unreliable, since the estimation had been carried out on a 200 ml. aliquot, supplied by the ward, taken from a 24-hour urine specimen collected in a clean Winchester containing toluene as a preservative. It seemed possible that the aliquot was taken from the upper part of the Winchester without adequate mixing, so that precipitated calcium phosphate remained undisturbed at the bottom of the bottle. Under such circumstances the aliquot clearly would not be representative of the calcium content of the entire 24-hour specimen. This hypothesis was tested by allowing a 24-hour specimen to stand in the laboratory overnight, after which it was found that the calcium content of the clear supernatant urine was equivalent to only 30 mg. in the 24-hour urine volume, whereas that of urine from the bottom of the Winchester was equivalent to 200 mg.

It seems therefore that inadequate mixing of 24-hour specimens of urine submitted for calcium and phosphate determinations may be an important source of error if the reaction of the urine is alkaline. This may be avoided by using 10 ml. of concentrated hydrochloric acid as a preservative when collecting such specimens, so that precipitation of calcium phosphate is prevented. Alternatively, specimens collected using other preservatives should be acidified before the aliquot used for the estimation is taken.—We are, etc.,

Varicose Ulceration

SIR,—Some years ago I published the results of some 100 cases of varicose ulceration treated with an aqueous solution containing 1% silver dinaphthylmethane disulphonate.¹ I have continued to use the solution during the past five years along the lines suggested in that article and with the same success. This solution does, however, exhibit the following disadvantages: (1) In certain cases it causes a stinging sensation for some minutes after application; (2) gauze impregnated with the solution tends to adhere to the ulcer, causing pain on removal when some granulations or early epithelization may be torn off; (3) it produces a thick firm scab round the edges of the ulcer which causes pressure pain when covered by tight supportive bandaging with localized pressure pad; (4) it is necessary to renew dressings of the solution twice daily, which is an inconvenience to the patient.

In an endeavour to find some agent which would retain the properties of silver dinaphthylmethane disulphonate but without these disadvantages, trials were carried out in my varicose ulcer clinic with an oil-in-water emulsion containing 1% of this compound ("viacutan" emulsion). Dressings were applied once daily by pouring a little of the emulsion on to 4-6 layers of white gauze which were placed on the ulcer and covered with cotton-wool and a built-up pad of plastic foam. The whole leg from the webs of the toes to the knee was then tightly, firmly, and uniformly compressed with a cotton elastic non-adhesive bandage. The patients were taught this technique—fully described in my original article; they came for inspection once weekly or fortnightly.

During the past six months I have treated 61 cases of gravitational and ischaemic ulcers with this emulsion. Thirty-two cases were healed outright, 20 improved, and nine cases showed no response. Those of my colleagues who are using the aqueous solution will doubtless be interested to learn that the emulsion has proved to be superior in that it caused no pain on application; dressings were applied only once daily and were removed without discomfort; there was less pain on pressure bandaging because of the smaller softer scab which was formed; and, most important of all, the healing time was shortened.—I am, etc.,

STUART MCAUSLAND.

REFERENCE

¹ McAusland, S. D., *Med. Press*, 1951, 226, 483.

SIR,—I agree with Dr. B. FitzGerald (*Journal*, December 22, 1956, p. 1484) that it is often necessary, and indeed desirable, to treat varicose ulcers without putting the patient to bed. I would, however, sound a note of warning about the use of chloramphenicol as a local application. Some years ago it was a common practice in our department to treat those varicose ulcers, in which secondary infection appeared to be an important factor, with chloramphenicol cream. Although results were good at the time, a considerable number of the cases were found to have acquired sensitivity to chloramphenicol when they were again treated later. I have since abandoned the use of chloramphenicol as a local application for any skin condition, as it appeared to be a potent sensitizer. That it is so is borne out by a

I shall be interested to hear his observations on this. Further correspondence from Dr. Margaret S. M. McGregor (*Journal*, December 15, 1956, p. 1427) under the same heading suggests that "heat spots" may be due to an acarus. It should be quite easy to prove this by repeated scrapings from early vesicles placed in two drops of 20% liquor potassae and examined under the microscope. I have done this many times with negative results, but, believing that the "heat spots" of papular urticaria were parasitic in origin, I turned my attention to other species in collaboration with Dr. E. T. Burt (*Journal*, May 19, 1956, p. 1130). We feel that most cases of papular urticaria can be explained on the basis of bites by fleas of various species, or even possibly by lice from certain animals, such as the dog, pig, or cattle. This is often difficult to prove, and neither patients nor doctors are easy to convince, but further work is being carried out in this connexion with visits to the homes of the sufferers. Children who have experienced repeated crops of heat spots for years with severe irritation obtain complete and lasting relief from these distressing symptoms if the search for the source of infestation is persisted in till it is traced, and then adequate treatment is

Mr. Hajnal's criticism of our test goes beyond this, since he maintains that we should have included, as giving "mixed" responses, those patients who failed to give two clear preferences. We feel, however, the questions answerable by reference to the "don't knows" and to the "mixed" are different. A full treatment of the data would certainly have classified each of the two responses of each subject as a preference for N.A.P.A.P., a preference for codein. co., or an inability to decide between the two. However, the main purposes of the trial were (1) to see whether preferences for N.A.P.A.P. were expressed more, or less, frequently than those for codein. co., and (2) to see whether there was any evidence that the relative frequency with which these preferences were made varied from one subject to another. It is a different question that the "don't knows" provide evidence about—that is, the frequency with which subjects are able to make up their minds which of these two drugs they prefer. It is true that the subjects who gave a clear preference on one of the two occasions provide some evidence on (1), and it may be worth recording that, of these single preferences, 7 were in favour of codein. co. and 1 in favour of N.A.P.A.P.; but in view of the clear evidence on (1) provided by the double preferences these figures were not presented in the paper. Subjects failing to give two clear preferences provide no information on (2), which is really the point at issue.

If we assume for the sake of discussion that a significant interaction has been established, it remains to consider how the data should be interpreted. The null hypothesis under test is that each patient who is willing to make two decisions has a certain probability p of expressing a preference for (say) codein on any one occasion, and that p is constant from one patient to another; this hypothesis (which, when explicitly stated, is perhaps not very plausible) we assume to be rejected by the data. As an alternative hypothesis, we may consider the probability distribution of p over the population of patients from which our sample was drawn. Various theoretical forms for this distribution suggest themselves; if we assume a *beta* distribution, we can estimate that about 20% of the population have values of p less than one-half—that is, prefer N.A.P.A.P. more often than not—though, on the small numbers involved, this estimate is doubtless very inaccurate. Mr. Hajnal's alternative suggestion that two groups of patients existed, one with a stable disease consistently preferring codein. co., the other making random responses under the influence of variation in their disease and other factors, amounts to assuming a distribution concentrated at the two points $p=1.0$ and $p=0.5$. These two forms of distribution have actually been proposed for use in inspection problems in industry, problems for which sequential techniques were first developed.^{1,2} The point is of more than theoretical interest, since the sampling scheme can be improved if the form of the distribution is known.

It is clearly impossible in practice to distinguish the two alternative forms of distribution from the present limited amount of data, and we must therefore concede that we have not established beyond any possible doubt the superiority of N.A.P.A.P. for a minority of patients. More importantly, the distinction between different forms of distribution is theoretically impossible. Any extension of the rejected null hypothesis uses up the one remaining degree of freedom and leaves nothing over to test goodness of fit. Thus our assumption of patient-drug interaction is not based on the excess of "N.A.P.A.P.-N.A.P.A.P." responses alone, but is intended as an explanation of the whole body of data once the original null hypothesis has been rejected. As it seems impossible to get any further with data of the present kind, it remains to consider improved methods of investigating patients' preferences for alternative treatments. Some improvement might result from using a 5-point scale of preference, asking the patients whether one drug was much better, better, the same, worse, or much worse than the other. But probably the most important step would be the inclusion of a placebo, a course we originally rejected on the grounds that patients would give unreliable responses if asked to compare as many as three weeks at a time. The alternative design of having three two-week periods instead of two we also rejected, on the grounds that the longer the trial lasted the more it would be upset by variations in the disease process. Mr. Hajnal's valuable discussion shows how very carefully one must try to reconcile the often conflicting demands of practical and theoretical requirements in work of this kind.

Another correspondent has drawn our attention to the fact that our labelling of the bottles with + and - signs would in theory have enabled a patient to spot which drug on the second comparison was the same as his preferred drug on the first. This could have led to spurious consistency of choice. In practice we do not believe this occurred, because the patients only had one bottle at a

time in their possession (the bottles were handed back at the end of each week), and because the + and - signs were typed in immediately after the number and the - sign was not obviously identifiable as such. We think it exceedingly unlikely that any patient recognized the nature or even existence of this code, particularly as they did not know two drugs were being compared and none even in fact inquired as to whether the bottles contained different preparations. However, we feel this is a very valid criticism of our procedure, and wish to draw attention to the fact that in any future trials of this sort the labels bearing the numbers should be torn off the bottle as the tablets are handed to the patient.—We are, etc.,

Prevention of Tuberculosis

SIR, As one would expect, Professor F. Heaf's article (*Journal*, December 15, 1956, p. 1383) is both refreshing and stimulating. In addition to recommending a miniature chest x-ray film for all patients attending hospital out-patients, I suggest that certain categories, such as diabetics and patients who have had gastrectomies for peptic ulcers, should have annual chest x-rays.

Professor Heaf has pointed out that the response in mass radiography surveys is better when some compensation is possible on discovery of the disease. I believe that the way to overcome the objection to compulsory chest x-rays for certain groups is to devise a scheme whereby old-age pensioners and those on National Assistance are offered annual chest x-rays. In return they would be assured of a liberal disability pension on the discovery of tuberculous disease, provided the appropriate medical advice was accepted and followed. We have profitably invested large sums of money in controlling tuberculosis in cattle. How much more profitable an investment, both in terms of hard cash and human happiness, would it be if we could control the pool of infectious tuberculous cases in this country. I am, etc.,

Bournemouth.

Delayed Emptying of the Gastric Stump

SIR,—I have followed the correspondence on this subject with great interest, having encountered my share of the complication—this in spite of using plain clamps applied solely to the jejunal wall, as described by Mr. Harold Burge (*Journal*, December 15, 1956, p. 1428). I subscribe personally to the view of Mr. Maurice Lee (*Journal*, December 8, p. 1364) that this condition—and, for that matter, "vicious circle vomiting" after gastro-enterostomy—originates in a paralysis of the gastric muscle; that, in fact, it is a manifestation of a gastric ileus, which name I prefer to attach to this complication. I do not think it is necessary to invoke small-bowel paralysis to explain it. In any gastro-jejunostomy the piece of small intestine actually used in the anastomosis has had its muscle coats cut completely through and has, therefore, no propulsive power. This being the case, we are relying in these patients on gastric peristalsis to "inject" the contents of the stomach into the efferent loop. Paralyzed gastric muscle will not only fail to do this but will allow a functioning afferent loop to pump its contents into an atonic stomach, whence they are vomited. Theories involving "oedema of the stoma" I cannot take seriously.

Like Mr. Burge, I have given a barium meal to a couple of my cases, with findings similar to his. On screening the patients, I was impressed by the way the gastric stump distended like a flaccid sac, and by the absence of any flicker of peristalsis in it while it was under observation. In one case a film taken four hours later showed no onward passage of barium. Most of my cases (like most cases of

intestinal ileus) have been transient, settling down after about 48 hours' suction and intravenous fluid replacement. In about half a dozen, however, encountered during the past ten years the gastric retention has persisted much longer, for periods of 6–12 days—incidentally, with remarkably little deterioration in the patient's condition; one of these was a case of simple gastro-enterostomy. In these obstinate cases of retention, acting on the presumption of gastric ileus, I have used a posterior splanchnic block (Kappis technique) to abolish sympathetic activity. The results of this have been uniformly satisfactory. The usual effect has been to produce a rapid diminution in the volume of the aspirate, so that the tube could be discarded within 24 hours. In one case the result was more dramatic; this patient, after over a week's retention, complained bitterly of hunger within an hour of induction of the block, and had no difficulty in keeping down the light meal upon which he insisted. I think, therefore, that this simple procedure should be given a trial before resorting to further surgery such as jejunostomy. It would be interesting to have the time and facilities to test it radiologically.

Finally, there has been considerable discussion on gastric intubation in this correspondence, and I am afraid I must confess that during the past year I have given up using it in any form, even in gastric operations when a vagotomy has been performed. When intubating routinely I was impressed by the small quantities aspirated, especially after Billroth I gastrectomies. Since abandoning it, it is only occasionally that I have had to have a tube passed in the post-operative period; most patients vomit not at all or very little. I think that they cough better for the absence of the tube, and that both patients and nursing staff seem less harassed without it.—I am, etc.,

Brighton.

KEITH POWELL.

Pregnancy Sickness

SIR,—Dr. Doreen S. Ball should speak for herself alone when she says, "I regarded these cases, as most doctors seem to, as . . . psychological" (*Journal*, December 22, 1956, p. 1487). Surely most obstetricians nowadays realize and teach that vomiting of pregnancy is due to a combination of several factors such as the distension of the gravid uterus with the products of conception, and the considerable hormonal upset that takes place in a woman at that time, to mention only two. Another small point arises later in her letter in which one infers that her own vomiting of pregnancy could have been aggravated by getting up in the morning after 14 hours' fasting. As far as I know, dry toast and tea in bed as soon after awaking as possible is well known as a valuable deterrent of vomiting of pregnancy.—I am, etc.,

Winchester.

P. G. CRONK.

SIR,—I was most interested to read the letter by Dr. Doreen S. Ball on her own experiences of pregnancy sickness (*Journal*, December 22, 1956, p. 1487). I have had two children and during both pregnancies also suffered from this a great deal.

During my first pregnancy I started to vomit six weeks after my last menstrual period. At that time my periods were irregular, and I did not then realize that I was pregnant. This vomiting continued several times daily, and often at night, for two to three months; a feeling of nausea persisted throughout pregnancy and disappeared completely immediately after delivery. During my second pregnancy I again started to vomit six weeks exactly after my last menstrual period. This time I was admitted to hospital with hyperemesis. At about three months I had a threatened abortion. The day preceding this I did not have any nausea or vomiting. The symptoms then continued as before. The only treatment which had any effect was the taking of small meals every two hours. Nausea again persisted throughout pregnancy and disappeared on delivery.

I was treated, quite obviously, mainly as a psychological problem. This I am perfectly convinced I was not. Why should I suddenly change from a normal individual to a

"psychological problem," in one instance even before I knew I was pregnant? I have no criticism whatsoever to make of my treatment. I also, before being pregnant, considered the cause of hyperemesis to be psychological, because that is what I had been taught to believe. Since these experiences I now consider that the cause of hyperemesis can be hormonal in origin for the following reasons: (1) The sudden onset of vomiting, and the time of onset in both cases being exactly the same; (2) absence of vomiting and nausea previous to the threatened abortion; (3) sudden and complete disappearance of symptoms following delivery.

The above could quite obviously be explained in some other way, but, until I am offered a more tenable theory than that usually given, hormones, in my case also, are to blame.—I am, etc.,

Marple, Cheshire.

MURIEL DALBY.

Diagnosis of Early Pregnancy

SIR,—In calculating that the average general practitioner sees some 23 pregnancies per year, Mr. D. G. Wilson Clyne (*Journal*, December 22, 1956, p. 1489) assumes that there are 460,000 births per annum in the United Kingdom. In fact, there were 673,651 live births in 1954.¹ Allowing for stillbirths and abortions, the number of pregnancies may well have been over 800,000. Some "general practitioners" have limited lists and attend only staffs of hospitals. Pregnancies are spread among the practices of true general practitioners at an average of about 47 each, of which about 40 reach viability. There is ample maternity work in the average general practice. It is, perhaps, because this fact has been misrepresented so often that Mr. Wilson Clyne did not realize that there was a fairly gross error in his calculations.—I am, etc.,

Hucclecote, Gloucester

IVOR COOKSON.

REFERENCE

1. *British Medical Journal*, 1956, 1, 1309.

SIR,—I read with great interest the letter of so distinguished a gynaecologist as Mr. D. G. Wilson Clyne, published in your issue of December 22, 1956 (p. 1489), and commenting on my letter in the *Journal* of November 10 (p. 1118). Statistics have been likened to bikinis, in that they reveal matters of interest but conceal vital parts. There are many general practitioners with a large proportion of young patients who see many more than twenty-three pregnancies per year, and I am one of them. Therapeutic abortion is an exceedingly controversial subject, and I propose to spare the Editor of the *Journal* a protracted correspondence on the subject.—I am, etc.,

Ruislip.

T. DAVID LAMBERT.

Bancroftian Filariasis Simulating Lumbar Disk Lesions

SIR,—Apart from symptoms of lymphangitis, funiculitis and orchitis, and fever, filariasis produces generalized aching pains, the latter being a common mode of presentation on Niue Island, where the entire population takes a single 50-mg. tablet of diethylcarbamazine ("hetrazan") every month. This scheme of mass dosage has not only a very definite suppressive action but also indicates, by producing aching pains, a considerable number of positive cases.

Another interesting symptom, unrelated to the diethylcarbamazine mass therapy, is not uncommon—namely, the sudden onset of very severe pain simulating a lumbar disk lesion, and crippling in its intensity. The pain is referred to the ankle of the affected side, and there is a point of tenderness one inch (2.5 cm.) from the midline at the level of the second or third lumbar spinous process. There is no appreciable depression of the knee jerk or tendo-Achillis jerk, and no fever. Blood examination invariably shows numbers of microfilariae, and treatment by diethylcarbamazine 50 mg. three times a day produces a somewhat dramatic alleviation of symptoms within 24 hours and a negative blood after seven days. I wonder if any other readers have come across this distressing variety of filariasis.—I am, etc.,

Niue, S. Pacific.

E. J. B. SIMPSON.

Obituary

W. G. BARNARD, C.B.E., F.R.C.P.

Professor W. G. Barnard, professor of pathology at St. Thomas's Hospital and dean of the medical school, died at the hospital on December 20, 1956. He was 64 years of age.

William George Barnard was born at Tangier, Morocco, on December 9, 1892, the second son of a missionary, Mr. E. U. Barnard, of Bath. He was a medical student at the London Hospital at the outbreak of the first world war, and for two years he served in the Royal Field Artillery in France. Gazetted out of the Army in 1917,

(Elliott and Fry Ltd.)

he returned to the London Hospital and qualified M.R.C.S., L.R.C.P. in 1920. He captained the hospital's Rugby fifteen for two years, playing full-back, and after he had given up playing he took to refereeing. Among the junior appointments he held at the London were those of house-surgeon, pathological assistant, and junior assistant director of the pathological institute. From 1923 to 1931 he was pathologist to University College Hospital and lecturer in morbid anatomy and curator of the museum in the medical school. In 1927 he went to Freiburg-im-Breisgau for six months to work with the late Professor Ludwig Aschoff. Becoming consultant histologist to the London County Council in 1931, he was also appointed pathologist in charge of the council's Central Histological Laboratory at the Archway Hospital. Professor Barnard was appointed to the chair of pathology at St. Thomas's Hospital Medical School in 1939, and eight years later he succeeded the late Professor B. A. McSwiney as dean of the medical school. He held both appointments until his death, and he was also a member of the hospital's board of governors. Only last year he was appointed dean of the Faculty of Medicine in the University of London, and was to have held this appointment until 1958. He was also a member of the senate of the university and an examiner in pathology. In 1948 he was one of the vice-presidents of the Section of Pathology at the Annual Meeting of the B.M.A. Before the recent war he at times reported for this *Journal* the proceedings of the Section of Pathology and Bacteriology at the Annual Meetings of the B.M.A. His reports were models of accuracy and brevity, and he was punctilious in producing his "copy" on time. His book, *Elementary Pathological Histology*, was first published in 1928 (3rd edition in 1953), and he was the author of numerous papers on pathological subjects in specialist journals. His work on "oat-celled sarcoma" of the mediastinum, published in 1926, was an important study, for he was able to show that this tumour was a primary carcinoma of lung. As a teacher he was rather reserved, but as dean of St. Thomas's the students found him very approachable and a wise and kindly adviser. Certainly he spared no pains in his work for the medical school,

which benefited from his administrative skill and wide professional experience.

Barnard gave unstintingly of his time and energy to the Royal College of Physicians of London. Elected a Fellow in 1938, seven years after taking his Membership, he served on the council of the College from 1942 to 1944 and was then elected treasurer. In that capacity he proved to be a wise and prudent custodian of the College's financial affairs during a period of great difficulty. But Barnard was much more than a treasurer responsible for seeing that a proper balance was kept between income and expenditure. He was one of a small group advising the President of the College on a wide range of matters relating not only to the welfare of the College as an institution but also to problems affecting the profession as a whole, in particular, of course, those taking part in the Health Service as consultants and specialists. Most Fellows will recall at this time his genial and friendly presence at the College dinners, for Barnard was a connoisseur of food and wine, and he saw to it that for a modest price the Fellows could dine off good fare chosen with a rare discrimination. As a man he was forthright and determined in his views, and, if at first acquaintance he seemed to be a bit formidable in aspect, this impression soon disappeared in moments of relaxation which revealed a man who believed above all things in the good fellowship of professional colleagues.

A very capable administrator, Barnard gave much of his time to committee work, not only at his hospital and at the College but on other bodies as well. From 1948 to 1950 he was a member of the Central Health Services Council, and he had been a member of the Joint Consultants and Specialists Committee for seven years. He also served on the Staff Side of Committee "B" of the Medical Whitley Council from 1953 until his death. At one time he was honorary secretary of the Medico-Legal Society, and for the past year he had represented the Royal College of Physicians on the council of the Imperial Cancer Research Fund.

Professor Barnard married Miss Margaret R. Osler in 1930 and had one son, who has recently qualified at St. Thomas's Hospital.

A memorial service to Professor Barnard will be held in the chapel of St. Thomas's Hospital at 12 noon on Thursday, January 17.

ROBERT CARMICHAEL, M.B.

By the tragic death of Dr. Robert Carmichael at Leeds on December 19 scientific pathology and the Leeds medical school have lost prematurely a highly skilled and experienced member. He was 55 years of age. Many generations of medical students, as well as his colleagues, will long recall with warm affection his wide knowledge, sound teaching, transparent sincerity, and his humour and kindness. A native of Falkirk, Robert Carmichael studied medicine at Edinburgh, graduating with honours in 1923. He won the Lesley gold medal and the Ettles scholarship, which enabled him to study for a time in Paris. On his return to Edinburgh he held appointments as assistant in pathology in the university and Royal Infirmary and as pathologist to the Royal Edinburgh Hospital for Mental and Nervous Disorders. Here he acquired a special taste for neuropathology and published his classical paper on the cerebral lesions in the chronic stage of epidemic encephalitis, a paper which was illustrated by beautiful water-colour drawings by his wife.

Appointed to the university department of pathology in Leeds, first as a lecturer and then as a senior lecturer, he spent the remainder of his life, over twenty years, there. Here he took a major share in teaching, and in the development, and especially the post-war revision and re-cataloguing, of the museum of pathology. He also participated as co-author in valuable papers on adenolymphoma of the salivary glands and on metaplastic changes in the cervix uteri. But his first love for neuropathology was maintained, as shown by his scholarly papers on cerebral aneurysms. His published work, however, excellent in quality though it was, was not the greater part of his contribution to the Leeds medical school and to British pathology. This was more intangible; it was his systematic thoroughness, his uncompromising love of accuracy and truth, and his scorn of slipshod, hurried, and untidy work of hand or mind. He himself refused to be a victim of routine mediocrity, and he set an example of care and precision for which his colleagues, students, and technicians alike will increasingly realize their imponderable indebtedness to him. Both in and outside Leeds his opinion on difficult histopathological problems was often sought, for his fellow pathologists well knew the value and maturity of his judgment. They will affectionately remember also his humorous twinkle, and the telling quip or epigram with which he often castigated ponderousness, pomposity, or insincerity. His work was his hobby and his happy home life his recreation.

For the last six months or more his friends anxiously saw his health decline; but, with a characteristic stoic cheerfulness, he carried on his work as though nothing was wrong until only a fortnight before his death. This was due to a retroperitoneal tumour, which there is no doubt he himself correctly diagnosed some weeks earlier and knew was irremediable. To the very last he smilingly sustained the courage of his friends, rather than they his. In some measure they share with his wife and daughter a unique sense of personal loss.—R. A. W.

F. S. F. writes: I first met Robert Carmichael when he came to Leeds as lecturer in the department of pathology in 1931. I was already in the same department as reader in the chemical pathology, and we quickly became friends, and the friendship deepened with the passing of the years. His outstanding characteristics were his innate modesty, his friendliness, and his sense of humour, which had a delightful flavour all its own. He never really hankered after a chair; this was partly on account of the modesty I have referred to, but perhaps mainly because he disliked the idea of having what he considered his real work frequently interrupted by the claims of administration which must inevitably have been made on him as a professor. Yet on three occasions he was called on to assume charge of a department until a permanent incumbent should be appointed, and each time he gave unstinted time and effort to administrative duties, so that he was able to hand over his charge in a healthy, flourishing condition. His last period as acting head of a department lasted for a little over a year, and taxed his strength greatly, for it was during this period that the illness which was to cause his death first manifested itself. Characteristically he ignored it and remained at his post to within three weeks of his end, which he faced with truly amazing courage. He will be sadly missed in Leeds, not least by those who, like myself, have enjoyed the inestimable privilege of his friendship.

C. D. LOCHRANE, M.D., F.R.C.S. Ed., F.R.C.O.G.
Mr. C. D. Lochrane, formerly consultant surgeon to the Derbyshire Hospital for Women, died after a short illness on December 13, 1956, at Nairn. He was 75 years of age.

Born at Busby, near Glasgow, Charles Damien Lochrane was educated in Catholic seminaries in Scotland and England, and his medical training took place for the greater part at Edinburgh University, though his final year was spent at Glasgow University. He graduated M.B., Ch.B. at Edinburgh in 1904, and proceeded to the M.D., with high commendation, in 1908. After graduation he had the good fortune to serve as house-surgeon at Glasgow under Sir William Macewen, some of whose aphorisms he was fond of quoting and whose teaching made a great impression upon him. Later he held the appointment of senior resident medical officer at the Royal Infirmary. His elder brother, Frank, had been honorary surgeon to the Women's Hospital, Agard Street, Derby, and on his sudden death Charles was appointed honorary surgeon there in 1907, having in the previous year obtained the F.R.C.S. of Edinburgh. At the same time he took over his brother's general practice. The hospital at that time only had about 20 beds, but he worked assiduously to perfect his surgical technique, and built up a large out-patient department. His patients were devoted to him, and so were the nurses. By wide reading he kept himself well informed of progress in his specialty, and he himself wrote a number of papers, mainly on obstetric subjects.

During the first world war Lochrane was appointed surgeon in charge of the military hospital at Etwell, where he worked with his accustomed enthusiasm and where he had the happiness to meet his future wife. Shortly after the war he developed a renal calculus, from which, however, he made a good recovery, but he determined to give up his general practice and devote himself entirely to his specialty. Becoming a member of the old Midland and Western Counties Obstetrical and Gynaecological Society, he was shortly afterwards elected to its presidency. He was also a past-president of the Derby Medical Society. When the Women's Hospital at Derby became too small for its many patients Lochrane was mainly instrumental in building the new Derbyshire Hospital for Women, which opened in 1929 with 60 beds and which has so abundantly fulfilled the purpose for which it was built. Elected an original Fellow of the Royal College of Obstetricians and Gynaecologists in 1929, Lochrane filled many appointments, so that his time was very fully occupied. Besides being on the staff of the City Hospital in Derby, he was consultant obstetrician to the Derbyshire and Staffordshire county councils. From 1939 to 1947 he was president of the Derby Branch of the B.M.A. A few years ago he developed acute appendicitis, which was followed by complications. This illness obliged him to give up his life's work—for him a most difficult decision. He retired to Scotland, but unfortunately his health remained indifferent.

Charles Lochrane was a man steadfast of purpose but governed by his faith. Our deep sympathy is extended to his devoted wife and two sons.—J. C. G.

Dr. D. G. McROBBIE died at his home at Turriff, Aberdeenshire, on November 20, 1956, at the age of 41, after battling manfully with ill-health for some time. An Aberdonian born and bred, Donald Graham McRobbie was an able family doctor blessed with patience, determination, and courage. At Aberdeen Grammar School he developed a great interest and facility in the classics and an enduring love of good music, but later decided to

study medicine at Aberdeen University. After graduating M.B., Ch.B. in 1938 he held hospital appointments in Aberdeen and at the Royal Hospital for Sick Children, Glasgow. This work with children seemed to help him master a long-established shyness of manner, which he never quite lost. In 1941, immediately after joining the R.A.M.C., he found himself in the Middle East. During much of his four years of active service in the Western Desert, Sicily, and Europe he was regimental medical officer to the 5th battalion of the Black Watch Regiment. His constancy in battle earned him the admiration and affection of all his comrades-in-arms. A fellow officer wrote about him: "While the rest of us were scrambling to get below ground level, Donald would go on treating the wounded." This strength and courage came not from a lack of fear but from overcoming fear. Devotion to duty often led him to neglect his own medical needs in attending to those of others. He adhered firmly to Christian principles throughout his life. After demobilization Dr. McRobbie worked as a house-surgeon at Aberdeen Royal Infirmary, and in 1946 took up general practice in Turriff. He followed a simple rule—the needs of the patients come first. In all matters of professional care and behaviour he set himself the highest of standards and was shocked by any attempt to abandon honourable traditions. His steadfastness in the face of illness and adversity was worthy of a true son of the north-east. We extend our deepest sympathy to his wife and to his mother in their sad loss.—W. R. C. I.

Dr. E. W. ROUTLEY died at Aldershot on December 5, 1956, at the age of 90. Edwin Walter Routley was born at Bath on October 27, 1866, and was educated at King Edward VI Grammar School, Bath, where he was a scholar. After leaving school he became a pharmacist and an expert photographer before taking up the study of medicine rather late in life. He received his medical training at Guy's Hospital, where he won the Golding-Bird gold medal and a scholarship in bacteriology in 1905. In 1902, while still a medical student, he was awarded a prize for an essay on consciousness by the Guy's Hospital Physical Society. He qualified M.R.C.S., L.R.C.P. in 1904, taking the Brussels M.D. in the same year and the Cambridge D.P.H. in 1905. He became a Member of the Royal College of Physicians of London in 1911. After qualification he held the post of assistant demonstrator in bacteriology at Guy's Hospital. In 1905 he was appointed medical officer of health for Aldershot, a post he retained until his retirement in 1931. He was also assistant tuberculosis officer to the Hampshire County Council and lecturer in sanitary law and administration at King's College, London. Other appointments he held at Aldershot included those of honorary bacteriologist and pathologist to the local hospital, medical superintendent of the isolation hospital, and medical officer to the education committee. During the second world war he reassumed the duties of medical officer of health while his successor, Dr. J. Craig Lindsay, was in the R.A.M.C. In the intervening period of eight years (1931-9) he was employed as a civilian medical practitioner with the R.A.M.C. and was medical officer to the 1st Guards battalion at Aldershot. By nature Dr. Routley was quiet and gentle, with a great love of children. He married twice and was a widower for the last 34 years of his life. He is survived by one daughter and two sons, one of whom is also medically qualified and a Guy's man.

Dr. W. A. ANDERSON, formerly senior surgeon to the Benn Eye, Ear, and Throat Hospital, Belfast, and chairman of the board of management of the Belfast Ophthalmic and Benn Hospitals, died on December 9, 1956, at the age of 71. From the Royal Belfast Academical Institution William Arthur Anderson went on to Clare College, Cambridge. He received his clinical training at the Royal Victoria Hospital, Belfast, and qualified by taking the London Conjoint diploma in 1910. After holding the appointment of house-surgeon at the Royal London Ophthalmic Hospital he graduated M.B., B.Chir. in 1914, and shortly afterwards joined the staff of

the Benn Hospital. During the first world war he served in the R.A.M.C. as an ophthalmic specialist in France, Belgium and Italy for four eventful years. He was mentioned in dispatches, and in 1919 was awarded the Médaille des Épidémies (d'Or) by the French Government. After the war he proceeded to the M.D. in 1921. When he returned home the Benn Hospital was a small establishment of twenty beds doing an immense amount of work with very scanty resources and struggling from deficit to deficit. Dr. Anderson, being a man of great energy, was a valuable acquisition, and for over thirty years he was to provide the additional force needed to secure the enlargement of the hospital. When he retired in 1950, as senior surgeon, it was an institution of which he could be proud. On his retirement he became honorary consulting surgeon to the hospital and was presented with an illuminated certificate on his election as an honorary governor. His services were also retained as a member of the Belfast Ophthalmic and Benn Hospitals management committee. Dr. Anderson had held office as president of the Irish Ophthalmological Society and of the Ulster Medical Society and as vice-president of the Ophthalmological Society of the United Kingdom. He was a member of the Ophthalmic Group Committee of the British Medical Association from 1945 to 1949, and for many years he was a deputy lieutenant for the city of Belfast. He was a skilled operator, and his opinions were always inspired by common sense and were respected and sought after by all his colleagues. He ultimately became chairman of the board of management of the Belfast Ophthalmic and Benn Hospitals and guided their fortunes successfully in a very difficult time. A true and sincere friend, he could always be relied on in any difficulty. He was always loyal to medicine, but farming was his second love. In 1945 he contributed an article to the *Ulster Medical Journal* on soil and nutrition. He took farming seriously with sound common sense and success until failing health compelled him to take life more easily. He is survived by his wife and two sons, to whom we extend our sincere sympathy in their loss.

Universities and Colleges

UNIVERSITY OF ABERDEEN

At a graduation ceremony on December 12, 1956, the following degrees were conferred:

M.D.—J. Watt (with honours), Jessie C. Yorston (née Millar) (with commendation).
 Ch.B.—T. L. Carr.
 M.B., Ch.B.—C. C. Constantinides, A. E. Silbergh, H. G. Tough, A. Tullett, A. J. Watt, D. Wilkinson.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH

At a meeting of the College held on December 12, 1956, with Sir Walter Mercer, President, in the chair, the following candidates, having passed the requisite examinations, were admitted Fellows:

J. E. B. Ailing, A. M. H. Y. Ansari, A. W. Beasley, F. H. Beddow, J. Blundell, S. P. Chandra, D. B. Chrisp, J. M. D. Crook, S. K. Das, H. L. Dunthie, T. J. El-Gailani, D. C. Evans, A. V. Foote, A. K. Ganapadhyay, E. R. Ghabbour, H. M. Hathout, W. R. Holmes, J. Hughes, A. E. Ikomi, T. K. Jagose, T. S.-B. Kelly, K. S. Kochhar, J. McArthur, I. W. A. McFarland, A. H. D. McJannet, I. J. MacQueen, G. A. Marin, A. Mulholland, J. Nayman, M. K. Panandikar, R. C. Patel, K. N. Pathak, R. Paton, J. A. Riedel, J. B. Ritchie, W. V. Rowe, T. L. Sarkin, C. H. Schulman, C. L. Shah, R. P. Singh, Mary E. O. Skinner, A. N. Smith, R. Stranz, E. C. Watson, C. U. Webster, C. H. Wolpe.

ROYAL AUSTRALASIAN COLLEGE OF PHYSICIANS

At a meeting of the Council of the College held at Melbourne on October 9 the following candidates, who were successful at an examination by the Australian Board of Censors, were admitted to Membership of the College: Dr. A. G. Zaver, of Queensland; Dr. C. S. H. Reed, Dr. D. E. Smith, and Dr. N. J. Yorkston, of New South Wales; Dr. C. W. Baird, Dr. R. H. D. Bean, Dr. J. L. Blunt, Dr. A. C. L. Clark, Dr. R. K. Doig, and Dr. W. H. Orchard, of Victoria; Dr. N. D. Abbott, Dr. R. G. Gold, and Dr. P. M. Last, of South Australia; Dr. D. D. Letham, of Western Australia.

Vital Statistics

Infectious Diseases

The largest variations in the notifications of infectious diseases in England and Wales during the week ending December 15 were increases of 515 for measles, from 5,978 to 6,493, and 72 for food-poisoning, from 247 to 319, and decreases of 147 for whooping-cough, from 2,126 to 1,979, and 80 for scarlet fever, from 846 to 766.

The largest rises in the incidence of measles were 188 in Lancashire, from 1,501 to 1,689, 109 in Staffordshire, from 200 to 309, and 57 in Gloucestershire, from 187 to 244; the largest fall was 48 in Kent, from 148 to 100. No large fluctuations were recorded in the local trends of whooping-cough. The largest decrease in the number of notifications was 39 in Durham, from 81 to 42. 6 cases of scarlet fever were notified, being 2 more than in the preceding week; 3 of the cases were recorded in Staffordshire, Coseley U.D.

73 cases of acute poliomyelitis were notified, and these were 6 fewer for paralytic and 3 fewer for non-paralytic cases than in the preceding week. The largest returns were London 12 (Lambeth 3, Lewisham 2, Wandsworth 2), Middlesex 9 (Tottenham M.B. 2), Lancashire 8 (Clitheroe M.B. 2), Surrey 5 (Sutton and Cheam M.B. 4), and Sussex 5 (Brighton C.B. 3).

The notifications of dysentery numbered 808 and were 22 fewer than in the preceding week. The largest centres of infection were Yorkshire West Riding 119 (Sheffield C.B. 26, Leeds C.B. 20, Huddersfield C.B. 13, Colne Valley U.D. 13), Warwickshire 109 (Coventry C.B. 94), Lancashire 88 (Salford C.B. 13, Wigan C.B. 13, Blackburn C.B. 11, Bury C.B. 10, Liverpool C.B. 10), Essex 69 (Chigwell U.D. 25, Romford M.B. 12, Thurrock U.D. 12, Ilford M.B. 10), Surrey 57 (Esher U.D. 19, Mitcham U.D. 10), London 50 (Islington 18), Kent 44 (Chislehurst and Sidcup U.D. 17, Bromley M.B. 14), Orpington U.D. 10), Bedfordshire 39 (Luton M.B. 39), Nottinghamshire 21 (Nottingham C.B. 19), and Middlesex 20.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1947-55 are shown thus -----, the figures for 1956 thus ———. Except for the curves showing notifications in 1956, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Food-poisoning in 1955

A review of food-poisoning in England and Wales during 1955¹ shows that 8,961 incidents were recorded—an increase of 2,945 on the total for 1954. The number of notifications (uncorrected) received by the Registrar-General was 12,717, but in the outbreaks reviewed here there were over 20,000 cases. Of the 8,961 outbreaks 7,626 were sporadic cases, 723 family outbreaks, and 612 general outbreaks. The causal agent was not established in 3,447 incidents. *Salmonella typhi-murium* was responsible for 47% of all incidents and 76% of the known causes, and other salmonellae were responsible for 12% of all incidents and 19% of the known causes. The fatal cases reported numbered 39; 25 of these were due to *Salm. typhi-murium* and 9 to other salmonellae. Four of the 34 fatal cases due to salmonellae were patients aged under 50 years; 20 were aged 50 and over.

The vehicle of infection was meat in 255 of the 312 outbreaks for which information was available; 228 of these were due to processed and made-up meat dishes. Reheated meats were the largest class in this group with 49 outbreaks, meat pies were second with 41 outbreaks, and in descending order cold meats, cold ham and bacon, and pressed meats. There was a close association between reheated meat and *Clostridium welchii* and between cold ham and bacon and staphylococci. The places where contaminated food was eaten or bought was known in 287 outbreaks; they were canteens 109, hospitals 69, shops 37, institutions 31, restaurants, cafés, etc., 24, and private parties 17.

Salmonellae were isolated in 5,383 incidents; 4,879 of these were due to 17 endogenous types (recognized before 1940), 443 to 65 exogenous types (recognized in 1940 or later), and 61 were unidentified or unnamed types. The most frequent among the endogenous types were *Salmonella typhi-murium* 4,276, *Salmonella thompson* 164, and *Salmonella stanley* 101. The largest groups among the exogenous types were *Salmonella heidelberg* 77, *Salmonella anatum* 50, and *Salmonella saint-paul* 37.

¹ Monthly Bull. Minist. Hlth (Lond.), 1956, 15, 263.

The high proportion of incidents with undiscovered causes was probably due to failure in reporting and delay in investigating these outbreaks. Recent experience suggests, says the report, that food-handlers cannot be incriminated as the cause of outbreaks, since they are generally infected at about the same time as the other patients. The latest food regulations may help to decrease food-poisoning from organisms other than salmonellae but can make little difference to the general picture so long as foodstuffs contaminated by salmonellae are allowed to be distributed.

Clean Air

Certain provisions of the Clean Air Act, 1956, came into operation on December 31. Similar provisions apply to Scotland. They enable local authorities to create smoke-control areas by Orders subject to confirmation by the Minister of Housing and Local Government. All new furnaces other than small domestic boilers must be, so far as practicable, smokeless. The Minister is empowered to make regulations requiring furnaces to be fitted with smoke density meters. The height of new chimneys, other than those of houses, shops, and offices, will require approval by the local authority. Owners of colliery spoilbanks must employ all practicable means for preventing combustion of refuse and for preventing or minimizing the emission of smoke and fumes from the refuse. Local authorities may make building by-laws requiring the provision in new buildings of such arrangements for heating and cooking as are calculated to prevent, so far as practicable, the emission of smoke.

Venereal Diseases

In England and Wales during the quarter ending June 30, 1956, 1,284 new cases of syphilis were reported as attending the clinics. Of these, 188 were classified as primary, secondary, or latent in the first year of infection. 10 cases of congenital syphilis in children aged under 1 year were reported, and 139 cases in persons over that age. New cases of gonorrhoea numbered 4,964, of chancroid 88, and of non-gonococcal urethritis (males only) 3,798.—*Monthly Bulletin of the Ministry of Health*, December, 1956.

England and Wales in Third Quarter, 1956

The number of live births in England and Wales in the quarter ending September 30, 1956, was 173,586, giving a rate of 15.5 per thousand population. This was 0.6 above the rate for the corresponding quarter of 1955. Stillbirths numbered 4,007, a rate of 22.6 per thousand live and stillbirths. This rate is 0.4 lower than that for the corresponding quarter of 1955. The number of deaths registered was 104,118, a rate of 9.3 per thousand population. The rate for the September quarter of 1955 and also the average rate for the corresponding quarters of the preceding five years 1950-4 was 9.1 per thousand population. The infant mortality rate was 20.3 per thousand related live births. This is the lowest quarterly rate ever recorded in England and Wales.

A new Table gives figures of accidental deaths in the March quarter. Of 4,670 deaths registered as accidental, 2,297 resulted from home accidents, 1,489 from transport accidents, and 884 from other accidents. Of the home accidents, 277 deaths were caused by coal-gas poisoning, 324 by burns and scalds, and 195 by choking and suffocation. Included in the 1,489 deaths from transport accidents were 222 of motor-cyclists, 126 of pedal cyclists, 621 of pedestrians, and 286 of motor-vehicle occupants. Of the total of 192 accidental deaths of children aged under 1 year, 154 were recorded as due to choking and suffocation.

Week Ending December 22

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 735, whooping-cough 1,732, diphtheria 10, measles 6,575, acute pneumonia 465, acute poliomyelitis 60, dysentery 696, paratyphoid fever 2, and typhoid fever 1.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending December 15 (No. 50) and corresponding week 1955.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire. A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

† Includes primary and influenza pneumonia.
‡ Includes puerperal pyrexia.

Medical News

B.M.J. Centenary.—On January 3, 1857, the *British Medical Journal* first appeared under its present title. Before that it had been the *Association Medical Journal*. The new name was a natural corollary of the Association's own change of title. This had been a time of evolution in the Association's affairs. After the annual meeting in York in 1855 voting papers were issued to the 2,094 members of the then Provincial Medical and Surgical Association, so that they could record their views on how their Association should be named. A thousand votes were cast in this poll, the title "British Medical Association" being advocated by a majority of 260. Next a special general meeting, convened at Birmingham in November, 1855, set up a committee to revise the Association's laws. The new code of laws it produced, which among their other provisions named the Association as the British Medical Association (Law No. 1) and its journal as the *British Medical Journal* (Law No. 24), was finally passed after discussion and some amendment at the next annual meeting—the Association's 24th—held at Birmingham in July, 1856. From being headed "*Association Medical Journal*: being the Journal of the Provincial Medical and Surgical Association" on August 2, at the next issue, on August 9, 1856, the *Journal's* title had become "*Association Medical Journal*: being the Journal of the British Medical Association." However, the final retitling had to wait upon formalities at the Stamp Office, and it was not until January 3, 1857, that the *Journal* first appeared under its present name.

Assistant D.-G. of W.H.O.—Dr. P. M. KAUL, formerly director of W.H.O.'s division of external relations and technical assistance, has been appointed Assistant Director-General in charge of the department of advisory services, in place of Dr. VICTOR SUTTER, who has become Minister of Public Health and Social Assistance in El Salvador. Dr. Kaul was born in India in 1906. He graduated in medicine from the King Edward Medical College, Lahore, later obtaining the D.P.H.(Eng.) and the M.R.C.P.(London) after postgraduate study in London at Guy's Hospital and King's College. From 1934 to 1945 Dr. Kaul was in the Indian Medical Service, latterly with the rank of acting colonel. Then he became additional deputy public health commissioner with the Government of India until joining the World Health Organization in 1948. For some years Dr. Kaul served as chief of the W.H.O. liaison office with the United Nations in New York. He then went to Geneva as head of the external relations division.

Schistosomiasis in Africa.—Under the auspices of the World Health Organization a conference of 30 experts met at Brazzaville, French Equatorial Africa, from November 26 to December 8 to discuss the problem of bilharziasis in Africa. Since 1950 W.H.O. consultants have been surveying the incidence of the disease there and studying the distribution of the intermediate snail hosts of the schistosome cercariae. These surveys have shown that infection is rife in most African territories, on both East and West Coasts, in Egypt, the Union of South Africa, and Madagascar; but it is thought to be absent from South-west Africa, Ruanda Urundi, Basutoland, and Mauritius; a single focus was reported in Bechuanaland. Animal bilharziasis is generally far more widespread than human disease, being found in cattle, sheep, goats, camels, rodents, dogs, equines, antelopes, buffalo, and even elephants. But the importance of the animal reservoir of infection remains rather uncertain; in the Philippines, for instance, epidemiological studies were stated to have shown that man is responsible for up to 75% of the production of the parasites, domestic animals accounting for the remaining 25%. Besides the epidemiology of the disease, the conference also discussed control measures of the disease, and by improving sanitation. Among those who attended the conference were Dr. W. ALVES,

Dr. D. M. BLAIR, and Mr. H. V. DE VILLIERS CLARKE, from Southern Rhodesia; Dr. BOTHA DE MEILLON and Dr. R. J. PITCHFORD, from South Africa; Dr. P. L. LE ROUX and Dr. J. NEWSOME, from Great Britain; and Dr. E. T. ABDEL MALEK, from the Sudan.

St. John Ambulance Brigade.—Major-General J. M. KIRKMAN has been appointed commissioner-in-chief of the St. John Ambulance Brigade in succession to the late Sir OTTO LUND. General Kirkman has had a distinguished military career. Before and during the second world war he was in Military Intelligence, and attended the Washington, first Quebec, Cairo, and Teheran conferences on the staff of the British chiefs of staff. In 1944 he was on the staff at Salisbury during the launching of operation "Overlord"; and then was appointed chief of staff to the British Forces in Greece and subsequently in Palestine. In 1948 General Kirkman became chief of staff, Land Forces Far East, until 1950, when he took up the post of chief of the intelligence division in Germany. He retired from the Army in 1954.

Chair of Physiology at Middlesex Hospital.—London University announces the appointment of Dr. E. NEIL to the John Astor Chair of Physiology at the Middlesex Hospital Medical School. The previous occupant of this Chair was the late Professor SAMSON WRIGHT. Dr. Neil, who until his present appointment held the university readership in physiology at the Middlesex Hospital Medical School, is a graduate of Leeds University. He obtained the B.Sc., with first-class honours in physiology, in 1939, graduated M.B., Ch.B. in 1942, and proceeded to the M.D., with distinction, in 1944 and the D.Sc. in 1953. He has carried out research on the reflex control of the circulation and respiration.

Release of "Prednisone" and "Prednisolone."—The Ministry of Health in conjunction with the Department of Health for Scotland and the Ministry of Health and Local Government, Northern Ireland, have made arrangements with United Kingdom manufacturers of prednisone and prednisolone which will enable preparations of these substances to be supplied on prescription from February 1.

Public Health Engineering.—A co-ordinating committee has been set up to deal with problems of public health engineering. The chairman is Sir ALLEN DALEY, and the constituent bodies, each of which has one representative on the committee, are: the Institute of Sewage Purification; the Institutions of Municipal Engineers, Public Health Engineers, and Water Engineers; the Royal Society of Health; the Royal Institute of Public Health and Hygiene; the Sanitary Inspectors Association; and the Society of Medical Officers of Health. The committee, whose address is 90, Buckingham Palace Road, London, S.W.1, will be pleased to consider appropriate questions put to it through the councils of other organizations.

Aerial Bactericides.—The British Standards Institution has published a British Standard describing a technique for the preliminary assessment of aerial bactericides (B.S. 2796: 1956, price 3s. 6d. from the sales branch, 2, Park Street, London, W.1). In addition to its primary purpose as a screening test for potential aerial bactericides, the technique is also recommended for "quality control" in manufacture. Details are given of the test-chamber, test-organism, and culture medium, physical conditions during testing, how to produce the bacterial spray; and of serial sampling, interpretation of results, and checking the technique by means of a "reference" bactericide.

Cambridge University.—Dr. L. B. COLE, senior physician of Addenbrooke's Hospital, has been appointed deputy for the Regius Professor of Physic until further notice, for all purposes except that of acting as head of the department of medicine. Dr. F. G. J. HAYHOE, university lecturer in medicine, has been appointed deputy head of the department of medicine from December 5 until further notice.

Reader in Pharmacology at Guy's.—Dr. J. A. NISSIM, senior lecturer in pharmacology at Guy's Hospital Medical

School, has had conferred on him the title of reader in pharmacology in the University of London.

Professor W. W. Mushin, professor of anaesthetics at the Welsh National School of Medicine, is going to the University of California Medical Centre during March as visiting professor of surgery (anaesthetics). On his way he will address the New York State Medical Society at its sesquicentennial celebrations in February.

First Southern Rhodesian African to Qualify.—The Secretary of Health of the Federation of Rhodesia and Nyasaland, Dr. R. M. MORRIS, announces that Mr. S. PAREREN-YATWA, who graduated in medicine last month at Witwatersrand University, Johannesburg, is the first African from Southern Rhodesia to qualify as a doctor. Mr. Pareren-yatwa also holds the B.Sc. (Hygiene) of Fort Hare University, Cape Province.

COMING EVENTS

United Hospitals Catholic Society.—Course of seven lectures in medical ethics on alternate Mondays, 6.15 p.m., at 13, Devonshire Place, London, W.1, starting January 7. Fee 5s. for non-members of the society.

Institute of Diseases of the Chest, London.—Clinical demonstrations open to medical practitioners will be held on Fridays at 5 p.m., January 11 to March 29. No fee.

Marc Daniels Lecture.—Dr. W. D. W. BROOKS will deliver the Marc Daniels lecture on January 15 at 5 p.m. at the Royal College of Physicians, Pall Mall East, London, S.W.1. His subject will be "The Prevention of Tuberculosis."

Goulstonian Lectures.—Dr. RAYMOND DALEY will deliver the Goulstonian lectures on January 17 and 22 at 5 p.m. at the Royal College of Physicians, Pall Mall East, London, S.W.1. His subject will be "The Autonomic Nervous System in its Relation to Some Forms of Heart and Lung Disease."

Disorders of Bone.—Details of a week's course (January 28-February 2) on disorders of bone, arranged by the Institute of Orthopaedics, London University, are given at p. 53 of the advertisements this week.

"Education for Motherhood."—Seminar for medical officers and divisional assistant medical officers will be held at St. John House, Collingham Gardens, London, S.W.5, February 26 to March 1. Professor W. C. W. NIXON will deliver the inaugural address. Details from the Medical Director, Central Council for Health Education, Tavistock House, Tavistock Square, London, W.C.1.

NEW ISSUES

British Journal of Ophthalmology.—The new issue (Vol. 40, No. 12) is now available. The contents include:

PERMEABILITY OF THE CORNEA AND THE BLOOD-AQUEOUS BARRIER TO OXYGEN. Kathleen Heald and Maurice E. Langham.
OCULAR ALBINISM WITH CHANGES TYPICAL OF CARRIERS. Václav Ohl.
VASCULARIZATION OF THE OPTIC PATHWAY. V. CHIASMA. J. François, A. Nectens, and J. M. Collette.
ECZEMA OF THE EYELIDS. Peter Borrie.
OXYPHENONUM BROMIDE AS A MYDRIATIC. H. Fraser.
ANOMALOUS DEVELOPMENT OF RETINAL VESSELS. Marjory B. Snodgrass.
PARAPHIMOSIS ORBICULARIS. Lloyd M. Weerekoorn.
RHABDOMYOSARCOMA OF THE ORBIT. N. S. Jain, D. V. Sethi, and K. C. Mahajan.
HERPES OPHTHALMICUS. R. S. MacLachly.
CORRESPONDENCE, BOOK REVIEWS, NOTES.

Issued monthly; annual subscription £4 4s.; single copy 8s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

Ophthalmic Literature.—The new issue (Vol. 10, No. 2) is now available. It contains a comprehensive selection of abstracts of the literature on ophthalmology and related subjects. Six issues and a volume index each year; annual subscription £4 4s. (or in combination with *British Journal of Ophthalmology*, £7 7s.); single copy 25s.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Saturday, January 5

E.E.G. SOCIETY.—At National Hospital, Queen Square, W., 10 a.m. to 4 p.m., meeting. Scientific papers.

Monday, January 7

MARLBOROUGH DAY HOSPITAL.—8.15 p.m., Dr. H. C. Beeble: Role of the Medical Superintendent in Modern Psychiatry.

● UNITED HOSPITALS CATHOLIC SOCIETY.—At 13, Devonshire Place, W., 6.15 p.m., The Reverend John McDonald: The Moral Law and Medicine.

Tuesday, January 8

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Sir Solly Zuckerman, F.R.S.: Biological Systems.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. Phyllis Wade: Radiation Treatment of Skin Cancer (Part I).

Wednesday, January 9

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. W. Riddell: Significance of Yeasts in Skin Diseases.

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Mr. D. S. M. Barlow: Oesophageal Obstruction.

ROYAL MEDICO-PSYCHOLOGICAL ASSOCIATION: PSYCHOTHERAPY AND SOCIAL PSYCHIATRY SECTION.—At 11, Chandos Street, W., 8 p.m., Dr. M. Balint: General Practice and Psychiatry. (Open to members and their guests.) SOCIETY FOR ANALYTICAL CHEMISTRY: MICROCHEMISTRY GROUP.—At "The Feathers," Tudor Street, E.C., 6.30 p.m., London discussion meeting.

Thursday, January 10

ALFRED ADLER MEDICAL SOCIETY.—At 11, Chandos Street, W., 8 p.m., Dr. E. Weissmann: The Unconscious in Adlerian Psychology and Psychotherapy.

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Professor Geoffrey Hadfield: Role of the Endocrine System in Breast Cancer.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. Phyllis Wade: Radiation Treatment of Skin Cancer (Part II).

LIVERPOOL MEDICAL INSTITUTION.—8 p.m., symposium: Advances in Control of the Circulation during Surgery. Dr. T. Cecil Gray: Induced Hypotension and Hypothermia; Dr. J. W. Dundee: Hypothermia in Neurosurgery; Mr. L. J. Temple: Development of Heart-Lung Pumps for Cardiac By-pass during Operations on the Heart.

LONDON UNIVERSITY.—At Wright-Fleming Institute Lecture Theatre, St. Mary's Hospital Medical School, 5 p.m., special university lecture in medicine by Professor C. A. Janeway (Harvard): Physiology of the Plasma Proteins.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., Watson Smith Lecture by Dr. R. M. B. MacKenna: Acne Vulgaris.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Professor J. I. P. James: Paralytic Scoliosis.

Friday, January 11

● INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. C. D. Calnan: clinical demonstration.

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. K. Robson: clinical demonstration.

INSTITUTE OF LARYNGOLOGY AND OTITIS.—3.30 p.m., Mr. A. R. Dingley: Cancer of the Mouth and Pharynx.

LONDON UNIVERSITY.—At Wright-Fleming Institute Lecture Theatre, St. Mary's Hospital Medical School, 5 p.m., special university lecture in medicine by Professor C. A. Janeway (Harvard): Physiology of the Plasma Proteins.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Ophthalmology Lecture by Professor A. Sorsby: Neomycin in Ophthalmology.

ROYAL MEDICAL SOCIETY, EDINBURGH.—8 p.m., dissertation by Mr. R. J. Wilson: Neoplasia.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Jones.—On December 26, 1956, at St. David's Hospital, Bangor, to Mary (formerly Snelling), wife of Dr. Ellis Jones, a son.

Watson.—On October 3, 1956, to Moira, wife of John S. Watson, M.D., M.R.C.P., of 22, Cambait Road, Putney, London, S.W., a sister for William.

Watts.—On December 18, 1956, at the Royal Free Hospital (Liverpool Road Maternity Annex) to Joan (formerly Lambert), M.B., B.S., M.R.C.O.G., wife of Richard W. E. Watts, Ph.D., M.B., B.S., M.R.C.P., a son—Richard Arthur.

MARRIAGES

Burrell—Osselton.—On December 12, 1956, at Newcastle-upon-Tyne, James T. J. C. Burrell, LL.B., to Bridget A. W. Osselton, M.B., B.S.

DEATHS

Brown.—On December 4, 1956, at Byron Bay, New South Wales, Australia, James Alexander Spence Brown, B.Ch., aged 57.

Hornby.—On December 13, 1956, at The Limes, Walkden, near Manchester, Mary Kate Hornby (formerly Carroll), M.B., B.Ch.

Lowe.—On December 10, 1956, at his home, 8, Alexandra Road, Burton-on-Trent, William Pickering Lowe, M.B., B.Ch.

Mills.—On December 2, 1956, at Downside, Bexhill-on-Sea, Sussex, Reginald Peter Mills, M.R.C.S., L.R.C.P., aged 41.

Patterson.—On December 8, 1956, at Dunedin Nursing Home, Deal, Kent, Thomas Charles Patterson, M.B., Ch.B., Surgeon Captain, R.N., retired, of Kingsdown, Deal, late of Christchurch, New Zealand.

Routley.—On December 5, 1956, at Aldershot, Hants, Edwin Walter Routley, M.D., M.R.C.P., D.P.H., aged 90.

Topping.—On December 8, 1956, at Catterick Military Hospital, York, Robert Ashley Ramsay Topping, M.R.C.S., L.R.C.P., D.T.M.&H., Lieutenant-Colonel, R.A.M.C., son of the late Professor Andrew Topping.

Waters.—On December 11, 1956, at his home, 176, Goring Way, Goring-by-Sea, Sussex, Alfred Charles Stanley Waters, M.R.C.S., L.R.C.P., late of March, Cambs.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Doctors with Cancer

Q.—Much stress is being laid on the importance of the early diagnosis of cancer in obtaining the best five-year cure rate. As doctors are themselves the best observers of the earliest symptoms of cancer, are there any figures to show that the cure rate of cancer in doctors is substantially better than in laymen?

A.—There are two facets to this very pertinent question: (1) Is the "cure rate" in doctors better than in laymen? (2) Do doctors seek investigation for suspected cancer sooner than laymen? Dublin *et al.*¹ investigated the first of these questions in the United States and found that "the death rate from cancer for each of the important sites is lower among physicians than among white males generally." The rate per 100,000 was 198 doctors to 245 laymen, a ratio of 0.81.

To the second question, Robbins *et al.*² were not able to return such an optimistic answer. They found, when comparing figures of 1923-8 with those of 1948, that there was during this time an improvement of 20% in the delay in seeking advice attributed to the patient, whereas the "culpability of the first physician consulted did not improve, in fact worsened from 17 to 23.4%." This "startling discovery" led them to wonder what sort of patient a physician himself would prove to be with regard to the early diagnosis of cancer. The answer was that there was no difference at all between a group of 229 physicians and 2,000 laymen, 39% of each group being considered to be blameworthy for delay in diagnosis and treatment.

Treatment of Ringworm in the Tropics

Q.—What treatment is advised for long-standing ringworm in tropical climates? What is the prospect of eventual cure?

A.—This is a very wide question and does not indicate the site affected by ringworm. Here ringworm of the scalp will be excluded and only some of the epidermophytoses considered.

Chronic tinea pedis may become troublesome in hot climates as a result of active blistering, secondary infection, and lymphangitis. In such an acute phase soaking in potassium permanganate solution (1 in 8,000) and the application of the following ointment are helpful: Gentian violet 0.5%, acid. salicyl. 1%, and equal parts of ung. emulsificans and paraf. moll. to 100%. Sulphonamide by mouth may be indicated for lymphangitis, and rest in bed is usually essential. In the more chronic phase microscopic examination of scrapings from the scaling areas should be carried out and cultures made from them. In the Tropics *T. rubrum* is common and is usually rather resistant to treatment. Locally ung. acid. benzoic. co. (Whitfield's ointment) is still as effective as most, though in the absence of the blistering dithranol (0.1%) in Lassar's paste is useful. The latter should not be applied to the tender skin of the instep. The nails of both the feet and hands should be carefully inspected and scrapings from any which are dystrophic examined for fungus. Infected nails require removal, but it is best to wait until the skin infection has been controlled. Within a day or two of removal the nail base should be treated with fungicidal ointment.

Tinea infection may be present in other sites. Tinea cruris usually clears readily with Whitfield's ointment, and more irritant preparations should be avoided. Pruritus ani may occur in a patient with tinea pedis as a result of infection in the perianal skin. Roughness of the palms of one or both hands resulting from hyperkeratosis may indicate infection with *T. rubrum*, and, indeed, it is now appreciated that smooth skin in any part of the body may become infected.

The prospect of cure is not good, though the infection can be kept controlled especially if care is taken in the toilet of the feet—daily washing with soap and water, especially between the toes, careful drying, and the use of fungicidal powders as a routine. The difficulty is to prevent re-infection either from socks, shoes, and slippers or from bath mats, duck-boards, etc.

Cheirpompholyx

Q.—What treatment would be likely to cure a case of cheirpompholyx? Local treatment with hydrocortisone ointment has not been successful in preventing recurrence.

A.—Cases of cheirpompholyx are among the most difficult with which a dermatologist has to deal. Some cases appear to depend upon chronic ringworm of the feet, and if this is present it should be treated along the usual lines. In most cases, however, no other lesion of the skin is present. The disorder may be associated with excessive sweating of the palms, and attacks may be brought on by hot weather or by emotional factors. In spite of this, drug treatment intended to reduce sweating seldom affects cheirpompholyx, and any psychiatric upset cannot usually be precisely defined and treated. Sedatives seem to be of no benefit. Treatment therefore resolves itself into a trial of various therapeutic measures which may from time to time help individual cases. Chief among these is x-ray treatment which is given during a period of quiescence with a view to preventing fresh attacks. Hydrocortisone is often unsuccessful, but in the worst cases the systemic administration of steroids—e.g., 30-40 mg. prednisone daily by mouth for a few days—will often cut short an attack. Provided the prednisone is given early in the attack, the lesions will often disappear completely within a few days or perhaps a week. After this, the prednisone must be gradually withdrawn, another week or ten days being taken over the process. Prednisone should not be given in the presence of pulmonary tuberculosis, high blood pressure, intestinal ulceration, and other usual contraindications. With a short treatment such as this, many of the complications of more prolonged treatment do not arise. The treatment is relatively trouble-free, though naturally reserved for the more serious case.

Two Anencephalic Monsters

Q.—A healthy woman in her early twenties has given birth to two anencephalic monsters. These resulted from her first and second pregnancies, during which she kept well. Neither in her own nor in her husband's family is there a history of any similar defect. How is anencephaly inherited, and what environmental factors are known to play a part in its aetiology? What is the prognosis as regards further affected children in the family cited?

A.—It is not known how anencephaly is inherited. No environmental factors have been shown to play any part in its causation in man.

A good estimate is available for the risk of anencephaly or spina bifida to later children of a mother who has had one child with anencephaly; the risk is about 1 in 30. But no well-founded estimate is yet available for a woman who, as here, had had two such malformed children. However, the risk is certainly not great. It is probably better than 1 in 10, and may be no more than the risk after one such child.

Sunbathing and Pulmonary Tuberculosis

Q.—*Is there any truth in the view that direct sunlight is harmful to patients suffering from pulmonary tuberculosis, even if the disease is quiescent?*

A.—After an earlier period of enthusiasm for sunlight in the treatment of pulmonary tuberculosis, medical opinion settled down to the general view that, on the contrary, sunlight was deleterious. The position is reviewed by Mayer.¹ More recently a number of cases of tuberculous pleural effusion have been described following sunbathing. Prolonged sunbathing, especially to the inhabitants of these islands who can indulge in it only occasionally, is apt to be exhausting, and any lowering of the body's resistance to the tubercle bacillus may be purely non-specific. Although it is not easy to prove a harmful effect, patients with pulmonary tuberculosis are probably wise to avoid erythematous doses of sunlight on their body.

Progressive Cerebral Arteriosclerosis and Hypertension

Q.—*My patient, aged 46, has been suffering from progressive slowing of the mental processes since a left hemiplegia eight years ago, presumably due to cortical thrombosis. The blood pressure has remained constant during this time around 200/110. His vision has begun to fail and memory is now extremely defective. Syphilis has been excluded. The diagnosis is progressive cerebral arteriosclerosis. Is there any specific treatment which might benefit this man? Would large doses of oestrogen be of help?*

A.—In the present state of our knowledge treatment of progressive cerebral arteriosclerosis with hypertension is at best experimental. Stellate ganglionectomy has been tried, but without result. Milder hypotensive agents like reserpine and hydralazine may be tried. Powerful ganglion-blocking agents (methonium, pentolinium) usually reduce cerebral blood flow when the pressure is very low and may aggravate the symptoms. Oral mecamylamine may be used in a dose which reduces the systolic pressure from 200 to about 150-160, but no attempt should be made to bring it down to normal figures. If symptoms become aggravated these drugs must be stopped. The subject of mental disturbance in malignant hypertension is discussed in a recent paper by Clarke and Murphy.¹

Large doses of oestrogens are under trial to limit the development of coronary atheroma. If proved successful they may later find a place in cerebral atherosclerosis. It should be remembered that no treatment will repair the destruction of brain tissue which has already occurred, and the best that could be anticipated would be arrest of the progression of the cerebral damage.

NOTES AND COMMENTS

Scientific Basis for Antenatal Relaxation Exercises.—Dr. ANTHONY RYLE (London, N.W.5) writes: May I comment on the reply on the question of the scientific basis for antenatal relaxation exercises ("Any Questions?" November 24, p. 1251)? There is, I feel, adequate scientific evidence that antenatal education, combined with careful handling of the labour, can reduce the pain of labour in a large proportion of women. The most significant report on this aspect is that of van Eps,¹ whose control series had no analgesia. Considerable reductions in forceps and caesarean rates, in perineal tears, and in neonatal asphyxia are reported by French and Russian writers summarized by Vermorel.² It is possible that these improvements, which are relative to previous experience of the writers, reflect no more than the ill effects of analgesics. They are none the less valuable. As regards pain relief, the mechanism is probably cortical rather than peripheral, and Vermorel gives a full explanation in Pavlovian terms of how this might act. Preparation should therefore be regarded as a combination of rational education and suggestion, and controlled series which lack the element of suggestion and

which ignore the importance of labour-ward atmosphere can clearly expect to achieve no demonstrable results.

REFERENCES

- ¹ van Eps, L. W. St., *Lancet*, 1955, 2, 112.
² Vermorel, H., *L'Accouchement sans Douleur par la Méthode Psychoprophylactique*, 1956. Camugli, Lyons.

OUR EXPERT replies: The original reply to the question made a clear distinction between the effect of relaxation and antenatal exercises on the course of labour and on the pain of labour. The latter is extremely difficult to assess scientifically, and for this reason only a guarded statement was made concerning it. The effect on the duration of labour, on the incidence of perineal tears, and on the need for operative intervention is easier to judge by controlled observations—although, even in this connexion, certain fallacies can arise. Dr. Ryle says that there is "adequate scientific evidence" to substantiate his claims, but gives no details of it. Why is the report by van Eps "the most significant"? Is it because the results support Dr. Ryle's contention, or is it because the inquiry leading to the report was better planned than the many others whose results are opposite? A careful and fair appraisal of the literature on this matter, as well as a detailed analysis of the results obtained in his own hospital, has been made by C. W. L. Burnett.¹ Those who consult his article will have little doubt where the truth lies.

Infirmity Mice.—Dr. A. J. K. DREW (Ramsgate) writes: With reference to the disappearance of the infirmity mice ("Any Questions?" November 17, p. 1190), rats are known to make occasional sudden departures from old haunts, and it may be that mice do the same thing—especially if given a formal invitation, as the following true story illustrates.

When my father was a young man his parents' stables at the end of a long garden in a small country town were infested with rats, no doubt attracted by the horses' oats and fodder. One day, when talking to the son of the corn merchant, my father mentioned the old Dorset belief or legend that rats could be induced to move if they were sent a polite invitation to a better hole. "If that is all," said the other, "I will write and ask the rats to come to our commodious corn stores, where they will find far more to eat than in your stables. But I shall be surprised if they accept." So a note to that effect was written and pushed into the largest rat-hole. As might have been expected, nothing appeared to happen at first. About two weeks later, however, a few friends returning home in the small hours reported that they had seen a large number of grey rats (definitely not pink ones) making their way along the street going east, that incidentally being the direction to the corn-shop from the stables. It is a fact that from that time our stables, and also another adjoining, became free from rats for many years, while what the corn merchant described as a great plague of rats attached themselves to his premises.

The above is an unvarnished account of what happened. Readers can judge for themselves as to cause and effect. If there are any doubters, let those with suitable premises write and deliver welcoming letters inviting the rats (or mice) from an infested house which is not too far away to their own, and await the result. If they do not like it when it happens—they have been warned.

Correction.—We are informed that the sum given by the Pharmaceutical Society to the Lord Mayor's Fund for Hungarian Refugees was 250 guineas, not 25 guineas as was previously stated (*Journal*, December 29, p. 1542).

Books of "Any Questions?" and Refresher Course Articles.—The following books are available through booksellers or from the Publishing Manager, B.M.A. House. Prices include postage. *Any Questions?* Volumes 2 and 3 (8s. each); *Refresher Course for General Practitioners*, Volumes 2 and 3 (26s. 6d. each inland, 26s. overseas); *Clinical Pathology in General Practice* (22s. 3d. inland, 21s. 9d. overseas).

VACCINATION AGAINST POLIOMYELITIS WITH LIVE VIRUS VACCINES**1. A TRIAL OF TN TYPE II VACCINE**

BY

D. S. DANE, B.A., M.B., B.Chir.
Lecturer in Microbiology

G. W. A. DICK, M.D., D.Sc., F.R.C.P.Ed.
Professor of Microbiology

J. H. CONNOLLY, M.B., B.Ch., B.A.O.
Research Fellow, National Fund for Poliomyelitis Research

O. D. FISHER, M.D., M.R.C.P., D.C.H.
Formerly Lecturer in Child Health

AND

FLORENCE McKEOWN, M.D.
Reader in Morbid Anatomy

WITH

MOYA BRIGGS, B.Sc.,² ROBERT NELSON,³ AND DERMOT WILSON, F.I.M.L.T.⁴
The Queen's University of Belfast

The successful immunization of children with an orally administered attenuated type II poliovirus has been described by Koprowski, Norton, Jervis, Nelson, Chadwick, Nelsen, and Meyer (1956). The virus used was the TN type II rodent-adapted strain (Koprowski, Jervis, and Norton, 1952; Koprowski *et al.*, 1956). One hundred and fifty children in institutions in the United States of America were vaccinated with this virus between 1950 and 1955. Prior to vaccination all children were without antibody to type II poliovirus; after vaccination nearly every child (in one series 86 out of 87) developed antibody. Reasonably high antibody titres were found and this antibody was shown to persist in a small number of children who were studied over a period of five years. No reactions or illnesses attributable to vaccination were observed in any subject vaccinated.

The TN vaccine virus which had been adapted to growth in mouse C.N.S. did not produce cytopathogenic changes when inoculated on to monkey-kidney-tissue cultures. Only when it was inoculated in large amounts intraspinally or intracerebrally into monkeys did TN vaccine virus cause paralysis or histological lesions. Virus was found in the faeces of about half the children vaccinated, and, like the vaccine virus, it was found to be non-cytopathogenic for tissue culture. For this reason it was detected by the intraspinal inoculation of mice. The last day after vaccination on which virus was found in the faeces was the 23rd day. The highest titre of virus found in any faecal specimen was 10 mouse-paralysing doses₅₀ (MPD₅₀) per gramme (Koprowski *et al.*, 1956). No further information was available about the nature of the faecal virus, but, in view of the very small amounts of virus excreted, transmission from vac-

cinated subjects to their contacts seemed highly improbable. TN virus was never recovered from the throats or from the blood of vaccinated children.

These results were encouraging. The TN type II vaccine appeared, so far as could be judged from the laboratory data and the relatively small numbers vaccinated, to be both safe and immunogenic. With this background a small trial was planned in Northern Ireland to confirm Dr. Koprowski's findings. The possible value of an attenuated type II vaccine in reducing the rate of paralytic poliomyelitis caused by all three poliovirus types is quite unknown, but it seemed reasonable to conduct initial studies with type II virus on general grounds of safety both to the individuals vaccinated and to the community.

The trial was executed in the following manner. In the first place the laboratory characteristics of the vaccine virus as described by Dr. Koprowski were confirmed, then a small number of adults were fed with the vaccine. These adults were members of the laboratory staff and medical students. Later a few infants and the children of the investigators were vaccinated. Finally, the vaccine was fed to a larger group of children. The parents of most of these children were medical practitioners or members of the university staff. A total of 190 individuals were vaccinated between February and July, 1956. Many of the children were vaccinated without prior knowledge of their immune status, and among these there were some already immune to type II poliovirus; however, the majority of children and all the adults were without type II antibody at the time of vaccination. Laboratory investigations and clinical observations were planned in the light of available data. Due allowance had to be made for the fact that normal volunteer subjects leading normal lives were being studied. While in some ways this increased the value of our observations, it meant that the collection of specimens

5010

¹Consultant Paediatrician, Midway and Gravesend Group of Hospitals.

²Technicians paid with grants from National Fund for Poliomyelitis Research, Medical Research Council, and World Health Organization respectively.

lacked the precision that might have been attained in an institution or penitentiary. Also such studies as the detection of viraemia, which involved daily bleeding, could not be carried out with volunteer children.

Materials and Methods

The vaccine was supplied by Dr. H. Koprowski. It had been prepared from a pool of mouse brain and cord suspension representing the 29th passage in PRI mice of TN type II poliovirus.

Tissue-culture Techniques.—Second-passage monkey-kidney-cell monolayers in roller tubes were used in the virus neutralization tests and for the isolation of cytopathogenic viruses. Lactalbumin medium described by Melnick (1955) was employed throughout.

Virus-neutralization Tests.—These were performed by the method described previously (Dane, Dick, Connolly, Briggs, and McLeod, 1956) using 100 TCD₅₀ of virus. British Standard immune serum against type II poliovirus was used as a control. The titre of this serum was 1 in 640. In this study donors of sera which did not neutralize 100 TCD₅₀ of virus at a 1 in 4 dilution were regarded as being without antibody.

Virus Isolations.—The techniques employed for the isolation of virus from faeces, throat swabs, and blood specimens are described elsewhere (Dick, Dane, Fisher, Connolly, and McKeown, 1957).

Storage of all specimens was at -20° C. The vaccine was stored at -65° C.

Monkeys.—Rhesus monkeys of approximately 7 lb. (3.2 kg.) weight were employed. They were anaesthetized with thiopentone sodium. Intracerebral inoculations were made by the method described by Bodian, Morgan, and Schwerdt (1950). Intraspinal inoculations were made into the lumbar enlargement by placing the inoculum between the second and third lumbar spines. Monkeys were examined each day up to 28 days after intracerebral inoculation and for 14–18 days after intraspinal inoculation. On most days the monkeys were removed from the cages and tested manually for evidence of paralysis. The power of the muscles of the upper and lower limbs was recorded, following the method described by Bodian (1948).

Mice.—The mice were of the VSBS strain of Swiss mice. Intracerebral and intraspinal inoculations were done by the usual methods.

Histology.—Animals were perfused by the method described by Bodian (1948), using 10% formalin containing 10% acetic acid. The usual blocks from brain, brain stem, and cord were embedded in paraffin and stained with gallocyannin.

Laboratory Tests of the Vaccine

The batch of vaccine used in this trial was tested in the following manner by Dr. H. Koprowski at Lederle Laboratories, Pearl River, New York: (1) Monkeys were inoculated by the intraspinal and the intracerebral routes with the vaccine. (2) Guinea-pigs were inoculated subcutaneously and intracerebrally. (3) The vaccine was inoculated onto a variety of bacteriological media.

These tests were repeated in our own laboratory. No evidence was obtained in either laboratory that any micro-organism other than TN type II virus was present in the vaccine.

Results of the inoculation of monkeys with the vaccine are shown in Table I. Our results were similar to those of

Dr. Koprowski; we found that large amounts of virus given by the intracerebral route caused no paralysis. But when given by the intraspinal route the vaccine virus did cause paralysis in some monkeys.

We found that the vaccine virus did not produce cytopathogenic changes in monkey-kidney-tissue culture; neither did it appear to interfere with the growth of small amounts of a cytopathogenic type II poliovirus in tissue culture.

Vaccination of Adults

Twenty-one adults were fed 500,000 MPD₅₀ of TN vaccine virus diluted in 4 ml. of milk. Tests have been completed for 18 (10 men and 8 women); their ages ranged from 20 to 50 years. None had type II antibody prior to feeding and nine had no antibody to any of the three poliovirus types. Only four subjects had developed type II antibody when their blood was tested two to three months after vaccination (see Fig. 1). Six of the non-reactors were fed a second time with the same dose of virus contained in gelatin capsules. Once more none of these subjects developed antibody. Of the four subjects who did develop antibody two were men aged 21 and 22, and two were women aged 44 and 50 years. No common factor has yet been found which might explain the failure of vaccination in 14 out of the 18 adults.

Throat swabs and blood samples were collected daily for the first 10 days after vaccination from 10 of the adults, and faecal specimens were also obtained during the first two weeks (see Table II). No viraemia was detected in any subject. A trace amount of virus was recovered from the throat of one subject from a pool of swabs taken during the first three days after vaccination. This virus was detected by mouse inoculation, but could not be detected in tissue culture. No virus was recovered in any faecal specimen either by mouse inoculation or in tissue culture, but in the light of later experience we consider that too few specimens were collected for too short a period for any conclusions

FIG. 1.—Type II antibody response in 18 adults fed with TN vaccine.

to be reached on the faecal excretion of TN virus by adults. In addition, it must be noted that only 3 of the 10 adults in whom these investigations were made developed antibody.

Vaccination of Children

One hundred and fifty-five children between the age of 10 months and 15 years were fed TN vaccine (500,000 MPD₅₀ in 4 ml. milk) during May and June. Paired specimens of sera, the first taken at the time of vaccination and the second six or more weeks later (see Table III), were available.

able for testing from 124 who had no type II antibody at the time of vaccination. The ages of the children in this group are shown in Table IV; there were 58 boys (this group are shown in Table IV); there were 58 boys and 66 girls. Twenty-eight children (23%) failed to develop type II antibody after vaccination. The remaining 96 (77%) developed antibody titres ranging from a trace to 1 in 2,048 (see Fig. 2). The geometric mean antibody titre for these 96 children is 1 in 66.

FIG. 2.—Type II antibody response in 124 children fed with TN vaccine. All children had <1/4 type II antibody at time of vaccination.

sibling developed antibody. If all the individuals in this group of siblings had responded independently then it would have been expected that 13.5 of the pairs of siblings would

have developed antibody, 1.5 pairs would have developed no antibody, and in 9 pairs one sibling would have developed antibody. The difference between the observed and expected antibody response of the siblings is highly significant ($\chi^2 = 8.7111$; $0.01 > P > 0.001$).

Of the 20 pairs of siblings where either or both children developed antibody, the higher titre was found in the younger child in 15 cases. In one case the titres were equal and in the remaining four the elder child developed the higher titre. If the antibody titres had not varied with age we would not have expected this difference ($\chi^2 = 5.0$; $0.05 > P > 0.02$).

It was not practicable to collect throat swabs or daily blood samples from any of the children. Faecal specimens obtained from 18 of them during the first few weeks after vaccination were tested for the presence of virus both by the intraspinal inoculation of mice and in tissue culture. The results of these tests are shown in Fig. 3. The pattern of virus excretion was varied and cannot be assessed fully because specimens were collected over too short a period on the assumption that our findings would be broadly similar to those of Dr. Koprowski. Of the 18 children studied, 15 developed antibody in response to vaccination and faecal virus was detected in these 15 children both by mouse inoculation and in tissue culture.

No virus was found in the faeces of the three children who did not develop antibody. The titres of the faecal virus tended to be higher in tissue culture than when estimated by mouse inoculation. Comparative titrations of early and late faecal specimens from one child in tissue culture and in mice showed that the virus from the early specimen had a higher titre by mouse inoculation than in tissue culture, but that the virus from the late specimen had a higher titre in tissue culture. Peak titres of 10^4 TCD₅₀ per gramme of faeces or higher were recorded for three children. One girl aged 10 months excreted $10^{4.4}$ TCD₅₀ of virus on the fifth day after feeding, and at this time her brother aged 2, who was vaccinated on the same day, was excreting $10^{3.1}$ TCD₅₀ per gramme of virus in his faeces. Unfortunately it was not possible to obtain further specimens from these children until the 55th day, when neither was found to be excreting virus. (It is possible, but improbable, that these siblings were infected naturally with a wild type II virus at about the time of vaccination.) Six other children were still excreting virus when collection of specimens ceased during the fourth or fifth week after vaccination. In Fig. 3 nine siblings have been grouped in the left-hand column. The pattern of their faecal excretion and their antibody response serve to illustrate the trend already mentioned that siblings responded to vaccination in a similar fashion, and that the younger sibling responded better.

Vaccination of Infants

Ten infants were fed TN vaccine. They received the same dose as that given to adults and children. The virus was administered in milk in a rubber-teated bottle. A blood sample from each infant was tested for type II antibody a few weeks prior to vaccination, on the day of vaccination, and again 6 to 11 weeks later. On the first occasion blood was also taken from the mother and tested for type II antibody. Six infants had antibody titres of greater than 1 in 16 when first tested. Antibody titres found in the blood of their respective mothers were of the order that might have been expected when allowance was made for the age of the infant. For this reason it was concluded that the antibody present in the blood of the six infants was passively acquired maternal antibody. At the time of vaccination three of these six infants still had antibody titres greater than 1 in 16. In response to vaccination 5 of the 10 developed antibody titres greater than 1 in 16 (see Fig. 4). A sixth infant (No. 287) had a rise in antibody from less than 1 in 4 on the day of vaccination to 1 in 6 seven weeks later. There was insufficient serum

Faecal excretion of virus was studied in all infants (see Fig. 5). Specimens were collected daily for periods ranging from 8 to 28 days. Six infants, all of whom developed antibody, excreted virus which was detected both by mouse inoculation and in tissue culture. One infant who did not develop demonstrable antibody excreted virus detectable

The Monkey Pathogenicity of Excreted TN virus was available. At the time of this trial no information was available about the pathogenicity of faecally excreted TN virus for monkeys inoculated intracerebrally or intraspinally. For this reason we decided to compare the relative virulence of the vaccine virus with that of the excreted virus by the intracerebral inoculation of monkeys. In view of the very low titres of virus found in stools by Koprowski *et al.* (1956) we thought that it would be advisable to investigate excreted virus in two ways; firstly, by the direct inoculation of stool suspensions; and, secondly, by the inoculation of first-mouse-passage faecal virus. The object of the second method was to raise the titre of virus inoculated to levels comparable with that of the virus used in the original monkey tests of the vaccine. At this time we were unaware that faecal TN virus was cytopathogenic and that tissue-culture-passage of faecal virus could have been used instead of mouse-passage virus. The results of the intracerebral inoculations of monkeys with faecal virus from two infants and one child are shown in Table V.

It will be seen that the mouse passage of faecal virus was unnecessary and could have been misleading. Mouse passage

Fig. 4.—Type II antibody response in infants fed with TN vaccine. Antibody prior to vaccination was passively acquired maternal antibody. Serial numbers and age at time of vaccination:

Antibody prior to antibody.	Serial numbers	and age at time of	No.	Age in months

possessed the same pathogenicity for monkeys by the intracerebral route as the SM vaccine virus. A final reason for limiting the size of the trial was that we were dealing with type I virus.

Our trial was planned to answer two questions. Was SM virus likely to be transmitted within a normal family? And did SM faecal virus possess the laboratory characteristics of attenuation shown by SM vaccine virus? The vaccine was first tested in the laboratory and then fed to a small number of adults without type I antibody (the investigators, their colleagues, and medical students). The home contacts of these adults were studied to see whether or not virus transmission occurred. It did not. Then two infants possessing maternal type I antibody were fed and their contacts studied. No transmission was observed. Finally, one child in the family of one of us was fed SM vaccine to see whether transmission occurred in a normal family living under normal conditions. Originally it was planned to increase gradually the number of family contact studies, but in view of the results obtained with the first family further investigation along these lines seemed unnecessary.

Materials and Methods

The vaccine used in this trial was SM (N 90) type I attenuated poliomyelitis virus vaccine (Koprowski). The virus which had originally been adapted to PRI mice by the intraspinal route had subsequently been given 13 chick-embryo tissue-culture passages plus six alternating passages in monkey-kidney and chick-embryo tissue culture.

The tissue-culture techniques, virus neutralization tests, monkey inoculation experiments, and methods of storage were similar to those described for the trial of TN type II vaccine (Dane, Dick, Connolly, Fisher, and McKeown, 1957).

Methods Used for Isolation of Viruses

Faecal Specimens.—Twenty per cent. suspensions were prepared by shaking faeces with tissue-culture medium or distilled water in the cold and then centrifuging this mixture at 4,000 r.p.m. for one hour. These suspensions were

diluted for inoculation into tissue-culture tubes to give a screening level of 10^{2.5} TCD₅₀ per gramme of faeces. Selected specimens were titrated. Tubes were examined daily for six days for signs of degeneration. The direct method of virus isolation described by Dane and Briggs (1956) was also used for screening most of the specimens. Negative results by the latter method were checked by the quantitative screening method.

Throat swabs were broken off into bijoux bottles containing 1 ml. of tissue-culture medium. 0.5-ml. amounts of this fluid were inoculated into roller tubes containing monkey-kidney monolayers from which the maintenance medium had been removed; the tubes were then incubated for 30 minutes, after which the throat-swab medium was removed and replaced by maintenance medium. Tubes were examined daily for 10 days.

Blood Specimens.—Heparinized blood was inoculated direct on to monkey-kidney monolayers in the manner described for the specimens of throat swabs. Tubes were examined daily for at least 10 days.

Laboratory Tests of SM Vaccine Virus

The SM (N 90) type I vaccine was supplied by Dr. H. Koprowski, Lederle Laboratories, Pearl River, New York. Dr. Koprowski tested the pathogenicity of the vaccine virus for monkeys inoculated by the intracerebral and the intraspinal routes. He also conducted appropriate tests to exclude the presence in the vaccine of micro-organisms other than type I poliomyelitis virus. These were similar to the tests described elsewhere for TN vaccine (Dane, Dick, Connolly, *et al.*, 1957).

Similar laboratory studies were carried out with SM vaccine in Belfast. The results of the monkey pathogenicity tests done in New York and in Belfast are shown in Table I. They are comparable, and demonstrate that, while the SM vaccine virus did not cause paralysis of monkeys when inoculated in large amounts by the intracerebral route, it was able to cause paralysis when moderate amounts were inoculated by the intraspinal route.

Vaccination of Adults

During February, 1956, three adults were fed 54 TCD₅₀ of SM type I vaccine virus in capsules. Only one (No. 235) (see Tables II and III) excreted the virus and developed antibody; the other two (Nos. 193 and 218) did not on this occasion become infected.

During March and April a further seven adults were vaccinated and the two who had failed to respond on the first occasion were revaccinated. Another adult was vaccinated in June. All these subjects received 3,500 TCD₅₀ of vaccine virus in capsules given by mouth. Faecal specimens were examined (except in the case of No. 314), and all subjects were found to be excreting virus (see Table II). Intestinal carriage lasted for up to 36 days and some specimens contained moderately high titres of virus. These results are in general similar to those reported for children by Koprowski *et al.* (1956). The homotypic antibody responses in vaccinated adults are shown in Table III. Every subject produced antibody, but the post-vaccination antibody levels showed wide variation. Tests on sera taken from seven of these individuals, six to nine months after vaccination, showed that the antibody titres had in most cases fallen. No estimate of the future rate of decline of antibody can be made at present.

An analysis of the relationship between height and duration of virus excretion with antibody production is not possible with such a small number of observations. However, we may speculate that there is some relationship. For example, the two poorest virus excretors (Nos. 326 and 330) produced very low levels of antibody, and the four subjects (Nos. 235, 193, 212, and 218) who excreted for the longest periods had late peak antibody titres (see Tables II and III).

* Reciprocal of serum antibody titre.
+ = > 1 in 4. — = < 1 in 4.

Daily throat swabs and blood samples were taken from 10 of the 11 adults for the first 10 days after vaccination. No throat virus was isolated, but one individual (No. 212) had a trace amount of virus in his blood on the eighth day. This isolation was repeated for confirmation. In connexion with his viraemia it is of interest to note that subject No. 212, unlike the other nine subjects, had no type II antibody and that he also produced the highest type I antibody titre. Studies of heterotypic antibody responses are incomplete, but it is worth mentioning that No. 212 developed low-titre type II antibody as well as the high-titre type I antibody after vaccination.

Vaccination of Infants with Maternal Antibody

Two infants (aged 2 and 3 months) who had maternal passive immunity were fed 6,400 TCD₅₀ of SM vaccine in milk. Three specimens of serum were obtained from each infant, one a few weeks before vaccination, one at the time of vaccination, and one five weeks later. Their mothers were also bled on the first occasion and a comparison of infant and maternal type I antibody titres demonstrated that the infants' immunity was passively acquired. Both infants became faecal virus carriers and both developed active immunity to type I poliovirus (see Table IV). The rises in antibody titre between the time of vaccination and five weeks later were small, but significant when allowance is made for the rate of decline of passive immunity. One infant (No. 242) excreted virus for at least 35 days (the negative specimen obtained on the 40th day is not by itself sufficient evidence of the cessation of virus excretion), and the other infant (No. 349) excreted faecal virus for at least 50 days. Peak titres of 10^{2.5} (No. 242) and 10^{4.5} TCD₅₀ (No. 349) of virus per gramme of faeces were recorded.

Vaccination of Family

Family and household contacts of the vaccinated adults and infants were investigated for signs of infection with SM virus. No evidence of transmission was found. However, we considered the crucial test of whether SM virus could spread within a family would come only when we vaccinated one young child in a family having other non-immune siblings. The family chosen for this study consisted of a father aged 41 who had been successfully vaccinated three months previously with SM type I vaccine, a mother aged 38, a son aged 2, and two daughters aged 4 and 6. Another son aged 8 was away at boarding school. All the family had naturally acquired immunity to type II poliovirus, but only the father had antibody to type I. When the father had been vaccinated he had failed to transmit SM virus to any other members of the family.

The daughter aged 4 was fed 6,400 TCD₅₀ SM virus in milk on May 3, 1956. She became a faecal virus carrier for about the next eight days (see Table V). A peak titre of 10^{6.5} TCD₅₀ virus per gramme of faeces was found on the fifth day after vaccination. No poliovirus was isolated from

her throat, and by the sixth week she had developed a type I antibody titre of 1 in 256. Her younger brother aged 2, who had not been vaccinated, became a faecal carrier of type I virus on the fifth day after his sister had received the vaccine. He continued to excrete virus in his faeces for about a week. The peak titre recorded for virus in his faeces was $10^{2.5}$ TCD₅₀ per gramme on the fifth day of excretion. No throat swabs were collected from this child. He developed type I antibody with a titre of 1 in 32 six weeks after his sister had been vaccinated. Insufficient specimens of faeces were collected from the mother to determine whether or not she became a faecal carrier of type I virus, but during the six-weeks study period she did develop low titre (1 in 6) antibody to type I. Her paired sera were tested on two separate occasions with the same result, and we consider that she became infected as a result of contact with one of the children. In view of the low titre of antibody which she developed she may have excreted faecal virus for only a

short period, like some of the vaccinated adults. The other child living at home, a daughter aged 6, did not develop detectable type I antibody. In our opinion SM virus spread within the family by the faecal-oral route. The children of this family had fairly close contact with children from two other families. The infection did not spread to these other children.

When considering the significance of this study we should remember that it was conducted during the time of year when notified cases of poliomyelitis were at a low level. We do not know whether the chain of infection would break as readily during the later months of the year.

Monkey Pathogenicity of SM Faecal and SM Blood Viruses

Monkeys were inoculated intracerebrally with faecal SM virus from an infant (No. 242), an adult (No. 212), the

All monkeys inoculated intracerebrally with 1 ml. of virus suspension. Non-specific deaths within 72 hours of inoculation have been excluded from the table. Monkeys showing mild transient weakness and their incubation periods are shown in bold type.

vaccinated child (No. 337), and her brother, whom she infected (No. 338) (see Table VI). The infant's faecal virus was from a late specimen taken on the 35th day after vaccination. The adult's faecal virus was from the specimen collected the day following his viraemia. The specimens from the two children were both taken on the fifth day after the commencement of virus excretion. Three specimens were given a single passage in monkey-kidney-tissue culture to enhance their titres before being tested. Twenty-two monkeys were inoculated and seven became paralysed (Table VI). Typical lesions of poliomyelitis were found in the central nervous system of 18 of the 22 monkeys. The amounts of virus inoculated into the five groups of monkeys varied from $10^{4.6}$ to $10^{5.1}$ TCD₅₀, but there was no difference in the numbers of monkeys paralysed or showing typical histological lesions between the five groups. There was no apparent difference between the SM faecal virus recovered from the child (No. 337) who was vaccinated and that recovered from the child (No. 338) who became infected after contact.

These results of the intracerebral inoculation of monkeys with faecal virus can be compared with those obtained with the vaccine virus (see Table I). Of 12 monkeys inoculated intracerebrally with large amounts ($10^{4.6}$ and $10^{5.1}$ TCD₅₀) of SM vaccine virus none showed paralysis, but two had histological lesions. A direct numerical comparison between the results obtained with the vaccine and faecal SM viruses is not possible because of the variations in titre of the different inocula. However, if these differences are ignored we may express the results of the intracerebral inoculations in the following manner: SM vaccine virus paralysed 0 out of 12 monkeys, and SM faecal virus paralysed 7 out of 22 monkeys. Histological lesions were found in 2 of the 12 monkeys inoculated with SM vaccine virus, and in 17 out of the 22 inoculated with SM faecal virus. The interpretation of these data may be open to argument, but we conclude from them that SM faecal virus is more paralytogenic than SM vaccine virus when inoculated intracerebrally into monkeys.

Another comparison of SM vaccine and faecal viruses was made by the intraspinal inoculation of monkeys. The faecal virus used in this experiment was from the child infected by his vaccinated sister and thus represented the second human passage of SM virus. The two viruses were inoculated in titres ranging from $10^{4.6}$ to $10^{5.1}$ (see Table VII). The results of these two titrations are broadly similar and show that the intraspinal pathogenicity of SM virus had not increased after two human passages.

TABLE VII.—Comparative Intraspinal Monkey Pathogenicity of SM Vaccine Virus and Second Human Passage SM Faecal Virus

Source of Virus	Log ₁₀ TCD ₅₀ Inoculated	No. of Monkeys Inoculated	Paralytic Ratio
SM N-90 Type I poliomyelitis virus vaccine	4.6	6	4/6
	3.6	4	3/4
	2.6	4	3/4
	1.6	3	2/3
	0.6	4	0/4
Second human passage SM faecal virus	4.6	5	3/5
	3.6	6	4/6
	2.6	4	2/4
	1.6	4	2/4
	0.6	4	0/4

Only a trace amount of virus was recovered from the blood of one subject (No. 212), but because of the possible importance of viraemia in the pathogenesis of paralytic poliomyelitis this virus, or more correctly its progeny, was inoculated into monkeys. Sufficient virus for the inoculation could be obtained only by using second-monkey kidney-tissue-culture passage of the blood virus. Eleven monkeys were inoculated intraspinally with amounts of virus ranging in titre from $10^{4.6}$ to $10^{5.1}$ TCD₅₀ (see Table VIII). None of these monkeys became paralysed. Assuming that two tissue-culture passages did not greatly alter the

nature of the virus, we may conclude that the virus isolated from the blood of subject No. 212 on the eighth day after vaccination was not of high intracerebral virulence for monkeys.

TABLE VIII.—Pathogenicity for Monkeys of Second Tissue-culture Passage SM Virus from Blood of Subject No. 212

Dilution of Tissue Culture Fluid	Log ₁₀ TCD ₅₀ Inoculated	No. of Monkeys Inoculated	Paralytic Ratio	Remarks
Undiluted	5.9	3	0/3	
10^{-1}	4.9	4	0/4	
10^{-2}	2.9	4	0/4	1 monkey died day 9; weak monkey

All monkeys inoculated intracerebrally with 1 ml. of virus suspension.

Reactions

All subjects vaccinated were under continual medical observation during the month following vaccination. No serious illnesses were reported, but minor illnesses or symptoms were recorded in 9 of the 16 persons who were successfully vaccinated or who were infected by contact (Table IX). A cytopathogenic virus was recovered from the throat of one child (No. 337) who had a fever following vaccination, but this proved not to be a poliovirus.

TABLE IX.—Clinical Observations in Individuals who had Minor Upsets after Vaccination with SM Vaccine

No.	Age	Sex	*Temp. (°F.) Rise, on Day ()	Symptoms and Signs on Day ()	Remarks
349	2 12	M	None	Colic (8)	
242	3 12	M	None	Off feed (8)	
338	2	M	101° (3)	Off colour for 8 weeks	Contact of 337 (see text)
337	4	F	103° (6, 7)	Fever	Non-polio virus recovered from throat (day 6) (see text)
235	25	M	None	Sore throat (4)	No virus in throat
353	24	F	..	Backache (2-4)	
331	31	M	..	Feeling unwell (0-3)	Anxiety
218	39	M	..	Occasional loose stool (3-5)	
326	53	M	..	Easily tired (0-14)	

* Twice-daily temperature records for 10-14 days after vaccination.

It is quite impossible to draw any conclusions from the small numbers observed. In our opinion the question of whether minor signs and symptoms may follow the administration of SM vaccine has still to be answered.

Summary and Conclusion

Eleven adults, two infants, and one child were fed SM type I poliomyelitis virus vaccine. In addition one adult and one child became infected in a study of the transmissibility of the vaccine virus.

None of these 16 subjects developed any serious illness. It was impossible to be certain whether or not some of the minor illnesses recorded were due to vaccination.

All subjects were without type I antibody at the time of vaccination and all developed antibody after vaccination. The two infants possessed moderate titres of maternal antibody at the time of vaccination, but this did not prevent them becoming faecal virus carriers and developing an active immunity. A decline in circulating antibody from the highest titre reached was observed in the majority of adults during the months following vaccination.

All subjects became faecal carriers of virus. The duration of faecal excretion varied from one week to

more than seven weeks, and high titres of virus were found in early faecal specimens from some individuals.

A trace amount of virus was recovered from the blood of one adult on the eighth day after vaccination. No throat virus was recovered from any of the vaccinated individuals.

SM virus was shown to spread within a normal family living under normal conditions of hygiene following the vaccination of one child in the family.

SM faecal virus was found to cause paralysis in some monkeys inoculated intracerebrally, whereas monkeys inoculated by this route with SM vaccine virus were not paralysed.

SM type I poliomyelitis virus was considered suitable for trial as a vaccine because it did not cause paralysis in monkeys when inoculated by the intracerebral route. However, the virus underwent a change after multiplication in the human gut, and SM faecal virus caused paralysis in a proportion of the monkeys inoculated by this route. In addition SM virus can spread from the vaccinated to the unvaccinated.

We thank the medical student volunteers who took part in this trial and also Dr. Ritchie Russell and his colleagues. This trial was financed by grants from the National Fund for Poliomyelitis Research, the Medical Research Council, the World Health Organization, and the Northern Ireland Hospitals Authority.

3. THE EVALUATION OF TN AND SM VIRUS VACCINES*

BY

G. W. A. DICK, M.D., D.Sc., F.R.C.P.Ed.
Professor of Microbiology

AND

D. S. DANE, B.A., M.B., B.Chir.
Lecturer in Microbiology

The Queen's University of Belfast

There are three approaches to active immunization against micro-organisms. The first of these is to inactivate the micro-organisms by chemical or physical means and to infect the host with measured amounts of the inactivated organism. Formalized tissue-culture poliovirus vaccines, which are now commonly referred to as Salk-type vaccines, are of this type. The second method is to immunize with living micro-organisms which have been rendered avirulent for their original host. This type of vaccine is exemplified by B.C.G. or the 17D strain of yellow fever. Attempts to produce attenuated strains of poliovirus have been undertaken by several investigators, and trials of attenuated living poliovirus vaccines in human beings have been described by Koprowski, Norton, Jervis, Nelson, Chadwick, Nelsen, and Meyer (1956), by Sabin (1955a), and in the preceding papers by Dane, Dick, Connolly, Fisher, and McKeown

(1957) and Dick, Dane, Fisher, Connolly, and McKeown (1957). The third method of immunization is to employ micro-organisms from a different species which are immunogenically related to the micro-organisms against which protection is required. The Jennerian method of vaccination with cowpox to protect against smallpox employed this approach, but it has not yet been investigated in the poliomyelitis field.

The reasons for using attenuated viruses for immunization against poliomyelitis are based primarily on the hope that they will produce long-lasting immunity, for there is as yet no evidence that the immunity which will follow immunization with inactivated (Salk-type) vaccines will be durable. Attenuated poliovirus vaccines can be given by mouth and thus present a considerable administrative advantage and dispense with the use of syringes. Furthermore, the cost of attenuated poliovirus vaccines should be very much less than that of inactivated vaccines.

Before attempting to evaluate TN and SM attenuated poliomyelitis virus vaccines some epidemiological aspects of a trial of these vaccines (Dane *et al.*, 1957; Dick *et al.*, 1957) are discussed: in conclusion we shall present the criteria which we, at present, consider are required for attenuated poliovirus vaccines.

Some Epidemiological Aspects of Trials of TN and SM Virus Vaccines

Antibody Production

While comparing the response of children and adults to vaccination it was found that 28 of 124 children (23%) and 14 of 18 adults (78%) who were devoid of type II antibody before vaccination failed to develop antibody after feeding with TN (type II) vaccine (diff./S.E. diff. = 4.7081). Part of the explanation of this significantly different response might be thought to be due to a higher proportion of the adults having had previous experience with heterotypic polioviruses which prevented infection with the TN strain. This does not, however, seem likely from tests of the heterotypic antibodies in the vaccinated adults.

All individuals who were fed with 3,500 or more TCD₅₀ of SM (type I) vaccine developed antibody, but only one out of three adults who were fed 54 TCD₅₀ developed antibody.† On the other hand, Koprowski *et al.* (1956) found that they were able to infect two out of three children with two plaque-forming particles (PFP)* of SM virus and that 20 PFP were adequate to infect four out of four children.

This difference in the response of adults as compared with children to infection with the TN and SM viruses suggests that in certain population groups some adults may develop barriers other than homotypic circulating antibody to infection with some strains of poliovirus. We stress certain population groups, for this did not appear to be so in adults of the inbred Eskimos of Chesterfield Inlet, in the Canadian Arctic (Peart, 1949), who may have been genetically highly susceptible to poliomyelitis.

There is a suggestion from our studies that in families where one sibling failed to develop antibody after vaccination with TN vaccine the other sibling also failed to respond (Dane *et al.*, 1957). We have already indicated in antibody surveys in Northern Ireland (Dane, Dick, Connolly, Briggs and McLeod, 1956) that siblings usually show the same pattern of antibody to the three types of poliovirus: thus if one sibling had either antibody or no antibody to one or other of the types, it was usual to find a

*Before vaccination each of these three adults had type II antibody and one of them who failed to become infected had also type III antibody.

†Comparative titrations have shown that one plaque-forming particle by the technique of Koprowski and his associates = 1 TCD₅₀ by our methods.

similar picture in the younger siblings. It may be, then, that some families are less susceptible to infection with poliovirus than others, and if such families are the least susceptible members of the community then the vaccination failures which we found with TN live virus vaccine may be of little consequence.

We do not know how far it is possible to draw an analogy between the response of an individual to an attenuated strain as compared with a wild strain. If some families are

FIG. 1.—Antibody levels months after vaccination with SM type I virus. (Drawn from results presented by Koprowski, 1955).

genetically relatively resistant to infection with wild strains of poliovirus then it may be that in serological surveys a proportion of the individuals devoid of antibody may nevertheless be resistant to infection. Thus a population group in which 80% of the individuals have antibody to type II virus could represent a group who are all resistant to infection with that virus.

Koprowski (1955) has claimed that the circulating antibody which follows vaccination with TN vaccine is durable for at least five years. After vaccination with SM vaccine he showed that none of seven subjects who were tested had

FIG. 2.—Antibody levels months after vaccination with SM type I virus. (Dick *et al.*, 1957).

any decline in the level of antibody induced by vaccination over a period of 12 to 15 months. These individuals (who were presumably children) had antibody titres at three weeks and at 12–15 months after vaccination as shown in Fig. 1.

In seven adults whom we vaccinated with SM virus and whose sera were tested at varying intervals up to nine months after vaccination, it was found that, with one excep-

Excreted Viruses

The most important disagreement between our results and those of Koprowski *et al.* (1956) is in the character of the virus which is excreted after vaccination and also, in the case of TN virus, in the duration of virus excretion. Koprowski *et al.* were of the opinion that TN faecal virus was, like the TN vaccine virus, non-cytopathogenic for tissue-culture-grown fibroblasts or epithelium of either simian or human (normal or neoplastic) origin. Their tests for faecal virus were accordingly made by inoculating faecal extracts intraspinally in mice. We have shown that TN faecal virus is also cytopathogenic for monkey-kidney-tissue culture (Dane *et al.*, 1957). In all individuals whom we tested (with one exception) the virus which was excreted after vaccination was not only paralytogenic for mice inoculated intraspinally but also cytopathogenic for tissue cultures. Since Koprowski *et al.* had stated that TN vaccine was never excreted for more than 23 days we did not collect many specimens for longer than that period. It is clear, however, from our results that virus continues to be excreted for periods in excess of 23 days after TN vaccination, and in many individuals for at least a month. Koprowski *et al.* were of the opinion that the excretion of TN faecal virus was sporadic and of low titre (never exceeding 10 mouse PD₅₀ per gramme of faecal material) and that it occurred in only about half of the successfully vaccinated individuals.

Quite apart from the tissue-culture tests we were able, by mouse inoculation, to detect TN faecal virus in all but one of the individuals who were successfully vaccinated, and titres of 10³ or more mouse PD₅₀ per gramme were found in some faecal specimens. We do not consider that the difference in our results compared with those of Koprowski *et al.* is due to minor differences in the techniques used in preparing stool samples, for we have found no significant differences in the titre of virus in stools prepared by the method of Dr. Koprowski (personal communication) and the method we employed. It may be, however, that the strain of mice which we used (VSBS) were more susceptible than the PRI strain used by Koprowski *et al.* Although the majority of individuals whom we tested excreted TN virus which was of relatively low titre in mice and in tissue cultures, there were individuals who were excreting from 10⁵ to more than 10⁶ TCD₅₀ of virus within five days of vaccination. The TN virus which is excreted by vaccinated individuals differs from the TN vaccine virus in its cytopathogenicity, and in some individuals this change from non-cytopathogenic to cytopathogenic virus occurs very rapidly. In addition, our results have clearly demonstrated that after multiplication in the alimentary tract the TN faecal virus is paralytogenic for monkeys inoculated intracerebrally (Dane *et al.*, 1957).

The majority of individuals whom we vaccinated with SM virus were adults (Dick *et al.*, 1957), and therefore our results on the excretion of SM virus are not strictly comparable with those of Koprowski *et al.*, whose studies were made mainly in children. It appears that, after vaccination with SM virus, excretion of virus in adults is usually of shorter duration than in infants or children. In our studies, SM faecal virus was present in highest titre during the first week after vaccination. By analogy this may explain why the natural disease is most infectious during the early stages of infection.

SM faecal virus is different from SM vaccine virus in its ability to paralyse monkeys after intracerebral inoculation (Dick *et al.*, 1957). The change found with SM virus after multiplication in the human gut is not so marked as that found with TN virus. The examination of stools taken on a single day may not, however, be sufficient to show any marked change, as it is possible that there are variations in the proportion of paralytogenic particles at different times.

Viraemia and Throat Virus

Koprowski (1955) found no viraemia or throat virus in any subject vaccinated with SM or TN viruses. Among

We have not yet considered the antibody response which is the primary object in evaluating a poliomyelitis vaccination procedure. The proportion of individuals developing antibody after TN vaccine is less than after Salk-type vaccine, but we have already noted that the failure to respond may be in those individuals who are relatively

insusceptible to infection with polioviruses. The fact that all individuals who were vaccinated with SM virus developed antibody is probably a reflection of the large dose of cytopathogenic virus which was fed to them; the wide range in their antibody titres may indicate the variation in their susceptibility.

Acceptable Attenuated Strains

Although we consider, with our present knowledge, that the TN and SM strains are not at the moment acceptable for mass immunization, this does not mean that suitable strains will not be developed. We have formulated what we believe are the minimum requirements for attenuated poliovirus vaccines. These are as follows:

1. The vaccine virus and any excreted virus should be intracerebrally avirulent for monkeys and perhaps also intraspinally avirulent. Intracerebral avirulence alone may be acceptable provided the other requirements are fulfilled.
2. The virus should not be transmissible from vaccinated to non-vaccinated individuals. This may be difficult to achieve with viruses which are given by mouth and excreted. Sabin (1955a) showed that after intramuscular injection of the KP34 type III strain there was no immunogenic response unless the virus localized in the alimentary tract, where it multiplied and was excreted. This does not mean that strains of poliovirus might not be found which would multiply in tissues other than the alimentary tract but not in the C.N.S. Lack of transmissibility is a characteristic of all established attenuated vaccines. Thus 17D yellow fever vaccine is not transmissible by mosquitoes, the spread of vaccinia is rare and limited, B.C.G. does not spread like naturally occurring *Myc. tuberculosis*. If oral vaccines are used, then the duration of faecal excretion of virus should be at such a low level and for such a limited duration (as was claimed for TN virus by Dr. Koprowski) that transmission would be unlikely to occur.
3. The vaccine virus and any of its progeny which are excreted should have some marker which differentiates them from naturally occurring wild strains of virus.
4. The vaccine virus should preferably not multiply in the throat.
5. The vaccine should prevent paralytic poliomyelitis in those who are susceptible. This may not require 100% antibody response in vaccinated individuals.

A live virus vaccine with these properties should be safe to the individual vaccinated and to the community.

Future of Attenuated Poliovirus Vaccines

The future for the types of attenuated viruses developed by Koprowski and by Sabin is not clear. Although Sabin (1955a) states that his KP34 type III strain which he fed to volunteers came out as avirulent as it went in, the KP33 (type I) and KP51 (type II) strains after multiplication in the alimentary tract "yielded a certain proportion of virus particles with increased virulence for brain-stem neurones of monkeys." Sabin indicated that he was continuing his studies to find better attenuated strains. In the evaluation of his published trials, which were done in adults, it should be remembered that the alimentary tract of the small child is probably a better milieu for polioviruses than that of the adult.

As already noted, it would seem to us that if strains are found which fulfil laboratory criteria for safety, then they must also be shown to have properties which make them different from wild strains. If these vaccine strains differ from wild strains only in their monkey or chimpanzee pathogenicity, and if they are transmissible, then trials in increasing numbers of people are rendered impracticable because of lack of control. While preliminary trials may be done in institutions, their final evaluation must be in children living in normal environments. There can be no assurance of how the vaccines will behave in a community, for it would seem that mutants of the less virulent naturally occurring strains may occasionally cause paralysis. How else can one explain the sporadic cases of poliomyelitis which occur in communities where extensive inapparent infections are occurring? We have no knowledge of how often mutants arise from naturally occurring avirulent strains, and whether or not they can cause epidemics. No one can

predict what may happen if a community is heavily seeded with a transmissible avirulent virus.

The risks involved in large-scale trials of avirulent poliovirus vaccines may be justifiable in communities where severe epidemics are common. Such trials should only be undertaken step by step, and never without careful laboratory control, however difficult this might be.

EFFECT OF HYPERMETABOLISM ON THE GOITRE OF A SPORADIC CRETIN

BY

HERMAN ZONDEK, M.D.

HANNAH E. LESZYNSKY, M.D.

AND

GERDA W. ZONDEK, M.D.

Bicur Cholim Hospital, Jerusalem, Israel

It is well known that non-toxic nodular goitres may decrease in size as the result of thyroid administration, though to a much less degree than diffuse thyroid enlargements. That this response may be especially evident with hypothyroid nodules was the subject of two of our own recent communications (Zondek *et al.*, 1955; Zondek and Leszinsky, 1956). It was shown that in two siblings with familial sporadic cretinism and large, partly diffuse, and partly nodular goitres the induction and maintenance of a euthyroid state succeeded in one case in considerably reducing the size of the nodules, and in the other in causing the disappearance of four out of five nodules. The diffuse enlargement subsided entirely in both patients.

The purpose of this communication is to show how hypothyroid nodules respond to short-termed overdosage—that is, to the induction of "spurious alimentary hyperthyroidism."

Case Report

The subject of the study was one of the above-mentioned siblings, a girl aged 14. She was first seen at the age of 12. At that time she had, together with the typical features of childhood myxoedema, a large diffuse goitre in which three nodules varying in size between large plums and peaches were embedded. The heart shadow was greatly enlarged (transverse diameter 14 cm.), the B.M.R. was -13% and the blood cholesterol was 310 mg. per 100 ml. Electrocardiography was within normal range. After 1.020 µg. of tri-iodothyronine given within eleven days the clinical picture had in every respect reverted to normal. Both the diffuse and nodular parts of the goitre had at that point greatly decreased in size, and continued doing so during the subsequent four months of maintenance therapy (though irregularly carried out) with tri-iodothyronine and desiccated thyroid. The nodules failed, however, to disappear completely. The patient stopped substitution therapy entirely during the following twelve months.

When she returned to us she was in every respect worse than before treatment: her external appearance and behaviour were even more noticeably myxoedematous, the heart shadow was larger (transverse diameter 15.7 cm.), the electrocardiogram showed definite low voltage and a prolonged Q-T, and the B.M.R. was -25% (oxygen consumption 140 ml. per minute). The blood cholesterol was again 310 mg. per 100 ml. The goitre had increased in size, the neck circumference being 39.5 cm. and the nodules varying in size between a large plum and a goose-egg (Fig. 1). Radio-iodine uptake after two hours was 63%, after twenty-four hours 26%, and after forty-eight hours 14%. These figures indicate that the thyroid was unable to hold and convert iodine into a biologically active protein-bound compound. Radio-iodine excretion was 51% after twenty-four hours and 73% after forty-eight hours. The conversion ratio after twenty-four hours was 30% and serum P.B.I. was 1.8 µg. per 100 ml.

After receiving 8 mg. of tri-iodothyroacetic acid ("triac") (Pitt-Rivers, 1953) in two days the patient showed prompt overall response. Within the next ten days she lost her puffiness and lethargy, the heart shadow grew progressively smaller, the E.C.G. became normal, the B.M.R. rose to normal values (oxygen consumption 198 ml. per minute = +8%) twelve hours after the first dose, and blood cholesterol fell to around 240 mg. per 100 ml. Since the ninth day oxygen consumption had dropped to 158 ml. per minute. A further 8 mg. of triac administered within two days raised the B.M.R. once more, although less so than after the first dose (gradual rise of oxygen consumption to 177-191 ml. per minute during the subsequent four days). A third dose of 10 mg. of triac had practically no effect at all on the B.M.R. (oxygen consumption remaining at 175-179 ml. per minute). During the period of observation the goitre steadily grew smaller from the second day onwards (Figs. 2-4). As in the smaller from the second day onwards, the diffuse parts responded first trial with tri-iodothyronine, the diffuse parts responded first, and the nodules somewhat later. After seventeen days the diffuse goitre was no longer palpable (neck circumference 35 cm.), and the nodules had decreased to the size of a small cherry and large olives respectively (Fig. 4).

At that time we tried to make the patient temporarily hyperthyroid (the transient nature of triac activity having already been established) with a view to finding out whether this might lead to complete disappearance of the nodules. For this purpose a total of 30 mg. of triac was given within three days, whereupon the B.M.R. quickly rose to +42% (oxygen consumption 252 ml. per minute) two days after the last dose. Within the following four days the B.M.R. gradually dropped to the baseline. The other indices of thyroid function (external appearance, weight, blood cholesterol, pulse rate, etc.) remained, however, in the euthyroid range during the entire hypermetabolic phase, the E.C.G. even showing a partial relapse. There was neither

tremor nor exaggerated sweating. Whereas the diffuse parts of the goitre were still absent, we were surprised to find a steady increase in the size of the nodules, which within six days almost reached their pre-treatment size (Fig. 5). Thereafter, along with a further decrease of oxygen consumption, they again started to regress. A control investigation with radio-iodine at the height of the hypermetabolic phase showed marked hyperactivity over all parts of the gland with regard to iodine collection (55% after twenty-four and 60% after forty-eight hours). Radio-iodine excretion was 35% after twenty-four and 37% after forty-eight hours, and the conversion ratio was 18% after twenty-four hours.

Discussion and Conclusions

It is generally accepted that the ultimate cause of thyroid enlargement, no matter whether of diffuse or of nodular nature, and whatever its primary cause, is to be sought in increased T.S.H. secretion or activity. Conversely, regression of diffuse and nodular goitres alike is ascribed to T.S.H. suppression. The quantitatively different response of diffuse and nodular goitres to T.S.H.-suppressing agents—that is, thyroid substances—indicates that a specific genetic factor should be postulated for the development and regression of thyroid nodules. This factor may probably be ascribed to a focal hypersensitivity of certain areas of thyroid tissue towards growth-stimulating influences (Zondek and Leszinsky, 1956). Circumscribed variations of thyroid function may be ruled out on the strength of isotope studies in this and previously reported observations, no differences having been found in the functional behaviour of diffuse and nodular areas. Neither is it probable that structural differences are of account. It could be shown that excised nodules of this patient and her brother showed uniformly colloid structure.

On the strength of this reasoning it was postulated that the hypersensitivity of the nodular areas towards T.S.H. might best be overcome by raising the levels of circulating thyroid hormone to such an extent as to remove the last vestige of T.S.H. from the circulation—that is, by creating a state of hyperthyroidism. Contrary to our expectations, however, the nodules not only failed to decrease but they even increased greatly in size, thereby indicating that another mechanism which counteracted T.S.H. suppression had come into play. In fact, it became clear that the nodules, in contrast to the diffuse goitre, showed a uniform behaviour with regard to size (Figs. 1 and 5) during the hypothyroid phase and the "alimentary hyperthyroid" phase, which was associated with hypermetabolism and actual, though incomplete, hyperfunction of the thyroid gland. The overall increase of radio-iodine uptake over the thyroid also came as a surprise, it being rather expected that thyroid activity would be entirely suppressed after the ingestion of thyroid substances (see above).

FIG. 1.—A 14-year-old girl with familial sporadic cretinism and goitre, before therapy. B.M.R. -25%. Note the three large nodules within voluminous diffuse goitre. FIG. 2.—Same girl 48 hours after 8 mg. of triac. Note volume decrease of diffuse goitre. FIG. 3.—Same girl seven days after above therapy. Note further volume decrease of goitre. FIG. 4.—Same girl three days after a second dose of 8 mg. triac. Note absence of diffuse goitre as contrasted with conspicuous volume increase of nodules. FIG. 5.—Same girl two days after a third dose of 10 mg. of triac in three days. Note absence of diffuse goitre as contrasted with conspicuous volume increase of nodules.

The paradoxical behaviour of the nodules with regard to size, and of the entire thyroid tissue with respect to function, can in our opinion best be understood in the light of the peripheral theory (Zondek, 1924, 1935), which postulates that primary rise of oxygen consumption in the peripheral tissues may result in secondary hyperfunction of the thyroid, eventually with corresponding increase of its volume. It may therefore be assumed that in our case the artificially induced hypermetabolism led to a secondary stimulation of thyroid function as far as a response of the seriously damaged thyroid tissue could be expected. (Increased formation of an active thyroid hormone was regarded as all the more unlikely, since the B.M.R. subsequently fell.) At the same time only those parts of the gland which exhibited hypersensitivity towards growth-stimulating influences—namely, the nodules—would and did also increase in size. The fact that functional increase was evident throughout the whole thyroid tissue, whereas the increase in size was restricted to the nodules, confirms the claim that function and growth within the thyroid are not necessarily correlated (see above).

It may therefore be assumed that complete regression of thyroid nodules cannot be achieved either in the hypothyroid or in the hyperthyroid respectively hypermetabolic stage, but only if and when a euthyroid state is maintained through adequate and prolonged substitution therapy.

Summary

The case of a 14-year-old girl with familial sporadic cretinism and a very large goitre of partly diffuse and partly nodular nature is reported in which the induction of a euthyroid state resulted in the disappearance of the diffuse goitre and a decrease in the size of the nodules. On the strength of the generally accepted thesis that nodular and diffuse thyroid enlargements are ultimately due to increased T.S.H. secretion and activity, and their regression to T.S.H. suppression, attempts were made to reduce the size of the nodules further by achieving the utmost degree of T.S.H. suppression—that is, by making the patient artificially hyperthyroid. Following the ingestion of large amounts of active thyroid substances (30 mg. of tri-iodothyroacetic acid—"triac"—in three days) a steep but spurious rise of the B.M.R. was obtained, whereas the other indices of thyroid function remained in the euthyroid range. Simultaneously the nodules not only failed to decrease but actually considerably increased in size, almost attaining their pre-treatment volume within six days. Radio-iodine uptake, which before treatment had been very low (with the exception of the two-hour value), rose to abnormally high "hyperthyroid" levels at the height of the hypermetabolic phase; hormone synthesis was not affected.

The unexpected and paradoxical behaviour of the nodules with regard to size and of the entire thyroid tissue with regard to function during the hypermetabolic phase is discussed.

In the light of our observations, regression of thyroid nodules may be expected to take place only in euthyroid conditions, and it must be the aim of treatment to maintain clinical euthyroidism through adequate and prolonged maintenance therapy.

We are greatly indebted to Dr. R. Pitt-Rivers, F.R.S., of the National Institute of Medical Research, for the supply of "triac." Our thanks are also due to Drs. Hochman and Stein, of the Isotope Unit, Hadassa Medical School, Jerusalem, for the ¹³¹I examinations.

ATRIAL SEPTAL DEFECT IN THE AGED

BY

N. COULSHED, M.D., M.R.C.P.

AND

T. R. LITTLER, M.D., M.R.C.P.

Liverpool Regional Cardiac Centre

Atrial septal defect accounted for 17% of a series of 200 cases of proved congenital heart disease described by Wood (1950). In his series of cases a sex incidence of 4:1 in favour of the female was encountered and the average age at death was stated to be about 36 years.

Recent advances in anaesthesia and surgical technique (Edwards *et al.*, 1955) have resulted in the inclusion of atrial septal defect among the increasing number of congenital heart lesions now amenable to surgical treatment.

Whilst recognizing the value of surgery in the treatment of a congenital lesion which hitherto has carried such a gloomy prognosis, we feel that this is an opportune time to describe five cases of atrial septal defect in elderly patients which have come to our notice during the past twelve months. All our patients have lived full and active lives, and two of them are still capable of a degree of physical exertion compatible with their advancing years.

Case 1

A widow aged 79 was admitted to the cardiac centre on July 7, 1955, in congestive cardiac failure. She stated that her first episode of cardiac failure had occurred when she was 54 years of age. Prior to that time she had enjoyed good health and was unaware of any cardiac defect. During the last 25 years she had three further attacks of congestive failure, and for the past 10 years dyspnoea on effort had forced her to limit her activities considerably. One month before admission her dyspnoea had increased and was accompanied by swelling of her feet, legs, and abdomen.

On examination she was an alert, intelligent patient who looked younger than her stated age. Slight cyanosis was noted, but she was not anaemic, and there was no finger-clubbing. The pulse rate was 74 a minute, and irregular owing to auricular fibrillation. The brachial blood pressure was 110/80 mm. Hg. The apex beat was difficult to locate and presented as a tumultuous heave extending beyond the midclavicular line. There were no palpable thrills. Marked jugular venous engorgement was noted. On auscultation the abnormalities found were a grade I systolic murmur together

FIG. 1.—Case 1. Auricular fibrillation and right bundle-branch block.

with a third heart sound at the apex. The second sound over the pulmonary area was accentuated and widely split. No diastolic murmurs were heard. The liver was enlarged, sacral and ankle oedema was noted, and moist rales were present at both lung bases.

FIG. 2.—Case 1. Generalized cardiac enlargement with enlarged pulmonary arteries.

Investigations.

An electrocardiogram revealed auricular fibrillation and a right bundle-branch block (Fig. 1). Chest x-ray film showed marked cardiac enlargement with prominent pulmonary arteries (Fig. 2). Cardioscopy confirmed the presence of pulmonary plethora, right ventricular enlargement, and vigorous pulsation of the pulmonary arteries. No selective left auricular enlargement was detected.

FIG. 3.—Case 2. Supraventricular paroxysmal tachycardia and right bundle-branch block.

FIG. 4.—Case 2. Sinus rhythm and right bundle-branch block.

Case 2

A retired butcher aged 68 attended a surgical clinic in March, 1955, complaining of prolapsing haemorrhoids. Routine examination revealed a marked tachycardia, and he was referred to the cardiac centre for further investigation.

FIG. 5.—Case 2. Generalized cardiac enlargement with pulmonary plethora and prominence of the pulmonary conus.

On examination he was seen to be a short thick-set man of cheerful disposition and in no obvious distress whilst at rest. Slight jugular venous engorgement was noted, together with slight pretibial oedema. The pulse rate was regular at 160. The brachial blood pressure was 160/100 mm. Hg. Because of his obesity and emphysematous chest contour, the apex beat could not be defined. No thrills

or murmurs were detected. An electrocardiogram showed a supraventricular paroxysmal tachycardia with right bundle-branch block (Fig. 3). The paroxysm terminated spontaneously, the pulse rate falling to 96. Sinus rhythm was confirmed by electrocardiogram, the right bundle-branch block remaining unchanged (Fig. 4). Further examination revealed a grade II systolic murmur over the pulmonary area, a third heart sound at the apex, and accentuation of the aortic and pulmonary second sounds. In addition wide splitting of the pulmonary second sound was noted.

Investigations.—An electrocardiogram revealed sinus rhythm with right bundle-branch block. Chest x-ray examination showed generalized cardiac enlargement, pulmonary plethora, and prominence of the pulmonary conus (Fig. 5). Cardioscopy confirmed these findings, and vigorous pulsation of the pulmonary arteries was seen. Cardiac catheterization was performed, when evidence of moderate pulmonary hypertension was obtained and blood sampling confirmed the presence of atrial septal defect (see Table).

Catheter Studies in Case 2

Catheter Tip	Pressure (mm. Hg)	Blood O ₂ Saturation (%) (Van Slyke)
Superior vena cava	—	59
Right auricle, high	—	62
mid	—	72
Inferior vena cava	—	56
Right ventricle	40/0	66
Pulmonary artery	50/20	67

Case 3

A man aged 67 was referred to the heart clinic of the Liverpool Royal Infirmary in August, 1954, with a request from his general practitioner that his dyspepsia and tachycardia be investigated. So far as the patient could recollect, he had suffered no serious illness in the past. When he was a child some cardiac enlargement had been noted, but the cause was not specified.

He was working a 40-hour week as a fitter, the work involving moderate physical exertion, and he had lost no time off work in 40 years. During the previous four months he had suffered from recurrent attacks of dizziness, associated with a feeling "as if my heart missed a beat." There had been no chest pain, dyspnoea, cough, or haemoptysis.

On examination there was no cyanosis, finger-clubbing, jugular venous engorgement, or oedema. The pulse rate

was 80, with a regular rhythm. The brachial blood pressure was 140/80 mm. Hg. The apex beat was difficult to locate because of emphysema, but was maximal in the left fifth interspace, 4 in. (10 cm.) from the midline. No right ventricular heave could be felt.

The first and second sounds were normal at the mitral, tricuspid, and aortic areas. No third heart sound could be

heard. The pulmonary second sound was accentuated and widely split, the second component being the louder. A grade I systolic murmur was confined to the apex; no diastolic murmurs could be heard.

Investigations.—An electrocardiogram revealed a sinus rhythm with a right bundle-branch block (Fig. 6). Cardioscopy showed a moderately enlarged heart, mainly right ventricular, with unfolding of the aorta (Fig. 7). There was also some calcification in the aortic arch. The lung fields were plethoric and there was a well-marked "hilar dance."

FIG. 6.—Case 3. Sinus rhythm and right bundle-branch block.

Investigations.—An electrocardiogram revealed sinus rhythm with a right bundle-branch block (Fig. 6). Cardioscopy showed a moderately enlarged heart, mainly right ventricular, with unfolding of the aorta (Fig. 7). There was also some calcification in the aortic arch. The lung fields were plethoric and there was a well-marked "hilar dance."

Case 4
A man aged 58 suffering from pulmonary tuberculosis was referred to the cardiac centre in September, 1955. Previous x-ray examinations of his chest had revealed an abnormality of the cardiac contour and pulmonary vessels. He had been in hospital twice during the past three years. On the first occasion a gastric ulcer was treated conservatively, and on the second he had lobar pneumonia. No comment was made about his heart on either occasion.

On examination he was seen to be a short, thin man of sallow complexion with a marked dorsal kyphoscoliosis and "pigeon chest." He had a high arched palate, but no finger-clubbing or arachnodactyly. He appeared slightly cyanosed, but there were no signs of congestive cardiac failure.

His pulse rate was regular at 108, the brachial blood pressure was 130/70 mm. Hg. The apex beat was felt as a tumultuous heave in the anterior axillary line in the sixth left interspace. No parasternal pulsation was detected. At the apex a grade II systolic murmur was heard together with a third heart sound. The second sound over the pulmonary

FIG. 8.—Case 4. Sinus rhythm and right bundle-branch block.

Case 5

A housewife aged 58 first developed congestive cardiac failure in July, 1950. Prior to that time she had enjoyed good health and her five pregnancies had been uneventful. She was alleged to have had rheumatic fever when aged 11 years, but could recall no other significant illness. A survey of her case notes recorded in 1950 revealed that she had auricular fibrillation with severe congestive cardiac failure. Cardiac enlargement, gallop rhythm, and a loud apical systolic murmur were heard. A pericardial friction rub maximal over the pulmonary area and left parasternal region was also noted, and was still audible three months later when she was discharged. The brachial blood pressure was 180/120 mm. Hg. Her electrocardiogram showed a right bundle-branch block with auricular fibrillation, and this record remained unchanged during the next five years (Fig. 9). Chest x-ray examination in 1950 was reported as showing "generalized cardiac enlargement with prominence of the pulmonary conus, and selective enlargement of the left

FIG. 9.—Case 5. Auricular fibrillation and right bundle-branch block.

auricle. Congestive changes are shown in the lung fields." A diagnosis of congestive cardiac failure secondary to rheumatic heart disease and hypertension was made. Between 1950 and 1955 she was readmitted to hospital on four occasions in severe congestive cardiac failure. The pericardial friction rub remained a constant finding throughout, and the diagnosis of rheumatic heart disease and hypertension was not questioned. Her last admission to hospital was in July, 1955.

On examination she was cyanosed, with marked jugular venous engorgement. No finger clubbing was noted. Pitting oedema of the legs and lumbar region was apparent, together with gross ascites. The apex beat was located in the sixth left interspace, in the anterior axillary line. There was no palpable right ventricular heave, but the pulmonary second sound was accentuated and widely split. The mitral and aortic sounds were normal, and no diastolic murmurs could be heard. The curious pericardial friction rub previously recorded was still present over the left parasternal area. The brachial blood pressure was 180/110 mm. Hg.

Investigations.—An electrocardiogram was similar to the first record taken in 1950, showing a right bundle-branch block with auricular fibrillation. Cardioscopy revealed generalized cardiac enlargement, pulmonary plethora, and vigorously pulsatile dilated pulmonary arteries. No selective left auricular enlargement was seen.

In view of these findings the previous diagnosis of rheumatic heart disease seemed unlikely; the right bundle-branch block, dilated pulsatile pulmonary arteries, and auricular fibrillation all being more compatible with a diagnosis of atrial septal defect.

The patient died in November, 1955, but unfortunately permission for necropsy was not granted.

Discussion

In this paper we have described five cases of atrial septal defect occurring in elderly patients. Their ages ranged from 58 to 79 years. All the patients were seen by us during a period of 12 months, a surprising fact when it is recalled that most patients with this type of congenital heart disease succumb before the age of 40 years (McGinn and White, 1933).

The criteria for diagnosis have been based mainly on radiological and electrocardiographic findings, as it is generally agreed that a purely clinical diagnosis cannot be made with certainty (Burrett and White, 1945).

All five cases showed the typical radiographic findings associated with atrial septal defect, as described by Roesler (1934) and Bedford *et al.* (1941)—namely, dilatation of the right auricle and ventricle, with marked dilatation and pulsation of the pulmonary artery and its branches. Associated left auricular enlargement was alleged to be present in Case 5, but we were unable to confirm this; the left ventricular enlargement noted in this case was thought to be due to the coincident systemic hypertension. Unfolding of the aorta with atheroma was present in Case 3, but otherwise the first four cases in the series showed no enlargement of the left auricle, left ventricle, or aorta.

The electrocardiographic pattern of right bundle-branch block was present in each case, thereby satisfying the criteria laid down by Barber *et al.* (1950), who pointed out that the diagnosis of atrial septal defect in the absence of partial or complete right bundle-branch block is almost untenable. In Case 5, negative T waves in leads V5 and V6 were thought to be due to the systemic hypertension. Two patients were shown to have auricular fibrillation, and one had episodes of supraventricular paroxysmal tachycardia.

Catheter studies were performed in only one patient (Case 2), and we are indebted to this man for his willing co-operation in a procedure from which he could derive no benefit. They revealed the presence of a left-to-right shunt in the atria and a mild degree of pulmonary hypertension,

the pulmonary artery systolic pressure being 50 mm. Hg. We did not consider catheterization justifiable in the other four cases, since it could have had no therapeutic application.

Apart from finding a widely split and accentuated pulmonary second sound in all our cases, clinical examination was of little help in establishing the diagnosis. No evidence of arachnodactyly was found in any patient, the only skeletal abnormality being a dorsal kyphoscoliosis in two patients. A high arched palate was found in only one patient, and finger-clubbing was uniformly absent.

Two patients, both of whom had auricular fibrillation, were in severe congestive cardiac failure when seen, two had marked dyspnoea on effort, and one (Case 3), apart from vague "palpitations," had no symptoms referable to his heart. In fact, three of the five patients were still capable of a degree of physical exertion compatible with their advancing years.

Apical or basal systolic murmurs (Grades I-III) were heard in all cases, but none had either pulmonary or apical diastolic murmurs, and in only three was a third heart sound audible. Splitting of the pulmonary second sound was a constant finding, and in three cases the tumultuous type of apex beat described by Barber *et al.* (1950) was found. The presence of the alleged pericardial friction in Case 5 deserves special mention, as it persisted for so long, and caused considerable confusion when first heard. It may have been mistaken for a "to-and-fro" pulmonary murmur due to relatively pulmonary incompetence, but it appeared to have a superficial quality and to become louder by increasing the pressure on the stethoscope on the chest wall. It seems probable, therefore, that the sound may have been produced by the enormously dilated pulmonary artery coming into contact with the anterior chest wall, its vigorous pulsation producing the friction sound.

In differential diagnosis, the presence of the bundle-branch block, together with peripheral pulmonary plethora and marked splitting of the pulmonary second sound, excluded the presence of idiopathic dilatation or of post-stenotic dilatation of the pulmonary artery. The absence of left ventricular enlargement in all except Case 5 excluded so far as was possible the existence of ventricular septal defect and persistent ductus arteriosus. Case 5 showed some left ventricular enlargement, but this was thought to be due to the systemic hypertension present in this case.

We have already stressed the difficulties in establishing the diagnosis of atrial septal defect on purely clinical grounds. In the present series Case 1 had been regarded as a case of congestive heart failure for over 25 years, presumed to be due to coronary artery disease until the diagnosis of atrial septal defect was made, and Case 5 had at varying times been thought to have coronary artery disease with hypertension and mitral stenosis. Case 4 had been thought to have chronic cor pulmonale, and Cases 2 and 3 had not been diagnosed. With these facts in mind the purpose of this paper has been to show that atrial septal defect and longevity are not incompatible; and we would therefore stress the importance of excluding this not uncommon congenital anomaly as a cause of obscure congestive cardiac failure in the older age groups. We suspect that many cases of this type occurring in the sixth and seventh decades have been missed in the past because the possibility of encountering a congenital heart lesion in an aged patient has not been entertained. It is all too easy in such patients to ascribe auricular fibrillation, when present, and bundle-branch block to coronary artery disease, and the pulmonary plethora to congestive cardiac failure or even uraemia occurring as a terminal event in an aged patient.

Summary

Five cases of atrial septal defect with clinical, radiological, and electrocardiographic findings are described in patients between the ages of 58 and 79 years.

The possibility is stressed of this anomaly being present in older patients with congestive cardiac failure of obscure origin.

It has been shown that atrial septal defect and longevity are not incompatible.

We are indebted to Drs. E. Noble Chamberlain, E. Wyn Jones, C. S. McKendrick, H. Fuld, and F. C. Crawley for allowing us to publish details of patients under their care at Sefton General Hospital, Liverpool, and the Royal Infirmary, Liverpool.

EPIDEMIC OF PULMONARY TUBERCULOSIS IN A CLOSED COMMUNITY

BY

C. PROTHEROE, M.B., Ch.B.
Captain, R.A.M.C.

The first scientific study of the epidemiology of tuberculosis was made by Villemin in 1868. He stressed the high incidence of the disease among those living in closed communities, such as prisoners, inmates of mental institutions, soldiers, and religious bodies. Tuberculosis among troops living in barracks was very common compared with those in the field or those living at home. He quoted, as an example, the Allied armies before Sebastopol during the winter of 1854-5. Although these troops were living under most unhygienic conditions, with poor food, and subjected to severe cold and excessive fatigue, cases of tuberculosis were rare. At this time the mortality rate in the Army due to tuberculosis varied between 5 and 12.5 per 1,000.

To-day we have the same modes of spread of the disease. It is only by the detection of early cases and by adopting strict precautions to prevent its transmission by the occasional "open" cases that we are able to improve on these figures. The following is an account of its rapid spread in a comparatively closed community in which normal precautions are taken but in which the opportunities for spread are so great.

The Closed Community

This community was a military band which returned to the United Kingdom from a tropical station at the end of September, 1954. Its members were given leave for four weeks before returning to barracks. In February, 1955, they went to Germany.

In peacetime, military bands have approximately forty members, mainly between the ages of 16 and 25 years. Few are married and live in quarters; the rest live together in barracks. Occasions arise, such as touring, when they all live together. Sleeping accommodation varies from station to station; while in the United Kingdom these men lived in rather old barracks and slept sixteen to a room, in Germany their barracks were excellent, and they slept four to a room. Food was good and there were ample facilities for recreation. These men are specialists and have little in common with other members of the regiment; their friends are usually other bandsmen.

The regiment to which a military band belongs has little bearing on the background of its bandsmen. They originate

from all parts of Britain, mainly large industrial cities. There is no reason to believe these people lacked natural immunity. When Mantoux tests were performed at the end of March, 1955, only one person under 21 years was Mantoux-negative. Of the seventeen members joining since, all are Mantoux-positive, none having received B.C.G.

The practice-room usually allocated to the band is a small one on the outskirts of the station, where their music does not interfere with other military activities. Rarely have they large particularly well-ventilated rooms.

On returning from tropical conditions to the wintry conditions in the United Kingdom, approximately half of the band developed some form of minor respiratory tract infection. Six of the finally proved cases experienced this change, which may have played a small part in lowering their resistance.

Presentation of Cases

On March 22, 1955, Case 1, a youth aged 17, reported sick with pleuritic pain in the right side of his chest. Clinically and radiologically he had a large right-sided pleural effusion. E.S.R. (Westergren) 38 mm./hour. White cells, 10,900 per c.mm. (polymorphs 69%, lymphocytes 27%, monocytes 4%). Aspirated pleural fluid: white cells, 4,900 per c.mm. (lymphocytes 80%); red cells, 6,400 per c.mm.; specific gravity, 1.012. Gram stain: no organisms seen. Ziehl-Neelsen stain of concentrated fluid: scanty distribution of *Mycobacterium tuberculosis*. These organisms were later cultured. This patient produced no sputum, and no organisms were detected in his resting gastric juices. Mantoux 1:10,000 was positive.

There was no family history of tuberculosis or any known contact with the disease. He had joined the band four months previously while in the United Kingdom, and his contacts were confined to the members of the band and the bandmaster's family, whom he visited frequently. These contacts were x-rayed and two further cases found—Case 2 and the bandmaster's wife.

Case 2, a man aged 23, had an advanced fibro-caseous lesion spread throughout the left upper lobe. There were two medium-sized cavities, one at the apex and the other in the mid-zone. He gave a history of having had cough with sputum for four months, and on one occasion a small haemoptysis. For some time he had noticed that playing his clarinet had become more exhausting. E.S.R. (Westergren) 30 mm./hour. Sputum contained a scanty distribution of acid/alcohol-fast bacilli. He had slept in the next bed to a man with pulmonary tuberculosis in Hong Kong in 1952. The band had been x-rayed in Hong Kong and again in the United Kingdom in the summer of 1953, but no further cases were detected.

The bandmaster's wife had an early infiltrative lesion at the right apex. She had no symptoms and no signs. No organisms were isolated from her sputum or resting gastric juices. Case 1 was a frequent visitor to the bandmaster's home, and she had met Case 2 socially on several occasions.

Further cases presented as shown in the accompanying Table, either clinically or with abnormal chest x-ray finding during follow-up examination. The last cases (Nos. 9 and 10) were admitted to hospital at the beginning of May, 1956. There were no cases when mass miniature radiographs were taken at the end of December, 1955.

All family contacts of infected bandsmen have been examined radiologically. No cases have been found. Case 2 had regularly seen his wife until going to Germany. She remains well.

Source of Infection

Myco. tuberculosis was isolated from three cases of this series. It was seen in the Ziehl-Neelsen stain and later cultured. In Case 1 the organisms were found in the pleural fluid; he produced no sputum, and no organisms were found in his resting gastric juices. X-ray examination revealed no pulmonary lesion to suggest he had had "open" pulmonary tuberculosis at any time. Case 2 had organisms in his sputum, and x-ray appearances were compatible with

"open" pulmonary tuberculosis. Case 6 was admitted to hospital for further investigation because a very faint shadow was seen at the left apex during follow-up x-ray examination. He had no symptoms and there were no chest signs. E.S.R. (Westergren) 2 mm./hr. A Ziehl-Neelsen stain of his first early-morning specimen of sputum showed a scanty distribution of acid/alcohol-fast bacilli identical with *Myco. tuberculosis*. These organisms were later cultured from this specimen. None were isolated from numerous other specimens, and after further scrutiny of x-ray films, bronchoscopy, and laryngoscopy, no further evidence of a tuberculous lesion could be found. Cases 4 and 5 were in hospital at the time, but there is no reason to believe their sputum specimens were confused with that of Case 6, and, anyhow, there has been no reason to consider either of these cases as being "open." I cannot explain this.

Of the group, only Case 2 has been proved capable of infecting others. He probably contracted the disease in Hong Kong in 1952, but only recently had his lesion broken down and resulted in dissemination of bacilli. It will be noted that all the cases in this series were men attached to

the band before April, 1955, when Case 2 was admitted to hospital. There is no radiological evidence of active disease in any of the seventeen joining since.

Methods of Spread of the Disease

Via Musical Instruments.—Many older musicians have the impression that oboe and bassoon players are more prone to pulmonary tuberculosis than other members of the band—presumably because these instruments have a double reed and it was thought that they retain organisms. There appears to be no actual evidence to support this theory, and the type of instrument played is of no significance. Bandsmen are dissuaded from playing each other's instruments, but a certain amount of interchanging is carried on. However, this mode of spread probably had little part in the present minor epidemic, as the clarinet played by Case 2 was his personal property, and he was very reluctant to allow others to play it and was himself very reluctant to play other instruments. Case 10 was the instructor on the clarinet, and did occasionally play Case 2's instrument. Reeds last for one to two weeks, and there is no way of

Details of Cases

Case No., Age, Married, etc.	Date of Joining Band and Countries Visited Before Germany	Any Known Previous Contact with Tuberculosis	Instrument	Date of Admission to Hospital and How Detected	Type of Disease Symptoms	Living Accommodation
1. 17 yrs. Not married	Nov., 1954. U.K. only. Germany Feb., 1955	None. Mantoux 1:10,000+	Oboe	22.3.55: Reported sick with symptoms and admitted to hospital	Pleuritic pain in right side of chest and breathlessness for five days. Clinically and radiologically a large right-sided pleural effusion	Lived in barracks

Band and contacts x-rayed at end of March, 1955 (large plates).

2. 24 yrs. Married	1948. Canal Zone, 1948-9. Hong Kong, 1949-52. Brit. Guiana Feb.-Nov., 1954. Germany, Feb., 1955	In contact with case of pulmonary tuberculosis in Hong Kong in 1952. Slept in same room. X-rayed—n.a.d.	B♭ clarinet	1/4.55: Picked up when band x-rayed	Cough and sputum 4 months. Haemoptysis on one occasion. Had noticed he could not play his instrument as well. E.S.R. 30 mm./hr. Radiologically fibro-caseous lesion with cavities in left upper lobe	Lived in barracks during his one month in Germany and for part of time in U.K. Shared a room with three others; Cases 4 and 9 were in this room
3. 23 yrs. Married	1948. Canal Zone, 1948-9. U.K. Brit. Guiana, Feb.-Nov., 1954. U.K. Germany, Feb., 1955	None	E♭ clarinet	26.5.55: Reported sick with symptoms and admitted to hospital	Pleuritic pain in left chest, fever and anorexia of 12 hours' duration. Clinically and radiologically a large left-sided pleural effusion	Lived with his family in quarters

Band and contacts x-rayed at beginning of June, 1955 (large plates).

4. 20 yrs. Not married	1954. Brit. Guiana, Feb.-Nov., 1954. U.K. Germany, Feb., 1955	None. Mantoux 1:10,000+ 31/3/55	French horn	11.6.55: Picked up when band x-rayed	Symptom-free. No signs. E.S.R. 2 mm./hr. Very early infiltrative lesion right apex	Lived in barracks. Slept in same room as Case 2 while in Germany—i.e., 1 month
5. 24 yrs. Married	1952. Hong Kong, 1952. Brit. Guiana, Feb.-Nov., 1954. U.K. Germany, Feb., 1955	Not in contact with case in Hong Kong	Cornet	11.6.55: Picked up when band x-rayed	Symptom-free. No signs. E.S.R. 17 mm./hr. Early infiltrative lesion right apex	Lived in barracks
6. 25 yrs. Married	1945. Canal Zone, 1948-9. Hong Kong, 1949-52. Brit. Guiana, Feb.-Nov., 1954. U.K. Germany, Feb., 1955	In Hong Kong, 1952. Contact of case there. X-rayed—n.a.d.	B♭ clarinet, saxophone	11.6.55: Picked up when band x-rayed	Symptom-free. No signs. E.S.R. 2 mm./hr. Admitted because of two faint opacities seen at left apex on x-ray examination. Sputum x 3—A.A.F.Bs. seen and cultured from one. Sent to U.K. for further investigation. No lesion found	Lived in married quarters

Whole band had chest x-ray films taken at end of September, 1955 (large plates).

7. 19 yrs. Married (Aug., 1955)	1953. Brit. Guiana, Feb.-Nov., 1954. U.K. Germany, Feb., 1955	None. Mantoux 1:10,000+ 31/3/55	B♭ clarinet	26.9.55: Picked up when band x-rayed	Symptom-free. No signs. E.S.R. 5 mm./hr. Small segmental collapse right middle lobe with pronounced hilar shadow	Lived in barracks. Married 3 months before development of disease
8. 16 yrs. Not married	1955. U.K. Germany, Feb., 1955	None. Mantoux 1:10,000+ 31/3/55	B♭ clarinet	30.9.55: Picked up when band x-rayed	Symptom-free. Diminished movement at left apex, otherwise no signs. E.S.R. 7 mm./hr. Early infiltrative lesion left infraclavicular region	Lived in barracks

Band and contacts x-rayed at end of December, 1955 (M.M.R.). No cases

Band and contacts x-rayed at beginning of May, 1956 (large plates)

9. 22 yrs. Married (Dec., 1955)	1954. U.K. Germany, Feb., 1955	None. Mantoux-neg. in Oct., 1954	Saxophone	5/5.56: Picked up when band x-rayed	Slight fatigue, otherwise symptom-free. No signs. E.S.R. 5 mm./hr. Radiologically an early infiltrative lesion left apex	Lived in barracks. Slept in same room as Case 2 while in Germany—i.e., 1 month
10. 24 yrs. Married	1946. Hong Kong, Brit. Guiana, U.K. Germany, Feb., 1955	2 brothers with tuberculosis. Last saw them in Aug., 1953	B♭ clarinet	5/5.56: Picked up when band x-rayed	Symptom-free. No signs. E.S.R. 3 mm./hr. Radiologically an early infiltrative lesion	Lived in married quarters 1 year. Slept in same room as case in Hong Kong in 1952

When seen in February, 1955, the patient complained of some tightness of the chest, but was otherwise well. A radiograph showed a right spontaneous pneumothorax. In March, while sitting in a chair at home, she had felt a

sharp pain in the left chest. A radiograph showed a small left spontaneous pneumothorax. The right side had re-expanded. She was admitted to hospital, where a left thoracotomy was performed. This showed the visceral pleura to be somewhat injected; there were a number of fine bullae over the surface and a few larger scattered bullae. The lung felt very firm and nodular, and a biopsy of lung showed pathological appearances typical of sarcoidosis. Pleurodesis was performed with camphor. There has been no recurrence of pneumothorax.

Case 4

A man aged 34 was admitted to hospital in January, 1954, for investigation of a painless swelling in the right groin. There was a history of shortness of breath over the previous six years. His medical history and family history were non-contributory. Examination revealed bilaterally enlarged lymphatic glands in occipital, supraclavicular, axillary, epitrochlear, and inguinal regions. The liver and spleen were not enlarged. The E.S.R. was 25 mm. at 1 hour (Westergren), and a tuberculin test was negative to 1/100 O.T. Laryngeal swabs were negative for tubercle bacilli. Other investigations, including blood count and plasma proteins, were normal or non-contributory. Chest radiographs showed massive hilar adenopathy, a large paratracheal mass in the right superior mediastinum, and diffuse reticular shadows throughout the lungs, most pronounced in the upper zones. Radiographs of the bones of the hands showed no abnormality. Biopsy of a gland showed appearances typical of sarcoidosis. The patient was discharged from hospital and kept under observation.

In March he complained of shortness of breath of some weeks' duration. A left spontaneous pneumothorax was found on physical examination and confirmed radiographically. Hospital admission was delayed for six weeks at the patient's request, and repeated x-ray pictures taken subsequently when he was an out-patient showed that the lung had failed to expand. He was then admitted with pyrexia and a pleural rub at the left base. Laryngoscopy, performed because of a history of hoarseness, revealed a left recurrent nerve palsy. The E.S.R. was 50 mm. at 1 hour (Westergren). Chlorotetracycline was prescribed and the lung gradually re-expanded over a total period of two months. Apart from shortness of breath, he has remained symptomatically well.

Discussion

During the last decade it has become obvious that sarcoidosis is a much commoner disease than was previously thought. It is certain also that many cases of pulmonary sarcoidosis were diagnosed in the past as pulmonary tuberculosis with a sputum negative for tubercle bacilli. The scarcity of reports of spontaneous pneumothorax complicating pulmonary sarcoidosis is difficult to explain. A number of such pneumothoraces have no doubt been regarded as complications of pulmonary tuberculosis, but this cannot be the only explanation. Either it is really uncommon or its occurrence has been taken for granted by many clinicians and hence not described. The occurrence of two patients with this complication among the 52 cases of pulmonary sarcoidosis reported by Riley (1950) possibly suggests the latter hypothesis. Until we searched the literature we had no idea that it had been reported only five times previously.

The underlying pathological changes in pulmonary sarcoidosis, both in its infiltrative stage and in its chronic fibrotic stage, are likely to be accompanied by areas of emphysema, and, apart from the absence of caseation and cavitation, are not unlike those of pulmonary tuberculosis. It is probable that when spontaneous pneumothorax occurs in sarcoidosis it is due to the rupture of an emphysematous bulla. This may happen in tuberculosis also, but the frequent presence of caseous lesions and cavities provides additional causes for spontaneous pneumothorax and an explanation of its commoner occurrence in tuberculosis.

Summary

Four cases of spontaneous pneumothorax complicating pulmonary sarcoidosis are reported. In two patients it was bilateral. Although this complication has been reported previously in only five patients, reasons are given for thinking that it may not be rare.

We are indebted to Dr. E. D. H. Cowen for permission to include the records of his patient, Case 4.

HERPES ZOSTER, CHICKEN-POX, AND CANCER IN GENERAL PRACTICE

BY

R. M. MCGREGOR, T.D., M.B., Ch.B.

Hawick, Roxburghshire

The belief is prevalent that an association exists between herpes zoster and chicken-pox, and recently it has been suggested that there is a relationship between cancer and herpes. Provided accurate and continuous note-taking is undertaken any such relationship should be capable of being investigated by the family doctor.

In my practice of some 2,400 patients I have kept accurate and complete records of all ailments since July 5, 1948. The practice is two-thirds suburban and one-third rural. The following information is based upon an analysis of the records of these illnesses in question during the seven-year period from July 5, 1948, to July 4, 1955.

Herpes Zoster

It is possible that all patients with herpes zoster consult their family doctor. This, of course, is due to the discomfort and sometimes severe pain that it causes, associated with the blemishing of the skin. During the seven-year period of this review I had 81 cases of herpes zoster. Table I shows that, while the frequency varies slightly between the sexes in different age groups, the overall picture is that the sexes are equally involved. In both sexes the older age groups are more often affected.

Table II shows the location of the disease; the sex is included for possible variations. In both sexes the thoracic wall is the area most frequently involved. The head and

neck are next in importance, and in this area the male takes precedence, while the extremities are more often involved in the female.

Table III shows the habitat of these 81 patients. It will be seen that this disease affects the rural patients just as often as it does the town dwellers.

Some observers have noted the occurrence of epidemics of herpes. Table IV clearly displays the endemic nature of the disease, and while variations do occur between years the

differences are not large. Where differences are present it is not because of any individual month having an undue proportion but rather because of fewer months when no cases were seen. Over the seven-year period the month of February has accumulated the most cases, but the numbers are not large enough for this to be considered a defined seasonal variation.

Infectivity of Herpes Zoster.—The infectivity of herpes zoster must be very low. This conclusion is derived from the fact that in no household were two cases affected concurrently or at an interval which would suggest one affecting the other. My records show that three households had more than one occupant with the infection during the seven years of the survey, but in each case the occurrence was separated by a period far beyond what would be regarded as an incubation limit. In one of these households two as an incubation limit. In one of these households two sisters who invariably slept together each had the infection. They were aged 15 and 16 years when they were attacked, and one was first seen for this on May 6, 1949, and the other on June 27, 1952. In the second household a husband and wife were affected. The husband was first seen for it on October 20, 1952, and the wife on August 12, 1953. The third household involved an elderly couple who lived alone in a one-roomed house. The wife, who was recovering from an attack of severe biliary colic, developed herpes on July 9, 1950, but the husband did not have herpes until May 13, 1952. In the case of the right lower zoster was in the area of distribution of the right lower intercostal nerves. In five female and in two male cases the victims lived alone and had very little contact with the outside world. In all the other cases there was ample opportunity to spread the infection either from the proximity of a husband and wife occupying the same bed or from other normal household contacts.

Chicken-pox

Unlike herpes zoster, it is possible that not every case of chicken-pox is seen by the family doctor. A mother with several children may seek advice about the first one or two cases, but when she finds that no treatment is prescribed she may elect to treat succeeding cases herself. During the seven years 147 cases of chicken-pox have been recorded, and I should estimate that not more than another 5% escaped my observation.

The slight variations between males and females (Table V) are of doubtful significance. The important point displayed is that chicken-pox is a disease of infancy and early childhood, with the adult only rarely involved. Table VI shows the habitat of the sufferers. It is seen that the rural dweller was not so readily infected as the town dweller in comparison with herpes zoster, but the numbers are too small to be of any significance.

Seasonal Distribution.—Table VII shows that, while each year has had a complement of cases, there are wide variations, and explosive outbreaks of considerable severity occur in some years. This was seen in 1952. This epidemic

started in September, 1951, and reached its height in January, 1952. A secondary flare-up occurred in the March, and it was May before it had completely settled down. Minor outbreaks occurred in July–August, 1949, and in the spring and early summer of 1954. January and July seem to be the months in which the condition is most prevalent.

Infectivity.—Chicken-pox is highly infectious: in this series there were 33 families two or more members of which developed the disease simultaneously or within the usually recognized incubation period. In a few families, however, there is no record of some member having had the infection. For reasons already given, this information is not reliable, and to confirm the absence of the infection would mean jogging the memory of the patient or parent—an untrustworthy procedure. In at least two families, however, the infection was present at intervals far beyond the accepted incubation period. Thus in the case of a brother and sister there was an interval of 10 months, and only two years separated their ages. In the second case the sister had the infection when she was 13 months old, while the brother, who was 3 years older, did not get it until two years later. It is possible, therefore, for individual members of a family to escape the infection at a particular period.

Relationship of Herpes Zoster and Chicken-pox

For many years it has been assumed that there is a close relationship between herpes zoster and chicken-pox. It was first suggested by Bokai, a Budapest physician, in 1888, on

clinical grounds. Serological tests by Amies (1933) confirmed this, and their similarity under the electron microscope appears to give final proof. A number of writers have described epidemics of chicken-pox which appeared to follow contact with a case of herpes. Pickles (1939), a shrewd observer of infectious diseases, is sure that two of his epidemics of chicken-pox followed such a contact, and he states that the epidemic peaks of the two diseases "roughly correspond." Cases in which herpes zoster follows contact with chicken-pox are thought to be very rare.

In my series the relationship of the two diseases is obscure. The totals of the two diseases occurring each year during the seven-year period (Tables IV and VII) show no real relationship between the peak period of herpes zoster and that of chicken-pox except in the year 1952, when each disease showed the highest number of recorded cases. The greatest number of herpes zoster cases occurred during the six months when no chicken-pox was seen, and in the month when chicken-pox was most rife there were no cases of herpes.

It is possible for the two diseases to attack the same patient simultaneously. This occurred in an elderly man. The rash of herpes was first seen on July 23, 1954; on July 28 the widespread rash of chicken-pox also appeared. This has been observed by other writers, but it is not a frequent occurrence. My notes show the case of a child who had chicken-pox on February 15, 1952, along with her brother. On December 15, 1952, she developed a one-sided rash on the inner thigh and labia majora. My assistant diagnosed herpes zoster, but when I saw the patient two days later I was rather doubtful, and I regret not having had this diagnosis confirmed. It is, however, retrospective examination of notes that reveals the lost opportunities and acts as a guide for further observation. Otherwise, my notes show no record of a patient who definitely had chicken-pox and, at a much later date, herpes zoster. The reverse sequence also applies.

In three households chicken-pox and herpes zoster were seen to affect different members of the same family during the seven-year period. In the first family a boy is recorded as having had herpes zoster on July 20, 1949. This was followed by two sisters with chicken-pox—one starting on July 30 and the other on July 31. At this period, however, a small epidemic of chicken-pox was present in the community, and the infection of these three occurred midway through it. In the second family the father developed herpes zoster on November 19, 1952, and although one of his two children was susceptible at the time she did not get chicken-pox until May, 1954. The girl was 7 years of age when she had chicken-pox, and the boy was only 2½ years at the time of infection. In the third family, of three girls, one had chicken-pox on January 19, 1953, the second on February 26, and the third child—the eldest—developed herpes zoster on March 5.

Malignant Disease

There is never any doubt about patients with cancer reporting to their family doctor. Sooner or later they all arrive. The pity is that some are rather late. During the seven-year period of this investigation 54 cases of some form of malignant disease have been encountered. The age and sex incidence and the rates per thousand at risk are given in Table VIII. It will be seen that the females suffered slightly more often from this killing disease than

TABLE VIII.—Age Incidence of Malignant Disease

the males and that those involved were predominantly elderly.

It is of interest to note that in 15 of these 54 cases of cancer the patients (13 females and 2 males) were alive at the end of seven years. This discrepancy is to a large extent due to the survival rate of cancer of the breast. Eight of the female survivors had cancer in this site. Table IX shows the habitat of the patients. The proportions in town and country correspond very closely with the proportions of suburban and rural patients in the practice, and suggests that cancer has occurred with equal frequency in the town and rural dweller.

Relationship of Cancer and Herpes Zoster

Wyburn-Mason (1955) investigated the frequency with which malignant change arises in tissues affected by herpes zoster. He found that 26 cases out of a total of 2,925 skin cancers and 2,580 breast cancers had had a previous attack of herpes varying in time from a few months to many years. Twenty-three other cases had a doubtful relationship. He states that no figures are known of the frequency of herpes in any community and that patients must be specifically asked about it, otherwise they will not volunteer a previous history of the disease. My figures of 81 cases in seven years correspond very closely with those of Pickles (1939), who saw 77 in the same length of time. It is possible that his practice is similar in size. I have not questioned the patients for the purposes of this paper, since I think it is an unreliable method of investigation. I have confined myself to information recorded in my notes. Therefore the period of time before the diagnosis of malignancy was made varies from one to seven years.

In this series 2 of the 54 cases of malignancy are recorded as having had herpes zoster. One man was first diagnosed as having had a lung cancer in 1951, and he developed herpes of an intercostal nerve root two years later, in 1953. The second case was that of a man in whom rectal carcinoma was diagnosed on February 12, 1953, and who showed the typical lesion of herpes zoster along an intercostal nerve root on February 19. None of the remaining 79 cases of herpes zoster followed up from one to seven years have so far shown any evidence of developing a malignant growth.

Discussion

While the virus of herpes zoster and that of chicken-pox may closely resemble each other, the clinical manifestations of the two diseases differ widely. Herpes zoster is a painful ailment, particularly in the elderly. The rash is confined to the distribution of one or more posterior nerve roots and the infectivity is very low. It is a disease of the elderly. Chicken-pox, on the contrary, is not painful, has a generalized rash over the whole body, and is highly infectious. It is a disease of the very young. The two diseases may affect the one individual simultaneously.

In one case of this series herpes zoster preceded an attack of chicken-pox on other members of the household, but, as already stated, an epidemic of chicken-pox was already in existence. The reverse sequence was also seen in one family. It is to be noted, also, that in the family where the father developed herpes zoster his daughter of susceptible age did not get chicken-pox until two years later, when her younger brother was also affected.

Both diseases occur with considerable frequency and some overlapping is inevitable. Indeed, it would be strange if it were not so. The final judgment must await a more prolonged period of note-taking, but the study of this series suggests that there is no epidemiological evidence of the virological relationship between these diseases.

Malignancy and herpes zoster affect the same age groups. Herpes occurs with greater frequency than does cancer.

The series of 54 cases of malignancy and 81 of herpes zoster do not show any tendency for malignancy to develop following herpes. In the two cases where herpes and cancer occurred in the same person the herpes followed the diagnosis of cancer and suggests that the herpes is caused by irritation of the posterior nerve root either by the original cancer or by concealed secondaries in the spinal column. It could also, of course, be unrelated.

Conclusion

A study of 81 cases of herpes zoster and 147 cases of chicken-pox occurring over a period of seven years failed to show any epidemiological association between the two diseases. While neither showed substantial sex or urban/rural variations, the diseases differed widely in age groups involved, in susceptibility, and in the annual and seasonal variations observed over this time.

The study of 54 cases of cancer and 81 cases of herpes zoster over a similar period does not suggest that a herpes zoster infection has any carcinogenic properties. In fact, in the only two cases in which both diseases occurred the cancer antedated the herpes.

My thanks are due to my assistant, Dr. T. C. Morton, for help in getting this information out and to my secretary, Mrs. Potts, for care with my notes.

PYLORIC OBSTRUCTION DUE TO PANCREATIC HETEROTOPIA IN A CHILD

BY

D. MacKINNON, M.D.
Consultant Pathologist

AND

F. W. NASH, M.D., M.R.C.P.
Consultant Paediatrician

Merthyr and Aberdare Group of Hospitals

Pyloric obstruction in childhood is rarely encountered except within the first few months of life. The following is an account of a child aged 5 years who died and in whom pyloric obstruction due to pancreatic heterotopia was discovered at necropsy.

Case Report

A girl aged 5 years 2 months was admitted to hospital in December, 1954. There was a history of recurrent attacks of vomiting for approximately one month, and at the onset of her illness she had suffered from dysuria and frequency of micturition. Since infancy the child had been undernourished and caused her parents considerable anxiety on account of frequent refusal to take food. This was regarded as part of a functional disturbance—for during a previous prolonged hospital admission for atopic dermatitis she was emotionally very upset and suffered from mutism.

On admission the patient was underweight (28 lb. 2 oz.—12.75 kg.) and was slightly dehydrated. She appeared extremely nervous and had badly bitten fingernails. There was an extensive monilia infection of the mouth; the urine contained numerous pus cells, and *E. coli* was cultured from the urine. There was a mild normochromic anaemia.

The thrush and urinary infection responded rapidly to treatment and the general condition improved. As the child was emotionally disturbed it was decided to discharge her home. However, before this could be done she developed a relapse of the urinary infection and the vomiting recurred. In the early hours of January 10, 1955, the child vomited copiously, collapsed, and died quite suddenly.

Post-mortem Examination.—The external appearances were those of a poorly nourished female child. There was bilateral pulmonary oedema. The air passages were clear. The stomach was dilated and there was an obvious tumour at the pyloroduodenal junction. On opening the stomach it was found that the pyloric canal would only admit a probe, 3 mm. in diameter. The pyloric tumour, which almost completely encircled the pyloric canal, measured 1 cm. in thickness and 1.6 cm. in its long axis. It was a hard tumour, and the cut surface resembled that of a leiomyoma. The other organs appeared normal to the naked eye. Microscopy showed the tumour to consist of pancreatic glandular tissue,

FIG. 2.—Higher-power view of the pyloric tumour showing pancreatic tissue supported by a muscle stroma. (×50.)

Reviews

HISTAMINE AND SIR HENRY DALE

Histamine. Joint symposium of the Ciba Foundation, the Physiological Society, and the British Pharmacological Society, in honour of Sir Henry Dale. Editors for the Ciba Foundation: G. E. W. Wolstenholme, O.B.E., M.A., M.B., B.Ch., and Cecilia M. O'Connor, B.Sc. (Pp. 472 + xvi; illustrated. 50s.) London: J. and A. Churchill Ltd. 1956.

The book bears witness to the fecundity of Sir Henry Dale's early observations, to the assiduousness and originality of those who now carry out research in an interesting and important field, to the significance of histamine in nature, and to the inspiration of those who arranged and recorded the various meetings. In the preface the statement is made that research on histamine is at a point at which important advances can be expected. For those who wish to prepare themselves for still further publications in an ever-growing subject this volume is confidently recommended.

F. G. YOUNG.

BIOLOGICAL EFFECTS OF RADIATION

Proceedings of the International Conference on the Peaceful Uses of Atomic Energy. Vol. XI: Biological Effects of Radiation. (Pp. 402; illustrated. 58; 57s.; 34 Sw. fr.) London: H.M. Stationery Office. 1956.

When we went to school we were given anthologies of verse and prose. Study of these was supposed to give us a review of the styles and to a less extent the modes of thought of great writers. Now that we are grown up we find books being published recording the papers presented at conferences. Literary style in scientific papers is good, bad, and indifferent (seldom good). The object of publishers therefore, apart from profit, must be to make readily available to us the thoughts and deeds of the great in specific scientific disciplines.

This particular volume records some of the papers—about half of those of medical and biological interest—from one of the most memorable scientific conferences of all time. The importance of the Geneva meeting in August, 1955, was that it brought East and West together after years of scientific as well as ideological divorce. It led to declassification of much in science and technology relating to nuclear energy that formerly was secret. In the biological field, however, there had been little or nothing classified, so in this field there was no spate of revelations as, for instance, in reactor-engineering. Instead we have the leading doctors of medicine and science of the various countries philosophizing on how ionizing exerts its biological effects or reporting what they considered their most significant but not necessarily latest research. The papers are grouped—as were the sessions—into biological effects of radiation; modes of radiation injury; carcinogenesis and metabolism of bone-seeking isotopes; effects on reproductive system and on foetus; mechanisms of radiation injury; protection and recovery; genetic effects—human implications.

J. F. LOUITT.

GREAT NEUROLOGISTS

Grosse Nervenärzte. Edited by Kurt Kolle. (Pp. 284+vii; illustrated. D.M. 29.40.) Stuttgart: Georg Thieme, 1956.

To medical historians with a facility in German this collection of short biographies will prove valuable as well as interesting. Professor Kolle, of the Ludwigs-Maximilian University of Munich, has edited a beautifully printed and illustrated volume written by a team of distinguished medical authors. An account is given of the careers of some 21 neurologists. This term is employed in the widest possible sense, for included are such psychiatrists as Freud, Jung, Bleuler, Kraepelin, and Wagner von Jauregg, among others; Cushing and Foerster among neurosurgeons; and Pavlov, Berger, and Sherrington among physiologists. The emphasis has fallen, naturally enough, upon the German-speaking neurologists. Great Britain is represented by two names only, including of course Hughlings Jackson, whose biographical essay has been contributed by Sir Gordon Holmes. France is represented by Charcot and Pinel. America's sole figure is Cushing, written up by Professor Fulton. Portraits are reproduced in almost every case, and there are a particularly charming photograph of Otfried Foerster and a striking likeness of Konrad Rieger. An unusual but very useful appendix lists the various holders of the chairs in neurology and psychiatry at most of the German, Austrian, and Swiss universities.

MACDONALD CRITCHLEY.

27 Hours.—There was now definite improvement: left ankle and left triceps jerks were present, there were more spontaneous movements, pupillary reflexes were present though sluggish, and the patient reacted strongly to supraorbital pressure. In these circumstances bemegride ("megimide") and amiphenazole ("daptazole"), which were considered probably the best drugs to use in this condition, were withheld.

40 Hours.—Now fully awake but disoriented and very ataxic. The ataxia slowly diminished, and five days after taking the primidone the boy was again normal.

The urine collected 24 hours after the drug had been swallowed appeared to be clear at first, but as it cooled to room temperature shimmering white crystals began rapidly to form in it until a very heavy crystalline precipitate had collected. The crystals were filtered off, washed with water, and dried *in vacuo*. They had a melting-point of 280° – 282° C., and chemical examination showed them to be pure primidone, as much as 21.5 mg. of the drug being obtained. No albumin, cells, or casts were present, and despite the marked crystalluria there was never any evidence of kidney damage. So far there has been nothing to suggest injury to the bone marrow, but neither the blood nor the marrow has been examined.

The results of acute primidone poisoning in this case, as in the cases reported by Arnold and Ceranke-Höfermayer and by Sciarra *et al.*, appear to confirm the opinion that this drug has a remarkably low toxicity. The heavy primidone crystalluria does not appear to have been observed in man before. Primidone is soluble in urine to the extent of 60 mg. per 100 ml. at 37° C. In the present case 21.5 mg. was filtered off from 10.5 ml. of urine—that is, more than three times the quantity of primidone which could normally be held in solution in that volume of urine at 37° C. Despite this there was no evidence of any effect on the kidneys.

We have been unable to find any references in the literature to specific antidotes against primidone poisoning. The commonly used analeptics could, of course, be tried, but we are of the opinion that the chemical structure of primidone is such that the new barbiturate antagonists bemegride and amiphenazole should be as effective in the treatment of acute poisoning with this drug as they are in acute barbiturate poisoning.

We are most grateful to Professor S. D. M. Court, of the Department of Child Health, for permission to publish this case and for help in preparing the paper. We also wish to thank Drs. A. S. R. Stewart and A. Spinks, of Imperial Chemical (Pharmaceuticals) Ltd., for information and for supplying a specimen of pure primidone for comparison with the crystals excreted in the urine in this case.

CASE REPORT

A boy of 4½ years had been treated for epilepsy and disturbed behaviour since he was 20 months old. For part of this period he had been treated with phenobarbitone, but for the last 2½ years he had been given 0.25 g. primidone twice daily. At 9.30 a.m. on January 1, 1956, the boy was seen playing with his box of primidone tablets. Later, it was clearly established that by this time he must have swallowed at least 50 tablets—that is, not less than 12.5 g.—of primidone. In the following account the times are reckoned from the time of ingestion of the drug.

30 Minutes.—His mother noticed he was sleepy, but thought this was due to a restless night and to a tablet of carbromal he had been given in the early hours of the morning. He went to sleep and was returned to bed.

4 Hours.—Found to be deeply asleep; the family doctor called in.

8 Hours.—Admitted to hospital. On examination found to be deeply unconscious; no reflexes elicited and no response to painful stimuli. Respirations 20 and pulse 120 per minute, blood pressure 80/65 mm. Hg, rectal temperature 97° F. (36.1° C.).

12 Hours.—Some improvement now apparent. There were occasional spontaneous movements, and painful stimuli produced slight stirring. Temperature had risen to 98.4° F. (36.9° C.) and pulse rate to 140 per minute; the blood pressure was 85/60 mm.

16 Hours.—Very little change in the condition, but the blood pressure had risen to 100/55 mm.

24 Hours.—Pulse rate now varying between 120 and 140 per minute and temperature 100° F. (37.8° C.). Lumbar puncture produced normal C.S.F. with 6 cells per c.mm.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY JANUARY 12 1957

NEGOTIATIONS CONTINUED

The Negotiating Committee met the Minister of Health and the Joint Parliamentary Under-Secretary of State for Scotland on Friday last week. The deputation from the Committee was composed of Sir Russell Brain and Dr. A. B. Davies, the two joint chairmen, together with Dr. S. Wand, chairman of the B.M.A. Council, and Dr. J. D. S. Cameron.

Sir Russell Brain summed up the position at a press conference subsequently when he said that this was not merely a pay claim but a crisis of confidence that went to the roots of the relations between the Government and the medical profession. And this, indeed, is the keynote of the widespread comment in the national press. A leading article in *The Times* considers that "the Government ought to be ready to discuss some adjustment of rewards now." The article ends thus: "If deadlock ensues—the omens are unfavourable—the Government will be as much to blame as anyone else for a dispute that could only injure the public." The *Manchester Guardian* concludes a leading article with these words: "It is the Government's bleakly negative attitude so far (*even before Suez*) which has stirred the doctors to their present wrath." (Our italics.) The *Economist* observes that doctors "know only too well that the Government will always be as firm with professional organizations as it will be weak with trade unions," adding: "On the whole, therefore, the main responsibility for breaking the present deadlock lies with the Minister of Health." The *New Statesman and Nation* notes that "the Minister of Health's stupidly brusque rejection of it [the present claim] has roused an ugly mood." "Legalistically," it adds, "the doctors have a strong case; the pledge to honour the Spens formula was repeatedly given when the Health Service was launched. The least the Government can do is to offer to re-negotiate it."

Conservative, Liberal, and Socialist comment is aimed accurately at these two things: the Govern-

ment's obligation, whether legal or moral, to consider the profession's strong case for taking a stand on the Spens formula, and the Minister of Health's curt and brusque rejection of a patient and painstaking presentation of it. And this is quite apart from some press opinion that doctors may generally be better off than some professions, or that, under the Spens terms, doctors would apparently be given immunity against the effects of rises in the cost of living; the punitive action of income tax at least takes care of this, apart from its deadly levelling effect and discouragement of that extra effort without which a society sinks into a condition of apathetic mediocrity. The medical profession is properly concerned with its own welfare. And this is not just financial. It is worried to see more and more of its number trying to emigrate to other countries; and these are not only the younger men fretting at the present frustrations of contemporary England and finding it hard to make their way in the world and support growing families. In their exasperation with the present, doctors are no less worried about the future of medicine and its power to attract able men and women into the profession and to hold them in it, here in this country. They see this present conflict, and all that is involved in it, as part and parcel of the position of the professional classes as a whole. No Minister and no Government would dream of treating the powerful trade unions as they have the doctors and the teachers, for example. After all these months of patient negotiation the Ministry of Health last Friday issued a statement to the press which, among other things, said: "Nothing he [the Minister] had said expressed any opinion one way or another on the merits of the claim. It simply was that it could not be afforded under present conditions. . . . He [the Minister] regretted that the claim could not be examined on its merits at the moment." The statement ended: "He [the Minister] invited the representatives to meet him again shortly."

The Minister of Health, Mr. R. H. Turton, is now implying that the economic consequences of the Government's action over Suez make it impossible to meet the present claim for more pay. But, as the *Manchester Guardian* has pointed out, the Government's "bleakly negative attitude" antedates the Suez intervention. Inflation is just one more excuse—not a reason. The reason is the Government's firm determination, so far, not to admit that the Spens recommendations still hold good, a mere eight years after the introduction of the N.H.S. in 1948. Mr. Turton and his advisers apparently still fail to comprehend that the profession attaches the highest importance to the principles of the Spens reports. They still fail to comprehend that in 1948 the profession made with

much misgiving a huge sacrifice of professional independence in return for a promise that their status and standard of living would be maintained. Now the profession is in the Service the Government is trying to go back on its promise—and its only response, so far, is to say: "Test it in the courts." At the press conference last week Dr. S. Wand, the Chairman of the B.M.A. Council, said that no drastic measures would be taken by the profession during the present month, and that no action would be taken until after the next promised meeting with the Minister. He gave the warning that anxiety and indignation in the profession would continue to grow, claiming, surely with justice, that doctors were reasonable people anxious that last words should not be said too easily. Whether or not the last word of the Minister of Health is "No!", many more words will have to be said about the National Health Service before it is something in which doctors can give of their best to their patients. Medicine is part of society, and, according to a remarkable article in that learned weekly periodical *The Times Literary Supplement* (December 28), "Human society is sick and convulsed as never before." The writer of the article sees, in the name of liberty, equality, fraternity, a flourishing of "as many unfreedoms, injustices, and enmities as humanity has ever had to bear." And he continues: "Everywhere, on both sides of the Iron Curtain, they are imposed by force of the State upon the sentient, patient individuals composing those societies." The writer, it is clear, includes Britain among those societies. In reacting against "the insignificance and frustration felt by individuals," and "the repressions imposed on them by States," the doctors of this country will bring some heart and encouragement to other professions as well as to their own.

LIVE POLIOMYELITIS VACCINES

A poliomyelitis vaccine in Utopia would be absolutely safe, confer complete protection against paralysis for life, and be administered in a single course. This stage has not yet been reached, and at present the comparative merits of the existing killed and attenuated vaccines have to be considered in the light of the two most crucial requirements—safety and persistence of immunity. In the last few years considerable progress has been made with the development of the killed type of vaccine, sometimes referred to as the Salk-type. Resistance to paralysis in vaccinated persons has been established,¹ and the problem of safety is now largely a matter of surveillance. The problem of the duration

of immunity still remains, though recent work by J. E. Salk on this aspect is distinctly encouraging.^{2,3} It is mainly to obtain durable immunity that the use of attenuated vaccines has been proposed as an alternative, and the work of A. B. Sabin and H. Koprowski and his colleagues in the development of this type of vaccine has been reviewed in this *Journal*.^{4,5} The rationale of this method is to produce an asymptomatic alimentary infection with subsequent formation of antibody by giving strains of virus which have lost their capacity to invade and cause paralysis. Recently Koprowski and his colleagues have shown that a total of 225 non-immune subjects, given either the type 1 (SM virus) or type 2 (TN virus), developed type-specific antibody without ill effect.⁶ In more recent articles these workers have shown that active immunity can be induced in infants in the presence of maternal antibody⁷ and in older children given immune serum globulin by injection at the same time as the virus was given by mouth.⁸

Koprowski's work raised a number of questions, of which the excretion of virus in the faeces of vaccinated subjects was the most important. During the last year a study along the same lines has been carried out by a team of workers in Belfast under the direction of Professor G. W. A. Dick using type 1 (SM) and type 2 (TN) attenuated vaccines supplied by Koprowski. Reports of their findings appear in the opening pages of the *Journal* this week. The organization of the trial was different from Koprowski's in that the study population consisted of normal people—infants, children, and adults, leading normal lives. The value of the trial was enhanced as a result, though at the same time laboratory tests were made more difficult, since the final evaluation of this type of vaccine must be carried out in a normal environment. In all, 190 subjects were given type 2 (TN) vaccine virus in milk. In the first report (p. 59) D. S. Dane and others show that the antibody response was much less regular than in Koprowski's series⁶; only 4 adults (22%) and 96 children (77%) developed antibody. The pattern of virus excretion was also different. Virus was excreted in the faeces for several weeks, and in some cases in high titre, but, what is more important, the character of the excreted or

faecal virus had regained paralytogenic properties after passage through the human alimentary tract and had also become cytopathogenic in tissue culture.

Koprowski and his colleagues⁶ had shown that transmission of type 1 (SM) virus could occur from vaccinated to non-immune subjects. The Belfast trial was designed to answer two important questions. Could SM virus be transmitted within a normal family, and would excreted or *faecal* virus maintain the same properties as the vaccine virus? Answers to both questions were obtained, and in the second paper (p. 65) G. W. A. Dick and others discuss their findings on giving type 1 (SM) virus. Of the 14 subjects who volunteered for the trial, all excreted virus and all developed antibody. In the majority of adults a decline in the antibody level was noticeable after a few months. As with the type 2 virus a number of minor illnesses were reported, though their true significance is not understood. The relation of these illnesses to vaccination is not yet proved. In one case evidence was obtained of transmission of virus from a vaccinated girl to her younger brother, and also, possibly, though with less certainty, to her mother. Virus was recovered from the blood of one adult without previous immunity to any of the three virus types on the eighth day after vaccine was administered. Again virus was excreted in the faeces, sometimes in high titre, for periods ranging from one to seven weeks. SM *faecal* virus, unlike the vaccine virus, was found to cause paralysis in monkeys inoculated by the intracerebral route.

The most important aspect of this work is concerned with the altered character and behaviour of the excreted virus, and in the third paper (p. 70) Dick and Dane discuss the implications of these findings. A distinct difference was demonstrated between the vaccine virus and the *faecal* viruses, particularly as regards the type 2 strain. Indeed, there appeared to be little to distinguish the latter from the wild virus strains. A. B. Sabin⁹ also found that a certain proportion of virus particles of his attenuated type 1 and type 2 strains had developed increased virulence for brain-stem neurones of monkeys after passage through the human alimentary tract. This work from Belfast quite rightly lays emphasis on the safety requirements of attenuated virus vaccines. In developing new strains for use in this way more attention will clearly have to be paid to the problem of transmissibility and to the character of *faecal* virus. What goes into the alimentary tract should come out the same. In the meantime, as Dick and Dane conclude, "such trials should only be undertaken step by step, and never without careful laboratory control, however difficult this might be."

PROGNOSIS OF PULMONARY TUBERCULOSIS

Though the treatment of tuberculosis has advanced fast in a few years, the stage is only just being reached where a first estimate is possible of the changes that chemotherapy have brought into the long-term prognosis of the disease. In a recent report to the Medical Research Council W. Fox and I. Sutherland¹ give the results of a five-year follow-up of three groups of patients in the Medical Research Council's trial of streptomycin (S), *para*-aminosalicylic acid (P), and streptomycin + P.A.S. (SP) in pulmonary tuberculosis. These patients, all of them young adults with recently acquired progressive pulmonary tuberculosis, had received in hospital for three months one of these three methods of treatment and for a further three months any method of treatment the clinician felt to be suitable—for instance, further chemotherapy, or surgical or other treatment. All were in bed in hospital during the whole period of six months, and regular clinical, bacteriological and radiographic observations were made. The report states that "by the end of five years 31% of the S, 36% of the P, and 19% of the SP patients had died; 53% of the S, 54% of the P, and 70% of the SP patients had arrested or quiescent disease." The benefit to the patients who had had streptomycin + P.A.S. is stated not to reach statistical significance, but it does reflect a consistent trend throughout the five years. Fox and Sutherland conclude that a number of patients in the trial have become "stabilized in a state of persistent active disease with cavitation" and they describe the serious medical and social problems created by such persons.

This report has been prepared with great care and skill and much work has been put into it, but the results are not altogether easy to interpret. As the authors point out, the prescribed course of treatment was followed for three months only in all patients. After that time there was considerable variation in the treatment different patients had. The better results seen with the SP patients may indeed be due not so much to their initial course of treatment as to the fact that these patients received considerably more additional chemotherapy during the first two years than the patients in the S series. It is certainly hard, however carefully the figures are analysed, to disentangle the events of the first three months of controlled chemotherapy from all the events occurring

in the course of a disease such as tuberculosis over the whole 5-year period.

In a recent paper C. L. Joiner and his colleagues² have reported successful results in a small group of patients with chronic pulmonary tuberculosis who received a "rotating" form of chemotherapy and whose progress has now been followed for two years. Treatment consisted of isoniazid 250 mg. daily by mouth and intramuscular streptomycin 1 g. twice weekly for the first month, isoniazid 250 mg. by mouth and P.A.S. 10 g. by mouth daily for the second month, and P.A.S. 10 g. daily by mouth and intramuscular streptomycin 1 g. twice weekly for the third month. This cycle of treatment was then repeated. Treatment was continued for 36 weeks after the last positive sputum had been obtained. Treatment was started again if there was a bacteriological relapse. Of 13 patients receiving this treatment, only one was classed as a failure (being still sputum-positive after six weeks of chemotherapy). The other 12 were classed as successes; they were all sputum-negative at two years although they had ceased having any chemotherapy for periods from a few weeks up to several months. In contrast, in a group of 14 patients who received isoniazid 250 mg. + P.A.S. 10 g. daily by mouth throughout treatment, there were 9 failures and only 5 successes. The authors discuss the possible reasons for the difference between the response of the two groups and conclude that the rotating therapy is safer, at least in this type of patient with chronic pulmonary tuberculosis, many of whom are likely to have had previous chemotherapy, if only with P.A.S. It remains to be seen whether these results will be maintained over longer follow-up periods and with larger series of cases. But certainly the need for prolonged treatment is clearly shown in this trial.

The very fact that we can now think in terms of chemotherapy extending over several months is almost certainly the result of acquiring a uniquely powerful drug in isoniazid, properly used. P.A.S. + streptomycin, though it represented the best form of combined chemotherapy five years ago, cannot be given for long periods continuously because relapse often occurs during treatment, accompanied by the development of drug resistance. Follow-up figures are not yet available for much more than two to three years for the results of treatment with some of the newer combinations of drugs, including isoniazid or its derivatives, but, judged by short-term results only, these combinations are far better than P.A.S. + streptomycin. One thing, however, has become clear in recent years, that in many forms of tuberculosis chemotherapy can and should be much more prolonged than was at one time thought to be safe or desirable.^{3 4 5} The dangers of prolonged therapy are

obvious, but the rotating method advocated by Joiner and his co-workers certainly seems to have produced excellent results over at least a two-year period. The figures for a five-year follow-up cannot be expected to be as good as this, since in contrast to the patients in the Medical Research Council trials these patients were suffering from advanced chronic pulmonary tuberculosis. But certainly the results up to date are much closer to the ideal of stabilizing the disease not in a state of persistent activity but in a state of quiescence more like that of an extinct volcano. If the mechanical damage such patients have suffered in their lungs is not too severe, many of them can continue to lead active lives, and because their sputum is no longer infectious they are not a danger to other people.

The ideal form of chemotherapy in pulmonary tuberculosis is still elusive, but it seems reasonable to suppose that it should be some form of combined treatment administered in such a way as to reduce the development of drug resistance (as, for example, by rotating treatment), that whenever possible isoniazid should be one of the drugs used, and that treatment should be prolonged in order to lessen the chances of relapse when it is stopped.^{3 4}

NEDERLANDSCH TIJDSCHRIFT VOOR GENEESKUNDE

There are only a few general weekly medical journals which have stood the pace for a hundred years or more. Last week, in Amsterdam, our professional colleagues in Holland celebrated the hundredth birthday of the *Nederlandsch Tijdschrift voor Geneeskunde*, with ceremonial addresses in the Senate Chamber of the University, and a banquet attended by leading members of the Netherlands medical profession, of the society which owns the *Tijdschrift*, the editors of the *British Medical Journal*, the *Lancet*, and the *Ugeskrift for Læger*—all centenarians—and by Dr. Charles Mayer, representing the Union Internationale de la Presse Médicale.

The *Nederlandsch Tijdschrift voor Geneeskunde* took the place a hundred years ago of a number of smaller periodicals, and the society which has since owned it came into being at the same time. Though separately owned, the *Nederlandsch Tijdschrift* was for very many years the official journal of the Netherlands Medical Association. But it ceased to be this towards the end of the war, and the *Medisch Contact*, dealing only with what we could call medico-political problems, became the official journal of the Royal Netherlands Medical Association.

The first number of the second century of the *Nederlandsch Tijdschrift* appears in an attractive new dress. Its size is enlarged to that of the *New England Journal of Medicine*—another centenarian. The contents list now appears on the front cover, for all to read at a quick glance. The text is printed in two columns instead of full out across the page, and a number of

other improvements in lay-out make our contemporary in the Netherlands one of the most attractive-looking medical periodicals now being published.

The editor, Professor J. R. Prakken, aided by his deputy, Professor J. W. Duyff, their staff, and the secretary, Dr. M. M. Hilfman, have collected in their centenary number a most interesting series of articles published in the *Tijdschrift* about a hundred years ago. With much ingenuity they have preserved the usual sections of the journal, but have, apart from the introduction by Professor Prakken and the advertisement columns, included in it nothing published later than 1866. Among them are papers by the great ophthalmologist Frans Cornelis Donders on paralysis of accommodation in "diphtheritis faucium" (1860), and by Hermann Snellen, of the test types, on "neuroparalytic ophthalmia" in trigeminal neuralgia. This centenary number of the "Netherlands Medical Journal" will be a collector's piece for all those interested in the history of medicine. Also in commemoration of the centenary is a magnificently produced history of the past fifty years of the *Nederlandsch Tijdschrift* by Dr. C. T. van Valkenburg, who has been a member of the Netherlands Medical Society since 1917.

During the ceremony at the University last Saturday the editor, Professor Prakken, was awarded the order of the Dutch Lion, and a former editor, Professor J. J. van Loghem, the Gold Medal of the Society, being the sixth recipient of this rare honour. And then the editor of this *Journal*, on behalf of the *B.M.J.* and the *B.M.A.*, had the pleasure of presenting the editor of the *Nederlandsch Tijdschrift voor Geneeskunde* with a gavel and block made from the mulberry tree which used to stand in Dickens's garden on the site now part of the Association's building in Tavistock Square.

CERVICAL MYELOPATHY

Chronic degenerative disease of the cervical vertebrae is exceedingly common. C. Pallis, A. M. Jones, and J. D. Spillane¹ showed this in a study of fifty hospital patients over the age of 50 admitted to hospital for conditions not related to the spine or central nervous system. Three-quarters of these patients were found to have radiological evidence of narrowing of the vertebral canal by osteophytes, subluxation, or loss of lordosis. The condition is usually symptomless, but occasionally it damages the spinal cord and roots. More than half these patients had neurological abnormalities, though all were not necessarily attributable to the cervical lesion.

The effects of cervical spondylosis on the spinal cord have recently received further exhaustive study by E. Clarke and P. K. Robinson,² who reviewed 120 cases. This series included patients who were treated either medically or surgically, or who received no treatment at all. They excluded from consideration all patients with acute herniation of cervical intervertebral disks. Also excluded were cases of ankylosing spondylitis, a condition which occasionally produces a similar myelopathy to that which follows cervical spondylosis. J. Sharp and D. W. Purser, as reported at p. 101 of the *Journal*

this week, recently described neurological complications of this nature produced by spontaneous atlanto-axial dislocation occurring in ankylosing spondylitis, but bony overgrowth and vertebral deformity alone may be sufficient to bring about damage to the spinal cord and roots.

The primary lesion in cervical spondylosis is a defect of the intervertebral disk; osteophytes are formed and may project into the vertebral canal or intervertebral foramina; these in turn produce chronic inflammatory changes in adjacent tissues, apart from any effects they may have on the spinal cord or roots.

The onset of signs and symptoms related to the spinal cord is insidious. Weakness of one or both legs is the commonest initial complaint, but sensory symptoms in the upper limbs and pain in the neck, shoulders, or arms come next in frequency. Important factors in the aetiology are chronic cervical trauma, which explains the higher incidence in men, the presence of congenital anomalies of the cervical vertebrae, and age—for this is a disease of the late middle-aged and elderly. Progress of the condition is often very slow but almost invariably unrelenting. It is usually episodic, and every newly acquired symptom or sign persists. A fifth of the cases show steady deterioration. Signs of the disease are due to a mixture of cord and root lesions, which are always found in association, so that it may be almost impossible to distinguish one from the other. A lesion at a single level is rare, but appropriate focal motor and sensory signs can usually be found. Multiplicity of lesions is partly responsible for the diversity of the clinical picture, but symptoms are most commonly referable to abnormalities at the intervals between the 5th, 6th, and 7th cervical vertebrae. Reflex and motor functions are nearly always abnormal, and there is usually subjective or objective evidence of sensory impairment. Motor abnormalities are generally in the lower limbs and sensory changes are most frequent in the arms. The sensory abnormalities are usually found in the fourth and fifth fingers and on the ulnar border of the hand, where two-point discrimination and postural sense are particularly affected. Sometimes a Brown-Séquard picture may be produced, perhaps in association with paraparesis, or sensory changes may be at the thoracic level (seldom higher); sensory abnormalities in the upper limbs usually enable the level of the lesion to be correctly assessed. Slightly more than a third of the patients have bladder symptoms, but these are seldom severe.

Plain radiographs will assist the diagnosis, but conclusions must not be drawn on this evidence alone. Manometric examination revealed blocks in 27 cases in Clarke and Robinson's series, but they found many more when the neck was extended during the test of jugular compression; this point was emphasized by A. R. Taylor,³ who drew attention to the additional constriction of the vertebral canal that occurs in this position. The level of protein in the cerebrospinal fluid is usually not raised, and, when it is, rarely exceeds 100 mg. per 100 ml. Myelography will confirm the degree and situation of thecal distortion and is necessary before surgery is undertaken.

Acute protrusions of a cervical disk occur in younger people, usually in association with trauma. Symptoms

may be similar to those of the chronic lesion, but there is a soft protrusion of disk material, which should be removed surgically. The frequency with which cervical spondylosis is diagnosed means that it may be a coincidental finding in other conditions. Clarke and Robinson stress the need for careful differentiation of disseminated sclerosis, pseudo-bulbar palsy, and spinal tumour from cervical myelopathy, because therapy and prognosis differ.

The changes which take place in the cervical cord and roots have been ascribed to various mechanisms, acting as intermediaries between the myelopathy and spondylosis. The more important among these are compression and trauma to the spinal cord (or more particularly the roots) by osteophytes, distortion of the cord produced by traction on dentate ligaments, adherence of the ligamenta flava to the dura, and compression by these ligaments when the neck is extended. Adhesions within and outside the dural envelope aggravate these factors, and further softening of the spinal cord may be produced by compression of the anterior spinal artery. More than one of these mechanisms is generally operating.

Clarke and Robinson recommend immobilization of the neck by means of a cervical collar for at least three months. If the patient's condition does not deteriorate, this treatment may be continued for a further three months, but any worsening or failure to stop the progress of signs or symptoms should lead to surgery being considered before the disability becomes too severe. Operation should consist of laminectomy to decompress the theca, and division of dentate ligaments to free the cord. This should cover a vertebra above and below the area of the main lesion. Bony protrusions anterior to the cord should not be removed, but root compression can sometimes be relieved by enlargement of constricted intervertebral foramina. Treatment is at present directed to relief of damage to the spinal cord and roots. The results are disappointing, though progress of the disease can generally be arrested even if improvement is seldom obtained. Future effort must surely be directed to discovering a means of arresting the vertebral disease.

RHYTHMICITY OF EPILEPSY

It is a common experience to be told by a female patient with epilepsy or migraine that her attacks are more frequent at or about the time of the menstrual periods. A possible relationship between epilepsy and menstruation was first suggested by W. A. Turner¹ in 1907, but W. Dickerson,² after a careful study of 270 women with epilepsy, found a positive correlation in only 10%. Furthermore, E. Toulouse and L. Marchand³ found that their patients had as many fits in the second half of the menstrual cycle as in the first (including the period of menstrual flow). R. Almqvist⁴ has recently studied 400 consecutive patients with epilepsy who were admitted to a Swedish State hospital, paying special attention to the rhythmicity of seizures. Some of these patients had too few attacks for an assessment to be made, while in others whose attacks were minor the frequency could not be recorded with certainty. However, 146 cases were selected for analysis, all having been under observation

for at least three years. Almqvist used an ingenious method of charting attack frequency, so designed as to reveal rhythmicity if it existed. In 47 cases the charts showed clearly that the occurrence of fits tended to follow a recurring pattern; this was true in 18 of 62 male cases and in 29 of 84 females. Almqvist concluded that rhythmicity was equally common in the two sexes and that it was unrelated to age. The charts revealed characteristic intervals between attacks, and these were specific to the individual; in addition there was often a simple mathematical relationship between intervals of different lengths in the same case. For example, one patient might have a regularly recurring interval between attacks of 8 days, another of 28 days, while in yet another attacks were seen to occur on the 4th, 8th, or 16th days. Even when the pattern was complex, the intervals were usually multiples of some figure which could be regarded as the basic number of days between attacks. The evidence, supported by detailed statistical analysis, suggested that the rhythmicity was not an expression of a refractory period after a "peak" of several attacks.

A critical review of Almqvist's female cases suggested that the relationship between the interval between attacks and the menstrual cycle followed a definite rule, both being multiples of one and the same basic interval. Thus, of 23 women in whom menstruation was regular, there was a definite relationship between the duration of the menstrual cycle and the interval between attacks in 17. It was apparent that the rhythmicity of epileptic attacks did not depend primarily on menstruation, since the phenomenon occurred equally as often in males as in females and also in children. There was certainly a relation in some women between menstruation and epileptic attacks, but it seemed that both may be manifestations of a single basic biological rhythm. In this connexion the recent report of P. C. B. MacKinnon and I. L. MacKinnon⁵ is of interest, for they showed that death from accident, suicide, or disease was much more common in the fourteen days preceding menstrual bleeding than in the other half of the cycle.

Other paroxysmal disorders of the nervous system sometimes show rhythmicity. For instance, H. Richter⁶ found a tendency for migrainous attacks to occur at 7-, 10-, or 14-day intervals, while E. Kraepelin⁷ described a type of confusional state with psychomotor agitation which recurred abruptly at remarkably regular intervals and which he called periodical catatonia. In two cases of this disorder studied recently by J. S. B. Lindsay⁸ the intervals between attacks were similar to those observed in some of Almqvist's epileptics. These observations support Almqvist's supposition that epileptic attacks occurring at relatively regular intervals may prove to be due to cyclical changes in cerebral metabolism, which, in turn, may possibly reflect a diffuse biochemical change in the entire organism.

EPIDEMIOLOGICAL ASPECTS OF COMMON INFECTIOUS DISEASES*

BY

J. E. JAMESON, M.R.C.S., L.R.C.P.

Brighton

My terms of reference are epidemiological aspects of the common infectious diseases. If I were to try to say something about all of them I should end by having said very little about any of them. I am therefore going to limit my remarks to two groups of common infections.

Haemolytic Streptococcus

The first is infections caused by the haemolytic streptococcus belonging to Lancefield's Group A. I shall refer to this streptococcus as *Streptococcus pyogenes*. The commonest infection in the group is streptococcal throat infection. When fresh cases prove to be nasal carriers the infection is particularly apt to spread to others.

An untreated case commonly harbours *Str. pyogenes* for several weeks after clinical cure. It is not very surprising, therefore, that when a mass swabbing is done at a school during a fairly large outbreak most of the ambulant carriers detected are earlier victims of the outbreak who have since returned to normal school life. It may be inferred from this that I am an advocate of laboratory screening of convalescents. That would be a correct inference within limits, but I cannot overemphasize the point that, when laboratory screening is used, findings must not be allowed to form the basis of a rigid regime of exclusion from school life. Many highly reputable institutions make no attempt to screen convalescents, and many of these fare no worse than other institutions which do make this attempt.

How can these conflicting facts be reconciled? A clue is provided by the work of Brown and Allison (1935) and others some 20 years ago. These workers made a study of scarlet fever cases in hospital. They showed that something like 50% were carrying *Str. pyogenes* on discharge. In spite of this the return-case rate was low, in the region of 2%, though higher with children than with adults. Not surprisingly, it was found that heavy carriers were more often associated with return cases than light carriers. But it was also found that patients discharged from hospital during the fifth, sixth, and seventh weeks were more infective than those discharged earlier. By the use of serological typing it was shown that in these hospital cases the primary infecting strains disappeared on average just before the end of the third week. Of 47 hospital cases investigated, 33 became cross-infected with other strains present in the ward at that time, some being infected with as many as four different types in succession.

There is a weight of epidemiological evidence which indicates that the great majority of patients with streptococcal throat infections become relatively harmless to their fellows within three to four weeks. Griffith (1934) has plausibly suggested that this may be due to a process of antigenic degradation with loss of virulence occurring in the throat of a person who has acquired a type-specific immunity to the particular streptococcus with which he is infected. Such specific immunity would not be expected to cause loss of virulence in a cross-infecting strain until immunity had been built up against the latter strain also. Occasionally we encounter a case of scarlet fever or streptococcal tonsillitis which not only continues to harbour *Str. pyogenes* for months or years but also gives rise to return cases throughout the whole period the organism is carried.

Chronic Carriers

The existence of persistent carriers such as these is an embarrassment when one is asked whether a carrier convalescent for three to four weeks should be allowed to return to school. Various pointers help in this decision: the great majority of chronic carriers of virulent streptococci have an abnormality in the nose or throat, such as enlarged tonsils; unhappily, one cannot place total reliance on the absence of clinical abnormality, because normal-looking tonsils removed from chronic carriers have occasionally been found after excision to have been bags of pus with thin coverings of normal-looking tissue. An important pointer is the heaviness of the carrier state: the dangerous carrier yields abundant *Str. pyogenes* in almost all swabs taken. You will remember that the heavy nasal carrier is especially infective. When in doubt about whether or not to recommend that a known carrier of three to four weeks' duration should go back to school, as a calculated risk, I ask that the child should be sent to the laboratory. When the clinical examinations and the nose swab are negative and when I fail to isolate *Str. pyogenes* from the clothing, I recommend that the risk is a justifiable one, even though streptococci in the throat may be quite numerous.

I am sure many children are kept away from school unnecessarily. One girl I know of who yielded very scanty *Str. pyogenes* intermittently from her nose was kept away from school for three months on that account. There must also be instances when children return to school too soon for the safety of their schoolmates. The bugbear to this problem is that no laboratory test has yet been found which will give a direct answer to the question, "Is this particular strain of *Str. pyogenes* virulent?" The only court of appeal is the human community itself. It is not exceptional to find carriers of *Str. pyogenes* in a community clinically free from streptococcal infections. Other communities with no higher carrier rates may become victims to high, intermediate, or low streptococcal case morbidities which cannot reliably be predicted. But once clinical cases of streptococcal infection have occurred, it is reasonable to assume that contact-carriers of the type-strain causing the cases are infectious.

Str. pyogenes is a versatile organism and causes infections as diverse as scarlet fever and tonsillitis on the one hand, and as erysipelas, puerperal fever, cellulitis, rheumatic fever, acute nephritis, septicaemia, otitis media, and impetigo on the other. Any particular strain of *Str. pyogenes* may under appropriate conditions give rise to more than one of the varied types of infection just mentioned. In any outbreak one should therefore be on the look-out for more than one clinical manifestation of the infection. A familiar example is puerperal pyrexia following a case of streptococcal tonsillitis.

In spite of their versatility, individual strains of streptococci have predilections. A case of scarlet fever is more likely than a case of streptococcal tonsillitis to give rise to a further case of scarlet fever. This is not a good example, because in scarlet fever the clinical result of the infection also depends largely upon the individual patient. A person who has circulating antitoxin as a result of a previous attack of scarlet fever will not develop a second scarlet rash no matter what strain of streptococcus he picks up, though he can and does succumb to streptococcal throat infections. In some instances the association between the infecting strain and the site of election is stronger; haemolytic streptococci isolated from impetiginous lesions fall predominantly into two closely related serological groups, one of which is rarely encountered in other situations. An equally close strain relationship exists between acute nephritis and *Str. pyogenes* of serological type 12.

Reservoirs of Infection

In an outbreak that has become established there are three reservoirs of infection to be taken care of. Firstly, the clinical cases themselves; secondly, the convalescent carriers

and chronic carriers; and thirdly, bedding, floor dust, etc. Spread of infection from these reservoirs is facilitated by overcrowding, so often seen in class-rooms and dormitories to-day, and by inadequate ventilation. If one could eliminate all the reservoirs the outbreak would die out rapidly. In practice total elimination is never possible, but the more complete the elimination the greater the chance of success. The balance between the hosts and the infecting organisms is often critical, and only a partial elimination of the reservoirs of infection may be sufficient to tilt the scales in favour of the community.

Laboratory aid for the elimination of ambulant carriers is sometimes sought after an outbreak has given rise to substantial inconvenience or anxiety. When this state of affairs has been reached it is worth while removing from the community all heavy carriers of the type-strain which has given rise to the clinical cases. Removal of these carriers does not necessarily entail their segregation; a similar result is obtained if the carriers can be rendered non-infective. This is possible temporarily in most, and in some carriers permanently, by an umbrella of parenteral penicillin held over them for a week or two. The penicillin umbrella is imperfect and leaky, but it does enable ambulant carriers to continue their normal occupations, and it may tilt the scales firmly in the right direction, provided the other reservoirs are not overlooked. Long-acting penicillin, such as benzathine penicillin, has considerable theoretical possibilities in this field, but I think its main practical disadvantage is that the injections are painful.

I hope I have conveyed reasons why I have discussed streptococcal outbreaks in general terms. Each outbreak is influenced by many variables, and each must be judged on its own merits as it gradually unfolds. The pattern of the big outbreaks in schools has generally been a gradual build-up of infection over several weeks. I am convinced that these outbreaks would have been brought under control more easily if the schools concerned had started taking serious preventive measures sooner.

Bacterial Infections of the Bowel

The second group of infections I have chosen are bacterial infections of the bowel, including typhoid and paratyphoid fevers, salmonella infections, and Sonne dysentery.

Typhoid and Paratyphoid Fevers

The key to the epidemiology of typhoid fever lies in the fact that, unlike paratyphoid, a few viable typhoid bacilli taken in food or drink are able to set up disease in man. This explains the differences in the epidemiology of the two diseases. A polluted drinking-water may readily give rise to an outbreak of typhoid fever, as it did in Croydon, but, though water supplies are polluted with paratyphoid bacilli as often as they are with typhoid, water-borne outbreaks of as often as they are with typhoid, water-borne outbreaks of paratyphoid fever are very uncommon. This is because pollution in drinking water is highly diluted and the number of pathogenic organisms in a gallon is small, high enough to infect with typhoid bacilli, but not high enough for paratyphoid. For the same reason typhoid fever, but not paratyphoid, is spread by lettuce and by watercress which has been exposed to remote pollution. Shellfish can spread both diseases, the reason being that they filter large volumes of water in a day and thus ingest a large number of organisms. Though these various means of typhoid infection are mentioned in textbooks they do not together account for a very significant proportion of typhoid fever cases. Typhoid fever is conveyed by means other than sewage. Owing to the permeability of toilet paper, typhoid bacilli can readily get on to the fingers of carriers, and thence directly or indirectly on to foods not destined for further cooking.

The channels by which paratyphoid infection is spread are necessarily more limited. An article of food is seldom at the outset contaminated by a sufficient number of bacilli to produce clinical paratyphoid fever. For the latter to

ensue a chain of circumstances must act together. Firstly, the food must become infected; secondly, the conditions must be favourable for bacterial multiplication in food; and, thirdly, the food must be consumed without a further period of cooking sufficient to kill the paratyphoid bacilli.

For bacterial multiplication to take place various conditions must obtain together; the food must contain a sufficiency of moisture and nutrients for bacterial growth, it must remain at a suitable temperature for a long enough time, and it must not be too acidic. When the temperature of the food is above 70° F. (21.1° C.) half a day may suffice for the necessary bacterial multiplication. When the temperature is near to blood-heat multiplication takes place within a few hours; below 50° F. (10° C.) multiplication is slow, and at refrigerator temperature it is negligible. These facts explain why paratyphoid fever is mainly prevalent during late summer and autumn, though we must remember that food does not always remain at atmospheric temperature. When a large mass of food is warmed up, cooling takes place slowly and the temperature-time combination in the centre is often favourable for multiplication of those bacteria that have not been destroyed by the cooking. An article of food often incriminated in outbreaks of paratyphoid fever is cream cakes. The reason for this is that the cream filling acts as a culture medium and unlike most bakery products is not subjected to baking. Cream cakes are often eaten after a lapse of hours or days from the time the cream fillings are prepared in the bakery.

Though both in typhoid and in paratyphoid fever the reservoir of infection is always human, careful examination of the staff of a bakery implicated in a paratyphoid outbreak often fails to reveal the presence of the carrier. Paratyphoid bacilli can enter bakeries in imported foodstuffs, especially in egg products used in confectionery. Working conditions may be crude. Appliances such as muslin strainers are infrequently sterilized, and are used for straining successive mixes of different kinds. It may thus happen that infection in one kind of mix passes to another kind of mix not destined for baking. Cream cakes may thus leave a bakery infected, although the ingredients from which they were made were free from infection and there were no carriers in the bakery.

Cream cakes are only one vehicle for the dissemination of paratyphoid infection. Similar principles apply to others—namely, a breakdown of hygiene leading to contamination, multiplication of the bacilli in the contaminated food, and consumption of the food in the absence of adequate cooking. I have used the word adequate because some cooking processes sterilize only the surface of the food. The uncoagulated yolk of a soft-boiled egg and the unaltered haemoglobin in the centre of a lightly done steak bear eloquent testimony to the absence of severe heating. A sausage must be very well grilled or fried if vegetative organisms near its centre are to be destroyed.

Salmonella Infections; Sonne Dysentery

Salmonella infections were formerly associated with names such as Aertryck or Gaertner. They are referred to now as *Salmonella typhi-murium*, *Salmonella enteritidis*, or as *Salmonella x*, *x* being a place-name. The epidemiology of salmonella infections has much in common with that of paratyphoid, for the reason that a relatively large number of salmonellae have to be ingested before clinical infection ensues. Apart from the shorter incubation period, the difference lies in the reservoirs of infection. In the case of salmonellae there is an extensive animal reservoir, especially rats and mice, poultry, pigs, and cattle. Other animals, including unlikely ones such as the tortoise, harbour salmonellae: cats and dogs occasionally fall victims to salmonella infection, and both have been known to pass this infection to man, but fortunately this is rare. Infected rats and mice leave droppings in any food to which they have access. An infected farmyard animal may itself become an article of food, and poultry eggs may carry infection. Hen eggs are rarely infected, but when brooded in large numbers, as in the preparation of dried egg, frozen liquid egg, or egg

*Read in the Section of General Practice at the Annual Meeting of the British Medical Association, Brighton, 1956.

albumen, the risk of salmonella infection is increased proportionately. Duck eggs are notorious for their association with *Salmonella typhi-murium*. In any large collection of hen eggs a few duck eggs are often to be found; this adds to the risk of salmonella infection in bulked-egg products. One would expect pork sausages to be a good vehicle for the spread of salmonella infections, and this is so in practice.

The most prevalent type of dysentery in Britain by far is Sonne dysentery. It accounts for over 95% of the cases. As in salmonella infections, the incubation period is a short one, from one to three days. In common with typhoid and paratyphoid fever there is no animal reservoir. As in typhoid fever the infective dose is probably a small one. Bacterial multiplication in food is not an important factor in its transmission, and it is noteworthy that this disease is now commoner in Britain in the early spring than it is in the summer. The factors which govern its spread are not yet fully understood, though soiling of lavatory seats by children is believed to play a part. In Scandinavia it is still a summer disease, as it was in Britain until the end of the war. There is a closer case-to-case linkage than with salmonella infections, and it is uncommon for an outbreak of Sonne dysentery to involve widely scattered households between which there is no link, as occurs in typhoid and paratyphoid outbreaks.

Discussion

In outbreaks of all these intestinal infections it is the rule and not the exception to find that there are persons exposed to risk but clinically unaffected who are excreting the organisms in their stools. In common with streptococcal infections of the throat, convalescents remain infective to others after clinical recovery. In intestinal infections these periods of infectivity tend to be long. The tendency for a prolonged carrier state is greatest with typhoid and paratyphoid, intermediate with salmonella, and least with Sonne dysentery bacilli, in which a carrier state lasting more than three months is rare. An outbreak of paratyphoid fever in Eastbourne was followed up eight years later. At the end of 18 months, 5% of the patients were still excreting paratyphoid bacilli. These persistent excretors were mainly among the under 5's and over 70's. One of the over 70's is still alive and still excreting paratyphoid bacilli.

One might wonder, in view of the long period convalescents remain infective, why it is that these diseases are not universal. Some of them are indeed at times widespread, and there is always a submerged number of undiagnosed cases the size of which we can only guess. But even taking this into consideration, only a minute fraction of the total population is ever infected at one time. The main limiting factor apart from hygiene is, I believe, natural immunity. We have much evidence that the ingestion of small numbers of paratyphoid and salmonella bacilli is followed by no undesirable clinical effects. Though with typhoid fever and Sonne dysentery the threshold of infection is lower, the prevalence of symptomless excretors in both these diseases is also strongly indicative of the natural resistance.

Further evidence of this resistance is the rarity of outbreaks in which the morbidity of adults exposed to risk reaches 50%. Similar evidence of a more direct kind is provided by the sauce chef of one of Brighton's leading hotels. There is retrospective evidence that this chef remained a heavy excretor of *Salmonella typhi-murium* for several months before he infected the residents and visitors to the hotel, although sauces, which are his whole-time professional occupation, may be an excellent vehicle for the dissemination of salmonellae.

Now a few words only on the treatment of intestinal carriers. Cholecystectomy is sometimes successful for typhoid and paratyphoid carriers, but not by any means always. Antibiotic treatment has in the main proved disappointing in its long-term results for chronic carriers. It is true that many temporary intestinal carriers appear to have responded permanently to antibiotic treatment, but we must not forget that the great majority of intestinal

carriers stop excreting in their own good time, whatever it may be, without treatment. An attitude of healthy scepticism rather than of blind faith is called for.

Before I end there is one more fact I should mention: the sauce chef I spoke of has now disappeared from Brighton and has not been traced by our health department. Doubtless he is now pursuing his culinary art in some other town.

In preparing this paper I should like to acknowledge my indebtedness to Topley and Wilson's *Principles of Bacteriology and Immunity*, by Wilson and Miles (4th edition, 1955), for some of the information relating to streptococcal infections.

Summary

Two groups of infections have been considered, those due to *Str. pyogenes* and those due to enteric bacilli.

Str. pyogenes, though versatile, has predilections. The most frequent site of infection is the throat, but nasal carriers are more infective. Throat cases usually become non-infective within three weeks, but exceptions occur and are discussed. In outbreaks there are three reservoirs of streptococcal infection. Though complete elimination of all the reservoirs is never possible, partial elimination, including removal or neutralization of contact carriers of the type-strain causing the clinical cases, may limit the outbreak. If these measures are applied early enough an outbreak may be prevented.

An attempt has been made to rationalize the known epidemiological facts concerning typhoid and paratyphoid fevers, salmonella infections, and Sonne dysentery. This has been made in relation to the relative infective doses of the organisms concerned, their reservoirs of infection, natural immunity in the population at risk, and current hygienic (and unhygienic) practices.

RHEUMATIC DISORDERS

HEBERDEN SOCIETY MEETING

Among the topics discussed at the Heberden Society's two-day scientific and annual general meeting last month were the reason for the persistently high E.S.R. sometimes found in patients with degenerative arthritis and a hitherto little commented upon complication of ankylosing spondylitis—namely, spontaneous atlanto-axial dislocation, of which 10 cases were reported. The meeting was held in London on December 14 and 15 at University College Hospital Medical School and the Wellcome Foundation, under the presidency of Dr. ERNEST FLETCHER. On the first day Professor R. E. TUNBRIDGE, of Leeds, delivered the Heberden Oration, on this occasion a review of recent advances in our knowledge of the connective tissue and its constituents. In the evening the society's annual dinner was held at the Apothecaries' Hall (*Journal*, December 29, 1956, p. 1557). Eight scientific papers were presented during the meeting, and here we summarize a few of them.

Unexplained Elevation of the E.S.R.

Dr. B. M. ANSELL and Dr. E. G. L. BYWATERS described a three-year study at the Postgraduate Medical School of London of patients with an unexpectedly high erythrocyte sedimentation rate. Sometimes, they said, routine estimation of the E.S.R. by the Westergren technique in new patients attending the rheumatic clinic had revealed a reading which could not be explained on the basis of the original diagnosis—for example, degenerative joint disease. Of 51 patients with such readings, out of approximately 900, they had now satisfactorily investigated and followed 45. These

fell into two groups: in 14 the E.S.R. returned to normal within a month; but in the remaining 31 it persisted at a high level. Besides a full clinical examination, investigation of these cases had included tests for C-reactive protein, plasma proteins, fibrinogen, and L.E.-cells, and, in some, numerous radiographs, electrocardiographic examination, and bone-marrow and synovial biopsies also.

As a result, it had been possible to make a definitive diagnosis in 20 of those with a persistently high E.S.R. and in 7 of those whose E.S.R. was only transiently raised. Although degenerative joint disease was the most frequent initial diagnosis a large number of these patients had subsequently developed rheumatoid arthritis as judged by strict criteria, while several others were probably also affected by it. In other cases, although the presenting symptoms were due to degenerative joint disease, the actual cause of the raised E.S.R. had proved to be an unrelated condition such as myelomatosis. Of those in whom no cause was found, in some the E.S.R. returned to normal as their symptoms abated, but no precise diagnosis could be established; in the others the E.S.R. remained high despite a satisfactory general condition and the disappearance of symptoms. Perhaps the high readings in these cases might be related to advancing years or to the presence of widespread degenerative changes.

The presence of a raised E.S.R. in the absence of obvious clinical cause, said Dr. Ansell and Dr. Bywaters in conclusion, called, therefore, for full investigation and follow-up before the patient could be reassured that the finding was of no significance.

Spontaneous Atlanto-Axial Dislocation

Dr. J. SHARP and Mr D. W. PURSER, F.R.C.S., of Manchester, said they had observed spontaneous atlanto-axial dislocation in 10 patients with advanced ankylosing spondylitis. The first patient had died with a tetraplegia, the cause of which had remained obscure until his post-mortem examination. The subsequent cases had presented in three ways. First, there were those with progressive deformity, a "falling forwards" of the head, difficulty in shaving under the chin, and decreased height of vision. A second group complained mainly of severe pain in the occipital and suboccipital regions, aggravated by sudden movement or riding in vehicles; several of these patients had been given x-ray therapy without relief of their pain. In a few cases the outstanding feature was the onset of severe neurological manifestations.

Damage to the cord appeared to be related not only to the degree but also to the rapidity of the displacement, and to the persistence of any abnormal atlanto-axial mobility. Although in some cases a degree of subluxation was also present at a lower level, the atlanto-axial dislocation probably accounted for the damage to the medulla or spinal cord. If severe pain or neurological changes were present, treatment consisted in correction of the deformity by skull traction, followed by occipito-cervical fusion. With this regime pain was relieved and neurological signs regressed. Atlanto-axial dislocation had also been observed in rheumatoid arthritis.

Although further experience might show that spontaneous atlanto-axial subluxation was a not uncommon sequel of ankylosing spondylitis and rheumatoid arthritis, it might well prove, suggested Dr. Sharp and Mr. Purser, not necessarily to be attended by disastrous consequences. Nevertheless, early diagnosis of the displacement was highly desirable, both to spare the patient from the possible dangers of unwarranted radiotherapy or injudicious physical treatment, and to allow him to be guarded against injury, as even trivial accidents might cause serious and perhaps fatal neurological complications.

Other Subjects

Among the other papers was a radiological study of 300 cases of ankylosing spondylitis, followed up for periods of 6 to 23 years, by Dr. J. FORESTIER, of Aix-les-Bains. He

pointed out that radiological evidence of sacro-iliac ankylosis did not imply that the disease was necessarily arrested. On average it took 14 years for the sacro-iliac joints to become ankylosed, and although the duration of clinical activity varied greatly from case to case the average time was 19 years, roughly during the period of sexual activity. As a rule, all cases that had been quiescent for several years showed complete bony ankylosis of both the spine and the sacro-iliac joints.

Papers were also read by Dr. J. S. LAWRENCE (Manchester), on physiotherapy in rheumatic diseases; Dr. V. WRIGHT (Stoke Mandeville), on diurnal variations in the grip; Dr. B. M. ANSELL, on a radio-isotope study of the sodium-retaining properties of cortisone and prednisolone, from which he concluded that in cases on cortisone where sodium retention had occurred prednisolone might exert a diuretic effect; by Dr. H. J. GIBSON and Mr. N. R. LING (Bath), on a new augmented agglutination test on the Rose-Waaler model; and by Dr. B. S. BLUMBERG and Dr. A. G. OGSTON (Oxford), on the effects of proteolytic enzymes on the hyaluronic acid complex.

MONOPOLIES COMMISSION ON OXYGEN

The "Report on the Supply of Certain Industrial and Medical Gases," of the Monopolies and Restrictive Practices Commission, published recently,* makes it clear that so far as oxygen, one of the gases considered, is concerned, it is practically the monopoly of the British Oxygen Company; for this company, in addition to supplying something like 98% of the oxygen used in Great Britain, also holds the agencies for the supply of most of the machinery used in its production.

B.O.C.'s Heavy Responsibility

In view of this position, the Commission points out, a heavy responsibility fell on the British Oxygen Company to ensure that the full requirement of industry, the hospitals, and the armed Services would continue to be met, and that in the field of research the United Kingdom would at least keep pace with other countries. In its long history the British Oxygen Company had not been responsible for the discovery of any of the successive important new processes for the production or distribution of oxygen, states the report. Indeed, almost all were discovered abroad, and the company's part had been to acquire the necessary patent rights or licences and exploit them in this country. On such evidence as was available it seemed that rapid technical progress was still being made abroad, notably in the U.S.A. and Germany.

"Medical" Oxygen

In the evidence considered by the Commission figures were submitted which showed that industrial oxygen was produced at a total cost of about 25s. 11d. per 1,000 cubic ft. (28 cubic metres). But, although industrial oxygen more than met the standard of purity required by the *British Pharmacopoeia*, medical oxygen, because of the need to handle and fill small cylinders, and for greater hygienic care, a day and night service, and similar overheads, cost 72s. 5d. per 1,000 cubic ft., nearly three times as much.

Dealing with medical oxygen alone, the Commission mentions there is no national price scale for medical liquid oxygen, but there is in force a national price scheme for compressed medical oxygen. In the evidence a number of hospitals had indicated that they regarded the absence of published prices as disadvantageous, and some said different hospitals within the same management group were paying different prices.

Owing to the arbitrary nature of the cost of medical oxygen and the variation in them of

*December 20, 1956. H.M.S.O., London. Price 6s. net.

oxygen supplied to the Air Ministry for high flying, it was not possible to say with any degree of certainty what was the loss (if any) on sales of oxygen for medical purposes in the strict sense of the term. The records of the company showed an average loss of 11% on cost for medical oxygen in all forms, including liquid oxygen for high flying, and there did not seem to the Commission to be any justification for any losses sustained on the sales of medical oxygen being in effect carried by the industrial consumers. They recommended that published price scales for medical oxygen should be prepared on the same lines as for industrial oxygen.

Commission's Conclusion

"We find that the British Oxygen Company charges unjustifiably high prices for oxygen—and that this operates and may be expected to operate against the public interest," states the Commission in its conclusions as to price. And further on, when dealing with the monopoly position which the company has built up, it is stated that the British Oxygen Company had taken advantage of the position to charge prices which the Commission regarded as unjustifiably high, and had pursued a price policy which was in other respects open to objection, and that all those things operated against the public interest and might be expected to continue to operate against them unless changes were made and safeguards introduced.

Nova et Vetera

WILLIAM HILLARY, M.D. (1697-1763)

William Hillary was one of the first physicians to attempt to correlate illness with climatic conditions. He was a careful and systematic observer of the weather and its effect upon prevalent diseases. He also wrote one of the earliest books to deal specifically with tropical disease, his *Observations on the Changes of the Air, and the Concomitant Epidemical Diseases, in the Island of Barbados* . . . being published in London in 1759. This work included one of the original and most accurate descriptions of tropical sprue. Apart from these bare facts, however, little has been known of the life and work of William Hillary. His publications *On the Small-pox, Diseases in Barbados*, and *Means of Improving Medical Knowledge* may be consulted in libraries, but they contain little or no biographical detail. Who was this intriguing eighteenth-century physician? Who were his friends? Where did he come from?

Some of these questions have been answered during a recent survey of the correspondence of John Fothergill (1712-80), the famous Quaker physician. William Hillary was well known to this philanthropic doctor, for in a letter written to his brother Alexander in Wensleydale, Yorkshire, and dated July 11, 1746, Fothergill discussed Dr. Hillary and his intended voyage to the Barbados. "Whilst he was here," Fothergill wrote, "news came of the Death of the only eminent Physician at Barbados: I procured him an interview with a person who gave him an exact account of the affairs of that Island, he likewise spoke with several others who jointly recommended the place as much preferable to Jamaica . . . there are several Meetings, the Island pleasant and healthy." Other letters included Fothergill's "kind love" to the Hillary family, and in November, 1746, he told his brother that he was glad that "Dr. Hillary's relations were satisfied with the part that I acted in his affairs."

These letters do more than indicate that Fothergill knew Hillary well, that he took an active part in helping him to secure his post as physician in Barbados, and that Hillary too was a Quaker. They also suggest that the Hillary family was well known to Alexander Fothergill, living at Carr End in the wild and isolated beauty of Wensleydale,

and that the Hillary family probably lived somewhere close by. They lived, in fact, in the Wensleydale village of Burtsett, where Hillary Hall still stands to-day, two or three miles from the Fothergill home at Carr End; and a search through Quaker records reveals that William, the son of John and Mary Hillary, was born on January 17, 1697, a winter's day when the snow must have lain deep in Wensleydale.

Apart from his Yorkshire origin, William Hillary had another link with John Fothergill, for he worked in Bradford with the same apothecary, Benjamin Bartlett, to whom Dr. Fothergill later served his apprenticeship. He took his medical degree at Leyden in 1722, at that time the acknowledged centre of medical learning in Europe, graduating M.D. with a dissertation on intermittent fevers. He then became a physician in Ripon, Yorkshire, but in 1734 moved on to Bath. His situation there, however, was "not the most agreeable nor the prospect very pleasant," and for these reasons he went to Barbados in 1747, where his observations of the weather and the prevalent diseases occupied him from 1752 to 1757. He returned to London in 1758, living quietly in retirement until his death on April 25, 1763.

Hillary and Fothergill were by no means the only well-known physicians of the eighteenth century who had associations with the Yorkshire Dales. John Dawson (1734-1820) and John Haygarth (1740-1827) came from near-by Garsdale, and John Coakley Lettsom (1744-1815) was apprenticed to an apothecary, Abraham Sutcliffe, in Settle, Ribblesdale. Further afield, Anthony Askew (1722-74), one of the owners of the famous gold-headed cane, was born in Kendal, over the border in Westmorland, but, like Fothergill and Haygarth, he was educated at Sedburgh School in Yorkshire. Among this illustrious company of Dales doctors William Hillary may claim an honoured place. He was a physician whose accuracy of observation and therapeutic skill were actuated by a constant search after perfection. His philosophy and his scientific approach to the practice of medicine cannot be better described than in the words of the introduction to his *Rational and Mechanical Essay on the Smallpox*, written whilst he was in practice in Ripon. This work was published later in 1735. An extract from his introduction follows:

"It appears how necessary it is for a Physician, who would be successful in his Practice, or make any tolerable Figure in his Profession, to be well acquainted with the structure of the Human Body, the use of all its Parts, the Principles of Mechanical Powers, the Laws of Motion and Hydraulics, with a sufficient skill in Geometry and Mathematics, to apply them; as well as a knowledge of Chymistry, Pharmacy, and the Virtues and Doses of Medicines. For it is by a proper Use and Application of these, both in our Practice and Reading, that we can account for the Causes and Effects of Diseases, and the manner of the Remedies acting, so as to produce their salutiferous effects. It is by these, and accurate observations in Practice, that we must improve our Knowledge in the State of Physic and Diseases; it is this Knowledge, and these Abilities, that must be the distinguishing Characteristic of a true Physician, from an Empiric; it is by this Method of reasoning from Data, founded upon observations and real Facts, that the *Healing Art* must be improved and brought to a State of Perfection; for if we once quit our Reason for Mystery, and abandon a just Method of Mechanical and Geometrical Reasoning, for the unintelligible terms of Occult Faculties and Qualities, with all such like Metaphysical and Chymical Jargon and Nonsense, heretofore too much used in the Schools; we must wander through endless Mazes, and dark Labyrinths, playing at Hazard with Men's Lives, and suffer ourselves to ramble where ever conceited Imagination, or Whimsical Hypothesis will lead us."

We record our sincere thanks to Mrs. A. Wallis, of Darlington, for permission to quote extracts from the letters of Dr. John Fothergill in her possession; and to the librarian of the Friends' Reference Library for help in consulting Quaker records.

C. C. BOOTH.
W. N. PICKLES.

Correspondence

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

Perinatal Mortality

SIR,—As a member of a small committee engaged in a pilot survey of the problems of perinatal mortality among domiciliary as well as hospital deliveries, I was naturally interested in the exhaustive data presented by Dr. J. P. Bound and his colleagues (*Journal*, November 24, 1956, p. 1191, and December 1, 1956, p. 1260), especially as I had already experienced the usual difficulty in finding any suitable classification of the causes of stillbirth and early neonatal death. A table based upon clinical diagnosis will inevitably be inaccurate, as so many asphyxial deaths are associated with multiple causes. The child that dies during the prolonged labour of a parturient who suffers from anaemia and chronic hypertension, and who is three weeks apparently post-mature, can be placed in no one clinical group.

I had therefore hoped that I should find an answer to my problem in the pathological classification put forward by the department of paediatrics and morbid anatomy of the University College Hospital Medical School. Unfortunately, despite the most painstaking cross-reference between the pathological and clinical findings, the result remains somewhat unsatisfactory. Asphyxial deaths are divided between three groups, partly on pathological findings and partly on clinical records. Asphyxial death occurring so slowly or so long before delivery that gross evidence of the asphyxial process could not be found is placed with unexplained cases of intrauterine death, despite possible clinical evidence pointing clearly to asphyxia. The division between intra-partum asphyxia and ante-partum asphyxia is made according to records of foetal heart tones and the clinical estimate of the onset of labour. While this may seem a natural separation of two contrasting groups, it ignores the fact that most intra-partum asphyxia has been preceded by ante-partum hypoxia, and it may well be fortuitous whether death occurs just before or after the onset of labour.

Further, a pathological classification inevitably fails to meet the needs of the obstetrician desirous of information on current problems. He must hunt for stillbirths associated with inexperienced delivery of the breech presentation among intra-partum asphyxia as well as intracranial haemorrhage, and the perinatal mortality of pre-eclampsia may be in almost any one of the pathological columns. It would seem that the ideal classification has yet to be propounded, but it must surely make use of both pathological and clinical factors.—I am, etc.,

Birmingham.

W. G. MILLS.

Diesel Fumes

SIR,—Mr. B. T. Commins, Mr. R. E. Waller, and Dr. P. J. Lawther (*Journal*, November 24, 1956, p. 1235) suggest that my previous letter (*Journal*, October 20, p. 939) shows confusion of thought, in that I have appeared to confuse figures for total hydrocarbons in exhaust gas given by Elliott *et al.* with figures for polycyclic hydrocarbons given by Kotin *et al.* I regret that this distinction was not made clear, but the purpose of the quotation was to point out that output both of total hydrocarbons from Chicago diesel buses in average condition in city streets, and also of polycyclic hydrocarbons from a test-bed diesel engine (except when in perfect condition), increases greatly with increase of load, and hence that conditions in a garage where engines are very and hence that conditions in a city street, which are what matter to the general public. In fact, Commins *et al.* have not given evidence for their statement (*Journal*, September 29, p. 753) that "the highest concen-

trations of exhaust products to which men are regularly exposed probably occur in garages." It may well be that the concentrations of certain of the more dangerous products reach levels in busy city streets on windless days as high as, or higher than, in garages, and that these levels are maintained for longer periods. It would be useful to have some British measurements to compare with those of Kotin *et al.* on the Los Angeles atmosphere.

In any case, it must not be assumed that 3:4-benzpyrene or even other polycyclic hydrocarbons are the only carcinogenic substances present in internal combustion engine exhaust, nor that the petrol engine is innocent in this matter. Kotin *et al.* noted that the concentration of 3:4-benzpyrene in the Los Angeles atmosphere was relatively low in contrast with the high yield of malignant tumours produced by painting extracts of the atmosphere on to the skin of mice, and low compared with the known high quantity of 3:4-benzpyrene emitted from all sources. They give evidence to suggest that hydrocarbon oxidation products may also be important carcinogens, and that oxides of nitrogen are partly responsible for oxidation of hydrocarbons in these substances. They also point out that atmospheric carcinogenic hydrocarbons are usually adsorbed on to soot particles, in which form they are biologically ineffective, becoming effective only upon elution from the soot particles. The sebaceous secretions of the skin may act as a natural eluting agent, thus accounting for chimney-sweeps' cancer of the scrotum, but there is no such natural eluting agent in the lungs. Unburnt petrol and fuel oil vapour (present in considerable quantity in the exhaust of petrol and diesel engines) can, however, act as a solvent to extract polycyclic carcinogenic hydrocarbons from soot and render them active in the lung. Hence the normally harmless 3:4-benzpyrene adsorbed on to soot particles from coal burning (including possibly those already deposited in the lungs) can be rendered actively carcinogenic by unburnt petrol and fuel oil vapours. It may even be that such unburnt vapours activate benzpyrene from tobacco smoke. This might account for the observation by Dr. C. J. G. Franklin (*Journal*, December 15, p. 1426) that cancer of the lung seems rare among heavy smokers in the West Indies.

With regard to oxides of nitrogen, I am at a loss to understand Commins *et al.* when they state (*Journal*, November 24, p. 1235) that the "assumptions" I made in my previous letter are "in direct conflict with data given in Fitton's summary of modern work." My statements on exhaust volume of diesel engines and total output (not concentration) of oxides of nitrogen are based on Elliott *et al.* and Fitton gives no data on these points. Fitton gives no figures for proportion of petrol to diesel vehicles in city streets, and his figures for total petrol and diesel vehicles apply only up to 1954, but it is known that all buses in London and most other cities, half London's taxis, and more than half the heavy lorries are diesel powered, and Fitton does not contradict this. The reason for my fresh calculations is that it is quite wrong to assume for calculation of air pollution in city streets, as Wilkins does, that "the relative quantities of these two types of [exhaust] gas emitted are indicated by the relative amounts of exhaust gases derived from the petrol and diesel fuel used by road vehicles in 1954, viz., 5.9 and 1.4 m. tons respectively." This would be true for the country as a whole, but in city streets where public transport is provided by diesel buses the proportion of diesel vehicles is almost certainly higher than for the country as a whole, probably by a factor of 2. In any case, Wilkins appears (though his method of calculation is not displayed) to have assumed that the relative amounts of exhaust gases from the two types of engine are in the same proportion as the relative amounts of the two types of fuel used. He seems to forget (1) that a diesel engine gives at least 50% more power in proportion to fuel used than a petrol engine; (2) that a diesel engine of given power gives an exhaust volume from 2 to 7 times as great as a petrol engine of the same power. Hence the ratio for petrol to diesel exhaust volume should be 5.9 : 1.4 × 2 × 1.5 × 2 to 7—that is, 5.9 : 8.4 to 29.4—that is, 1 : 1.5 to 6 (approx.). At a ratio of 1 : 3, assuming Wilkins's and Fitton's figures for exhaust gas composition, oxides of nitrogen may reach 6.25 p.p.m.—if the ratio is 1 : 4, oxides of nitrogen may reach 8.1 p.p.m.

I am very glad to see that Commins *et al.* have realized the importance of air pollution by oxides of nitrogen and that my letter has prompted them to make some measurements. It is difficult to evaluate the significance of their results, in view of the wide variation in the figures for carbon monoxide concentration, pointed out by Dr. Handley Howell (*Journal*, December 22, p. 1487). This, the wide variation in the figure for NO₂, and the complete lack of correspondence between the two figures, suggests that the results are the purely chance figures that must be expected from individual instantaneous samples taken in the turbulent air near moving traffic. May I suggest that it would be more

reliable to take a continuous series of instantaneous samples, say, every minute for an hour, and give the maximum, minimum, and mean values? In addition to the questions which Dr. Handley Howell raises, data as to wind speed and weather conditions for each test would be helpful. It would also be useful to carry out the tests at various times of day, including times of peak travel. Nevertheless, the results at first sight seemed reassuring, but unfortunately Commins *et al.* omitted to mention that Saltzman's method (which they used for estimating oxides of nitrogen) is actually a method of estimating nitrogen dioxide only—it is not sensitive to nitric oxide. According to Faith¹ the major component by far of oxides of nitrogen from internal combustion engines is nitric oxide. This gas is important, partly because of its direct toxic effects and partly because it is steadily converted to nitrogen dioxide in the atmosphere. This conversion may well occur more readily in tissues such as the lungs in the presence of oxidizing enzymes. Perhaps Commins *et al.* could give some figures for total oxides of nitrogen.

I note that Commins *et al.* emphasize "the limited significance of the preliminary garage results." Would that much of the popular and the motor press had emphasized this instead of giving the report misleading publicity. Assuming that the London Transport Executive realizes this limited significance, surely it is its duty to admit that the diesel engine has not yet been proved harmless to health.—I am, etc.,

London, E.4.

Treatment of Acute Appendicitis

SIR,—I read with interest Mr. Eric Coldrey's article on acute appendicitis (*Journal*, December 22, 1956, p. 1458), but I would question the wisdom of his remark: "One sometimes wonders whether it would not be a sound procedure to treat all cases of acute appendicitis conservatively."

In general practice one sees from time to time cases suggestive of acute appendicitis which subside on conservative treatment in hospital and which, on returning home, repeat their symptoms and signs in maybe two or three months' time and which have to be readmitted for an emergency appendicectomy. The result is an increased call on acute surgical beds, prolonged absence of the patient from work or school, and (dare one mention it?) more work for the family doctor, who has to answer two calls for an acute abdomen instead of one, and whose advice when he suggests hospital on the second occasion is apt to be met with some remark such as, "Well, you told me last time, Doctor, my appendix would have to come out: are you quite sure this time?"

In case I appear sententious, I should add that I have probably sent in far more than my fair share of mesenteric adenitis, acute pyelonephritis, etc., wrongly labelled as acute appendicitis, and am only too aware of my own diagnostic limitations, but I do feel that from everyone's point of view an uncomplicated acute appendicitis in this country is best treated by its removal.—I am, etc.,

J. C. FOSTER

Nettlebed, Oxon.

SIR,—As G.P.s we are a little tired of reading articles on appendicitis by specialists who grumble that the case is not always admitted within 24 hours of the onset of pain. The latest "offender" is Mr. Eric Coldrey (*Journal*, December 22, 1956, p. 1458). Have these specialists all worked in general practice, and do they realize the difficulties?

The patient does not always consult the G.P. until the pain has been present some time. The diagnosis can be very difficult in the early stages, especially in children. Some children seem to start as simple gastro-enteritis, and show

signs of localization to the appendix only after a day or two. It is easy for the specialist. The period of doubt is over and the diagnosis made when the patient reaches hospital. Why do not specialists make it easier for the G.P. to get a specialist opinion instead of walling themselves in behind their appointment systems and registrars? If we want a specialist opinion we must usually wait about a week for an appointment. If we phone the registrar at hospital we are frequently told (after waiting 15 minutes while he is found), "Yes—he would see the case, but as he has no bed available anyway would we please try elsewhere?"

When we are worried by the cases we failed to diagnose within 24 hours we comfort ourselves thinking of cases we have diagnosed correctly and sent to hospital. A few of these have waited quite long periods for operation, as an alternative diagnosis, such as chest infection or adenitis, has appeared more likely to the specialist. So the differential diagnosis must be difficult.—We are, etc.,

JOAN WAGSTAFF.

HELEN WAGSTAFF.

London, E.4

Methyltestosterone Therapy

SIR,—In response to the letter by Drs. G. L. Foss and S. L. Simpson (*Journal*, December 15, 1956, p. 1426), we have recently had under our care a patient who became jaundiced while having methyltestosterone.

A woman, aged 24, and five months pregnant, was referred on August 8, 1956, to the skin department of the Gloucester Royal Hospital with severe generalized pruritus of one month's duration. In her only previous pregnancy she had had similar irritation which had cleared up on the day after childbirth. When seen on the present occasion there were no abnormal signs, and a diagnosis of pruritus of pregnancy was made. Local and sedative treatment was ineffective, and a month later the itching was so intense that she was threatening suicide. On the advice of Dr. R. E. Bowers, methyltestosterone 10 mg. twice daily by mouth was started on September 10. Relief of irritation was immediate, but on September 26 her sclerotics were noticed to be yellow and the urine contained bilirubin, urobilin, and a trace of albumin. Additional investigations were as follows: direct van den Bergh reaction, positive; serum bilirubin, 2 mg.%; alkaline phosphatase, 20.7 K.A. units; ZnSO₄ turbidity, 3 units; thymol turbidity, 1 unit; total serum proteins, 6 g.% (albumin 4 g.%, globulin 2 g.%); paper electrophoresis, within normal limits.

Because of the jaundice, methyltestosterone was discontinued. Within a few days the irritation returned and by October 8 was again intolerable. On October 12 she was admitted for the gradual reintroduction of methyltestosterone under observation, since the alternative seemed to be termination of the pregnancy. On admission the sclerotics were only faintly yellow. Investigations were as follows: urine contained a trace of bilirubin and urobilinogen; serum bilirubin, 0.9 mg.%; alkaline phosphatase, 33 K.A. units; ZnSO₄ turbidity, 3 units; thymol turbidity, 2 units; serum proteins, no change. On October 13 methyltestosterone was started in a dosage of 10 mg. daily. By the next day itching was less and the dose was reduced to 5 mg. daily. This dose failed to control itching, and on October 19 it was increased to 5 mg. three times a day. Pruritus was no longer relieved, and the patient became more jaundiced, with nausea and anorexia. The serum bilirubin rose from 0.8 mg.% on October 19 to 1.25 mg.% on October 22. The methyltestosterone was therefore again reduced to 5 mg. daily, and within a few days the nausea and anorexia disappeared and the sclerae became less yellow. The patient stated that she preferred the pruritus, now somewhat less intense than before admission, to the nausea and anorexia associated with increasing the dose of methyltestosterone, and she was discharged home on methyltestosterone 5 mg. daily and phenobarbitone $\frac{1}{4}$ gr. (16 mg.) three times a day. A week later she went into labour, and, as in her previous pregnancy, the itching completely disappeared on the day after parturition.

We concluded that initially pruritus was relieved by 20 mg. daily of methyltestosterone, and that this dose produced jaundice; that 5 mg. daily neither relieved pruritus nor increased the jaundice; and that subsequently 15 mg. daily increased the jaundice but failed to relieve pruritus. Pruritus is a well-recognized but uncommon complication of pregnancy. Standard textbooks offer no clues to its causation. We have not made a search of the literature, but a recent monograph on jaundice in pregnancy¹ suggests that pruritus

is due to hepatotoxaemia, even when jaundice is not present. In our patient jaundice was not noted when she was first seen but was discovered by the same observer (K. M. T.) after she had been given methyltestosterone. The subsequent variation of the jaundice with the dosage of methyltestosterone is, we believe, good evidence of an icterogenic effect of the drug in this patient. It seems probable, however, that pruritus of pregnancy is due to hepatic dysfunction, and that methyltestosterone aggravated in our patient a condition already present.—We are, etc.,

B.C.G. Vaccination after Replacement Blood Transfusion

SIR,—We were interested to read the paper by Drs. A. S. Hutcheson and P. Macpherson (*Journal*, October 13, 1956, p. 863) suggesting that babies who have had an exchange transfusion may show an abnormal reaction to B.C.G. vaccination. As we had recently vaccinated twin babies who had each received two exchange transfusions, and have since been able to trace the donors of the blood used, we feel it may be of interest to report these two cases.

The twins, female and male, were born at full term to a primigravida of blood group O rhesus-positive. They weighed 5 lb. 4 oz. (2.4 kg.) and 5 lb. 2 oz. (2.3 kg.) respectively and each received "synkavit" 5 mg. intramuscularly at delivery. Jaundice was noticed in both six hours after delivery and was progressive. There was no anaemia, and both babies were of group A rhesus-positive with negative Coombs tests. At 48 hours the boy developed athetosis and head retraction, and a diagnosis of kernicterus associated with the administration of vitamin K was made. Accordingly an exchange transfusion using group A rhesus positive blood was carried out on both twins at 57 hours. Despite this, the jaundice progressed, and a second replacement transfusion was performed 36 hours later with rhesus-positive group O blood, on a revised diagnosis of haemolytic disease due to group A incompatibility. Both babies subsequently showed clinical improvement, and the diagnosis was later confirmed by the finding of an anti-A haemolysin in the maternal blood.

On the 18th day both twins were given 0.05 ml. B.C.G. intradermally, with the production of nodules which did not discharge and without enlargement of the axillary lymph glands. At 15 weeks the Mantoux reaction using 0.1 ml. of 1:1,000 O.T. gave areas of induration of 10 mm. and 11 mm. in diameter. The five donors of the blood used, and the mother, were given the same Mantoux test, and reacted positively, having areas of induration of 13, 15, 16, 28, 32, and 18 mm. respectively.

We believe that the evidence of these two cases, together with the large series reported by Drs. W. A. B. Campbell and H. M. Purser (*Journal*, November 10, p. 1115) and Drs. M. d'Avignon and G. Berglund (*Journal*, December 8, p. 1363), supports the idea that an abnormal reaction to B.C.G. following exchange transfusion is most unusual, and is not related to the tuberculin sensitivity of the donors. It must be noted that vaccination of the patient described by Drs. Hutcheson and Macpherson was performed four days after the transfusion, whereas it is customary in the Charing Cross Hospital unit not to give B.C.G. until a sick or premature baby is almost fit to go home. Also, we used the reduced dose (0.05 ml.) of the Danish B.C.G. recommended by Gaisford,¹ and this may be a further difference between these twins and the original patient.

Our thanks are due to Dr. J. D. James, of the North London Blood Transfusion Centre, for help in tracing the donors, and to Dr. A. Doyne Bell for permission to study the babies.—We are, etc.,

J. B. BENWELL.

DAVID BURMAN.

Pregnancy Sickness

SIR,—There is little doubt that Dr. Doreen S. Ball (*Journal*, December 22, 1956, p. 1487) is right in assuming the organic origin in many cases of pregnancy sickness. The hormonal causation might apply to some of them; but it occurs to me that the following considerations may not have been taken up. It has been accepted in the teaching of embryology that ontogenesis is only a shortened repetition of phylogenesis. That means that the embryo passes through the various stages of its ancestral "run," as represented by the corresponding specific anatomical and, probably, biochemical features. The sickness in question would thus be understood as allergic in type and the effectiveness of antihistamines in some of these cases explained. To prove or disprove this hypothesis must naturally be left to maternity wards equipped accordingly, unless past evidence be already available.—I am, etc.,

Cardiff.

R. BAUER.

SIR,—I am most interested in Dr. Doreen S. Ball's observations (*Journal*, December 22, 1956, p. 1487) with regard to pregnancy sickness. I have had two babies and suffered greatly with each owing to sickness. Three months after my first child was born I took stilboestrol for one day to stop lactation and had the identical sensations of nausea and vomiting as during pregnancy. The second day I decided to take one dose at bed-time, hoping that sleep would prevent me being conscious of nausea. To my amazement when I got up next morning I was very sick and still suffering from nausea identical to that of pregnancy. Dr. Ball appears to have noticed a relationship between lack of food and sickness. To prevent actual vomiting I had to eat two-hourly during the first 4–5 months of pregnancy. I studied all the available literature and sampled all the recommended drugs. They were useless.

If all obstetricians in the United Kingdom were to take stilboestrol for a couple of days, and if those who were made sick by it were willing to continue with daily doses for three months so as to experience a long-term sickness similar to that of some unfortunate woman, then they might afterwards do research into this matter with considerable determination (I should be grateful for the names of male volunteers). Those who consider neurosis as a possible cause would no longer do so. From Dr. Ball's and my own humble observations I too feel it is possible that this trouble may be due to hormonal imbalance.—I am, etc.,

Hereford.

MARGARET MACFETRIDGE.

Ocular Nerve Palsy Associated with Severe Headache

SIR.—Dr. A. P. B. Waind (*Journal*, April 21, 1956, p. 901) reviewed a syndrome of ocular nerve palsy associated with severe headache recently described in diabetic patients, adding some cases of his own. In view of the infrequency of this syndrome I would appreciate an opportunity to record a further case.

A woman, aged 71, first came under the care of the diabetic clinic of the German Hospital in December, 1954, with untreated glycosuria since 1951, complaining of numbness and pain in the left lower limb, loss of weight, and excessive thirst. She then had signs suggestive of diabetic peripheral neuropathy in her left leg. Some three months later she developed sudden diplopia due to an isolated external rectus palsy, without any other concomitant symptoms or signs, which gradually recovered over the next three months. Soon after this incident her right knee- and ankle-jerk became depressed with additional sensory impairment over the right foot, and later she developed weakness and proximal wasting of her left arm, loss of sensation, and diminished brachial and supinator reflexes. All investigations were normal except for a histamine-fast achlorhydria, C.S.F. proteins 60 mg.% with increased globulin. Electromyography suggested a neuropathy as the cause of her paresis.

About mid-October, 1956, she suddenly developed severe right-sided headache, almost continuous, for five days. As this pain abated, blurred vision in her right eye, diplopia, and ptosis developed. She then had a pure right-third-nerve palsy, a dilated

right pupil reacting very sluggishly to light, and ptosis of the upper lid, but no other additional C.N.S. signs. Repeat lumbar puncture showed 90 mg.% protein, increased globulin, but normal pressure; x-ray of her right orbit showed a normal sphenoidal fissure. Her headaches have not recurred and her diabetes has remained well controlled. After a lapse of three weeks, recovery of ptosis and pupillary reaction began, and to-day, after five weeks, most of her ptosis has recovered, her right pupil is small but still reacts only sluggishly to light, while her oculomotor palsy is still substantially unchanged.

This case appears very similar to those described by Dr. Waind. It cannot be due to any intracranial lesion, such as a tumour or aneurysm of the internal carotid artery, in view of the spatial and temporal scattering of the lesions described and the definite recovery now taking place, but must represent an unusual form of peripheral diabetic neuropathy. It is interesting to note that her diabetes was well controlled at the time of occurrence of both these ocular palsies. There is no explanation for the fact that her abducens palsy was not associated with headaches in contrast to her present attack.—I am, etc.,

London, E.8.

P. S. ELIAS.

Glycyrrhetic Acid

SIR.—The letters from Drs. Brian Russell, I. M. Patricia Smeed, and K. M. Tomlinson (*Journal*, December 22, 1956, p. 1483) are interesting and show results varying considerably from those of Dr. E. Colin Jones (*Journal*, December 1, 1956, p. 1305) and my own (*Journal*, November 24, 1956, p. 1239). All are of fairly small numbers and with apparently different brands of glycyrrhetic acid preparations. All clinicians would agree that hydrocortisone topically has an excellent but limited application in dermatology, and that now it is no longer used as indiscriminately as previously. In the same way glycyrrhetic acid has limited but apparently definite application, I agree with Dr. Colin Jones, more in the subacute and chronic dermatoses.

It would appear that the disparity in results is due very largely to selection of cases. I would point out also that glycyrrhetic acid is not a clear-cut constant chemical (Drs. E. M. Donaldson and D. A. Duthie, *Journal*, November 17, 1956, p. 1161), and the majority of my trials have been made with "biosone G.A.," a preparation which is claimed to contain the active isomers of glycyrrhetic acid. However, a few cases (reported earlier) where I tried "genodex" were more encouraging than those recorded by Dr. Smeed. Dr. Tomlinson's light-hearted comments are appreciated and taken in the spirit in which they were made.

My trials with biosone G.A. are being conducted on both out-patients and in-patients, in subacute and chronic conditions. The reactions to the drug are being recorded and mostly independently and objectively observed. I hope shortly to be able to give a comprehensive survey of the results of my trials.—I am, etc.,

Herne Bay, Kent.

QUENTIN EVANS.

Pavlov's Works

SIR.—Dr. W. Ritchie Russell's letter (*Journal*, December 22, 1956, p. 1432) embodies a very sound idea, but is rather unfortunately worded. It is to be regretted that he had found it necessary to invent a man of straw—a "psychologist." The psychologist is apparently preoccupied with the avoidance of avoiding trauma; tends to belittle traditional disciplines in a harmful way; lacks a sufficiently energetic approach to problems of national education, and so fails to provide the nucleus for a philosophy thereof; and generally manifests a negative attitude.

This sounds more like the popular stereotyped idea of the psychologist than what one would have expected from Dr. Ritchie Russell. It certainly does not sound like a colleague of the late Clark Hull, of Skinner, of Mowrer, or any of the learning theory exponents—a body of workers almost in the direct line of descent from Pavlov. It does not sound like any of the Gestalt school. It could hardly be Piaget. It does not sound like any of the educational, industrial, experi-

mental, or clinical psychologists known to me. Least of all does it sound like Hebb, whose own hypotheses have done so much to bridge the gap between the physiologist and the psychologist.

I really think that Dr. Ritchie Russell must be referring to the psychoanalysts. If so, perhaps one of that particular discipline will deal with his representation of their attitude. In the meantime, might I point out that psycho-analysis and psychology—even medical psychology—are not identical? It is a pity that such a distinguished physician as Dr. Ritchie Russell should contribute to the perpetuation of this vulgar error.—I am, etc.,

Willesden, E. Yorks.

J. AMOR ARDIS.

SIR.—For the past seven or eight years I have been under the impression that some rapprochement had been effected between the brain mechanists and the mental dynamists. Yet here is Dr. W. Ritchie Russell clapping on his brakes and incontinentally going into reverse (*Journal*, December 22, 1956, p. 1482). Had he been content with saying that he believed in brain physiology and had no faith in psychology, one could have found no quarrel with him, but he also, and unwisely, gives reasons. He talks about positive and negative attitudes as if these arbitrary arithmetical symbols could factually be applied to emotional or intellectual "attitudes." This is the sort of thing one reads about in American books on psychology of the popular sort. Secondly, it would be most enlightening to hear of methods whereby "desirable" behaviour patterns could be developed by brain physiologists, to say nothing about a "philosophy" being erected around grey matter, surely a unique spectacle. One can visualize the embalmed body of that arch brain-washer Stalin comfortably turning over on his Moscow catafalque.

Dr. Ritchie Russell would have us believe that the argument from a laboratory-conditioned mongrel to the intricacies of a civilization-conditioned human is a valid one. Here, surely, he has out-Pavloved Pavlov himself and proved himself to be more out of date than Freud or Pavlov, both of whom he so cavalierly sends to limbo. And, anyway, who says that we have to choose between physiology and psychology? Are they not both different facets of the same human unity?

Men who were fed on brain physiology all their lives and who dare not look further than the point of their dissecting scalpels should think twice before embarking upon the problem of shaping the future of the human race. Shades of Sherrington!—I am, etc.,

Kingswinford, Staffs.

W. A. O'CONNOR.

Perforation of Oesophageal Peptic Ulcer

SIR.—The report by Drs. D. D. Gellman and K. Silberstein (*Journal*, December 15, 1956, p. 1413) of a case in which there had been erosion of the pericardium by a simple peptic ulcer of the oesophagus has encouraged me to review a somewhat similar case which occurred in 1952.

A retired male farm worker, aged 75 years, died suddenly three-quarters of an hour after eating a large meal. He had vomited about half a litre of blood. Up to the time of his death he had been in good health except for occasional attacks of bronchitis. He had never complained of symptoms referable to his oesophageal ulcer. Necropsy revealed a deep elongated ulcer (3×2×2 cm. deep) in the anterior wall of the oesophagus 8 cm. above the attachment of the diaphragm. The edges of the ulcer were thickened and overhanging. Above the level of the ulcer the oesophageal mucosa was of normal appearance and was found on histological examination to be lined by normal squamous epithelium. Below the ulcer the oesophagus was dilated and lined by inflamed gastric mucosa. There was thus post-mortem evidence of the presence of a diaphragmatic hernia. The upper posterior part of the pericardial sac was obliterated by the fibrous tissue in the base of the ulcer, and the sudden fatal termination was due to direct erosion of the left auricle of the heart. The perforation measured

8×6 mm. and was situated 1½ cm. above the mitral ring. The stomach contained one litre of fresh clotted blood, but was otherwise normal. No other abnormality was revealed at necropsy. Examination of the sections from the edges of the ulcer showed simple peptic ulceration with surrounding inflamed but otherwise normal gastric mucosa.

In recording this case I wish to thank Mr. Norman Butters, H.M. coronor, for access to the statements taken on his behalf.—I am, etc.,

Ipswich.

A. B. LINTOTT.

Sudden Infant Deaths

SIR.—Dr. J. L. Emery and Miss E. M. Crowley (*Journal*, December 29, 1956, p. 1518) rightly draw attention to the importance of the clinical history in sudden infant deaths. There is no doubt that minor malaise precedes death in nearly all cases; this is well known to the average coroner's officer. I do not think their assumption that histories taken by coroners' officers are inadequate can be accepted without comment. The history taken after the coroner's inquiry is likewise open to question, in view of the time given to the parents to produce explanations and symptoms which may or may not be founded on fact.

The whole-time coroner's officer is a very experienced man who may inquire into as many as 500 deaths a year. This implies an experience of bereaved persons which one hopes is denied to paediatric workers. He usually visits the home in plain clothes for the purpose of taking the history. It is my experience that the coroner's officer shows great tact and sympathy on all occasions.

The description of the inquest is sensational and unfair to the modern coroner. It is not usual to read over a written statement to a witness, neither have I ever seen a witness's eyes wander from the coroner's face to the reporter's pencil. In such cases every effort is made to respect the feelings of a distressed young mother. It is often unnecessary to require her to give evidence, and identification can be established by the father or some other person. Most natural sudden deaths in infancy can be cleared up without inquest.

Death of a baby is a catastrophe. All concerned are anxious to find the cause by every means possible. I do not think that Dr. Emery and Miss Crowley have made their case that a subsequent history is more correct than the one taken by the coroner's officer. It is the constant care of the modern coroner to exclude fear from his investigation. There are indifferent interrogators in every organization: I do not think the coroners' services have a monopoly of these.—I am, etc.,

London, W.6.

GAVIN THURSTON.

Prevention of Tuberculosis

SIR.—Professor F. Heaf in his comprehensive survey (*Journal*, December 15, 1956, p. 1383) appears to advocate the universal use of B.C.G. vaccine in children over 12, but not in those under 12 because of three disadvantages, none of which appears to be really formidable. Are the disadvantages not greatly outweighed by the advantages observed in the countries where B.C.G. is applied in all observed in the countries where B.C.G. is applied in all tuberculin-negative reactors? Such advantages include the almost complete disappearance of progressive primary (acute miliary tuberculosis), as well as the most dangerous complication of benign primary disease (tuberculous meningitis) in B.C.G.-vaccinated children. Professor Heaf himself emphasizes the advantage of B.C.G. used in this way, when he quotes the Stockholm figures of 65.3% of non-vaccinated children developing clinical tuberculous lesions following primary infection, compared with 1.22% in the vaccinated.

Instead of B.C.G., he proposes serial tuberculin-testing of all children under 12, and the routine use of chemotherapy in the tuberculin-positive child. With regard to the first, an important principle should be adopted right away with-

out qualification—namely, that tuberculin-testing should always be combined with chest radiography in order to make a diagnosis, and that action should not be based on one of these signs alone. A good example was the demonstration of the combined method in the examination of household contacts in Glasgow by Drs. W. F. Tyrrell and J. Smith (*Journal*, December 22, 1956, p. 1451). With regard to the routine use of chemotherapy when a child is merely found to be tuberculin-positive, without reference to the possible quiescence or the activity of the disease, this would surely be a most unwise use of drugs as well as of skilled labour, very wasteful indeed, and conducive to drug resistance. Even if conversion to tuberculin-positive is known to be recent, and the benign primary complex can be diagnosed radiographically, all but the small proportion of benign primary cases that have complications are naturally healing and building up resistance in the process, and do not need chemotherapy. If a complication does occur, or if the primary complex is progressive (5% of cases), that will be shown by urgent symptoms which would clearly indicate immediate chemotherapy. Early diagnosis and treatment of this fraction should be the aim rather than an enormous and costly umbrella.

In addition, Professor Heaf makes no clear distinction between primary and secondary tuberculosis. The latter gives rise to much more disease than the former, and, apart from social measures, requires for its prevention again an early diagnosis by means of combined tuberculin-testing and radiography. The most practical means of prevention can be outlined briefly but clearly in these terms: (1) B.C.G. from infancy; (2) combined tuberculin-testing and radiography in order to make an early diagnosis, of both primary and secondary tuberculosis; (3) chemotherapy and the appropriate treatment for malignant primary, complications of benign primary, and all secondary disease; (4) maintenance of a high standard of living to strengthen resistance; (5) the chest clinics should be developed sufficiently to deal with this programme, and completed with the static mass radiography units.—I am, etc.,

London, N.W.8.

MILOSH SEKULICH.

REFERENCE

¹ Sekulich, M., *Tuberculosis Classification, Pathogenesis and Management*, 1955. Heinemann, London.

SIR.—With reference to Professor F. Heaf's article on the prevention of tuberculosis (*Journal*, December 15, 1956, p. 1383), I was very interested in his remarks concerning the giving of general practitioners reader access to chest x-ray facilities. In the area in which I practise only one local hospital has open access for chest x-rays. In the other hospitals the patient must, at least, see the casualty officer before a chest x-ray can be arranged. This adds considerably to the time which patients must spend at the hospital, and because of this they are often reluctant to attend. Could not all hospitals offer open access x-ray facilities to general practitioners?—I am, etc.,

London, E.5.

BERNARD TAYLOR.

Varicose Ulcers in Ambulant Patients

SIR.—Dr. B. FitzGerald (*Journal*, December 22, 1956, p. 1484) is to be congratulated on his efforts in the domiciliary treatment of "varicose ulcers." From personal experience of nearly seven years in general practice I know this is no easy matter and very different from the treatment of these patients in a hospital clinic run for the purpose. It is not surprising that Dr. FitzGerald's patients cannot be convinced that strict resting of the limb is necessary, for it has been demonstrated by many surgeons during the last 200 years that ambulant treatment is best.

Although chloramphenicol in propylene glycol may be beneficial for infected ulcers if used for a few days, the risk of allergic sensitization is so considerable that its use is regarded by many as unjustifiable. One cannot but wonder

how many of the patients mentioned by Dr. FitzGerald as having widespread eczema did not owe this to chloramphenicol. The most important point in the treatment of these ulcers in ambulant patients is control of the oedema. Abolish the oedema and the ulcer will heal, usually irrespective of local treatment. Ignore the oedema and healing will not take place. Although firm bandaging with crêpe may help, elastic crêpe, elastic webbing, or one of the elastic adhesive bandages is better. If the ulcer is offensive and Gram-negative organisms are present, phenoxylethanol (2%) in Lassar's paste is an effective and harmless application.—I am, etc.,

Leeds, 1

S. T. ANNING.

Supply of Bodies for Dissection

SIR,—So far in vain I have waited for a more able pen than mine to write on this subject. Your annotation (*Journal*, December 8, 1956, p. 1357) reads: "There is thus an urgent need for more people to leave their bodies." I believe it is not unwillingness on the part of the individual, but failure on the part of those responsible to furnish adequate facilities. When an individual in a household dies, there is usually sadness and a desire "to get things over" as soon and as easily as possible—"We don't want no fuss." Clearly everything should have been arranged beforehand, and in my view it is the duty of those who want the bodies to do it. I suggest that forms, particulars, and suitable notices to hang in waiting-rooms for those willing to show them, be sent to all general practitioners. This could readily be done through the agencies that send out advertisements. Is it reasonable to expect poorly paid general practitioners to bother to send up for forms? There must not be too many forms to fill up, and there must be a quick willingness to collect the bodies. Much of the above applies also to corneas. Let those who want them act.—I am, etc.,

Pettwood, Kent.

G. C. MILNER.

Increase in Scabies

SIR,—Having had a considerable experience in the diagnosis of scabies in this country during the last war, I was puzzled by the last paragraph of Dr. Margaret S. M. McGregor's letter (*Journal*, December 15, p. 1427): "I regret that I have not isolated an acarus, as I have lacked facilities for making a determined attempt to do so." Surely, if an acarus is responsible for the lesions she describes, all that is needed to detect it is a watchmaker's lens; and to extract it, a sterile needle.—I am, etc.,

Haywards Heath.

H. LYNDBURST DUKE.

Mercury Absorption and Psoriasis

SIR,—My colleagues have asked me to write and express our gratitude to Dr. R. W. Smithells (*Journal*, December 15, 1956, p. 1428) for his information regarding the origin of the term calomel disease and for his lucid comments on our original article (*Journal*, November 24, 1956, p. 1202). If we have minimized the risks of mercury poisoning from cutaneous absorption, we feel we have done so with some justification. Despite the common usage of mercurials for the even more common condition of psoriasis, nephrosis nevertheless remains a very rare disease. We do feel, however, that the danger is somewhat greater at the present time with the increased usage of the new types of occlusive dressings—i.e., tubular stockinet and tube-gauze in the treatment of psoriasis.

That syphilitic nephrosis was most probably due to the treatment rather than the disease is a conclusion which we also reached, but felt it was inappropriate to enter such a supposition into a paper in which we had brought no evidence to substantiate such a statement, and, in fact, we felt it irrelevant to the points under investigation. As Dr. Smithells states, there is obviously no toxic level of urine

mercury. High urine mercury levels simply indicate good absorption and the ability of the kidney to excrete the mercury. We believe, however, that after a time some kidneys may become "allergic" to mercury and so give rise to the nephrotic syndrome. In such event the ability to excrete mercury is greatly reduced, and this would explain why in some fatal cases of pink disease the urine mercury was found to be relatively low.—I am, etc.,

Sunderland.

B. GORDON.

No Rest for the Feverish

SIR,—Your leading article "No Rest for the Feverish" (*Journal*, December 29, 1956, p. 1531) is certainly very welcome to all those doctors who have been wondering on this part of the management of their patients. No doubt fashion and custom have played a great part in determining the length and quality of bed-rest for the sick and the feverish in general, but in this case, as in many similar matters of habit, the question arises of why this habit has been established or this custom become fashionable.

One aspect which is very often forgotten is that habits and customs depend on the state of consciousness of the individual making up the society in which he lives, just as much as it is the other way round. In especial with regard to bed-rest it is very frequently forgotten, and it appears also to have been forgotten by you, Sir, that bed-rest has a psychological effect and a psychological symbolic significance. It is the expression of withdrawal from the world and regression in general. Some people react to stress by inactivity and others by withdrawal, and when a doctor has to advise as to the management of a patient he ought to know his patient well enough also from the psychological angle to be able to advise on the just course to take with regard to rest in bed. It is also important that a patient's state and reserves in situations of stress both somatically and psychologically are accurately assessed. It may be perfectly all right to keep out of bed a person whose alarm reaction and reaction of defence are powerful enough to overcome these stressful situations, but it has to be recognized at an early moment when it is necessary to anticipate a state of exhaustion, again both somatically and psychologically, and in its prevention bed-rest is invaluable and irreplaceable.—I am, etc.,

Derby.

D. J. SALFIELD.

SIR,—Oh, Abilene! I hope your leading article (*Journal*, December 29, 1956, p. 1531) will not start another new fashion. Even if your writer sleeps well in his day clothes, and feels just as refreshed by a night on the hearth-rug as by one in bed, I pray the enthusiast, young or old, to remember the many who rest better in the more usual way. We do need rest when we are ill. Feeling the need for it is the common factor of "feeling unwell." The amount varies with the cause and the patient; the best way to obtain it changes with age and circumstances; but all need it. As all experienced G.P.s know, recovery occurs not on the day of discharge from hospital nor even of return to work, but on the day when the patient feels really well again. And ambulatory treatment does not always expedite it. So, please, not a new fashion.—I am, etc.,

Cromer.

A. HENRY GREGSON.

Alternative Approach to Prostate

SIR,—My attention has been drawn to Mr. G. T. Watts's article (*Journal*, December 1, 1956, p. 1283) on prostatotomy, in which he refers to "the Wells operation" before proceeding to describe his own vesico-capsular approach. If Mr. Watts will agree that his operation is not fundamentally different from that of Mr. Ogier Ward, I will concede that mine bears a not altogether fortuitous resemblance to that of the late Mr. Wilson Hey.—I am, etc.,

Liverpool, 7.

CHARLES WELLS.

Obituary

W. G. CLARK, C.B.E., M.B., F.R.C.P.Ed., D.P.H.

Dr. W. G. Clark, formerly medical officer of health of Edinburgh, died suddenly at his home in that city on January 4. He was 68 years of age.

A native of Glasgow, William George Clark was educated at Hill Head High School and Glasgow University, graduating M.B., Ch.B. in 1918. Not long after he had completed a number of house jobs at the Glasgow Royal Infirmary, he joined the Royal Navy to serve as a surgeon lieutenant in the first world war. Returning to civilian life, he decided to adopt a career in public health and took the D.P.H. at Cambridge in 1920. Before joining the public health department of the Corporation of Glasgow as an assistant medical officer of health he had held posts at the Brook Hospital, London, and at the Woolwich tuberculosis dispensary. In Glasgow he rose to the position of deputy medical officer of health before moving to Edinburgh in 1935 as deputy to Dr. John Guy. Three years later he became medical officer of health for Edinburgh, retiring in 1953. He was elected a member of the Royal College of Physicians of Edinburgh in 1938 and a Fellow in 1942.

Clark was a man whom everyone liked and who expressed sound and determined opinions on public health policy. An expert on housing, he did much to make more generally known the evils of overcrowding and unhealthy living. He was, in fact, a well-known advocate of health education by lectures, film shows, and demonstrations of all kinds. During the war he was tireless in organizing the civil defence services in Edinburgh. An outbreak of smallpox in the city in 1942 added greatly to his responsibilities, and about a quarter of a million people were vaccinated.

At the university Clark was a lecturer in public health. In 1941 he became Honorary Physician to King George VI, and he was appointed C.B.E. in 1953, the year after he had served as president of the Society of Medical Officers of Health, of the Scottish branch of which he had been secretary for some years. He was a member of the Scottish Health Services Council and had served on the Staff Side of Committee C of the Medical Whitley Council since 1951. In 1954 he presided at one of the plenary sessions at the Annual Meeting in Glasgow of the B.M.A. In 1921 Dr. Clark married Gladys Catherine Harrison, and she survives him with one son.

Sir ALEXANDER MACGREGOR writes: I shall be glad if you will allow me to contribute a personal appreciation of the late Dr. George Clark, as our professional lives were closely intermingled since the close of the first world war. He came to the public health department in Glasgow when the post-war developments in preventive medicine were taking place, and passed quickly from a junior to a senior deputy medical officer until his transfer in 1935 to Edinburgh as deputy and successor to Dr. John Guy—a notable career in public health, justified by his great abilities.

Dr. Clark left his imprint on Glasgow's health services. He made a name for himself in the housing and slum-clearance activities which began in earnest after the war and in which he became an expert and exponent. He organized and conducted a complete and effective venereal-disease scheme for the city. He later played a prominent part in the big developments which followed the Local Government (Scotland) Act of 1929, when the general and mental hos-

pitals of the former parish councils, as also the education health services, passed to the control of the health department. The subsequent growth of these services owed much to his skill as an organizer and to his capacity to guide and, if necessary, to compromise. Dr. Clark's easy mastery of the problems at issue and his faculty for expounding them made him a popular and respected figure among the members of the housing and health committees of the Glasgow Corporation. He had a way of making difficulties vanish, and could be depended upon to solve them by common sense, resourcefulness, and the influence of an attractive personality. His warmth of nature and his interest in people led him quite early to take a deep interest in health education; he became well known as a popular lecturer on health subjects. His activities in this direction will long be remembered, especially in Edinburgh. He made friends easily, who will be deeply affected by his sudden death in the early period of his retirement. For myself, I mourn the tragic severance of a warm friendship of close on forty years.

Dr. R. J. PETERS writes: George Clark had by training and experience as well as by ability and instinct all the equipment required for a successful health officer and administrator. In Glasgow his interests were wide and varied, as they had to be in a unit of that size, but he concerned himself especially with housing—a problem which in that city gave full scope for his talents. He became an acknowledged authority on all the complications and ramifications of that difficult subject and served on Government advisory committees.

Shortly after taking over the post of medical officer of health for Edinburgh he had before him all the problems of civil defence and the running of his department, including the hospitals, under wartime conditions. He had by then inspired major changes in the corporation's hospitals, and worked continuously towards their upgrading, co-operating happily in this with the university medical school and the consultants. He was—as indeed were many of his colleagues in public health—not favourably disposed to relinquishing the important hospital work he was doing when the National Health Service came into being, for he had many doubts about the proposed new regime and did not hesitate to express them. Nevertheless, in the end he sought how to make the new service a success, for always his main interest was the individual concerned most of all—namely, the patient. A guiding thought, always uppermost in his mind, was: What is best for the people?

After the inception of the National Health Service he turned his attention to the new functions and the further development of the old ones that were left with health departments. Health education of the public claimed a great deal of his attention, and Edinburgh displayed much activity in this field. He also geared his department to pursue special investigations and research into medico-social and public-health subjects. He served on the Scottish Health Services Council and some of its standing advisory committees, taking part in the production of many of the reports issued by these bodies. Throughout his career he had the interests of nurses at heart, and as a member of long standing of the Scottish General Nursing Council his sympathetic understanding of nursing problems was warmly appreciated especially by his nursing fellow members.

Clark was a big man physically; in his youth and middle age his favourite pastime was golf, at which he was no mean performer—a scratch man and a Glasgow University "blue." He was one of a band of enthusiasts who carved out two superb 18-hole courses in unpromising moorland and hill country north of Glasgow, and he was the first captain of that club. He had a delightful genial personality, friendly and forthright. With councillors, his medical colleagues, and other staff alike he was exceptionally popular, and had many marked characteristics of speech and manner that his associates will long remember with affection. He leaves a widow and one son, who is in the Oversea Civil Service in Nigeria. To them our sincere sympathy is extended.

W. G. BARNARD, C.B.E., F.R.C.P.

The obituary of Professor W. G. Barnard was published in last week's *Journal* (p. 50). We are indebted to Dr. R. W. JOHN for the following appreciation:

Barnard's arrival at St. Thomas's in 1939 to take up his appointment to the chair of pathology coincided with the outbreak of war. Thus it was that he was confronted immediately with the tasks of arranging for the teaching of his subject to students who were widely dispersed and to the setting up of a laboratory to deal with the histological work of Sector 8 of the Emergency Pathological Service which he undertook to do in his department. His successful accomplishment of these tasks amidst the confused conditions of those days soon revealed to his colleagues his gift for organization. In 1940, when most of the work of the hospital was transferred to Hydestile, in Surrey, and shortly afterwards it was decided to set up the medical school in the vicinity, Barnard played a major part in finding the necessary accommodation in near-by Godalming. His department, housed at first in company with the physiologists in the somewhat cramped quarters afforded by the stables of the Manor House at Godalming, clearly required more space, and when a neighbouring house called Bernina became for sale he saw in it what was needed. Bernina was bought by the school, and quickly and cleverly he designed into it laboratories for teaching and technical work and private rooms for himself and his staff. Under his vigorous direction the necessary alterations were completed in a very short time, and in all this business his ability to see clearly and swiftly the proper course became evident to all who worked with him.

Meanwhile his beautiful dissections in the post-mortem room and his stimulating teaching delighted students and clinical staff alike. The keenness of his eye and his almost uncanny visual memory made him an outstanding morbid anatomist and one, moreover, whose great store of knowledge was accumulated largely from his own experience. He was never content, however, with a merely static anatomical account of a pathological condition, but always sought to understand how the morphological changes he observed had been brought about. This attitude led him to look for the basic processes underlying pathological changes and to appreciate the great importance of a knowledge of such processes. To pursue this knowledge and encourage others to do likewise were the aims of his work and teaching.

As time went by his organizing ability and grasp of affairs were used more and more in the management of the school, so that when in 1947 Professor B. A. McSwiney died Barnard was his obvious successor as dean. Doubtless others will write of the great work he did as dean not only for the medical school but also for the hospital during the years following the war. Last October he became dean of the faculty of medicine of the University of London, and would surely have contributed much in this wider field had he been spared.

Barnard had many interests outside his work. With his technical excellence as a dissector went an appreciation of all things nicely made, and such things he gathered about him. He loved and collected furniture and books, and shared with his son a great pleasure in their collection of vintage motor-cars. He was very interested in gardening, and it is sad that he was denied the pleasures of carrying out the plans he had made with his wife for work during the years of his retirement in the extensive garden of the period house he had recently bought at Chiddingfold, in Surrey.

The intimacy of the life at the hospital and in the medical school during the war years enabled many to break through the reserve which his natural shyness produced and thus to come to know him for the very friendly and kindly man he was. His kindness and generosity were unbounded, as those who were examined by him and others who went to him with more serious troubles will remember with gratitude. He never lost patience with those whose ideas and

feelings differed from his own. Though his cheerful and optimistic nature made it impossible for him to comprehend the difficulties of those of a less happy turn of mind, he accepted the fact of such difficulties and did everything in his power to help. Only those concerned know the extent of his kindness and sympathy, for much of the good he did was covertly done. Except with those he knew well he was reserved and sometimes a little brusque, so that some felt his manner to be rather remote. This reserve was not only the result of his shyness but also was partly a cover for his irrepressible sense of fun, which was sometimes apt to bubble up even when serious matters were on hand. When this happened among people who did not know him sufficiently well their surprise was only matched by his own consternation. He was a lovable man and so vital a person that it is scarcely possible to realize that the "Prof" has gone from amongst us for ever. Our deepest sympathy is with his widow and son.

The Royal College of Physicians has arranged a memorial service to Professor Barnard on the afternoon of the Comitia on Thursday, January 31. The service will be at St. Martin-in-the-Fields at 3 p.m.

G. T. HEBERT, M.D., F.R.C.P.

Dr. G. T. Hebert, formerly physician in charge of the tuberculosis department at St. Thomas's Hospital, died at the hospital on January 4. He was 68 years of age.

Godfrey Taunton Hebert was born on January 27, 1888, the son of the Rev. S. Hebert, vicar of Seal, near Sevenoaks. From Harrow he went on to Christ Church, Oxford, where he obtained first-class honours in natural science (physiology). Continuing his medical education at St. Thomas's Hospital, he graduated B.M., B.Ch. in 1913. After holding the posts of casualty officer and house-physician at St. Thomas's, he decided to specialize in tuberculosis, becoming resident medical officer at Victoria Park Hospital. Thereafter he worked for a time as a tuberculosis officer in Hackney and Bethnal Green. Proceeding to the D.M. in 1918, he took the M.R.C.P. in 1921.

Appointed physician in charge of the tuberculosis department at St. Thomas's in 1920, Hebert made it his life work to serve the patients who attended this busy clinic from a large area of south London. Though reserved in manner, he was exceedingly conscientious and kind, and even the illest patients in his wards took courage from his calm efficiency and helpfulness. If a student wanted to learn how to examine a chest or to induce a pneumothorax Hebert was the man to go to, but he had no great interest in teaching those who were not keen to learn. He wrote a short book entitled *Pulmonary Tuberculosis* in 1927, and contributed a number of articles on tuberculosis to this and other journals. One of his last papers, on rational pneumothorax treatment, was published in the *Journal* in 1936. Elected F.R.C.P. in 1932, he was president of the Tuberculosis Association in 1940. He retired from St. Thomas's in 1948.

Dr. Hebert married Constance Tatton, and she survives him with two daughters.

T. A. B. HARRIS, M.D., F.F.A. R.C.S.

By the sudden death of Dr. T. A. B. Harris at the age of 59 Guy's Hospital has suffered the sad loss of its senior anaesthetist and director of the department of anaesthetics.

The son of a medical man who was a well-known political figure in Australia, Thomas Alexander Britten Harris graduated M.B., B.S. at Melbourne University in 1922. For several years he helped his father in

general practice in a small community: this invaluable experience helped him to become a good doctor. He started his career in Britain as an anaesthetist at the West London Hospital, and in 1935 became an anaesthetist at Guy's. He took the D.A. in 1936 and was elected F.F.A. R.C.S. in 1948. He proceeded to the M.D. of Melbourne in 1953. During the second world war Harris served for the most part in India, becoming adviser in anaesthetics to Eastern Command and attaining the rank of lieutenant-colonel. At the time of his death he was also anaesthetist at St. Peter's and St. Paul's Hospitals.

W. S. McC. writes: On a momentous day in February, 1935, Harris and the writer were among those who faced a selection committee for two appointments to the staff of Guy's Hospital. The comparatively unknown Australian was appointed in open competition with other Guy's men. It was a fortunate day for the hospital, for it secured the lifetime devotion of a loyal and dynamic worker. He so identified himself with the hospital that he resented even mild criticism of Guy's and its traditions by an outsider. His enthusiasm and search for knowledge soon made him well known to practically every member of the staff and school: when not teaching anaesthetics, he himself was picking the brains of the departments of physiology, pharmacology, or biochemistry.

Tommy, as he was known to all, felt it his calling to teach anaesthetics to students in such a way that not only should they understand the mode of action of the drugs they used but become good, practical doctors able to give a simple anaesthetic with confidence and safety. As an anaesthetist he was superb. Although not an imposing figure—he was short and had not completely conquered a slight stutter—he conveyed to me and to his other patients a remarkable degree of confidence and assurance. For the surgeons he provided operating conditions and an atmosphere of tranquillity which set a standard for his colleagues. Surgeons at Guy's and St. Peter's demanded his services for their private patients. It was while he was happily making final arrangements to meet a request for an anaesthetic in Bombay that he was taken from us.

At the time of his death he was also occupied with academic work. A second edition of his fundamental textbook, *Mode of Action of Anaesthetics*, original work on barbiturate antagonists, and an extensive survey on the relationship between the use of muscle relaxants and anaesthetic mortality absorbed all his spare time. He worked too hard for too much of the time. After a coronary thrombosis had compelled him to rest for two months, all the senior members of the staff pleaded with him to plan his life to a less strenuous programme, but to no avail. He literally worked himself to death for the sake of his patients, hospital, and medical school. In the years to come Tommy will be remembered as an individual who had a remarkable capacity for making friends. He was proud of his friends and valued their affection, but he had the courage to offer criticism and advice if he thought it would help them. Although he was forthright in his comments, his loyalty was constant.

He leaves a widow and four sons, to whom we offer all our sympathy. At a memorial service in Guy's Chapel on January 4 the congregation included not only his friends at Guy's but representatives from many London hospitals, the Association of Anaesthetists, and the Faculty of Anaesthetists of the Royal College of Surgeons.

H. K. A. writes: May I add a note on Dr. T. A. B. Harris's wartime service in the R.A.M.C., which lasted from the outbreak until he came home from India with the rank of lieutenant-colonel in September, 1945? Tommy served at Tidworth until 1942, when he went out to India and arrived in Calcutta with No. 57 British General Hospital. At that time in India the standards of anaesthetic arrangements as regards trained personnel, equipment, and technique were, to put it mildly, somewhat below those obtain-

ing at home. It was soon obvious that intensive training courses would be the only answer to the shortage of personnel, and such courses were quickly established in each of the four Commands in India, with men on the pre-war staff of teaching hospitals in England to run them. Tommy ran the Eastern Army course in Calcutta with the characteristics with which he was so richly endowed—namely, energy, conscientiousness, and scrupulous fairness to the candidates. Whenever Tommy decided that a candidate would not make the grade—and it was on his recommendation alone that an officer was or was not posted for anaesthetic duties after attending his course—he nearly always wrote me a personal letter wondering whether or not he was right. But after a month of intensive tuition from Tommy there were few who did not make the grade and fewer still who subsequently did not prove in practice the soundness of his teaching.

In the monthly intervals between courses Tommy constantly toured the forward areas on the Assam and Arakan fronts, staying with the mobile surgical units and casualty-clearing stations, watching them at work, and, after his return to Calcutta, sending clear, concise, and practical reports on what could and should be done to improve the anaesthetic service and equipment of these units.

In 1944 his sterling work was recognized by his appointment as adviser in anaesthetics to Eastern Command, and he was promoted to lieutenant-colonel.

Tommy's energy was boundless. He wrote such an excellent statement of the case for a monetary grant for technical help in his research on the mode of action of anaesthetic drugs that he miraculously extracted it from G.H.Q., India, in spite of that august body's preoccupation with the war. Much of his book was planned and written in his small, comfortable, and always hospitable flat in Calcutta, where Tommy was never happier than when entertaining his friends and colleagues. It is perhaps this aspect of Tommy Harris that those of us who were privileged to be his closest friends in India will treasure most of our many happy memories of him. In spite of his serious demeanour and his quiet and deliberate speech in the pleasant Australian accent which he never lost, Tommy was always gay and full of fun and often literally "the life and soul of the party." It is with gratitude for the happiness which he exuded that we now mourn the loss of our friend who served his country and his fellow men so enthusiastically and so faithfully, both in war and peace.

HUBERT WYERS, M.A., M.D., D.I.H.

Dr. Hubert Wyers, editor of the *Transactions of the Association of Industrial Medical Officers*, died on December 11, 1956, at the age of 56.

A native of Birmingham, where he was born on January 21, 1900, Hubert Wyers received his early education there at King Edward's School. Later, his family moved to Glasgow, where for a time he worked in a foundry before entering the university. His bent towards the classical, and his great interest in mediaeval literature, evidenced afterwards in his editorials, probably led to his first entering the faculty of arts. He took the M.A. in 1927, and two years later graduated M.B., Ch.B. Then, after some house posts, he became a successful general practitioner at Rainham, in Essex, before taking up industrial medicine. Among the posts he held were those of medical officer to the Cape Asbestos Company, to May and Baker Ltd., and to Murex Ltd. At the Cape Asbestos Company he made a very complete study of the effects of asbestos dust, and made this the subject of his thesis for the M.D., which he obtained, with commendation, in 1947. As a result of this work he became an acknowledged authority on asbestosis. In 1948 Wyers took the

Diploma in Industrial Health of the English Royal Colleges, and became in his turn an examiner for the diploma. He made some valuable contributions on the subject of industrial toxicology and was a familiar figure at conferences on industrial health. He was chairman of the London group of the Association of Industrial Medical Officers, and from 1952 was the honorary editor of the *Transactions*. Apart from these industrial interests, he acted as a clinical assistant in the skin department of the Oldchurch Hospital. He was chairman of the South Essex Division of the B.M.A. in 1955-6 and was a valuable member of a number of committees concerned with occupational health. He was a man of gentle and understanding manner, always helpful, and a good friend. He will be greatly missed by all who knew him, and particularly by the members of the Association of Industrial Medical Officers.—C. L. S.

G. F. K. writes: Hubert Wyers was a very remarkable person and was outstanding among his contemporaries in many respects. He was a classical scholar of the first order, and in addition to an intimate knowledge of Latin and Greek he was also well versed in metaphysics and ethics. His erudition was immense, and he was well acquainted with the writings on philosophy of almost every authority, ancient or modern, and he could always be relied upon for an apt quotation. It was not surprising, therefore, that he wrote admirable prose. His wide learning in classics, coupled with a deep knowledge of general medicine, made him the ideal editor of a medical journal, and during the last six years he was responsible for the production of the *Transactions of the Association of Industrial Medical Officers* in their present form. The success which this journal achieved and the respect in which it is now held are a lasting tribute to his memory. Wyers loved literature, and on more than one occasion he said that he held his post as editor of the *Transactions* in higher esteem than any other honour which the Association of Industrial Medical Officers could confer on him. He was a founder member of the small Thackrah Club, which meets twice a year to study an occupation and the philosophy of occupational medicine, and his fellow members who had the privilege of knowing him well will not soon forget his wit as well as his wisdom, and above all they will mourn the loss of a true friend. Hubert Wyers had had more than his share of anxiety and troubles one way or another, but he never gave more than a hint of his difficulties; there is no doubt that he was greatly sustained by his deep religious feeling, which led him through Anglo-Catholicism to be received quite recently into the Roman Catholic Church.

Dr. A. C. S. WATERS died suddenly at his home at Goring-by-Sea, Sussex, where he had been living in retirement since 1944, on December 11, 1956, five days before his 81st birthday. Alfred Charles Stanley Waters, who was born on December 16, 1875, was a well-known and well-liked figure in the town of March, Cambridgeshire, where he succeeded to the medical practice of his father, Dr. A. J. G. Waters, soon after the turn of the century and where he remained in practice himself for over forty years. He received his early education at March Grammar School and from there entered Cambridge University. After receiving his clinical training at St. Bartholomew's Hospital he qualified M.R.C.S., L.R.C.P. in 1901. Dr. Waters was held in high esteem by his medical colleagues, having been, at the time of his retirement, honorary secretary of the Isle of Ely Division of the British Medical Association for thirty-two years and of the Isle of Ely Panel Committee for a similar period; he was also president of the Cambridge and Huntingdon Branch of the B.M.A. in 1931-2, and long periods of office in other organizations, notably in the field of music, testified to his great popularity. He was himself an accomplished vocalist,

and his bass solos delighted audiences both local and some not so local over a period of many years. In his younger day he was a keen athlete, and won many prizes for skating and cycle racing. Dr. Waters was always impeccably dressed, and his almost old-world courtesy and charm of manner endeared him to all who knew him. The world of medicine is the poorer for his passing. He married rather late in life, in 1934, but was nevertheless able to enjoy nearly twenty-two years of happy married life before his wife predeceased him last March. There was no family.—C. T.

We much regret that there were some inaccuracies in the obituary notice (*Journal*, November 17, 1956, p. 1181) of the late Dr. C. E. BEVAN, who was murdered by terrorists in Cyprus on November 8. Dr. Bevan came from a Church of England family, and went to Ethiopia with the British Red Cross and not with the Friends' Ambulance Unit. He had not suffered from tuberculosis, as stated. At the time of his death he was medical officer to the Cyprus Asbestos Company, having resigned from the post of consulting thoracic surgeon to the Cyprus Government. These inaccuracies arose because of our having to rely upon accounts published in the national press.

Medico-Legal

SURGEON THREATENED WITH GUN

A 30-year-old Clapham labourer, alleged to have threatened with a loaded revolver a plastic surgeon who had operated on his nose, was sentenced to 10 years' imprisonment at East Sussex Quarter Sessions on January 4. The man, Alfred Allan Smith, of London, S.W., pleaded guilty to stealing a revolver and ammunition at Westminster in August or September, 1956. He pleaded not guilty to having the revolver and ammunition with intent to endanger life on October 1; to assaulting the surgeon, Mr. F. T. Moore, of East Grinstead, with intent to murder him or cause grievous bodily harm; and to carrying a revolver at the time of the alleged assault.

The prosecution alleged that because he was dissatisfied Smith paid a midnight visit to the surgeon. Mr. Moore said in evidence that on September 30 the doorbell rang. "When I opened the door the defendant was standing there with a revolver in his hand. His finger was on the trigger and he said, 'I told you I would be back.' He was pretty agitated and I thought the gun might go off. I asked him in to have a drink because I thought I would get one of his hands with something in it. He came in and I poured him a drink and poured myself one too. I asked him to have a cigarette, but he offered me one of his. He said he would give me time to smoke a last cigarette before he shot me. He said all the bullets were for me and it would probably take 20 seconds to kill me. He had several drinks, which he swallowed neat in one gulp. I was sitting while he walked up and down. All this went on for some time—30 or 40 minutes. I told him I would feel a lot happier if he would unload the gun. He bent over me and broke the gun, and I grabbed it from him."

Smith had been dissatisfied with the results of another surgeon's operation on his nose and had gone to Mr. Moore. He said that Mr. Moore operated, and that afterwards the scars went, but that was the only improvement. Mr. Moore had not promised that he could effect any improvement. He was later examined by three different surgeons and Mr. Moore told him they shared his opinion that it would be unwise to do anything more. He said he called on Mr. Moore to make him realize that he had nothing to lose by performing another nose operation. The gun was in his pocket and he pulled it out and said, "If you can't help me I shall use this on myself." Smith denied he had stuck the gun in Mr. Moore's stomach or that he had pointed it at him with his finger on the trigger.

The jury found Smith guilty on all counts.

Vital Statistics

Industrial Accidents and Diseases

The number of workpeople (other than seamen) in the United Kingdom whose deaths from accidents in the course of their employment were reported in November was 120, compared with 98 in the previous month and 115 in November, 1955.

The numbers of cases of industrial diseases in the United Kingdom reported during November, 1956, were as follows: Lead poisoning 4, aniline poisoning 1, compressed air illness 1, epitheliomatous ulceration 18, chrome ulceration 7; total 31. There was one death from epitheliomatous ulceration due to mineral oil.—*Ministry of Labour Gazette*, December, 1956.

London's Health in 1956

The estimated number of births in London in 1956 was 52,000, giving a birth rate of 15.8 per 1,000 population, the highest since 1950. Deaths numbered 38,700, giving a death rate of 11.7 per 1,000 population. This was 0.2 above the 1955 rate and 1.0 above the 1954 rate. The infant mortality rate was 23 per 1,000 live births, the same as in 1955. 22 deaths were attributed to maternal mortality.

Notifications of new cases of tuberculosis again fell—from 4,122 in 1955 to just under 4,000. The death rate also declined—from 0.17 per 1,000 population in 1955 to 0.14 in 1956. The incidence of most of the other infectious diseases was light to average. 4 deaths from whooping-cough were recorded, 3 from scarlet fever, 2 from diphtheria, 1 from enteric fever, and 26 from infantile diarrhoea in children aged under 2.

Week Ending December 29

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 524, whooping-cough, 1,265, diphtheria 3, measles 6,878, acute pneumonia 400, acute poliomyelitis 49, dysentery 348, paratyphoid 2, and typhoid fever 2.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1947-55 are shown thus ———, the figures for 1956 thus ———. Except for the curves showing notifications in 1956, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending December 22 (No. 51) and corresponding week 1955.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenzal pneumonia.
‡ Includes puerperal pyrexia.

Infectious Diseases

The largest fluctuations in the notifications of infectious diseases in England and Wales during the week ending December 22, 1956, were decreases of 247 for whooping-cough, from 1,979 to 1,732, 142 for food-poisoning, from 319 to 177, 112 for dysentery, from 808 to 696, 85 for acute pneumonia, from 550 to 465, and 31 for scarlet fever, from 766 to 735; the only large rise was 82 for measles, from 6,493 to 6,575.

The largest rises in the incidence of measles were 146 in Yorkshire East Riding, from 202 to 348, 75 in Yorkshire West Riding, from 428 to 503, and 55 in Sussex, from 82 to 137; the largest falls were 86 in Staffordshire, from 309 to 223, 75 in Westmorland, from 178 to 103, 67 in Yorkshire North Riding, from 209 to 142. The largest fluctuations in the trends of whooping-cough were a fall of 50 in Lancashire, from 245 to 195, and a rise of 32 in Essex, from 127 to 159. The largest variation in the returns of scarlet fever was a decrease of 25 in Yorkshire West Riding, from 72 to 47. 10 cases of diphtheria were notified; these were 4 more than in the preceding week; 2 cases were notified in Liverpool C.B. and Manchester C.B.

60 cases of acute poliomyelitis were notified, and these were 7 fewer for paralytic and 6 fewer for non-paralytic

cases than in the preceding week. The largest returns were London 7, Lancashire 7 (Liverpool C.B. 2), Surrey 4 (Woking U.D. 2), Sussex 4, and Glamorganshire 4 (Cardiff C.B. 2).

The largest centres of dysentery were Yorkshire West Riding 110 (Bradford C.B. 18, Sheffield C.B. 14, Leeds C.B. 13, Thorne R.D. 13), Warwickshire 106 (Coventry C.B. 84, Birmingham C.B. 11, Meriden R.D. 10), Lancashire 79 (Salford C.B. 15, Liverpool C.B. 13, Lancaster M.B. 10), Essex 62 (Thurrock U.D. 30, Chigwell U.D. 14), London 51 (Hackney 9), Bedfordshire 38 (Luton M.B. 38), Surrey 36 (Esher U.D. 11), Kent 34 (Orpington U.D. 17), Durham 30 (South Shields C.B. 14), and Yorkshire East Riding 26 (Haltemprice U.D. 9, Kingston-upon-Hull C.B. 9).

Medical News

Travelling Fellowships.—The Medical Research Council invites applications for the following travelling fellowships for the academic year 1957-8: Rockefeller travelling fellowships in medicine; Dorothy Temple Cross research fellowships in tuberculosis; and Alexander Pigott Wernher memorial travelling fellowships in ophthalmology and otology. Full particulars and application forms may be obtained from the Secretary of the Medical Research Council, 38, Old Queen Street, London, S.W.1. The closing date for applications for Rockefeller and Dorothy Temple Cross fellowships is March 15, and for the Alexander Pigott Wernher memorial fellowships March 31. All these fellowships provide for a maintenance allowance, and also for an allowance for travelling and other approved expenses. The usual maintenance allowance for a single fellow is £650 or \$2,700 a year, depending on whether the fellowship is held in a sterling area or the United States; for a married fellow £900 or \$3,900 a year. In general, these fellowships are intended to broaden the experience of those aiming at higher teaching or research appointments.

Pathological Specimens by Post.—Twice in the last 15 months—the last time this Christmas—tubes containing cultures of *Salmonella typhi* have broken in the post as a result of inadequate packing. The consequent contamination of Post Office workers and of other mail, not to mention the wastage of the specimens themselves, caused considerable nuisance as well as some danger to health. Other recent breakages due to faulty packing have included several bottles of urine being posted by patients to their doctors, and a specimen of blood being sent to a V.D. laboratory. The Post Office asks for the co-operation of doctors in ensuring that pathological specimens they themselves send through the post, and also those sent to them by their patients, should be properly packed. Appropriate containers were illustrated in one of the articles in our Refresher Course series on clinical pathology (*Journal*, 1953, 2, 876), which also forms a chapter in the book *Clinical Pathology in General Practice* (obtainable from the Publishing Manager, B.M.A. House; price 22s. 3d. inland, 21s. 9d. overseas). The regulations concerning the packing of pathological specimens are printed in the *Post Office Guide*, which may be consulted at any post office.

Tavistock Institute of Human Relations.—Grants totalling £12,525 were made by American foundations last year to aid training and research at the Tavistock Institute of Human Relations, London, for periods up to seven years. The Old Dominion Foundation has given £89,286 for the general support of the mental health training programme which the Institute has developed in association with the Tavistock Clinic; and the Grant Foundation £24,964 for the training of personnel for work with children and parents. The Grant Foundation has also provided £4,955 for a pilot study of selected London families. The two major research grants, however—£80,357 from the Ford Foundation and

£12,964 from the Josiah Macy Jr. Foundation—go to support the work of the Institute's child development research unit, directed by Dr. JOHN BOWLBY. Here studies are being made of the earliest human "behaviour patterns," such as smiling in infants.

Volunteers Wanted.—The Common Cold Research Unit at Harvard Hospital, Salisbury, now entering into its eleventh year of research, urgently needs more volunteers. People who are willing to take a fifty-fifty chance of a running nose and sore throat in return for a free 10-day "holiday" are particularly wanted for the next two sessions, starting on January 15 and 29. From now until the end of March some 100 volunteers are wanted, and there will be vacancies during the rest of the year for some 400 to 500. Comfortable living quarters are provided for volunteers. Fares to and from Salisbury are paid up to a maximum of £3, and 3s. a day pocket money is allowed. Volunteers should be between 18 and 45 years of age and in normal health. A postcard to the medical superintendent at Harvard Hospital will bring full details. The unit is a joint enterprise of the Medical Research Council and the Ministry of Health.

Odontological Centenary.—The centenary of the founding of the Odontological Society of London was celebrated by a dinner on January 4 at the Royal College of Surgeons, under the chairmanship of Mr. J. A. S. WRIGHT, president of the Section of Odontology of the Royal Society of Medicine. In October, 1856, the "Memorialists," a small group of pioneer practitioners in dental surgery, led by John Tomes, having failed to win the support of the Royal College of Surgeons for their repeated demands, met in Old Burlington Street and founded the Odontological Society of London. On January 5, 1857, was held the first formal meeting of the society, which, some fifty years later, as the Section of Odontology, became one of the founder sections of the Royal Society of Medicine. At the centenary dinner Miss PAT HORNSBY-SMITH, Parliamentary Secretary to the Ministry of Health, was principal guest. Sir ZACHARY COPE, proposing the health of the Section, referred to the close association of the founders of the Odontological Society with the Royal College of Surgeons, and to their persistent, far-sighted, and eventually successful efforts to establish dental education on a firm and independent basis and dental surgery as a specialization in its own right. But their recommendation that a fellowship of the College should be granted for work in this field was not implemented until after more than a century had passed. The centenary was marked by a historical display in the College, which included the first Minute and Obligation Books of the Odontological Society and a collection of founders' portraits.

Nuffield Dental Fellowships.—One of the objects of the Nuffield Foundation's dental fellowships is to make it possible for selected graduates in medicine (or science) to train for teaching and research on dental health and disease. So far comparatively few applications from such candidates have been forthcoming. Further details of these fellowships, whose annual value is between £500 and £800, will be found at page 59 of our advertisement columns.

"Tubercle."—This medical journal, which began its life in 1919 as a monthly journal, has since the beginning of last year been appearing two-monthly, but enlarged and in an improved format. In addition to tuberculosis, it deals with the laboratory, clinical, and epidemiological aspects of with the respiratory disease in general, and with such related infectious diseases as leprosy. Dr. J. R. BIGNALL, of the Institute of Diseases of the Chest, was appointed editor in April last, succeeding in this chair J. R. EARP (1919), S. ROODHOUSE (1920-37), N. LLOYD RUSBY (1938-44), and Stephen GLOYN (1944-56). *Tubercle*, which became the journal of the British Tuberculosis Association in 1948, is published by Staples Press Ltd. at an annual subscription of 45s.

Board for Correlation of Medical Science and Physical Education.—The final William Hyde Award of £300 has been made to Squadron Leader C. B. WYNN PARRY in recognition of his outstanding contribution in the field of physical medi-

cine in the R.A.F. The Research Board for the Correlation of Medical Science and Physical Education, which makes this award, is now being wound up, as it has completed its research investigations. Its remaining funds are being transferred to the Physical Education Association of Great Britain and Northern Ireland.

British Association of Plastic Surgeons.—At a meeting on December 14, with Mr. WILFRED HYNES in the chair, the following officers were elected: President-elect and treasurer, Mr. R. P. OSBORNE; honorary secretary, Mr. C. R. McLAUGHLIN.

Durham University.—Dr. J. A. SAUNDERS, senior lecturer in biochemistry, has been appointed to a personal readership in chemical physiology.

Aberdeen University.—Mr. J. G. MURRAY, F.R.C.S.Ed., assistant lecturer in the department of anatomy at University College, London, has been appointed lecturer in surgery. He graduated at Aberdeen in 1942.

Dr. C. L. Greening, formerly director of the Kitwe Laboratories of the Tuberculosis Research Association and of the Hull Public Health Laboratory, has been appointed production officer at the Wellcome Research Laboratories, Beckenham.

Dr. Harry Pigott, of Manchester, has been appointed a member of the National Assistance Board. His appointment is until the end of 1958.

Dr. K. G. Bergin has been appointed chief medical officer of British Overseas Airways Corporation. He was previously B.O.A.C.'s medical superintendent of air services.

COMING EVENTS

Ernest Jones Lecture.—Dr. MARGARET MEAD, the American anthropologist, will deliver the British Psycho-Analytical Society's next Ernest Jones lecture at the Royal Society of Medicine on January 30 at 8.30 p.m. Her subject will be "Changing Patterns of Parent-Child Relations in an Urban World." Admission is free.

Milroy Lectures.—Dr. D. D. REID will deliver the Milroy lectures on February 5 and 7 at 5 p.m. at the Royal College of Physicians, Pall Mall East, London, S.W.1. His subject will be "Environmental Factors in Respiratory Disease."

Institute of Dermatology.—Semi-permanent exhibitions on "The Neurohistology of the Integument and Changes in Leprosy," February 5-25.

Hunterian Festival Dinner.—Will be held at the Royal College of Surgeons on February 14. Limited number of tickets (£2 10s.) available to fellows and members of the College. Details from Mr. W. F. DAVIS, Royal College of Surgeons, Lincoln's Inn Fields, London, W.C.2.

Radio.—Two fifteen-minute programmes on "The Alcoholic." Home Service, January 16 at 10.25 p.m., and January 17 at 10.45 p.m.

NEW ISSUES

Thorax.—The new issue (Vol. 11, No. 4) is now available. The contents include:

- ADENOCARCINOMA OF THE OESOPHAGUS. D. W. SMITHERS.
- CARCINOMA OF THE OESOPHAGUS AS A COMPLICATION OF ACHALASIA OF THE CARDIA. J. L. WILLIAMS.
- RECONSTRUCTION OF THE CARDIA AND FUNDUS OF THE STOMACH. Geoffrey Wooler.
- NON-BRONCHOSPIROMETRIC MEASUREMENT OF DIFFERENTIAL LUNG FUNCTION. G. H. ARMITAGE and A. BRIAN TAYLOR.
- MASSIVE PULMONARY FIBROSIS FROM THE INHALATION OF TALC. A. C. HUNL.
- ANEURYSMS OF THE PATENT DUCTUS ARTERIOSUS. John B. DAS and Judson T. CHESTERMAN.
- RESPIRATORY FUNCTION AFTER PNEUMONECTOMY. M. B. McILROY and D. V. BATES.
- SIX CASES OF TRAUMATIC RUPTURE OF THE BRONCHUS. Michael BATES and Harvey J. BEARD.
- INVESTIGATION OF IDIOPATHIC PLEURAL EFFUSIONS BY THORACOSCOPY. S. J. FLEISCHMAN, A. I. LICHTER, G. BUCHANAN, and R. J. S. SICHEL.
- SURGERY IN THE TREATMENT OF PULMONARY TUBERCULOSIS IN PATIENTS AGED 50 AND OVER. Arnold PINES and Richard ROWLANDSON.
- INTRATHORACIC MENINGOCELE. J. C. A. RAISON.
- INDEX.

Issued quarterly: annual subscription £2 2s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

British Journal of Venereal Diseases.—The new issue (Vol. 32, No. 4) is now available. The contents include:

INTRADERMAL TESTS IN THE DIAGNOSIS OF LYMPHOGRANULOMA VENEREUM. A. J. King, C. F. Barwell, and R. D. Caterall.
VENEREOLOGY IN TRANSITION. Joseph Earle Moore.
DIAGNOSIS, PROPHYLAXIS, AND TREATMENT OF CONGENITAL SYPHILIS. B. M. Pashkov.
ORGANIZATION OF SYPHILIS CONTROL IN THE SOVIET UNION. Pyotr Vasilievich Kozhewnikov.
VENEREAL DISEASES CAMPAIGN IN CHILE: ORGANIZATION AND RESULTS. Waldemar E. Coutts, Florencio Prats Roberto Vargas-Zalazar, and Luis Infante-Varas.
TRICHOMONAS VAGINALIS IN URETHRITIS OF THE MALE. Louis G. Feo, Nicholas R. Varano, and Theodore R. Fetter.
LATE HERPATIC SYPHILIS. I. A. Kellock and S. M. Laird.
ROLE OF TREPONEMA REITER IN MODERN SEROLOGY OF SYPHILIS. H. G. S. Ruge.
FURACIN URETHRAL SUPPOSITORIES IN THE TREATMENT OF CHRONIC NON-GONOCOCCAL URETHRITIS. R. R. Wilcox.
ORAL PHENOXYMETHYL PENICILLIN IN ACUTE MALE GONORRHOEA. L. P. Sheil.
SYNTHETIC L-α-DIOLEYL LECITHIN IN ANTIGENS FOR THE SERO-DIAGNOSIS OF SYPHILIS: COMPARISON WITH OTHER LECITHINS. David B. Tonks and Ravelle H. Allen.
HOG'S GASTRIC MUCIN AS AN AID IN THE ISOLATION OF N. GONORRHOEA. A. F. MacCabe.
CARDIOLIPIN KOLMER TESTS ON PLASMA. Roger D. Coleman, Harrison M. Kurtz, and Milo D. Appleman.
BOOK REVIEW.
SYMPOSIUM ON TRICHOMONAL INFECTIONS, MAY 28-30, 1957.
ABSTRACTS.
INDEX.

Issued quarterly: annual subscription £2 2s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, January 14

INSTITUTE OF NEUROLOGY.—5.30 p.m., Sir Rudolph Peters, F.R.S.: Biochemical Aspects of Vitamin-B Group Disorders in Relation to the Central Nervous System.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Dr. A. C. Dornhorst: Pulmonary Physical Signs.

Tuesday, January 15

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Professor A. J. Lewis: Social Psychiatry.
LIFORD MEDICAL SOCIETY.—At King George Hospital, 8.45 p.m., general-practitioner clinical meeting.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. Christine Hodges: Conservative Radiotherapy.
ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., Marc Daniels Lecture by Dr. W. D. W. Brooks: Prevention of Tuberculosis.
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Institute Theatre, 5 p.m., Professor L. S. Penrose, F.R.S.: Inheritance of Foetal Deformities.
SOUTH-WEST LONDON MEDICAL SOCIETY.—At Bolingbroke Hospital, Wandsworth Common, S.W., 8.30 p.m., Dr. C. E. Newman: Changing Paediatrics.

Wednesday, January 16

EUGENICS SOCIETY.—At Royal Society, Burlington House, W., 5.30 p.m., Mrs. Barbara Simonds: Twin Research in Tuberculosis.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. A. Tickner: Minerals in Skin Metabolism.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. E. H. Hudson: Results of Prolonged Chemotherapy in Pulmonary Tuberculosis.
INSTITUTE OF UROLOGY.—4.30 p.m., Dr. S. B. Osborn: Radiotherapy in Urology.
MIDLAND MEDICAL SOCIETY.—At Selly Oak Hospital, Birmingham, 8.15 p.m., clinical meeting.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Professor G. Payling Wright: Cell Regeneration and Pathological Processes.
ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—5 p.m., Weill Lecture by Professor E. Dahl-Iversen: Diagnosis and Treatment of Hyperplasias and Adenomas of the Adrenals.
WILLESDEN GENERAL HOSPITAL MEDICAL SOCIETY.—At Department of Physical Medicine, 8.45 p.m., Professor B. W. Windeyer: Use and Hazards of Ionizing Radiation.

Thursday, January 17

BRITISH INSTITUTE OF RADIOLOGY.—8 p.m., subject: Aspects of Radiation Damage Likely to be Involved in Tumour Regression. (1) Dr. John Read (Otago): Radiation Damage to Individual Cells. (2) Professor H. B. Chase (U.S.A.): Radiation Damage to Cells Dependent on their Tissue Environment.
BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Professor E. G. T. Liddell, F.R.S.: Calal and Sherrington.
EDINBURGH CLINICAL CLUB.—At Jordanburn Hospital, 8 p.m., Professor A. Kennedy: Hypnotism in Medicine.
GLASGOW UNIVERSITY MEDICO-CHIRURGICAL SOCIETY.—7.30 p.m., Honorary Presidential Address by Professor D. Fyfe Anderson.
INSTITUTE OF CHILD HEALTH.—5 p.m., Professor C. A. Janeway (Boston, U.S.A.): Resistance to Infection in the Child.
LIVERPOOL MEDICAL INSTITUTION.—8 p.m., pathological meeting. Professor C. V. Harrison: Vascular Changes in Pulmonary Hypertension.
NORTH-EAST CLINICAL SOCIETY.—At Prince of Wales's General Hospital, N., 2.30 p.m., clinical meeting.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Mr. D. W. C. Northfield: Tumours Involving the Floor of the Third Ventricle.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., Goulstonian Lecture by Dr. Raymond Daley: Autonomic Nervous System in its Relation to Some Forms of Heart and Lung Disease.
ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.—7.30 p.m., symposium: Toxoplasmosis. To be opened by Professor P. C. C. Garnham, followed by Professor C. P. Beattie, Dr. I. A. B. Cathie, and Dr. R. Lainson.
ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Dr. Desmond Curran: psychiatry demonstration.
WEST OF ENGLAND CHILD HEALTH GROUP.—At Department of Child Health Lecture Theatre, Bristol Royal Hospital for Sick Children, 5.30 p.m., Mr. D. E. Milner: Child Art.

Friday, January 18

FACULTY OF RADIOLOGISTS.—At Royal College of Surgeons of England, 5 p.m., Dr. R. Morrison, Mr. C. J. L. Thurgar, and Dr. J. Boland: Supravoltage Radiotherapy Technique.
● INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. H. Meara: clinical demonstration.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. K. Robson: clinical demonstration.
KING'S COLLEGE HOSPITAL MEDICAL SCHOOL.—4.45 p.m., Fifth Dorothy Platt Memorial Lecture by Dr. Cuthbert Dukes: Recent Advances in the Pathology and Treatment of Cancer of the Colon and Rectum.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Professor A. Haddow: Modern Views of Carcinogenesis.
ROYAL MEDICAL SOCIETY, EDINBURGH.—8 p.m., dissertation by Mr. W. J. Irvine: 5-Hydroxytryptamine.
ROYAL MEDICO-CHIRURGICAL SOCIETY OF GLASGOW.—At Western Infirmary, Glasgow, 8.30 p.m., clinical night.
YORKSHIRE SOCIETY OF ANAESTHETISTS.—At General Infirmary at Leeds, 8.30 p.m., Dr. W. M. Shearer: Steroid Anaesthesia.

Saturday, January 19

BIOCHEMICAL SOCIETY.—At Department of Biochemistry, London Hospital Medical College, 11 a.m., scientific papers.

APPOINTMENTS

BREWSTER, T. B., M.B., B.S., M.R.C.P., D.M.R.T., Assistant Radiotherapist to Hamilton Clinic of Ontario Cancer Foundation, Canada.
JOHNSTON, J. McLAUCHLAN, M.B., Ch.B., Physician Superintendent, State Institution for Defectives, Carstairs.
SOUTH-WEST METROPOLITAN REGIONAL HOSPITAL BOARD.—Alex Sakula, M.D., M.R.C.P., Consultant Physician in Chest Diseases, Redhill Chest Clinic, Surrey, and Horsham (Crawley) Chest Clinic, West Sussex.
SOUTH-WESTERN REGIONAL HOSPITAL BOARD.—R. T. D. Franklin, M.B., Ch.B., D.P.M., Assistant Psychiatrist at Digby-Worford Hospital, Exeter; M. K. A. Yousef, M.B., Ch.B., Orthopaedic Registrar with duties at Winford Orthopaedic Hospital and in the United Bristol Hospitals; Margaret E. R. Stoneman, M.B., Ch.B., D.C.H., Registrar in Paediatrics at the Royal Devon and Exeter Hospital; E. C. Lewis, M.B., B.S., Registrar at Mount Gold Orthopaedic Hospital, Plymouth; T. I. Gailani, M.B., Ch.B., F.R.C.S.Ed., and M. A. Azam, M.B., B.S., F.R.C.S.Ed., Surgical Registrars, and Margaret T. Hyde, M.B., B.Ch., Anaesthetic Registrar, at South Devon and East Cornwall Hospital, Plymouth; Edith P. Pringle, M.B., B.Ch., D.P.M., Senior Psychiatric Registrar at Moorhaven Hospital, Ivybridge, South Devon.
WILLIAMS, CATRIN M., M.B., B.Ch., F.R.C.S.Ed., Consultant Ear, Nose, and Throat Surgeon, Clwyd and Deeside Hospital Management Committee.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Erooga.—On January 2, 1957, at Luton Maternity Hospital, to Shirley, wife of Mark A. Erooga, M.B., B.S., a son.
Scott.—On December 2, 1956, at Karachi, Pakistan, to Anne (formerly Calder), M.B., F.R.C.S.Ed., wife of A. W. Scott, a daughter.
Torley.—On December 29, 1956, at Wednesbury, Staffs, to Dr. and Mrs. John Torley, a daughter.

DEATHS

Crawford.—On December 19, 1956, at the Bartholomew Hospital, Goole, Yorks, John Crawford M.B., B.Ch., aged 61.
Cuthbert.—On December 15, 1956, at 7, Blenheim Place, Edinburgh, Andrew Hume Cuthbert, M.B., Ch.B.
Dewdney.—On December 27, 1956, at 24, Mount Street, Taunton, Som., Edward Lucius Day Dewdney, T.D., L.S.A., aged 86.
Evans.—On December 28, 1956, at the Kent and Canterbury Hospital, Grace Catherine Evans, M.R.C.S., L.R.C.P., J.P.
Goulden Bach.—On December 26, 1956, Lorna Muriel Adelheid Goulden Bach, M.R.C.S., L.R.C.P., D.P.H., of 14, St. Augustine's Mansions, Vincent Square, London, S.W.
Hermon.—On December 15, 1956, at his home, Ambleside, Hasle, Yorks, James Milne Hermon, M.D., formerly of Wakefield, Yorks, aged 89.
Hick.—On December 26, 1956, at The Grove, Chippenham, Wilts, Alan Provde Hick, M.R.C.S., L.R.C.P., aged 44.
Holland.—On December 24, 1956, at Overstrand, near Cromer, Norfolk, Edward Torriano Holland, M.R.C.S., L.R.C.P., formerly of Chelsea, London, S.W., aged 79.
Houlton.—On December 13, 1956, at St. Francis, Whitby, Yorks, Charlotte Leighton Houlton, C.B.E., M.D., F.R.C.O.G., formerly of India, aged 74.
King.—On December 15, 1956, at 5, St. Helens Road, Brigg, Lincs, Francis Joseph Ord King, M.B., B.Ch., aged 65.
Miller.—On November 14, 1956, at Poole General Hospital, Arthur Hallowes Miller, M.D., M.R.C.P., formerly of Branksa Towers, Parkstone, Dorset.
Poppie.—On December 14, 1956, at Bryn Mair, Penmaenmawr, Caern., Thomas Mills Poppie, M.B., Ch.B.
Sutherland.—On December 13, 1956, in hospital, Charles Russell Sutherland, L.R.C.P.&S.Ed., L.R.F.P.S., of "Windfalls," 6, The Park, Scalby, Scarborough, Yorks, aged 81.
Thomas.—On December 6, 1956, at 48, St. Marks Road, East London, South Africa, Thomas Harold Thomas, M.D., M.R.C.P., Lieutenant-Colonel, I.M.S., retired, aged 65.
Watson.—On December 17, 1956, at 3, Elm Grove, Salisbury, Wilts, Frank Herbert Cheney Watson, M.B., Ch.B.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Blood Loss in Patients with Coronary Disease

Q.—In patients with coronary disease, how important is it to deal with a chronic cause of blood loss such as bleeding piles? A patient who had a coronary thrombosis a year ago believes that the bleeding from his piles, which is sometimes rather profuse, benefits him. In such a case, provided any primary cause for the piles has been excluded, is it safe to leave the piles untreated? If not, are there any special hazards to be anticipated from their treatment by injection or operation?

A.—Many patients with angina often have some degree of dyspnoea at the time of an attack. Bleeding from any cause may give remarkable immediate relief in such patients. On the other hand, heart failure cannot be treated by repeated bleedings, as anaemia is induced, with a consequent further demand on the heart and even the precipitation of anginal pain. It seems almost certain that the patient's physical state would be improved by treating his bleeding piles. If the piles can be successfully treated by injection, this can be done without fear.

Chemotherapy in Bact. Coli Urogenital Infections

Q.—What is the best treatment for a chronic Bact. coli infection in (a) the urinary tract of a girl aged 12; (b) the prostate of a male, the prostate being otherwise normal—that is, not enlarged? Would polymyxin B or E, for example, be of value?

A.—The first necessity is to make a full diagnosis. Persistent urinary tract infection at the age of 12 strongly suggests some anatomical abnormality which may be revealed by pyelography. Non-specific prostatitis may be a sequel of gonorrhoea: the criteria on which this diagnosis is based should also be carefully reviewed. A few bacteria cultivated from prostatic secretion are of no certain significance: it must be shown that the secretion contains threads of mucus in which bacteria are numerous.

On the assumption that chemotherapy is indicated, it is better to ask the laboratory for guidance than to proceed by guesswork. *Bacterium coli* and other coliform bacilli found in the urinary tract stand next to staphylococci in the frequency with which they are resistant to some of the antibiotics. The drugs to be considered are the sulphonamides, the tetracyclines, streptomycin, and polymyxin (chloramphenicol is unpromising for this purpose because most of it is excreted in an inactive form, and it is clearly necessary to exert an action in the urinary tract itself as well as in the tissues). Of these four, only streptomycin and polymyxin are actively bactericidal, and a bactericidal drug has a better chance than one that is mainly bacteriostatic of eradicating a long-standing infection.

If the organism is sensitive to streptomycin this should be given intramuscularly in a dose of 0.5 g. at 8-hour intervals for three days, but only after the urine has been rendered constantly alkaline by full doses of sodium bicarbonate. Alternatively, the organism is almost certain to be sensitive to polymyxin. Polymyxin B or E in moderate doses for a limited period is safe, but the injections are apt to cause persistent pain. A daily total of 2 mg. per kg. body weight may be given in divided doses for three or four days. If such treatment succeeds and the organism is sensitive to sulphonamides, a very small dose of one of the more active sulphonamides—for example, sulphathiazole—may be given for several weeks or months to prevent recurrence: a total of 0.25 g. daily in divided doses is enough for this purpose.

Infective Hepatitis and Foetal Abnormality

Q.—Is there any evidence that maternal infective hepatitis in the first three months of pregnancy causes foetal abnormalities similar to those now recognized as being due to maternal rubella?

A.—There is no conclusive evidence that maternal infective hepatitis in the first trimester has caused foetal abnormalities similar to those attributed to maternal rubella. In one reported series¹ babies born to women who had suffered from infective hepatitis at any stage of pregnancy did not show a higher incidence of foetal abnormalities than that expected in the general population. Although foetal abnormalities did not occur the incidence of miscarriage was high (about 30%), abortion not so high (about 10%), and foetal mortality considerable (about 36%). It has been suggested² that the virus of serum hepatitis may pass the placenta and cause neonatal hepatitis. The mother, however, is usually a healthy carrier of the virus rather than an overt sufferer, and this theory moreover has not been proved.

Sensation of Chilliness

Q.—What is the physiological basis for the sensation of chilliness so often experienced in febrile illnesses and at the onset of a cold?

A.—The rise in body temperature which is the physical basis of fever is achieved by a diminution in the loss of heat by the body, and in extreme cases by an increase in heat production. In these extreme cases where the rise of body temperature is considerable and rapid a chill or rigor is the outward expression. In milder infections, such as at the onset of a cold, there may be no real shivering, and the rise of body temperature would seem to be achieved largely through vasoconstriction in the skin. These changes are believed to be due to a change in the level at which the mechanism regulating body temperature is set. It may be that this change represents an increased sensitivity of the mechanisms conserving heat, and thus an increase of sensitivity to the stimulus of cold upon the skin. At any rate, the sensation of chilliness is presumably the subjective phenomenon accompanying this disturbance in mechanism.

Trace of Reducing Material

Q.—What action should a practitioner take on discovering a trace of reducing material in the urine of a symptomless patient? What is the probable significance? If a faintly positive result is obtained with one of the new enzyme tests for glucose—for example, "clintix" or "tes-tape"—which is not confirmed on testing with Fehling's or Benedict's solution, what is the significance of this finding?

A.—The discovery of a trace of reducing substance in the urine raises two questions: Firstly, is the substance glucose, and, secondly, if so, is its presence due to a raised blood-sugar level or a lowered renal threshold? The first question can easily be decided by means of "tes-tape" or "clintix," which are specific tests for glucose and give negative results with all other reducing substances. The second question can often be answered by a single blood-sugar estimation taken about two hours after a good carbohydrate meal such as breakfast. If the figure does not exceed 120 mg. per 100 ml. it is safe to assume that the patient is not diabetic. If it exceeds 180 mg. the diagnosis is almost certainly diabetes; if the blood-sugar level is between these limits a blood-sugar curve is indicated.

It is not usually necessary to confirm the presence of a low renal threshold except for purposes of insurance and employment, etc., but it is wise to retest the urine of all patients with minimal glycosuria at intervals of three months to make sure that it is not increasing.

The discovery of constant slight reduction in all specimens, associated with a negative reaction to tes-tape or

clintix, is suggestive of "pentosuria," especially in Jews. A faintly positive test with tes-tape or clintix, even if Benedict's test is negative, must be regarded as indicating the presence of glucose in the urine. If this finding is confirmed by repeated tests it would be wise to have a blood-sugar estimation two hours after breakfast, as the new enzyme tests are more sensitive qualitatively than the older tests for sugar in the urine.

Diet and Disseminated Sclerosis

Q.—What influence has the diet in disseminated sclerosis? Relatives of a patient with the disease have asked me about a treatment consisting in the use of a low-fat diet (30 g. fat and 60 g. protein). Is there any evidence to suggest that such a diet might be helpful—or even harmful?

A.—There is no proof that diet in any way influences disseminated sclerosis. It is true, however, that the disease is almost confined to countries with a high standard of living, and in these it appears to be commoner amongst the more prosperous levels of the community. But whether dietary differences account for this distribution is not known.

In a patient who had already developed the disease it would be extremely difficult to prove that any alteration in the diet had resulted in improvement, and observations would have to be carried out for many years before any such claim could be upheld. Thirty grammes of fat is well below the usually considered minimum amount of fat for a satisfactory diet, and it seems very probable that such a drastic reduction in fat intake (which would have to be covered by a very large carbohydrate content) over a period of years might well result in further complications, such as vitamin-A deficiency. In the present state of our knowledge, therefore, drastic reduction of the fat in the diet is contra-indicated in disseminated sclerosis.

Value of Procaine in Parkinsonism

Q.—Has procaine any place in the treatment of Parkinson's disease?

A.—There is no evidence that procaine has any place in the treatment of Parkinsonism. Procaine amide has been used with remarkable success in the treatment of the involuntary movements of Huntington's chorea, but there is no evidence that it has any effect on the tremor of Parkinsonism.

Penile Smarting after Coitus

Q.—A healthy man with no history of venereal infection often experiences a burning sensation in his penis immediately after coitus. The sensation lasts for 5 or 10 minutes. What are its possible causes? If the sensation is physiological, why does it not always occur after coitus?

A.—Although there is no history of urethritis an examination should be carried out before the first morning micturition and bath, as the man may be suffering from a mild but unobserved non-gonococcal infection. In the presence of infection inflammation of the posterior urethra could account for the symptoms. If, on the other hand, no infection is detected then prostatic congestion could be responsible, the occurrence or non-occurrence of the symptoms being determined by the length of sex-play before ejaculation. In the absence of infection no treatment is recommended.

NOTES AND COMMENTS

Trichinosis.—Dr. JAN JAWORSKI (London, N.W.1) writes: May I include my method for the treatment of trichinosis ("Any Questions?" November 24, p. 1251)? I have treated 15 cases in Poland, all just before the outbreak of the second world war, as a result of which I had no opportunity of publishing a report in the Polish medical press. Early in the spring of 1939 14 students of the technical high school in Warsaw managed to kill a wild pig on their campus. They made sausages of the flesh, which was infected with trichinosis, smoked, and ate them. Of the 14, 13 ate smoked sausages and became heavily infected with trichinosis, but the fourteenth student preferred to boil his

portion and avoided infection. I still correspond with two of those who were infected, and they have both kept in good health since.

About two or three days after eating the sausages all 13 students were taken seriously ill. The illness manifested itself by the symptoms of severe gastroenteritis, a high temperature—103–104° F. (39.4–40° C.)—swelling of the eyelids, neck, and chest muscles, and partial paralysis of the diaphragm, as judged by the laboured shallow movements. The limb muscles were also painful. At the beginning the students were divided into three groups. The first group of three students were treated only by heavy purging, being given calomel and enemas of 5% borax solution. The second group were treated in the same way, but with the addition of arsphenamine intravenously. The remainder were treated with the calomel and borax enemas and with large doses of sodium iodide intravenously. This treatment brought no improvement and one student died. The rationale of the treatment was as follows: The calomel, being a heavy metal, was given to kill the trichinella embryos which develop in the intestinal mucosa and to accelerate their elimination in the faeces; the alkaline borax enemas to facilitate the detachment of the debris containing embryos from the colonic haustra; and the arsenic and sodium iodide because they are supposed to kill embryos which have already reached the intestinal lymphatics or the blood stream. When all hope failed and there was no sign of any improvement in the students' condition I started to treat them with calcium chloride injections mixed with ascorbic acid. After the first injections the improvement was striking and very obvious. All the patients fell into a deep sleep, lasting in some cases for 12 hours. Observing them in their sleep, I noticed their breathing had become easier and deeper, their pulse rate slower, and their temperature began to fall. After twelve hours I repeated the injections, and usually, after the second or third injections, the temperature returned to normal within 24 to 48 hours, the swelling diminished, and pain disappeared. In spite of this improvement the injections were given for another two or three weeks, but after the temperature had dropped they were given every other day intravenously. All the patients were cured. The eosinophilia persisted for two to three weeks. Since then I have treated only two further cases, with similar successful results. The injections of calcium and vitamin C were based on the results of the very old and numerous experiments I had made on frog's peritoneum, probably familiar to every student, which showed that calcium tightens the endothelial cells and diminishes the permeation of liquid through the capillary walls, acting as an anti-inflammatory factor. The addition of the vitamin C enhanced the tightening of the endothelial cells. I shall be very glad to hear whether others can confirm the effectiveness of this simple treatment in cases of trichinosis.

Menstrual Oedema.—Dr. RAYMOND GREENE (London, W.1) writes: I cannot agree with the last paragraph of your expert's answer on the subject of menstrual oedema ("Any Questions?" December 8, p. 1382). Restriction of salt and fluid, as mentioned in his first paragraph, is certainly important, but he makes no mention of the use of diuretics, to which many mild cases respond. He is unduly pessimistic about the use of hormone therapy. It is true that ethisterone improves only one case in three, but injections of progesterone in a dosage of 25 mg. on alternate days will produce relief or improvement in about 80% of cases.

Correction.—Drs. Mary Crosse and Jean Mackintosh are the contributors to *Recent Advances in Paediatrics* to whom Dr. J. A. Black referred in his letter on perinatal mortality (*Journal*, December 29, 56, p. 1543).

Books of "Any Questions?" and Refresher Course Articles.—The following books are available through booksellers or from the Publishing Manager, B.M.A. House. Prices include postage. *Any Questions?*, Volumes 2 and 3 (8s. each); *Refresher Course for General Practitioners*, Volumes 2 and 3 (26s. 6d. each inland, 26s. overseas); *Clinical Pathology in General Practice* (22s. 3d. inland, 21s. 9d. overseas).

The graph above is of an experiment to measure the effect of Transvasin on skin temperature on a subject. The red line plots the skin temperature before and at intervals after a single application of one inch of cream (0.924 grams) from a tube of Transvasin. The black line gives similar information with regard to the application of a plain vanishing cream used as a control. Skin temperatures were measured with an electro-thermo couple every five minutes for two hours. Photographs show the affected area before application; three minutes and thirty minutes later.

COMPOSITION OF TRANSVASIN

Salicylic acid tetrahydrofurfuryl-ester	14%
Nicotinic acid ethyl-ester	2%
Nicotinic acid n-hexyl-ester	2%
p-Aminobenzoic acid ethyl-ester	2%
Water-miscible base ad	100%

Transvasin

"Transvasin" is a registered trade mark of Lloyd-Hamol Ltd

IT is generally agreed that cases of soft-tissue rheumatism and of many types of arthritis benefit by hyperaemia of the affected tissues. Transvasin, which contains two quick-acting esters of nicotinic acid, induces such a deep and prolonged hyperaemia at the same time as it produces superficial erythema.

In addition to the esters of nicotinic acid, Transvasin contains the fat- and water-soluble esters of salicylic and p-aminobenzoic acids. Both these well-tried analgesic drugs are readily conveyed through the skin in therapeutic quantities and enable an effective concentration to be built up where they are needed.

Transvasin is now being widely prescribed, with successful clinical results. Since a very small quantity is sufficient for each application, the cost of treatment is extremely low.

Transvasin is available in 1 oz. tubes, basic N.H.S. price 2/6 plus P.T., and is not advertised to the public. Samples and literature will be gladly sent on application.

MALIGNANT MELANOMA*

BY

Sir STANFORD CADE, K.B.E., C.B., F.R.C.S., F.R.C.O.G., F.A.C.S.

Senior Surgeon, Westminster Hospital, London

Pigmented lesions of the skin are very common and the vast majority of them are harmless. Malignant melanoma is rare—only about 3% of all skin cancer—and at times very difficult to distinguish from the benign pigmented mole. Malignant melanoma has a very grave outlook and yet the prognosis of an individual patient is unpredictable, as spontaneous regression even in the late stages of dissemination is known. Five-year survival rates are of less significance in malignant melanoma than in other types of cancer, as many patients die in the sixth to tenth year, although the majority are lost in the first two years. In diagnosis the personal opinion of the clinician and that of the histologist are often at variance, and in the management of the patient there is the gulf between conservatism and radicalism. This black lesion has indeed cast over the profession and the educated patient a dark pall of uncertainty and the gloom of fear. The most important recent contributions on the histogenesis and pathology of these tumours are those of Spitz (1948, 1951), A. C. Allen (1949), and Allen and Spitz (1953) based on their unrivalled experience at the Memorial Hospital, New York. Their studies on the correlation between histological findings and clinical course resulted in a reorientation of the rationale of treatment.

The experience of 132 cases of malignant melanoma seen at Westminster Hospital has been reviewed in the light of this modern concept, and this has proved of value in achieving greater accuracy in diagnosis and as a guide in the selection of the most suitable method of treatment.

Histology of Pigmented Skin Lesions

The theories as regards the origin of pigmented skin lesions, epidermal or neurogenic—are well known, and to-day the majority of pathologists accept the epidermal theory. This, however, has no practical influence on the management of patients. It is now accepted that the histological types fall into one of four groups: (1) the junctional; (2) the intradermal; (3) the compound; and (4) the blue naevus. The recognition of these varieties is of practical importance and of prognostic significance.

The junctional naevus is so named as histologically the naevus cells are seen in the basal layer of the epidermis at its junction with the dermis; from there the tumour is seen to spread to the surface through the

stratum spinosum, granulosum, and corneum. At the periphery of the main lesion there is often to be seen a superficial spread where the cells are separated from the main lesion by areas of normal epithelium. This is of importance, as an apparently complete surgical removal showing normal epithelium beyond the naevus may still have left naevus cells at the periphery. Histologically the lesion must be distinguished from other intra-epidermal growths such as the keratoses, Bowen's disease, and Paget's disease. The degree of pigmentation varies.

The intradermal naevus, as its name implies, is situated entirely in the dermis; neither the epidermis nor the junctional areas are involved, although the epidermis may be atrophic. The naevus cells form masses without any encapsulation and often penetrate into the subcutaneous fat; pigmentation is usually less marked or absent in the deeper parts of the lesion.

The compound naevus was so named by Allen (1949) to define those naevi composed of two elements—junctional and dermal; it is much more often found in children than in adults.

The blue naevus differs from the other varieties as the main cellular element is a spindle cell; the arrangement in whorls or fascicles is common and its neurogenic origin likely. Pigmentation is marked, hence the name. The lesion is always situated in the dermis.

Clinical Features

The clinical features and the malignant potentialities of the four types are now clearly recognized. They can be briefly summarized as follows:

The junctional naevus is a pigmented lesion of every shade of brown; it varies in size, is smooth, nearly always flat, and hairless. It may occur on any part of the skin, but those on the palm of the hand, the sole of the foot, and the genitalia are always "junctional" in type. It is the "immature" naevus (Hicks, Rank, and Wakefield, 1955). It is not uncommon in children. Allen (1949) and Allen and Spitz (1953) emphasize its relationship to malignant melanoma. Quiescent junctional naevi may become active; "activity" in junctional naevi or in the junctional component of a compound naevus is recognized histologically by nuclear anaplasia, hyperchromatism, increase in nuclear size, mitotic figures, and subepithelial lymphocytic infiltration. Such changes in an adult are considered pre-cancerous, and such lesions are potentially malignant

*Dorothy Platt Memorial Lecture given at King's College Hospital on February 28, 1956.

melanomata. Although only a very small proportion of junctional naevi develop into malignant melanoma, Allen and Spitz draw attention to the fact that "with the exception of a few malignant blue naevi, every melanocarcinoma of the skin or mucous membrane arises from a junctional or compound naevus."

The *intradermal naevus* is the commonest variety and nearly all "common moles" belong to this group. Its colour, like that of the junctional naevus, varies from light to dark brown. It can be flat and smooth or papillary and warty. The hairy mole is always of the *intradermal* type. It is the most stable variety and does not undergo malignant changes. It never occurs on the palm of the hand, the sole of the foot, or the genitalia. Pigmented lesions in these sites should therefore be presumed to be other than the *intradermal* type. They are rare before puberty and become more common with increasing age. The *intradermal naevus* is the "mature" pigmented skin lesion (Hicks *et al.*, 1955).

The *compound naevus* is clinically indistinguishable from the *intradermal* one. Its incidence according to Allen (1949) is 12% of all naevi in adults and as high as 98% in children. The junctional element of the compound lesion renders it potentially dangerous. When a hairy mole spontaneously loses the hair it can be presumed that there is a compound element and that the junctional part has become active. It is estimated that less than one in ten malignant melanomata arise from a pre-existing compound naevus; whereas nine in ten arise from junctional naevi.

The *blue naevus* occurs most commonly on the face, on the dorsum of the hands and feet, and on the buttock. It is dark brown, blue, or black in colour and nearly always hairless and smooth. Its malignant variant is extremely rare and is described as a *melanosarcoma*.

Juvenile Melanoma

It is now well known that a pigmented skin lesion occurring before puberty may have histological features indistinguishable from malignant melanoma and yet pursue a benign course clinically. Such lesions have been described by Spitz (1948, 1951) under the name of juvenile melanoma and by Pack (1948) as pre-pubertal melanoma. The discrepancy between histological findings and clinical course has attracted a great deal of attention. McWhorter and Woolner (1954) reviewed all the cases of pigmented skin lesions in children at the Mayo Clinic and found 11 patients previously diagnosed as malignant melanoma who came into this group. Spitz maintains that histologists of great experience can differentiate the malignant melanoma from the juvenile melanoma in almost but not all cases. The occurrence of true malignant melanoma in the pre-puberty patient is very rare, and McWhorter and Woolner summarize 18 such patients varying in age from 3 to 12; of these, 12 had died of the disease. It is important to recognize juvenile melanoma as a clinical and pathological entity, as it influences treatment. Thus in the pre-puberty patient conservative surgery is always indicated. It should also be remembered that this variety may occasionally persist after puberty and is known to occur in adults. Allen and Spitz (1953) point out that the post-pubertal juvenile melanomata are always diagnosed as malignant melanoma and that this erroneous diagnosis leads to disproportionately radical surgery and also falsely raises the cure rate of malignant melanoma.

The juvenile melanoma may occur on the trunk or on the limbs, but the most frequent site is the face. The lesions vary in colour from yellow to brown, are hairless and warty. Histologically they show the features of malignant melanoma.

Malignant Melanoma

This is a rare condition. Willis (1948) found only 9 cases in 1,200 cancer cases submitted to necropsy. They account for 3 to 4% of all skin cancer. In a period of 27 years there have been 132 cases of malignant melanoma at Westminster Hospital. The age incidence is shown in Table I.

TABLE I.—Age Incidence of 132 Patients with Malignant Melanoma

Age:	0-20	21-30	31-40	41-50	51-60	61-70	71-90
No. of patients	9	29	25	25	25	9	10

The majority of malignant melanomata occur on the skin; those in the eye form a separate entity. Primary malignant melanoma may originate in mucous membrane; the common sites are the nasal cavity, the mouth, the ano-rectal junction, and the urethra. The intestinal lesions may be primary, but may also be metastatic (even when solitary) from a small undetected skin tumour, or from a tumour previously excised and not recognized as a melanoma. Melanomata of the larynx and bronchus have been recorded. Malignant melanoma on the head and neck seems to be of a less sinister prognosis, and in this site five-year survivals are more frequent than with lesions on the limbs. No part of the skin is immune, but there is a preponderance in certain sites. Table II shows the anatomical distribution in this series; it coincides with other published series. The lower limb, specially the sole of the foot and ankle, are common sites; this may be related to the fact that the junctional type of naevus is also common on the sole of the foot.

TABLE II.—Site Distribution in Malignant Melanoma (132 Patients)

Site	Incidence
Lower limb	62
Head and neck	24
Trunk	20
Upper limb	17
Unknown primary	4
Mouth and nose	3
Genitalia	2

Clinical Features

The lesion is generally of the low warty type with a macular edge. It often is quite insignificant, and its removal may even be entirely forgotten by the patient by the time metastases develop. The alteration of a benign birthmark into a malignant melanoma is heralded by an increase in size by peripheral spread, increased pigmentation, increase in bulk from the surface, a nodularity, oozing of serum which forms a crust, bleeding either from slight trauma or spontaneously, and by the appearance of minute satellite pigmented spots at the periphery of the lesion. In the papillary type rapid increase in size leads to the formation of cauliflower masses, some of the new tissue being quite devoid of pigment. Some masses ulcerate and the ulcer discharges serum.

Spread of Malignant Melanoma

These tumours spread by lymphatic permeation, by emboli to lymph nodes, and by blood-stream dissemination. The spread is unpredictable, and there is no other tumour as malignant as the melanoma and with such power of dissemination. Lymphatic permeation is common, and manifests itself by the formation of numerous cutaneous and subcutaneous nodules (Fig. 1) some deeply pigmented, others devoid of pigment. These nodules spread with the lymph flow; the number of nodules increases, they grow in size, some lose their pigment and become chamois-leather coloured; coalescence of nodes occurs and leads to the formation of tumour masses oozing a serous discharge. Lymph-node metastases occur sometimes without formation of satellite nodules, as if emboli were carried direct by the lymph stream to the lymph nodes (Fig. 2).

In no other malignant growth is the blood dissemination so widespread; every tissue and organ can be invaded. Nodules develop in the liver, lungs, brain, spleen, kidneys,

FIG. 1.—The primary tumour was on the front of the left leg. Metastatic spread by permeation of the subcutaneous lymphatic plexus. It illustrates the futility of removing a "strip" of skin between the primary site and the main regional lymph nodes in limb lesions.

wall and mesentery of the alimentary canal, the intestinal mucosa, and in the heart itself, in the myocardium, the chordae tendineae, and the valves. Freely circulating melanin in the blood leads to deep discoloration of the skin and mahogany-coloured urine. Mucosal metastases in the

FIG. 2.—Small primary growth on forearm with extensive axillary lymph-node involvement. No intervening lesions. Metastatic spread by lymphatic embolism.

mouth and the rectum form large fungating tumours devoid of pigment. Skeletal metastases in any bone can occur. The course of the disease is unpredictable; some tumours show a periodicity of growth with intermittent quiescence; some lesions lose their pigment and regress whilst the disease continues to spread. The survival period varies; one-third of the patients died within the first two years and one-sixth within the first year. The virulence of the disease is great and the control of it very difficult. Cures are exceptional; a five-year survival is no indication that reactivation of disease will not occur. The survival periods in this series of patients are shown in Table III.

TABLE III.—Malignant Melanoma Survival in 132 Cases

	Alive	Dead
1st year	16	21
2nd "	12	26
3rd "	11	9
4th "	2	6
5th "	6	2
6th to 10th year	9 (4 with disease)	5

Seven patients were untraced.

Only 14 patients survived five or more years; of these, five died between the fifth and tenth year with disease; four are alive more than five years with disease; and five remain free from recurrence more than five years.

Hormonal Influence

The hormonal influence on pigment formation and on the depth of pigmentation in existing pigmented skin lesions has been recognized for many years. More recently Lerner, Shizume, and Bunding (1954) have shown that the melanocyte-stimulating hormone of the pituitary (M.S.H., or intermedin) causes darkening of the human skin and of pigmented moles, and may also cause the formation of new pigmented skin lesions. Depigmentation following cortisone administration is believed to be due to the inhibition of the pituitary. In pregnancy there is increased production of M.S.H., and the areas of increased pigmentation correspond accurately to those found in untreated Addison's disease with the addition of the areola and genitalia.

The rarity of malignant melanoma in children, the benign course of juvenile melanoma before puberty, and the increase of virulence of malignant melanoma in pregnancy all suggest that there is some hormonal influence or control, yet there is no evidence that the transformation of a harmless pigmented mole into a malignant melanoma is initiated or caused by hormonal action any more

than there is proof that pregnancy can cause mammary cancer, although it is obviously patent that pregnancy will aggravate breast cancer. Hence, although it is accepted that prognosis of malignant melanoma is even worse in pregnancy than otherwise, termination of pregnancy does in no way improve the prognosis or lead to regression of malignant melanoma. Spontaneous regression of disseminated malignant melanoma after delivery has been recorded (E. P. Allen, 1955), but other instances of spontaneous regression without the added factor of pregnancy and in men are also reported (Sumner, 1953; Levison, 1955). Neither has treatment with androgens and oestrogens or the few trials of gonadectomy and adrenalectomy altered the course of established melanotic tumours. It remains to be seen if hypophysectomy will control malignant melanoma or merely result in its transformation into an amelanotic melanoma. The problem remains unsolved, but there are several practical implications as regards the management of pigmented skin lesions in children and in pregnancy. These can be summarized as follows:

1. Parents can be reassured that pigmented lesions are not dangerous before puberty. Their removal is dictated for cosmetic reasons and as a prophylactic measure, as some of these lesions may become dangerous in later life. Local excision with a small margin of normal tissue is adequate. Segmental resection of very large lesions is safe.

2. Pack (1948) suggested that the antenatal examination of pregnant women should include a survey of any pigmented lesions. Those on the genitalia and on the feet, known to be potentially dangerous, should be excised. The dark moles exhibiting activity, such as marked increase in size or pigmentation, should be excised. Patients who have had a malignant melanoma should be advised to avoid pregnancy for three to five years. Termination of pregnancy in patients with malignant melanoma is not indicated.

Management of Malignant Melanoma

It has been repeatedly stated that tragic results follow incorrect treatment. Tod (1944) rightly condemns "casual excision, ligature, or cauterization"; Ewing (1934) draws attention to the fact that "familiarity with these apparently insignificant lesions constantly invites meddling interference by patient, surgeon, dermatologist, and other specialists"; and Sylvén (1949), from the experience of 341 cases at the Radiumhemmet, concludes that "great harm was done by doctors, chiropodists, and beauticians who treated early

cases of malignant melanoma by freezing, caustics, and electric needling, whereby diagnosis and adequate therapy were delayed."

The review of the clinical histories of the 132 patients treated at Westminster Hospital shows clearly that often, even to-day, the initial management of pigmented lesions is poor and that "tinkering" is not confined to "beauticians" and chiropodists. Doctors and surgeons are far too frequently content with a local excision of the lesion, often under a local analgesic (Fig. 3). Small linear scars, the seat of sinister black satellite recurrences, bear witness to this form of practice. Yet there is no definite evidence, only a presumption, that these interferences with a pigmented lesion were actually the trigger action which transformed a benign lesion into a malignant melanoma and initiated the malignant process with an explosive violence. An alternative explanation is that the reason why advice was sought and inadequate treatment received for a pigmented lesion present for "as long as I can remember" is that the malignant metaplasia had already begun and that inadequate treatment merely failed to control it.

Treatment of the Primary Growth

All new pigmented lesions in adults showing activity, as distinguished from senile keratosis, pigmented rodent ulcers, or epithelioma, must be looked upon as potentially malignant melanoma. The period of "activity" in pre-existing so-called moles or pigmented naevi may vary from six months to five years, and two or three years of active growth has been noted in 29 patients of this series, or 22%.

The treatment in such cases should be wide excision. The larger the lesion the wider the excision; this should include a margin of 2 cm. in small lesions and 3 cm. or more in lesions exceeding 2 cm. in diameter; in depth the excision must include the deep fascia (Fig. 4).

If this principle is followed, only the very small melanomata can be excised and the wound closed without a skin graft. In most lesions a graft is essential if the excision is to be wide enough. This is brought out quite clearly from the study of 112 patients who lend themselves to a detailed analysis. These patients were subdivided into three groups: (1) Those who had had no previous treatment when first seen. (2) Those who had had "adequate" previous treatment to the primary growth and were referred for post-operative management or for the treatment of metastases, without local recurrence. (3) Those who had received "inadequate" treatment before being seen at Westminster Hospital. The definition of "adequate" treatment was: excision wide enough, and no local recurrence. "In-

adequate" treatment includes all forms of "tinkering" such as cautery, electrolysis, diathermy, "some" x-ray treatment, biopsy of part of a lesion with subsequent delay of two weeks and upwards, excision with closure without graft in lesions larger than 2 cm. in diameter. According to the previous treatment the end-results were tabulated as "good" or "bad." The results were regarded as "good" if no local recurrence occurred and "bad" when local recurrence developed. The results are shown in Table IV.

Those who had received no previous treatment of any kind had a 50% chance of control of the primary growth; those who had any form of "inadequate" treatment—in fact, the majority of patients—fared much worse, 73% developing local recurrences. Of those who received "adequate" treatment in the first instance 42% remained free from recurrence

FIG. 4.—"Adequate" and "inadequate" excision. The linear scar above the tendo Achillis indicates that excision was inadequate, as a recurrence developed in the vicinity. This was widely excised and grafted—yet not quite wide enough, as the scar of the first operation should have been included. A further local recurrence in the original linear scar developed; the area to be re-excised is indicated.

TABLE IV.—Results According to Previous Treatment (112 Patients)

Previous Treatment	Results of Definite Treatment	
	Good	Bad
None	13 (50%)	14 (50%)
Adequate	11 (42%)	15 (58%)
Inadequate	16 (27%)	43 (73%)

"Good" and "bad" apply only to primary growths, not eventual dissemination.

in the vicinity of the primary growth. It is emphasized that this subdivision into "good" and "bad" results does not refer to the ultimate five-year survival or to lymph-node or blood-borne metastases. It indicates solely the possibility of controlling the disease at the primary site according to the initial treatment. But the initial treatment profoundly influences the prognosis. Most patients in whom the initial treatment was inadequate are in fact beyond help. Preston *et al.* (1954) found in their series of 225 patients that when the initial treatment failed to control the primary lesion the five-year survival rate was 1 patient among 58, or only 2%. The experience at Westminster Hospital has fully supported the importance of the initial treatment.

Problem of the Regional Lymph Nodes

Patients with malignant melanoma can be subdivided into those with and those without clinically enlarged lymph nodes.

Nodes not Involved

The grim outlook of the disease focused attention on the question of prophylactic block dissection in the absence of clinically enlarged lymph nodes. In favour of prophylactic dissection are the following points: (1) the fallibility of clinical assessment of enlarged lymph nodes; (2) the much worse prognosis in patients with enlarged lymph nodes; and (3) the occurrence of lymph nodes in 42% of patients in whom "no glands" was followed by "no action." Against prophylactic block dissection is mainly the fact that only a few sites are suitable for prophylactic block in continuity

FIG. 5.—Primary growth was a subungual melanoma of the thumb. Local excision was followed by local recurrence. Amputation of the terminal phalanx of the thumb was followed by the removal of axillary lymph nodes. Between these two sites widespread permeation of the subcutaneous lymph plexus occurred. This was followed by widespread blood-borne metastases.

with the primary site—such as the face and neck, and the pectoral or scapular areas when the lesion is well away from the midline. However, in the common site—the limbs (and the commonest site is below the knee)—a prophylactic block is remote from the primary site and leaves a large intervening area with an extensive deep lymphatic plexus potentially invaded. The removal of a "strip" of skin from the primary growth on the foot (or the hand) up to the main regional lymph node areas is a futile gesture, if the anatomy of the lymph vessels is kept in mind (Figs. 1 and 5). The results of treatment were therefore analysed according to the presence or absence of glands, and the performance of block dissection or an expectant policy. Table V shows the

TABLE V.—Results According to Lymph-node Management

	Good	Bad	Total
No glands and no block	27 (57%)	20 (43%)	47
Glands involved. Block performed	8 (23%)	27 (77%)	35

results; "good" indicates control of the disease for at least two years and "bad" indicates recurrence of disease at the site of the "block" or proximal to it. It does not refer to blood-borne visceral or skeletal metastases.

It seems, therefore, that the best results were obtained in early cases from wide local excision without block dissection of the regional lymph nodes. An "expectant" policy in cases without lymph-node involvement showed that 43% of patients subsequently developed lymph nodes, and that a "block" performed for fully established lymph-node metastasis failed to control the disease in 77% of cases. The conclusion, therefore, is that a block dissection in continuity with a wide excision of the primary growth (feasible only in certain anatomical sites) is the method of choice.

Nodes Involved

As already stated, when the patients develop metastatic lymph nodes the prognosis is very bad; in this series a radical block dissection gave a satisfactory result in only 23%—that is, a 23% survival of at least two years (a very modest achievement). The result in 70 patients assessable for five years or more shows only a 20% survival, and, as already stated, of these 14 patients five died in the sixth to tenth year from recurrence, four are alive more than five years with the disease, and only five (7%) are alive from five to ten years free from the disease. Cunningham (1952), from a review of the literature, states that patients with palpably involved regional nodes have only a 5% five-year survival. In view of this the question of wide limb ablation advocated by Pack and Scharnagel (1951) must be given serious consideration (Fig. 5). Against such procedures are the facts that blood-borne metastases are not controlled by it, that not infrequently local recurrences develop in the amputation flaps and proximal to it, and that neither a forequarter nor a hindquarter amputation prevents further lymph-node involvement in the neck, the mediastinum, and the abdomen. It seems clear that there is not enough evidence to justify the adoption of wide limb ablation as a routine; it is justified only in exceptional cases and as a palliative measure in patients with the burden of a widely affected limb.

Other Methods of Treatment

Although it is generally recognized that malignant melanoma is a radio-resistant tumour, authentic regression of lesions has been recorded after radiotherapy (F. Ellis, 1939; Cade, 1952). It has a place in a small proportion of patients as a supplementary measure following operation, as a palliative, and when surgery is inapplicable. Chemotherapy has also been tried, and occasionally nitrogen mustard or Haddow's compound C.B.1348 has proved of temporary value. Adrenalectomy in a few cases has proved a failure and there are as yet no reports on hypophysectomy. Surgery, however poor the results (20 to 30% of five-year survival in most reported series), remains the most effective weapon.

Summary and Conclusions

In a period of 27 years, 132 patients with malignant melanoma have been treated at Westminster Hospital; of these, 122, fully documented and histologically proved, were followed up to date or to death, and seven could not be traced. I personally treated 82 of these patients; the other 50 were under the care of my colleagues, to whom I am indebted for the use of the notes and sections and the opportunity of seeing some of their patients. Treatment consisted of wide local excision and block dissection in a selected number of cases. A review of this series of patients leads to the following conclusions.

1. The initial treatment is of vital importance. A strong plea is made that no patient should be submitted to minor excisions, biopsies, or other interference, as these result in a negligible chance of survival.

2. The prognosis in children is much better than in adults, even when the histological findings are those of a highly malignant growth. The "safe" period for the local removal of pigmented lesions is before puberty.

3. Pregnancy activates pigmented lesions, and the prophylactic removal of pigmented moles in dangerous sites (feet, hands, genitalia) in the early months of pregnancy is advisable. Prognosis of malignant melanoma in pregnancy is bad. Termination of pregnancy is not indicated, although remissions and regressions after delivery are recorded.

4. Wide local excision of the primary growth is the only treatment which offers some prospect of permanent control of the disease.

5. Prophylactic block dissection in the absence of enlarged lymph nodes is always indicated when it can be done in continuity with the excision of the primary growth. It is probably indicated in other sites too, although less likely to control the disease, as the intervening untouched area may develop lesions. Removal of a "strip" of skin as a bridge between the site of the primary growth and the main lymph nodes is not considered a reasonable or sound procedure.

6. The presence of enlarged lymph nodes from distant lesions in the limbs raises the problem of amputation. There is to date not sufficient experience to recommend it as a routine measure.

7. Spontaneous regression of widely disseminated lesions has been recorded. Prognosis is therefore unpredictable in any individual patient. In the absence of visceral metastases, repeated surgical attack and major mutilating procedures are justifiable.

8. The commonest error in the management of malignant melanoma in adults is to do too little. Delay before definitive treatment is achieved is common.

9. Radiotherapy is of value as a post-operative measure and as a palliative treatment in cases which are not amenable to surgical excision.

I thank my colleagues for the opportunity of seeing some of their patients and Dr. Peter Hansell for the photographs.

Vladimir Bechterev, the Russian neurologist, was born on January 20, 1857. He began his studies during a vital period in the development of neurology. In 1885, while a pupil of Flechsig in Leipzig, he described the superior vestibular nucleus which bears his name. He returned to Russia, where he was appointed to a chair at Kazan. Moving to St. Petersburg (1893), he entered the most fruitful period of his career. He made valuable contributions to the knowledge of cerebral localization, experimental psychology, and clinical neurology. A colleague of Pavlov, he studied the relationship between brain and behaviour, but as an anatomist, experimental psychologist, and clinician rather than as a physiologist. After 1905 he concentrated on the problems of abnormal social behaviour. He died in 1927.

ARE ALL "T's and A's" REALLY NECESSARY?

BY

JOHN FRY, M.D., F.R.C.S.

General Practitioner; Beckenham, Kent

We pride ourselves that we live in a scientific and a rational age, yet many apparently unscientific and irrational procedures based on faulty premises, uncontrolled impressions, and rash conclusions still obtain.

A good majority of these procedures are carried out on young children (who have little chance to voice their opinions) and include various orthopaedic procedures, circumcisions, treatment of naevi, and removal of tonsils and adenoids. Of these, removal of tonsils and adenoids is by far the most frequently performed operation on the human body, accounting for one-third of all surgical operations carried out in the U.S.A. since 1924 (Boies, 1948).

Are all these procedures really necessary? Do one-third of our children really require to have their tonsils and adenoids removed? Why has this century seen such a savage attack on these normally present and easily accessible structures? There has been much discussion on this topic over the years amongst paediatricians, physicians, surgeons, family doctors, and even the lay public, but in spite of this there is still no uniformity of opinion. The surgeons seem most convinced of the benefits of the operation, whilst others regard the procedure as "a prophylactic ritual carried out for no particular reason with no particular result" (Medical Research Council, 1938).

FIG. 1.—Numbers of tonsillectomies carried out in elementary and primary school children annually in England and Wales, 1920-54.

What are the Facts?

In spite of their antiquity—removal of the tonsils was described by Celsus in A.D. 50—these operations were only rarely performed until the turn of the present century. Since then there has occurred a fantastic rise in their popularity, reaching a peak in the early 'thirties, when some 50-75% of all children in this country were having their tonsils and/or adenoids removed. The highest figures were those quoted by Glover (1938), who gave a figure of 83% for an English boys' public school, and by Denzer and Felshin (1943), who in a study of 1,000 11-year-old New York children found that 94% eventually had their tonsils out.

A record of the incidence of these operations over the years is seen graphically in Fig. 1, which has been compiled from figures given by Glover (1938, 1950) for the numbers of elementary-school children having their tonsils removed every year from 1919 to 1948 and from Ministry of Education figures till 1954.

Fig. 1 shows four main points—the steep rise in the popularity of the operation from 1920 to 1930; the peak at 1930 and 1931; the drop at 1933-6, as a result of propaganda; and the fairly constant level during and since the war (the low figure in 1947 was on account of the poliomyelitis epidemic).

These figures were for elementary- and primary-school children of lower social groups. Those for the country as a whole would have been much larger, and the estimate of 200,000 operations a year by Glover (1938) must have been a fairly accurate estimate for 1936. That the operation has not lost its popularity is shown by the fact that during 1954, 226,211 such operations were carried out in this country in N.H.S. hospitals (Ministry of Health, 1955), and this does not include those done in private hospitals and nursing-homes.

It is rather difficult to account for this high incidence of an operation which has been a major medical phenomenon of this century, but two explanations are possible on medical and social grounds. Medically we can only presume that the operations must have been necessary in our children for the treatment of some very common endemic disease which has been most frequent in the upper social groups, since the incidence of the operation is greatest in public schools as opposed to elementary schools. But in actual fact, apart from this evidence of the incidence of the operation, there is little to suggest that there has been this serious endemic disease most prevalent in the "upper classes."

Situation at Present

It is a little difficult to assess the present position accurately, as there are few available figures. It is probable, however, that the situation has not altered appreciably over the past two decades, for in 1954 nearly a quarter of a million persons (226,211) (over 90% of whom were children between 5 and 10) were treated in N.H.S. hospitals in this country for removal of their tonsils or adenoids (Ministry of Health, 1954).

The frequency of the procedure is further evident from the fact that in two of the leading paediatric units in this country between one-sixth and one-quarter of all admissions are for "T's and A's" (Spence and Taylor, 1954; Burke, 1956).

A conservative estimate suggests that between 20 and 40% of our children to-day are having their tonsils and/or adenoids removed, and this is confirmed by Carne (1956), who found that 31.9% of R.A.F. entrants had had their tonsils removed.

A procedure so common must of necessity have certain economic, social, and medical drawbacks and complications. The hospital beds occupied by this large number of patients every year must cost the country almost £3 million—a fantastic and a ridiculous sum spent on a mass ritual which has never yet been scientifically proved to be necessary and which has certain possible dangers. Over the past five years

the Registrar-General's figures show that at least 190 children have died from this operation—a yearly rate of almost 40. In how many of these was the operation really necessary? Whilst it is admittedly a simple and relatively safe operation which is easily performed by all and sundry with various grades of completeness, it has its difficulties and complications. The rate of post-operative ear infections is far from negligible. Cross-infection of children in hospitals is a definite risk; the mental stress and trauma to which these young children are subjected is being more appreciated, and the anxieties of the parents should also be remembered; finally, there appears to be a definite increased risk to bulbar polio-encephalitis in the immediate post-operative period and possibly at later times as well.

These, briefly, are the risks and dangers which must be balanced against the advantages of the operation. It is on this assessment of the pros and cons that the crux of the matter rests, and in this assessment it is necessary to examine the common indications critically in order to find a proper perspective.

Assessment of the Indications for Tonsillectomy and Adenoidectomy

It is in children under 10 years of age, and largely in those between 4 and 8, that the majority of operations are performed for various reasons, and the variety of the indications for which they are carried out is almost unbelievable. The following represent the most usual reasons for operation.

1. Size and Appearance

Although not such a frequent reason as in the past, "enlargement" of the tonsils and "evidence of chronic infection" are still quoted as indications for their removal. It is doubtful, however, whether the enlargement is anything more than a physiological and natural hypertrophy which is common to all lymphatic structures in children between 3 and 8, and which undergo a spontaneous decrease in size after this period. Although I have seen children with apparently massive tonsils that meet in the midline, I have never been convinced that they cause any mechanical ill-effects. With the adenoids the matter is somewhat different, as there may be some consequent post-nasal obstruction, but even this is probably less frequent and less harmful than is generally supposed.

Clinical evidence of "chronic infection" is very indefinite and uncertain. Many of the features that are described are present in many symptomless and normal children. Epstein (1937), in an attempt to correlate clinical signs with histological appearances, found that no such correlation was possible, and he concluded that "the physician did not know an infected tonsil when he saw one."

2. A History of Recurrent Sore Throats

Recurrent sore throats are another frequent reason for tonsillectomy in children. But before we accept them as a definite indication for operation we should look more closely into their natural history.

Tonsillitis and other varieties of sore throat are extremely frequent conditions in general practice—the average family doctor in this country must see between 100 and 200 new cases each year. Most of these have to be labelled as "non-specific," for in only a little over one-third can a recognizable cause, such as the haemolytic streptococcus, Vincent's organisms, or glandular fever, be discovered. It is assumed that the remainder are due to an unidentifiable virus, but, as yet, there is no absolutely conclusive proof of the presence of such an agent.

In order to shed some light on the natural history I would like to quote from a series of 300 consecutive cases of tonsillitis (with fever and red tonsils with exudate) observed in my own practice.

Tonsillitis is rare in children under 4 years of age. It is common in those aged 4-9 years: one-third of all such cases

occur at this period. It is not infrequent between 10 and 30, but its incidence falls with age, being distinctly rare in the elderly.

Fig. 2 illustrates the incidence of acute tonsillitis in children under 10 years who have not had their tonsils removed. The low rate in infancy is apparent, a peak at 5-6 is followed by a steady decline. It is not possible to draw any definite conclusions from this small series, but it is suggestive that there is a tendency to a spontaneous diminution in incidence after the age of 6. If we accept this trend as a natural one, then it is reasonable to expect these children "to grow out of" their attacks.

3. The Catarrhal Child

Under this rather vague term I would include that very large group of children that the British family doctor sees every year for recurring symptoms of infections of the respiratory tract. It is difficult to separate off any specific syndromes, but we are all familiar with the persistent nasal catarrh, the chronic cough, the acute wheezy chest, the earache and transient deafness, which are all accompanied by variable degrees of debility.

Although these conditions are generally accepted as "infections," it is possible that other factors such as allergy, atmospheric pollution, climatic changes, psychosomatic reactions, dietetic errors, and others, may play an aetiological part. In view of this uncertainty about aetiology it is difficult to dogmatize on therapy, and the use of tonsillectomy must be critically assessed.

Of all indications for tonsillectomy it is this group of "catarrhal" conditions that figures most prominently. But are we certain that this procedure really influences their course? This can be answered only by carrying out a planned clinical trial, but some insight into the natural history may be obtained by a follow-up of a group of children.

Over the past 10 years I have followed a group of 55 unselected children (born in 1946), and have recorded the frequency of these common respiratory conditions in each year. Fig. 3 shows the proportions of children who required medical attention each year.

Three phases are apparent. From birth up to 4 years there is a fairly constant level of incidence, around 40-50% of those at risk being seen. At 5-6 there is a marked peak, presumably associated with starting school. An equally remarkable fall occurs at 7-8, and it is this natural decline which should be appreciated, for it suggests that by this time the child has acquired an immunity to the infections or other agents that are responsible for the condition. Although these are the figures from a very small series

FIG. 2.—Age incidence (under 10 years) in a group of cases of acute tonsillitis.

FIG. 3.—Age incidence of children under 10 years attending for upper respiratory tract infections, 1947-55.

FIG. 4.—Age incidence of acute otitis media in children (under 10) in a consecutive series of 114 cases.

of cases from a single practice they are very suggestive of certain natural trends in these common conditions which account for 10% of the family doctor's work and for 25% of all attendances in a paediatric clinic (Kempton, 1954).

These patterns should be remembered whenever the question of treatment arises. When faced with parental pressure "to do something" we should seriously consider whether to advise conservatism and expectancy or to submit the child to a procedure which may not really influence the natural course. We should be grateful for the long waiting-lists and use them to reassess each child before operation to see if they have not "outgrown" their symptoms.

4. Recurrent Earache and Otitis Media

The third most frequent reason for tonsillectomy or adenoidectomy is a history of recurring bouts of earache with a red drum and with or without discharge. This condition of otitis media is a particularly common one in our children, and between the ages of 3 and 8 approximately one in four of all these children suffers from earache. Since it is one of the components of the syndrome of the catarrhal child it is not surprising that its epidemiological pattern is very similar, as can be seen from Fig. 4. Here again we see the moderate incidence under 5, a peak at 5-6, and then a progressive decline.

In addition to this natural tendency towards a spontaneous decline in incidence it is a definite fact that otitis media has itself changed in its severity over the past two decades. This change has probably come about as a result of the introduction of the antibiotics and sulphonamides, but there has also been a natural change, for in the majority of children the condition will now settle without any specific therapy and without any complications. For both of these reasons the decision to carry out removal of the tonsils and adenoids should be tempered with a considerable amount of thought. Even children with recurrent attacks accompanied by temporary deafness will eventually "grow out" of this, with no residual damage.

5. Enlarged Cervical Glands

Enlargement of the cervical lymphatic glands is quoted as an indication for tonsillectomy in most of the standard textbooks, but the fact that three out of four apparently normal children between 4 and 9 have palpable cervical glands should make us reconsider this. This latter figure was obtained by an examination of 100 consecutive children in my own practice who were not suffering from any respiratory tract infections and who were apparently quite fit and healthy. In 76 of these there were definite and palpable glands in their necks.

In my opinion such a normal finding should not serve as an indication for tonsillectomy, and it is probable that this enlargement is merely part of the physiological hypertrophy of lymphatic structures in the neck at this period.

6. Miscellaneous

"Tonsillectomy has at some time been recommended for almost every disease of children and for many conditions, such as mental retardation or enuresis, which can hardly be called diseases" (Gale, 1954).

The majority of these "diseases" are not now accepted as valid reasons for advising the operation, but there are two—focal sepsis and debility—which even now lead to the performance of a procedure for which there is little proof that it has any beneficial effects.

Comment

These, then, are the reasons for removing the tonsils and/or adenoids in some quarter of a million children in hospitals and private nursing-homes in Great Britain every year. From these figures it is estimated that one-third of children leave school minus these organs. Again we may ask whether all these operations are really necessary. In my opinion this figure is grossly excessive.

It is very difficult to lay down any definite criteria for their removal, because each medical practitioner has his own opinions to guide him, but I would like to quote my own experiences.

Over the past 10 years only 40 children in my own practice have had their tonsils or adenoids removed. This represents a rate of 5% of those at risk. Reviewing these cases, I find that there were three main reasons for the operation being carried out: recurrent otitis media in 24; recurrent attacks of tonsillitis in 10; and parental pressure that could not be resisted in 6.

What of the children who did not have the operation? A very large proportion of these passed through this catarrhal phase with its already well-known features and then emerged from it to develop along normal lines to enter healthy adolescence. None of these adolescent patients have residual deafness or aural discharge, none have recurring sore throats, none have chronic nasal catarrh, none have chest deformities or adenoid facies, none have defective speech. There have been no cases of rheumatic fever in my practice over the past 10 years and only one case of acute nephritis. In fact, I consider that I have a really healthy collection of children and young adults to care for in spite of their low rate of tonsillectomy. This is confirmed by the fact that the morbidity rates of my practice are no higher than those quoted in the reports of the General Register Office (1953, 1956).

If not by tonsillectomy, then how are these children to be managed? For there is no doubt that they need careful management. They should be treated expectantly in the knowledge that within a couple of winters or so they will be much improved whatever their treatment. If the child is in otherwise reasonable health then symptomatic treatment, with reassurance, explanation, and encouragement of the parents, is all that is necessary. Acute episodes of otitis media, tonsillitis, and chest infections should be treated as they occur, on their merits, with suitable specific antibacterial drugs when indicated, but many of these episodes will settle without these specific measures. In my experience these simple measures suffice to tide the children and their parents over this rather difficult phase, and there are no apparent risks of serious complications or permanent disabling after-effects.

Discussion

There is no doubt that tonsillectomy and adenoidectomy are useful and valuable procedures in properly selected cases, and the problem which concerns them is not whether they are of any use, but rather whether they are at present being abused.

It has already been stated that nearly a quarter of a million such operations are being performed every year in

our N.H.S. hospitals and that the tonsillectomy rate in our children is around one-third of those at risk. My own views are that these rates are excessive and could with proper selection be reduced by at least two-thirds with no serious consequences to the children in question. This would effect a national saving of £2,000,000 a year to the Health Service. If we are to carry out any reduction in this high rate we should first know the causes for it.

What are the underlying reasons for this high rate, or, in other words, what are the factors leading to the operation?

An important influencing factor is the geographical distribution. Alison Glover (1938, 1950) has shown that in England and Wales marked differences are apparent in the various areas. He compared the rates of tonsillectomy in elementary-school children in counties and boroughs in England and Wales in 1936 and 1948. It is astonishing how variable are these rates, varying by as much as twenty-fold. Thus, in 1936 a child living in Rutlandshire was nineteen times more likely to undergo tonsillectomy than one living in neighbouring Cambridgeshire. A child living in the Enfield area of London was twenty times more likely to have the operation than one in near-by Hornsey. A child living in Bexhill and enjoying the full benefits of its climatic advantages was seen to be twenty-seven times more likely to be submitted to an operation than one living in northerly Birkenhead. Similarly, in 1948 a child from Eastbourne or East Ham was more than ten times as likely to be operated on than one from Manchester or Reading.

These differences were in no way related to climatic conditions—areas with the highest and the lowest rates were often neighbours. Nor were they related to the efficiency of the school dental services, nutrition, overcrowding, unemployment, or poverty. Urbanization, which might have been considered a factor, was rather ruled out by the fact that some of the highest rates occurred in certain agricultural counties and in boroughs which are health resorts famed for their beauty, climate, and spaciousness.

There seems to be one paramount factor in all these—the local medical opinion. It seems that where and when the local medical opinions were that tonsils and adenoids were harmful in schoolchildren, and a hindrance and a nuisance, then we had approximately 65% of elementary-school children in Eastbourne and East Ham having these structures removed during their school life (from 5 to 15), according to the figures of 1948; where the reverse opinions held sway, only 5% were so treated in Manchester and Reading (Glover, 1950).

Although the social incidence of tonsillitis and "catarrhal children" seems common to all classes of society, the incidence of tonsillectomy is at least three times greater in the children of the well-to-do (Glover, 1938). Thus Glover estimated that, whereas in 1936 some 20% of elementary-school children had been tonsillectomized by the age of 14, at one of our "famous boys' public schools" between 75 and 83% had already had their tonsils removed before entry at the age of 13-14. Other figures for public schools of 50-70% (boys) and 42-63% (girls) were quoted in a report of the Medical Research Council (1938).

If we assume that the incidence of the conditions for which tonsillectomy is carried out is similar in the various social classes, then the only explanation for these differences is that, by reason of parental pressure and anxieties, and because of different medical opinions and advice, the children of the upper classes are the more unfortunate.

Of course the major factor responsible for the high rate of tonsillectomy is the very nature of the conditions for which it is undertaken. These have already been discussed in the section dealing with the indications. They are not conditions which are dangerous to life, but are irritating, trying, and demoralizing for the child, the family, the school, and the family doctor. They are both persistent and recurrent. They produce worrying signs and symptoms, and there is little apparent response to simple therapeutic measures. The parents become more anxious; grandparents, uncles, aunts, and neighbours remark that "surely

something can be done for poor little Willy"; the schoolmistress adds to parental worries by remarking on the lack of scholastic progress; and the family doctor despairs because of the lack of the response to his treatments and refers the unhappy child to an F.N.T. surgeon, possibly with a suggestion that tonsillectomy is necessary.

The surgeon-specialist is in a quandary. What has he to offer? The family doctor has already tried the usual remedies without any success and the parents are becoming desperate. He has two possible lines of action. He can decide that there are no real indications for removing the tonsils and attempt to explain and reassure the parents that all will eventually be well; or he may take the line of least resistance and agree to place the child on the waiting-list for the operation. The demand for something to be done is acceded to and the train is set in motion. Next comes the long wait. The length of the waiting-lists for tonsillectomy varies all over the country from six months to over two years. The child who is usually 5 or 6 when referred to hospital will be that much older when admitted, and quite likely free of symptoms. Should he still be routinely operated upon? I think not. All patients should be individually reassessed before being operated upon, and if found to be improving or symptom-free operation should not be proceeded with. Even if symptoms are still present subsequent improvement cannot be directly attributed to the operation, for, as Illingworth (1950) stated, "a child is older after the operation than before, and the fact that he improves is no proof that the improvement is due to the operation."

A further suggestive feature that patience might be rewarded by a spontaneous resolution is a comparison of the data given by Glover (1938) for the age incidence of the operations and the age incidence of tonsillitis in my own practice (Fig. 5). These show an amazing correspondence, and it is very suggestive to conclude that after the age of 7-8 few children will need tonsillectomy and that if we wait long enough they will get well and "grow out of it."

What of the reported results of the operation? Are they really so worth while in the treatment of the conditions for which they are advised? Obviously the fact that nearly a quarter of a million children are operated on each year suggests that the outcome is satisfactory, but is there any real scientific proof or are we jumping to conclusions without any proper controlled surveys?

There is little evidence of any properly controlled clinical trial in all the voluminous literature on this subject. There are many reports producing evidence for the pros and the cons.

Fig. 5.—Comparison of age incidence of acute tonsillitis (Fig. 2) with age incidence of tonsillectomy (Glover, 1938).

Hadfield (1950) and Walker (1953) report benefits from the operation, but as their assessments are based on parents' opinions it is difficult to accept them. Kaiser (1930, 1940) in a 10-year follow-up of 4,000 children, half of whom had had their tonsils removed, and the other half had not, found that whilst early results seemed to indicate some benefits these were not apparent at the end of 10 years.

An appreciable number of reports find no obvious benefits from the procedure (Glover, 1938; Medical Research Council, 1938; Paton, 1943; Mertz, 1954).

Dingle and his associates, in their Cleveland families study (McCorkle *et al.*, 1955), report that in a long and continuous study of 230 children there were no differences in the attack rates and loss of school time for the common respiratory disorders in those children with their tonsils intact and those who had had their tonsils removed.

Conclusions

The aims of this intentionally provocative paper are to set the spotlight once again on this "tonsil and adenoid problem," and to try to stimulate some further thoughts on the matter in all those who are concerned with the medical care of our children—particularly family doctors, school medical officers, paediatricians, and ear, nose, and throat surgeons.

The operation is unquestionably of real value in a small proportion of children, but that it is really so necessary that almost a quarter of a million patients should have to have their tonsils removed every year—a rate of one in three of our population—seems unbelievable. Or is it merely a fashionable and misguided procedure carried out in a desperate attempt to treat a normal phase of child development which, it is suggested, will naturally and spontaneously subside and disappear in the course of two to three years? The problem might be solved by carrying out a planned clinical trial, but this presents great practical and ethical difficulties. Nevertheless it is necessary to obtain an answer. In the meantime we should give this matter serious thought, assess each child carefully, and have greater moral and clinical courage in the knowledge that the great majority of children will "grow out of" their common respiratory infections around the ages of 7-8 without any harmful effects.

Summary

An attempt is made to focus attention once again on "the problem of tonsils and adenoids," and to examine critically the reasons and indications for the high rates of the operation over the past three decades.

The popularity of the operation has been a major medical phenomenon of this century, reaching a peak in the early 'thirties, when some 50-75% of all children were being operated on, and showing no real fall at the present time, when some 33% of children are having their tonsils and adenoids removed. In 1954, 226,211 persons were admitted to N.H.S. hospitals in England and Wales for this operation. This costs the nation approximately £3 million each year. In paediatric units between one in four and one in six of all admissions are for this purpose. The operation has its risks, and some 40 deaths occur each year from its performance.

The accepted indications for the operation are critically assessed in the light of the natural course of many of the conditions for which it is carried out. My records from a South-east London suburban practice suggest that there is a tendency towards a natural and spontaneous "cure" of the common respiratory infections of children at the age of 7-8, including tonsillitis, otitis media, and bronchitis, which are the major indications for the operation. The size and appearance of the tonsils, enlargement of the cervical glands, focal sepsis, and debility should not in themselves be factors indicating removal.

During the past 10 years I have referred only 40 children for removal of tonsils and/or adenoids—a rate of 5% for the child population at risk. This figure is much lower than the national average of 33%, but in spite of this it has not resulted in any apparent harmful effects to the children in question. These "catarrhal children" and their parents require careful management during a phase of child development which is so common in this country as to be a normal feature in children between 3 and 7 years of age.

An examination of the reasons for the high rates of tonsillectomy shows marked geographical and social differences. Neighbouring areas show rates which differ twentyfold. Children attending public schools (upper social groups) show a much higher rate than those attending the old elementary schools (lower social groups). Reported results of the operation are by no means in agreement concerning its benefits.

A plea is made for a more rational approach to the problem, an approach which should take into account the fact that the "catarrhal stage" in young children is a relatively normal one which the vast majority of our children will "grow out of" at 7-8. Each child should be carefully and conservatively assessed when referred for this operation, and this reassessment should be repeated at the end of the long waiting period before admission to hospital, and if the child is improving or is free of symptoms the operation should not be proceeded with.

I wish to thank Dr. G. E. Godber, of the Ministry of Health, and Dr. P. Henderson, of the Ministry of Education, for supplying some of the data, and Mrs. K. Sabel.

ANTIBIOTICS AND HOST RESISTANCE*

BY

P. N. SWIFT, M.R.C.P.

Consultant Paediatrician, Farnborough Hospital,
Farnborough, Kent

During the past twenty years our approach to the treatment of infections has been radically altered by the pre-eminence of powerful antibacterial drugs, which alone enable us to control infections with but few exceptions and regardless of the part played by the patient's own defences. Although modern antibiotics might be expected to control all infections by micro-organisms shown to be susceptible in the laboratory, in practice they do not consistently do so. There are many cases, particularly in infancy and old age, where the expected response does not occur. The causes for these therapeutic failures are various, and not least amongst them is inadequacy of host defence due either to immaturity or to impairment and disturbance of the host-parasite relationship. While the inhibitory action of the antibiotic on invading bacteria can be readily measured and used as a guide to treatment, there is no such direct method of estimating the lethal action of the host defence, which can only be estimated roughly on clinical impressions.

Even with optimal antibiotic therapy the ultimate eradication of the invading micro-organism and the resolution of pathological changes depend upon effective host reaction.

The efficiency of antibiotic therapy has now reached a pitch where further improvement in results must be sought by reconsidering this important and decisive aspect of infection. Its importance is reflected in the mortality figures for pneumonia and meningococcal meningitis, to take two examples. Since 1934 a remarkable fall in the mortality from pneumonia (Fig. 1) has taken place in children and young adults

Fig. 1.—Number of deaths from pneumonia per 100 deaths in 1934 for those aged <1, 1-2, 10-14, 15-20, and 65-75 years. Number of deaths per million living is shown in parentheses.

which contrasts sharply with that in the aged and very young. The relative and absolute numbers dying at the extremes of life remain disproportionately high, although presumably treatment is similar.

Of infants under the age of 1 year the number dying in 1954 was 7,110 per million living, and thus exceeded the total deaths for all years up to the age of 75 and was about a hundred times as great as for those aged 4-5

*Read in the Section of Child Health at the Annual Meeting of the British Medical Association, Brighton, 1956.

years. The possible causes are many, but only those which are relevant can be considered here. For example, opportunities for infection and the virulence of invading micro-organisms, which vary in the different age groups, cannot alone account for this discrepancy, though they may play a secondary part. One must conclude from the figures that there is some quality of the infant inherent in its size or ability to react to infection which accounts for the poor response to antibiotic therapy.

In meningococcal meningitis there has been a relative deterioration in the results of treatment of children under the age of 3, since the broad-spectrum antibiotics have become generally available (Fig. 2). This distur-

Fig. 2.—Number of deaths from meningococcal infections per 100 deaths in 1934 for those aged 0-2 and 3-20 years.

ing trend, which is doubtless due in many instances to masking of the early symptoms by suboptimal therapy (Ounsted, 1955), also serves to illustrate the special vulnerability of the very young.

The Infant's Response to Infection

Our understanding of the defence mechanisms of the infant and the ways in which they differ from those of adults is far from complete. The information available provides evidence, however, which suggests that the infant's reaction to infection is immature and relatively inefficient to an extent which may account for the poor response to treatment.

Among the studies of the cellular responses that of Matoth (1952) is relevant in that he was able to show differences in capacity for phagocytosis and amoeboid activity between the leucocytes of newborn infants and those of maternal controls. In the performance of phagocytosis infants' cells were, under experimental conditions, only 30-50% as efficient as those of the controls.

Further indirect evidence of immaturity is provided by the character of the infant's leucocytic response, which is a remarkably variable and labile phenomenon ranging from an extravagant leucocytosis with the outpouring of many immature cells to one so small that it can hardly be detected.

Whether this implies deficiency in quality or quantity of effective phagocytes is uncertain, but there may be some support for the old teaching which maintains that failure to show a leucocytosis indicates a poor prognosis.

Although the cellular response is normally of first importance in the immediate reaction to acute infection, the humoral defences act prophylactically and curatively in the later stages of infection. During the first weeks of life the humoral defences depend upon passive transfer of antibodies from the mother's serum. At birth the titre in the infant's blood is as high as, and sometimes higher than, that in the mother's blood, but falls steadily to very low levels during

the first six months (Fig. 3). Towards the end of this time active antibody is increasing and takes over the responsibility for humoral defence.

At best, transferred immunity is inferior to acquired immunity in that it does not confer the ability to react anamnistically with the enhanced speed and intensity which is found in association with active antibody. Thus an

Fig. 3.—Antibody titre from birth to 6 months.

apparently sufficient concentration of antibody may not confer a commensurate ability to react with the vigour necessary to control the infection.

Circulating passive antibody may, on the other hand, actually depress the formation of active antibody produced in response to an initial stimulus—a phenomenon which is related directly to the height of the titre of passive antibody and inversely to the potency of the antigen (Osborn *et al.*, 1952b).

Passive antibody has, however, the advantage of possessing a broad antibacterial spectrum by virtue of its origin in an adult of wide experience. It can thus provide protection against micro-organisms which the infant has had no opportunity of contacting. When this antibody disappears around the sixth month of life the infant's protection depends on his own antibodies, and these are necessarily limited by the extent of his experience of bacteria. Nevertheless he will, more or less rapidly, acquire these antibodies during the next few years, and, concurrently, second and subsequent infections will boost the titres of antibodies already present, resulting in an immunity which is progressively widening in range and increasing in efficiency.

Even at the age of entering school some children, particularly those who have had little social contact, still lack resistance to the newly encountered infections; as the lack of immunity is only partial, the consequences are seldom serious, and consist usually of an inability to throw off mild respiratory infections, whereas in a small baby, in whom immunity may be virtually absent, the outcome may be a serious systemic infection.

The capacity to produce antibody appears to be fully developed by the age of 2 months, though before this age, as Osborn *et al.* (1952a) have shown, there is a significant delay before detectable antibody appears and the final concentration is low, even in the absence of any depressive action by passive antibody (Fig. 4).

In man the majority of antibodies are associated with the gamma-globulin fraction of the serum proteins, and it is therefore interesting that the amount of gamma-globulin in the serum of infants is low by adult standards. Whether it is merely an incidental finding associated with their normal hypoglobulinaemia or whether it is due to lack of antigenic stimulation and antibody formation has not been determined. Although the hypoglobulinaemia is associated with low resistance to infection, its precise significance and causal relationships are undetermined. The fact that administration of gamma-globulin, given as a prophylactic measure to the newborn and to older children suffering from the effects of agammaglobulinaemia, is protective

does not constitute proof that the normal hypoglobulinaemia is the only or indeed major factor in defence against infection.

Whatever its exact place in the complexities of defence it is nevertheless another link of doubtful strength in the infant's protective screen.

Fig. 4.—Antibody titre during six months after immunization (modified from Osborn *et al.*, 1952b).

Supportive Measures

Individually the inadequacies which have been outlined may be insignificant, but cumulatively their potential effect is great. In spite of the gaps in our knowledge it is not difficult to see the probable causes for the infant's great susceptibility to non-pathogenic micro-organisms and also his inability to localize and eradicate them. Furthermore, it is important to bear in mind the depressive influence which disturbances of internal environment exert on resistance. Among such conditions, malnutrition, dehydration, vitamin deficiencies, and imbalance of the tissue electrolytes, which may develop with great rapidity during infections, must be prevented or corrected not only because of their direct influence on prognosis. When the defects of the infant's defences are appreciated, it is possible to see more clearly what qualities in the antibiotic and what modifications in regime are required to compensate for the deficiencies. The measures which we can apply may be divided broadly into those which act by supporting and augmenting host resistance and those which act by directly inhibiting the invading micro-organism. Of the agents employed specifically to augment host resistance, antisera, fresh blood, and gamma-globulin are well established, though perhaps not employed as often as they should be.

In recent years cortisone and corticotrophin have acquired an important place in the treatment of certain severe infections—apart from their purely endocrine use in the management of the Waterhouse-Friderichsen syndrome—by virtue of their influence on the tissue's reactions to infection. They also diminish the undesirable effects of toxæmia by bringing about a fall in temperature, increase in appetite, and sense of well-being, so preventing to some extent the harmful effects of metabolic disturbance. In fulminating infections, and particularly in those associated with collapse, their timely administration may indeed be life-saving.

Their anti-inflammatory effect is utilized to prevent serious complications of inflammation such as spinal block in bacterial meningitis and adhesions following peritonitis, and to prevent raised tension within the bone in osteomyelitis. In normal dosage there is little risk of interfering with phagocytosis or antibody formation or of causing deleterious metabolic disturbance (Montgomery *et al.*, 1955).

The last but not the least important feature of infection in the very young, which must be mentioned because it is so often overlooked, is the special difficulty of securing free drainage. The small calibre of the passages, be they bronchial, nasal, or meningeal, retards the flow of viscous exudate and converts them to the state of undrained abscesses, so that the best chemotherapy is likely to end in failure if free drainage is not secured. In respiratory infections, for instance, postural drainage, tipping, aspiration, or even tracheotomy and aspiration are just as essential to recovery as surgical drainage in the case of an abscess cavity or relief of obstruction in the urinary tract.

Antibacterial Measures

The preceding observations on the host-parasite relationship in infants and its influence on the course of infections provide the rationale for certain modifications in antibiotic therapy. In infancy the lack of ability to eradicate the organism makes it necessary to employ an agent which is completely effective—that is, bactericidal—without assistance from the cellular or humoral defences. The uninhibited multiplication of organisms and their rapid spread make it particularly important to use an antibiotic which can be brought into effective action with the least delay and which is little influenced by the size of the bacterial population.

It is necessary to state here that these considerations do not override the sensitivity of the micro-organism, which remains the most important guide in choosing the correct antibiotic.

If these features are considered in more detail it becomes apparent that the antibiotics which are bactericidal in low concentration—namely, penicillin, streptomycin, polymyxin, and erythromycin—have advantages over the broad-spectrum antibiotics which are bacteriostatic in usual concentrations.

The speed with which the organism can be inhibited is subject to several variable factors. In the first place it depends upon the time taken for absorption from the gastrointestinal tract or site of injection and diffusion to the focus of infection.

For this reason, and in order to avoid delay through vomiting or refusal of the initial doses, it is often preferable in a potentially serious infection to ensure absorption by giving the first dose by injection. Injection of the first dose

Fig. 5.—Blood and tissue concentrations of penicillin after single oral and intramuscular doses.

may save an hour or more in the time required to establish therapeutic levels in the blood, and, what is more important, many hours in producing similar concentrations in the tissues (Fig. 5). In most instances, as infection is in the tissues, it is the concentration in the tissues, not that in the blood, which determines the concentration bathing the organism. The rate of diffusion into the various organs and the ultimate concentration attained therein vary, broadly speaking, with their vascularity. Levels always fluctuate less in the tissues than in the blood stream; and in the relatively

avascular structures such as brain and bone the final concentration remains much lower than that in the blood. For the treatment of tissue infections, therefore, higher but less frequent dosage is therapeutically sound and, when involving repeated injections, more convenient. In this connexion it is interesting that a single large intramuscular dose of penicillin sodium is as effective as depot penicillin continued over five days in reducing the size of an abscess. In practice this principle has been successfully applied to the treatment of throat infections by a single injection (MacKeith, 1955).

Even when adequate concentrations have been obtained in contact with the organism there is an interval before inhibition begins. This interval may be as long as six hours, and varies to some extent with the type of antibiotic, but especially with the size of the bacterial population, as Hobby *et al.* (1950) have demonstrated in the case of oxytetracycline. This finding provides another reason for checking infection in its earliest stages while the number of organisms is still small and is consequently of greatest potential significance in infancy, when bacterial multiplication is unchecked and rapid.

Inability to complete the process of bacterial eradication may also result in undesirable consequences when antibiotic therapy is discontinued. Not infrequently there is a recrudescence of infection with either clinical and bacteriological relapse or the development of a low-grade chronic infection. In my experience this has been more common following the use of bacteriostatic agents, but it is uncertain whether it is due to their mode of action or to the convenience of administration and consequent laxity in prescribing. Whichever is the true reason, the fact that cure is not obtained emphasizes the need for a bactericidal agent, and, if bacteriostatic antibiotics are employed, to avoid sub-optimal dosage or to continue therapy, as in pertussis, typhoid, and urinary infections, for periods of 14 days or more. By this means one hopes to suppress the organism until such time as the host's defensive processes can reach an effective pitch.

Toxicity

The last aspect of antibiotic therapy which has a particular importance in infancy is the hazard of toxic and harmful side-effects. They are to be avoided not only on account of their intrinsic danger but because the additional burden may further depress the infant's resistance and swing the balance in favour of the parasite.

Chief of these, on the grounds of incidence and severity, is the risk of superinfection by insensitive micro-organisms. Virtually any disturbance of the normal bacterial equilibrium may cause serious illness in small babies, particularly when the flora of the gastro-intestinal tract is affected.

The broad-spectrum antibiotics, suppressing nearly all the natural flora, not only cause a profound disturbance but also lay the field open for invasion by organisms such as monilia, *Ps. pyocaneae*, and proteus, which are notoriously resistant to treatment. Superinfection, complicating treatment by narrow-spectrum antibiotics, is usually less troublesome, as the micro-organism will be amenable to treatment by another antibiotic.

The organisms associated with superinfection, with the notable exception of oxytetracycline-resistant staphylococci, are generally of low virulence in the presence of normal host resistance. To a small baby, on the other hand, they may be highly virulent, causing serious or even fatal illness. The rising incidence of meningitis due to two such organisms (namely, *pyocyanea* and proteus) is, as Alexander (1952) has pointed out, a consequence of the use of broad-spectrum antibiotics—which may perhaps become more common—and serves to emphasize the danger.

The second toxic action of antibiotics worthy of attention is that associated with their direct action on cell growth. Antibiotics differ from poisons such as arsenicals by exerting their lethal action against a limited range of living organisms: the wider their range the closer do they approximate

to the general protoplasmic poisons and the smaller is the margin between therapeutic and toxic concentrations.

The concentrations required to cause injury to human cells, under experimental conditions (see Table), are lower with the broad-spectrum antibiotics than with narrow-

Concentrations Required to Inhibit Growth of Human Skin Tissue Cultures

	Least Injurious Dose ($\mu\text{g./ml.}$)	Minimal Inhibitory Dose ($\mu\text{g./ml.}$)
Penicillin sodium	1,250–2,500	2,000–10,000
Streptomycin	210–415	2,220–6,665
Polymyxin B	105–210	830–1,665
Chloramphenicol	135–275	555–830
Chlortetracycline	105–210	830–1,250
Oxytetracycline	25–50	100–200

spectrum antibiotics. Similar findings are also reported by Cruickshank and Lowbury (1952). Lépine *et al.* (1950), using explants of chick-embryo lung, found that lower concentrations of chlortetracycline were inhibitory; a difference which might be attributable to the greater rate of growth, for it is known that rapidly dividing cells are more vulnerable to inhibitory influences.

While the evidence is by no means conclusive it is possible that the margin of safety with, for instance, oxytetracycline may be narrower in the case of newborn or premature babies than is generally realized. That this is not merely a point of theoretical interest is emphasized by the photograph (Fig. 6) of an indolent ulcer at the site of a subcutaneous infusion in a neonate who received chlortetracycline and chloramphenicol for 10 days. Microscopical examination of sections from the margin of the ulcer showed

FIG. 6.—Indolent ulcer at site of subcutaneous infusion in a neonate.

complete absence of any inflammatory reaction, yet within three days of withholding treatment healing became apparent. It is therefore not unreasonable to assume that minor degrees of depression can also occur and perhaps pass unnoticed.

For small infants correct dosage, neither so high as to cause toxicity nor so low as to be suboptimal, is a matter of greater importance than at other ages, when considerable latitude is normally harmless.

Discussion

From the foregoing it is apparent that the infant's imperfect reaction to infection can best be countered, so far as antibiotic therapy is concerned, by employing a bactericidal in preference to a bacteriostatic agent, and a narrow-spectrum in preference to a broad-spectrum antibiotic whenever bacteriological sensitivities permit. Of critical importance are early diagnosis and the speed with which inhibitory concentrations can be obtained in contact with micro-organisms and not merely in the blood stream.

The infant's susceptibility to certain toxic effects which are seen most commonly and in severest form with the broad-spectrum antibiotics must always be considered when deciding upon the most suitable antibiotic. In order to reduce to the minimum the number of babies receiving broad-spectrum antibiotics when narrow-spectrum antibiotics would be as effective, the administration of broad-spectrum antibiotics should be limited to cases which fall into one of the following categories: (1) when the infecting organism is insensitive to bactericidal antibiotics; (2) where temporary cover is necessary while awaiting the bacteriological diagnosis; and (3) when the bacteriological investigations have failed to demonstrate a pathogenic organism, and the nature of the causative organism remains obscure.

The modifications in antibiotic therapy which the conditions of infancy dictate may not in themselves seem great. They do, however, demand of the physician greater attention to exact bacteriological diagnosis, greater care in the choice of drug and dosage, and the avoidance of delay in bringing effective treatment to bear. They may also involve some inconvenience in that injections are more often required. Nevertheless, it is by such means that improvement in the present mortality figures must be sought.

Whatever the extent of the progress that can be brought about by these means there is little doubt that great progress could be achieved if we had the knowledge and ability to raise the efficiency of host resistance in infancy.

Summary

Successful treatment of infections with the aid of modern antibacterial drugs depends *inter alia* upon healthy host resistance. When host resistance is depressed to any great extent the therapeutic effect of antibacterial agents may be nullified and the clinical response unsatisfactory.

In contrast to the state in old age, or resulting from prolonged illness or cortisone therapy, poor resistance in infancy is primarily a manifestation of the immaturity of the various defensive mechanisms, rather than a depression of previously normal resistance. Characteristically, the phagocytic ability of the leucocytes of infants is less than that of the cells of adults. The antibody response may be slow and incomplete through lack of previous stimulation, and may also be affected by the presence of circulating maternal antibody. It is, moreover, usual to find the response delayed and incomplete, even in normal infants below the age of 2 months. After this age the level of the gamma-globulin in the serum is still abnormally low and may well exert an adverse influence on defence, though at present the exact significance of this finding is uncertain.

Taken together, these deficiencies go much of the way to explain the inability of infants to limit spread of infection and to bring about the ultimate destruction and eradication of the invading micro-organisms. The rapid dissemination of bacteria throughout the body makes prompt control a point of special and often decisive therapeutic importance, which must be taken into account when deciding upon the most advantageous method and route of administration. The infants' poor killing power that permits bacteria suppressed by bacteriostatic agents to remain viable makes it necessary to employ antibiotics which are themselves actively bactericidal.

When treating infections of infants the physician has a greater responsibility to prevent further impairment of host resistance resulting from additional stresses such as metabolic disturbance, superinfection, or direct toxicity of the antibiotic on tissue cells. In this respect narrow-spectrum antibiotics are usually less injurious

and therefore safer in practice than those whose spectrum is wide. It follows that the best antibiotics for use in infancy are those like penicillin, which combine narrow antibacterial range and bactericidal action. Not only is the need for discrimination in selecting the correct antibiotic more pressing but also the more serious consequences, particularly those due to suboptimal dosage, make care and accuracy in prescribing of greater and more decisive importance in infancy than at any other age.

AND

G. E. FRANCIS, Ph.D., F.R.I.C.

From the Surgical Professorial Unit, St. Bartholomew's Hospital, and the Departments of Physics and Biochemistry, St. Bartholomew's Hospital Medical College

In this investigation plasma protein labelled with radioactive iodine (^{131}I) (R.P.P.) has been used to study the lymphatic circulation in normal subjects and in patients suffering from lymphoedema.

Three questions were considered. (1) Are extra-vascular protein molecules removed solely by the lymphatics or does absorption by the blood capillaries occur? (2) Does the absorption of protein from the subcutaneous tissues of lymphoedematous patients differ from that in normal subjects? (3) Could the removal rate of R.P.P. from the subcutaneous tissues be used as a test of lymphatic function in clinical practice?

Six normal subjects and ten patients suffering from lymphoedema were investigated. Similar determinations were made in normal rabbits and in rabbits with a limb rendered oedematous by acute lymphatic transection (Reichert, 1926). In addition, the clearance rate of crystalline solution iodide (^{131}I) from the subcutaneous tissues was determined in some patients and animals.

Experimental Method

The method of Wormall, Francis, and Mulligan (1951) was used to prepare R.P.P. solutions of high specific activity by labelling human or rabbit autogenous serum protein with radioactive iodine (^{131}I). Small volumes of solutions

*B.M.A. Research Scholar.

and radio-iodine of high specific activity were used so as to give a final preparation of 1 to 2 ml. of 2% protein solution containing 0.5 to 1 millicurie of ^{131}I per ml. ^{131}I in the form of iodide was removed by dialysis with normal saline, changed every half-hour, and mechanically stirred. To reduce bacterial activity during this part of the preparation the dialysis was carried out in a refrigerator. The preparation was then sterilized by filtration through an M.S.E. centrifugal Seitz filter and tested bacteriologically before use.

Injections and Observations in Human Subjects

The R.P.P. solution was injected subcutaneously into the limbs of the patients and normal subjects. It was considered important to keep the volume of R.P.P. injected as small as possible in order to minimize disturbance of tissue tension, and usually 0.1 ml., containing about 100 microcuries of ^{131}I , was used. When the specific activity of the R.P.P. was low and a larger volume had to be used, several injection sites were employed, close enough together to be regarded as a single site for counting purposes. No more than 0.1 ml. of R.P.P. solution was injected at any one site.

In the early stage of this investigation the counting rates over the areas surrounding the injection site were observed with a shielded Geiger counter of small aperture held in contact with the skin. Although this method demonstrated well the local diffusion of R.P.P. around the injection site, it was unable to separate the effect of local diffusion into the tissues from that of actual removal from the limb. For this reason it was necessary to discard the results of local counting obtained in the first seven patients. In the last three patients to be investigated and in six normal subjects this difficulty was overcome by using a counter of larger aperture, held at a distance of 22 cm. from the skin.

The arrival of R.P.P. in the blood was estimated in five patients and four normal subjects by taking 3-ml. samples of venous blood from an arm vein. Frequent specimens were obtained during the first 12 hours and sampling was continued at intervals for seven days. The radioactivity of each blood sample was measured by plating 1 ml. into 1-in. (2.5-cm.) planchettes and counting with an end-window Geiger counter in a lead castle. The diagnosis in four of the patients in this group was lymphoedema praecox of the legs. The remaining patient had an oedematous arm following invasion of the axillary nodes by carcinoma of the breast. One patient had unilateral oedema, and her normal leg was also studied and included in the normal control group.

Injections and Observations on Rabbits

Two groups of animals were used—transected and normal. In the transected animals a soft-tissue transection of the thigh, except for the main blood vessels, was carried out before the R.P.P. injections. In these animals the R.P.P. was injected under the skin of the paw of the transected leg.

Counting over the injection site was done using a small unshielded Geiger counter in a thin brass case. The counter was held in a wooden jig so that its axis lay about 2 cm. from the skin and parallel to the paw.

Blood specimens were obtained by means of a "polythene" tube inserted in the superior vena cava via the jugular vein. 1 ml. of each blood specimen was placed on a planchette, dried, and assayed in the same way as the human blood.

The completeness of the lymphatic division was tested by injection of patent blue (Kinmonth, 1952) when the transection was performed and also at the end of the investigation.

Experimental Results in Human Subjects

Results of Local Counting over the Injection Site

The observations with the small-aperture counter, after correction for natural background and the physical decay of the radioactive material, and after an approximate correction for the imperfect collimation of the counter, were used to

plot contours of equal activity. These results indicated in a general way the diffusion of the injected R.P.P. through the tissue. It was found that the size of the diffusion area after a given time was greater in the more oedematous limbs. It is also of interest to note that in all cases of lymphoedema the point of maximum activity gravitated appreciably towards the most dependent part. This movement was usually smaller in normal legs.

With this counting technique, however, it was found that the true removal of R.P.P. from limbs was masked by the effects of diffusion. A semilogarithmic plot of the maximum counting rate against time gave a curve instead of a straight line, which would correspond to a simple removal process. A detailed analysis of this curve, to separate the diffusion and disappearance effects, was thought not to be practicable. In later investigations a counter was used with a large aperture held at a sufficiently great distance to cover the whole of the diffusion area. Readings with this counter over the injection site could then be fitted to a single exponential decay, giving a straight line in a semilogarithmic plot even with observations extending over about 50 hours. The slope of this line gives the mean removal rate of the R.P.P. from the injection site, and these values are given in Table I. In this table both groups are arranged in descending order of

TABLE I.—Results of Local Counting Over Injection Site in Human Subjects

Subject	Degree of Physical Activity	Removal Rate of R.P.P. (Percentage of Dose Removed per Hour)
Control Group		
J.R.	Very active	3.9
F.S.	Active	2.2
F.B.	Slight	1.2
M.A.H.	Bed	2.5
E.W.H.	"	1.6
E.J.	"	1.7
Mean		2.2 ± 0.4
Lymphoedematous Group		
V.S.	Active	1.45

L.A.P.	"	1.7
Mean		1.4 ± 0.2

physical activity, and in addition the lymphoedematous group is tabulated in order of decreasing severity of lymphoedema.

The results show that the clearance rate of R.P.P. in normal subjects is influenced by physical activity and that there is no significant difference in the removal rate in control subjects during bed rest and in active patients with lymphoedema. The mean values of the removal rate in the two groups show no significant difference, but the results suggest that clearance of R.P.P. is slower in patients with lymphoedema than in active normal subjects.

The following conclusions were drawn from the findings of local counting over the injection site in normal control subjects and in patients with lymphoedema. (1) A wide subcutaneous diffusion of the injected R.P.P. occurs around the injection site. This local diffusion is influenced by gravity and is greater in the lymphoedematous patients than in the normal controls. (2) The removal rate of R.P.P. in normal subjects is increased by physical activity. (3) The removal rate of R.P.P. from the limb is greater in normal active subjects than in the lymphoedematous patients.

Measurements of Blood Specimens

The rise of radioactivity in the blood following the injection of R.P.P. for a typical case in the control group is shown in Figs. 1 and 2. Correction has been made for the natural decay of the ^{131}I . Fig. 2 has an expanded scale and shows the result during the first few hours after the injection. It is seen that after an initial rise and flattening of the curve increases steeply; it then reaches a maximum and falls slowly owing to the removal of the R.P.P. from the blood.

The observed initial rise and flattening of the curve is attributed to the presence of traces of ^{131}I iodide in the injection solution. This is based on the blood activity curve of a control subject who received a subcutaneous injection of R.P.P. containing a known proportion of ^{131}I as iodide. From this observation a correction could be made for that fraction of the observed activity corresponding to iodide contamination.

FIG. 1.—Appearance in the blood of R.P.P. injected subcutaneously into the leg of a normal subject.

FIG. 2.—Early portion of the curve shown in Fig. 1 on an expanded time scale. After an initial rise, a plateau is formed and is followed at 50 minutes by a further steady rise in R.P.P. concentration in the blood.

activity is obtained from the initial slope of the curve and expressed as the percentage of the injected dose per ml. of blood per hour. The values found for the controls and for lymphoedematous cases are summarized in Table II.

In Table II the subjects in the control group are analysed in descending order of degree of physical activity, and it is noticeable that the initial rate of rise corresponds closely to this. The following conclusions were drawn from these estimations of the appearance in the blood stream of the injected R.P.P. in normal control subjects and in patients with lymphoedema. (1) There is a delay in time of from 0.5 to 3.25 hours following the subcutaneous injection before the R.P.P. can be detected in the blood. (2) This delay is greater in patients with severe lymphoedema than in the normal control subjects. (3) The initial rate of rise of R.P.P. content in the blood is greater in the normal control subjects than in the patients with lymphoedema. (4) In normal subjects the initial rate of rise of R.P.P. content in the blood is increased by physical activity.

Experimental Results in Rabbits

Results of Local Counting over the Injection Site

In six normal animals R.P.P. was injected subcutaneously into a hind paw and the counting rate observed over the injection site. The counting rate was found to decay

exponentially and the removal rate of R.P.P. was calculated in the same manner as in the human investigations. Similar measurements were made in five animals with transection of lymphatics in the injected limb. It was found that the removal rate of R.P.P. as determined by local counting did not differ significantly in the control and transected group of animals. Further investigation showed that a high local concentration of R.P.P. was occurring at the site of transection around the cut end of the lymphatics. Thus the R.P.P. was being removed from the paw only to be dumped at the site of the transection, and a true removal rate of R.P.P. from the limb could not therefore be determined.

FIG. 3.—Appearance in the blood of R.P.P. after subcutaneous injection into a normal leg. The observed points have been corrected for iodide contamination of the R.P.P. and there is a delay period of approximately 50 minutes before the R.P.P. contribution becomes detectable.

TABLE II.—Estimation of Arrival in Blood of R.P.P. Injected Subcutaneously in Human Subjects

Subject	Initial Delay (in Hours)	Initial Rate of Rise of Radioactivity in Blood. (10^-4% of Dose/ml. of Blood/Hour)

Measurements of Blood Specimens

The ^{131}I content of the blood in the control group was found to vary with time in the same way as in the human subjects—that is, it showed a rapid initial rise to a plateau followed by a further rise. Corrections for the small fraction of ^{131}I injected as iodide were based on observations of the activity in the blood of a rabbit injected with ^{131}I in the form of sodium iodide.

In those animals, however, whose lymphatics had been transected the variation of the ^{131}I blood content with time had a different character, as is shown in Fig. 4. It is seen that the significant difference between this analysis and that of Fig. 3 is that the R.P.P. component shows no initial delay. The results obtained for these transected animals and the control group are summarized in Table III.

FIG. 4.—Appearance in the blood of R.P.P. injected subcutaneously into the paw of a rabbit in which acute lymphoedema had been produced by lymphatic transection. The initial part of the curve is shown with the correction for free iodide. The symbols are as for Fig. 3. There is no delay before the R.P.P. contribution becomes detectable in the blood.

TABLE III.—Estimation of Arrival in Blood of R.P.P. Injected Subcutaneously in Rabbits

Rabbits	Initial Delay (in Hours)	Initial Rate of Rise of Radioactivity in Blood (% Dose/Estimated Total Blood Volume/Hr.)
<i>Control Group</i>		
11/52	0.3	0.4
8/53	1.8	3.5
11/53	0.8	1.4
19/53	0.9	2.5
8/54	0.85	4.8
9/54	0.8	4.3
Mean	0.9 ± 0.2	2.8 ± 0.7
<i>Transected Rabbits</i>		
13/53	0	1.4
20/53	0	0.7
21/53	0	0.6
11/54	0	0.45
17/54	0	1.2
Mean	0	0.87 ± 0.19

The blood volumes of the rabbits were estimated on a weight basis from the data of Armin and Grant (1951).

and it is concluded that: (1) In normal rabbits there is a delay in time following the injection of R.P.P. before its arrival in the blood is detected. This delay is of the same order of magnitude as that observed in normal human subjects (Table II). (2) In the transected rabbits R.P.P. could be detected in the blood immediately following the injection. (3) Despite the immediate appearance in the blood of detectable amounts of R.P.P. in the transected rabbits, the initial rate of rise of R.P.P. content in the blood was greater in normal animals.

Interpretation of Experimental Findings

The present concept of tissue fluid formation and absorption is based on the original hypothesis of Starling (1896), which described a hydrodynamic process governed by the outward filtration force of capillary hydrostatic pressure and the absorbing force developed by the osmotic pressure of the plasma proteins. This hydrodynamic process is slow and is concerned largely with the net volume flow of fluid. Pappenheimer (1953) has summarized evidence to indicate

that diffusion rather than hydrodynamic flow is the mechanism of molecular exchange between the blood plasma and interstitial fluid. Molecular diffusion is rapid, is independent of filtration or absorption, and can occur against the flow of bulk transference of fluid. Thus Hyman, Rapaport and Paldino (1952) found no significant difference in the clearance rate of radioactive iodide from normal skin and from skin in which outward filtration of fluid from the capillaries had been promoted by infiltration with a 12.5% protein solution.

Pappenheimer, Renkin, and Borrero (1951) have postulated that diffusion of water- and lipid-insoluble molecules takes place through channels or pores in the capillary wall. Although the diffusion rate of small molecules through these channels is rapid, it is slower than if free diffusion was taking place. This is explained by the concept of restricted diffusion, which becomes increasingly important as molecular size approaches the diameter of the channels through the capillary wall. Thus for large protein molecules, at normal filtration rates, a high degree of molecular sieving occurs, and the resulting filtrate or tissue fluid contains small quantities of protein only. This protein leak into the tissue spaces is small, and is not sufficient to disturb the osmotic relationship on which the Starling hypothesis depends.

The fate of this extravascular protein is obscure, but it is generally held that the lymphatics offer no barrier to protein molecules and readily remove such protein as has reached the tissue space. This problem has been investigated previously by several workers. Field and Drinker (1931) injected horse serum subcutaneously into dogs and detected its presence in blood and lymph by serological methods. They found that after subcutaneous injection the protein found its way rapidly into the lymphatics and could be detected in the cervical lymph trunks after 30 minutes. When lymphatic entrance into the blood stream was prevented by ligation of the thoracic and cervical lymph ducts, the foreign protein could not be detected in the blood stream for periods of up to seven hours. Similar results were reported by Lewis (1921) and Conklin (1930).

Jepson, Simeone, and Dobyns (1953) investigated the fate of R.P.P. injected intradermally in dogs and reached the conclusion that absorption through blood capillaries was the major factor in removal of the protein. Their experiments differed from those reported here in that the R.P.P. was injected into the skin itself instead of subcutaneously, and it may be that the higher pressure required for such injections deranged the local physiological equilibrium, and permitted direct absorption into the blood capillaries.

In this investigation the disappearance of R.P.P. from the injection site in human subjects shows a tendency to be slower when the lymphatic circulation is impaired. The lack of differentiation between the R.P.P. removal rates observed in transected and control animals is probably caused, among other factors, by diffusion of the R.P.P. into the oedema of the transected limb, which makes the removal rates appear too high. A further effect which would make the observed removal rate too high in the transected animals would be produced if the lymphatics were able to carry R.P.P. away from the injection site, only to discharge it through their cut ends into the oedema fluid at the transection. This possibility is supported by the higher activity observed in the tissue specimens which were taken from just below the transection.

The time and rate of appearance of R.P.P. in the blood can be interpreted in terms of the mechanism by which the R.P.P. is removed from the injection site. The two possible removal mechanisms to be considered are: (1) passage of R.P.P. from the tissue fluids directly into the blood, through the capillary walls; and (2) absorption of R.P.P. into the lymphatic system with its subsequent discharge into the blood system. If the former mechanism only were operative the R.P.P. would appear in the blood immediately after its subcutaneous injection and the rate of increase of the R.P.P. content of the blood would be the highest at the initial stage. The magnitude of this rate of increase would be directly

related to the rate of passage of R.P.P. back through the capillary walls. The second mechanism, on the other hand, would involve some delay after the injection before the R.P.P. content of the blood began to rise, corresponding to the time it takes for the R.P.P. to pass through the lymphatic system and hence into the blood stream. Longer delays would be associated with slower functioning of the lymphatic system, and it might be expected that the subsequent rate of increase of R.P.P. in the blood would be correspondingly slower.

With the exception of the result for the transected animals the variation of R.P.P. in the blood has followed the pattern expected from the second mechanism. In human subjects the initial delay is longer and the initial rate of increase of R.P.P. in the blood is much smaller in the patients with severe lymphoedema than in the control group of normal subjects. In the latter the observed values are also related to the degree of physical activity. It appears, therefore, that in the cases examined the lymphatic system is the most important mechanism for the transport of proteins from the tissue fluids. The iodide contamination of our R.P.P. made it, unfortunately, impossible to decide whether there is a return of a small proportion of protein directly to the blood through the capillary walls.

The transected animals are the only group in which blood absorption of R.P.P. appears to be taking place. Here the lymphatic route is destroyed and the normal physiological conditions are disturbed by trauma so that appreciable passage of R.P.P. in the reverse direction through the capillary walls becomes possible. Even in these conditions the removal of protein from the tissue, as measured by the initial rate of increase of R.P.P. in the blood, is considerably (about three times) slower than in the control animals.

The results of this investigation indicate that the behaviour of R.P.P. injected subcutaneously can be used as a test of lymphatic function. The method is useful as a research tool, but it is too expensive and time-consuming for routine clinical purposes.

Summary and Conclusions

The absorption of plasma protein labelled with radioactive iodine (R.P.P.) from the subcutaneous tissues has been studied in normal subjects and in patients suffering from lymphoedema. A similar investigation was performed in normal rabbits and in rabbits with a limb in which lymphatic transection had been performed.

The behaviour of radioactive plasma protein injected subcutaneously in the limbs of human subjects and animals is consistent with its removal by the lymphatic route.

Detectable direct absorption of protein into the blood stream occurred only after acute traumatic destruction of the lymphatic pathway.

The rate of removal of R.P.P. is slower in patients with severe lymphoedema than in normal subjects.

In normal subjects the rate of removal of R.P.P. is hastened by exercise.

We thank Dr. R. A. Shooter for the bacteriological testing of the R.P.P. solution and Miss P. Morley and Miss J. Rogers for their technical assistance.

CASE OF REVERSE COARCTATION SYNDROME

AN AORTIC ARCH SYNDROME

BY

S. N. SEN GUPTA, M.B., M.R.C.P.Ed.

AND

J. C. GHOSH, M.B., D.T.M.

From the Department of Medicine, Calcutta National Medical College Hospital, Calcutta

The interesting clinical syndrome characterized by absence of pulsation in the arteries arising from the arch of the aorta, though very rare, has been reported from time to time. In this condition one or more of these arteries are involved in an obliterative process. A large variety of pathological lesions may be responsible for such arterial occlusion. Of these, a primary panarteritis of unknown aetiology is in a class by itself, and has been variously described as 'Takayasu's disease,' 'pulseless disease,' and 'young female arteritis.'

The largest series of pulseless disease seems to have been reported from Japan, and a comprehensive list of 58 cases was given by Caccamise and Whitman (1952) along with the report of their own case. Skipper and Flint (1952) summarized 16 cases of 'syphilitic' and 'non-syphilitic' origin and recorded two non-syphilitic cases of their own. Ross and McKusick (1953), in an extensive review of the world literature, analysed over 100 cases, 35 being previously unreported. They discussed the whole subject of pulse anomalies in the branches of the aortic arch under the title 'aortic arch syndrome,' a term first suggested by Frovig in 1946. Other possible aetiological factors besides the panarteritis, according to their analysis, are syphilis and trauma, with or without aneurysm formation, chronic dissection of the aorta, atheromatosis, congenital anomalies, mediastinal tumours, and thrombophilia. They concluded that syphilis is the commonest and primary atheroma a very rare cause of aortic arch syndrome.

Recently two more cases of 'pulseless disease' have been reported in the Anglo-American press (Barker and Edwards, 1955; Trias de Bes *et al.*, 1955). From India the first case of aortic arch syndrome was published by Shikhare (1921), and so far as we know the case reported below is the second. Our case is of interest not only because the syndrome itself is rare but also because it belongs to a very rare aetiological variety.

Case Report

A sweeper of a veterinary hospital, aged 51, was admitted to hospital complaining of low pyrexia, breathlessness, productive cough, and generalized body ache of ten days' duration. He had been a chronic sufferer from productive cough for a long time, with occasional exacerbations, especially in the winter months, but his activities had not previously been limited by breathlessness. He had occasional attacks of vertigo, though they were never very severe. A hospital discharge ticket in his possession showed that he was sent home a fortnight previously after successful treatment of a hypopyon ulcer of his right eye.

The patient was thinly built and looked very ill, with sunken eyes and cheeks. Bilateral lenticular opacity and a scar on the lower part of the right cornea were present. The fundus oculi could not be properly visualized because of the lens opacities. The palpebral conjunctiva looked rather pale. He was slightly cyanosed; the respiratory rate was 42 a minute. Clinically the chest was grossly emphysematous. The breath sound was vesicular in character with

prolonged expiration, and plenty of rales and rhonchi were heard all over the chest. The cardiac apex was not palpable and the heart sounds were faintly audible. There was no cardiac murmur. The tender liver was palpable 1 inch (2.5 cm.) below the costal margin, and the caecum was thickened and slightly tender. There was no clinical abnormality in the nervous system.

Pulsation in the radial arteries on either side was completely absent, although the arteries were well palpable at their usual site. Further examination revealed absence of pulsation in the brachial, axillary, subclavian, carotid, and temporal arteries of both sides. The vigorously pulsatile aortic arch was, however, easily palpable at the suprasternal

notch, but its wall seemed to be unusually hard to the touch. There was good pulsation in the abdominal aorta and in all the arteries of the lower limbs. The dorsalis pedis was visibly throbbing. Several small tortuous and pulsatile arteries were also visible over the abdominal and chest walls.

It was obviously impossible to record the blood pressure in the upper limbs. Over the popliteal arteries it was 220/75 mm. Hg. The patient had a temperature of 99.8° F. (37.7° C.) and his pulse rate was 120 a minute. The extremities were warm. The patient was co-operative and was talking intelligently.

On further interrogation he denied any history of severe trauma on the chest. He had never suffered from chest pain or paralytic attacks and firmly denied a past history of syphilis.

Fluoroscopy in the out-patient department showed patchy opacities scattered in both lung fields. The heart size appeared to be within normal limits. The aorta was unfolded and extensively calcified.

Treatment with penicillin and oxygen was immediately started, but the patient died suddenly, rather unexpectedly, within a few hours before complete investigation could be made. The leucocytes numbered 10,600 per c.mm., with 82% neutrophils, and the blood Wassermann reaction was negative. A skiagram taken immediately after death confirmed the fluoroscopic findings. The patient obviously died as a result of bronchopneumonia.

Necropsy Findings

Only a limited post-mortem examination was allowed, and the arch of the aorta with about 1 inch (2.5 cm.) of each of its branches could be removed. A piece of the adjacent part of the right lung was also taken out.

The aortic arch was of cartilaginous consistency and cracked under pressure. When split open its walls were found to be plastered with innumerable calcific plaques, and a big greyish-white friable clot about 5 by 1.5 cm. was found

attached to its upper wall, completely occluding the mouths of all three branches. Less than about two-thirds of the diameter of the arch was patent (see Fig.). There was no aneurysmal dilatation of the arch.

The left common carotid artery was flattened in the antero-posterior direction and its cross-section was oval in shape. The cut ends of both the left common carotid and subclavian arteries were found occluded with a firm greyish-white mass which could not be removed from their lumina. The whole length of both these arteries felt like solid cord. The distal ends of the right common carotid and subclavian arteries were, however, patent, although the innominate artery would not admit a probe. When cut across, the latter was also found stuffed with a firm clot.

Histology.—Examination of sections of the aorta revealed gross atheromatous changes in all stages of development. There were large areas of ulceration and calcification. No cellular infiltration was found in the media or adventitia. The lumen of the left common carotid artery was filled with a mass of connective tissue which was continuous at places with the proliferating cells of the subintimal layer. In the left subclavian artery there was a loose connective-tissue mass with numerous intercommunicating capillaries and scattered areas of fibrous-tissue formation. A similar picture of recanalizing thrombus was found in the lumen of the innominate artery. No pathological change was evident in the walls of any of these arteries. The section of the lung showed areas of consolidation with surrounding emphysema suggestive of a bronchopneumonic lesion.

Discussion

The interesting presenting features in this patient were the absence of pulsation in all the arteries arising from the aortic arch and a high systolic blood pressure in the vigorously pulsatile arteries of the lower limbs, together with evidence of collateral circulation over the abdominal and chest walls. This resembles the clinical syndrome of coarctation of the aorta upside down, and we have preferred to call it a reverse coarctation syndrome. The term "reverse coarctation" has been criticized because the lesion here is not congenital (Barker and Edwards, 1955). This critical consideration does not apply when we mean a clinical complex only. We are, however, conscious that the particular syndrome under consideration has been already described under a large number of inadequate terms, and we may be responsible for suggesting another which is essentially descriptive and not nosological.

Obliteration of pulsation of all the arteries arising from the arch of the aorta is not an uncommon feature of aortic arch syndrome. It was present in 29 of the 40 best-documented cases discussed by Ross and McKusick (1953). Thrombosis occurring independently in any of these arteries, due to primary pathological conditions in their walls, can produce loss of pulsation in individual arteries. One or other of them may also, on rare occasions, be the site of embolic occlusion. In such cases the term "aortic arch syndrome" seems inappropriate. When all the branches of the aortic arch are obliterated the pathological lesion almost invariably involves the aortic arch itself, and there should not be any hesitation in calling it an aortic arch syndrome. The main symptoms

The main symptoms due to loss of cerebral blood supply such as vertigo occurred in 25, syncope in 15, hemiparesis and hemiplegia in 13, and convulsion in 8 of the 40 cases referred to. In our patient there was only a history of occasional vertigo, which was never very severe. His intelligence and memory seemed fairly good. Facial hemiatrophy and atrophy of facial bones with perforation of the nasal septum have been described as trophic changes due to diminished circulation in the face (Harbitz, 1926; Marinesco and Kreindler, 1936). In our patient, sunken eyes and cheeks may indicate atrophy of retro-orbital tissue and facial muscles. But such an appearance is not very uncommon in some otherwise normal persons. Poorly healing infections of face and scalp and premature cataract have also been reported (Ross and McKusick, 1953). The patient had a healed hypopyon ulcer in his right eye. He also had

JAN. 19, 1957

REVERSE COARCTATION SYNDROME

BRITISH MEDICAL JOURNAL 139

bilateral cataract, which is by no means uncommon at his age. It is, however, possible that reduced blood supply and age were complementary factors in the opacification of the lenses. Ophthalmoscopic assessment of the condition of retinal blood vessels was not possible in the presence of the cataracts.

A rather intriguing point is how the cerebral blood supply was maintained. Obviously the supply through the left common carotid artery was completely cut off. Although the right common carotid was patent it was not in communication with the main current of aortic blood, since the innominate artery was totally occluded. There was no expansile pulsation in it. We may be justified in assuming that the process of occlusion was slow enough to allow collateral channels to open up adequately through whatever communication was available. The only other arteries that can carry sufficient blood to the brain are the vertebrals. The left subclavian artery was completely occluded as far as it could be removed. Whether the thrombus extended and involved the left vertebral artery is unfortunately not known. The lumen of the right subclavian artery was patent. It seems reasonable to conclude, in spite of the small material evidence, that anastomotic channels were established between the intercostals, internal mammary, and lateral thoracic arteries which fed the right subclavian, common carotid, and vertebral arteries.

The presence of tortuous pulsatile arteries on the chest wall evidently lends further support to such a conclusion. From the existence of similar arteries on the abdominal wall it appears that these collaterals were also reinforced with a supply from the external iliac and femoral arteries. While this can also explain the circulation in the right upper limb, it is not easy to suggest any possible channel of supply to the left, which was also apparently well nourished and warm. It would certainly be interesting to know if the left vertebral artery, and the subclavian artery beyond it, were patent.

The popliteal blood pressure was recorded with a standard arm cuff, and due allowance for this should be made. But the high pulse pressure is striking. It is probably a common expression of the extensive collateral anastomosis and atherosclerosis.

Unfortunately a complete post-mortem examination was not possible. In compliance with the sentiments of the patient's relations we were obliged to content ourselves with removing only the aortic arch with the proximal parts of its branches and a small piece of the right lung. From the clinical and fluoroscopic findings it was thought that the mouths of the three branches were blocked with atheromatous lesions, which are known to occur predominantly around the ostia of aortic branches. The necropsy findings of the big ante-mortem thrombus were very much unexpected. Thrombus formation in an aneurysmal sac is not very uncommon. But in its absence it is surprising how such a big clot can form in the arch where the turbulence of blood is very great indeed. Ross and McKusick (1953) found only three examples in 44 patients, and in all of them the thrombus was in syphilitic aneurysmal sacs.

In our case the histological picture of an atheroma of the aorta was unmistakable. Primary atheroma of the aortic arch is rare. Ross and McKusick think that trauma may play some part in the pathogenesis of atheroma in the arch. Our patient gave no history of physical violence on the chest, at least of any severe degree which he could remember. Atheromatous changes can occur on pre-existing syphilitic aortitis. There were no pathological changes suggestive of aortitis. There were no pathological changes suggestive of such a lesion in the media and adventitia. Furthermore, there was no history of syphilis and the blood Wassermann reaction was negative. The only abnormality found in the left subclavian, left common carotid, and innominate arteries was the presence in them of organizing and recanalizing thrombi. There was absolutely no pathological lesion in their walls. It may naturally be concluded that the primary atheromatous ulcer on the wall of the aortic arch helped in the formation of the thrombus which gradually increased in size and extended into all the three branches of the arch of the aorta.

Summary

A case of aortic arch syndrome characterized by absence of pulsation in all the arteries of the upper limbs and neck, with high systolic blood pressure in the vigorously pulsatile arteries of the lower limbs and evidence of collateral circulation on the abdominal and chest walls, is described. From its resemblance to the clinical syndrome of coarctation of the aorta it has been called reverse coarctation syndrome. The patient died as a result of associated bronchopneumonia.

The patient had very few symptoms and physical signs referable to impaired blood supply to the head and neck and to the upper limbs. The possible collateral channel of supply is discussed.

Only a limited necropsy study was possible. There was extensive atheroma with calcification in the wall of the aortic arch. The upper third of its lumen was occupied by an ante-mortem thrombus which extended into and completely obliterated the lumina of the innominate artery, and the left common carotid and subclavian arteries as far as they could be removed. The right common carotid and subclavian arteries were patent. Histologically, organizing and recanalizing thrombi were found in the occluded arteries. Except atheroma in the wall of the aortic arch no other pathological lesion was found in the walls of any of the arteries.

We are grateful to Dr. M. N. Sarkar, superintendent, Calcutta National Medical College Hospital, and to Dr. J. C. Saha for permission to publish this case. We thank Professor A. C. Guha, Professor S. N. De, and Dr. Shyamal Sen for their help in the pathological studies; and Dr. Amal Ghosal and Dr. Subhas Mukherjee for their valuable assistance in the study of the case.

INTERMITTENT HYDRARTHROSIS

BY

S. MATTINGLY, M.B., M.R.C.P., D.Phys.Med.
*Late Senior Registrar, Department of Physical Medicine
and Rheumatism, the Middlesex Hospital*

"Of periodicity in disease, no more striking example can be quoted than the recurrent effusion into joints, with little or no febrile disturbance or local signs of inflammation, which goes by the name of intermittent hydrarthrosis."

Garrod (1910).

Intermittent hydrarthrosis is a condition of unknown aetiology characterized by transient joint effusions which recur at regular intervals; one or both knee-joints are usually affected, but occasionally other joints such as the hip, ankle, or elbow are involved (Ragan, 1949). The periodicity of the effusions was first noted in 1852 by C. H. Moore (1864), a surgeon at the Middlesex Hospital.

The onset is often sudden, the effusion lasting two to six days and recurring in cycles of 7 to 11 days, though extremes of 3 and 30 days have been reported. The duration of joint swelling and the length of each cycle

are remarkably constant in any one patient, although they may vary from time to time. If more than one joint is affected the effusions do not always coincide, but the cycle for each joint remains constant (Garrod, 1910; Bierring, 1921; Baker, 1929). When one joint ceases to swell another may become involved.

Both sexes are affected equally, usually between the ages of 20 and 50, although May and Robin (1947) and Ragan (1953) believe intermittent hydrarthrosis to be most common in young women with onset at or after puberty. The age of onset and sex incidence of 101 cases reported in the literature does not support this view (Fig. 1).

Once established, intermittent hydrarthrosis may persist indefinitely, but is subject to spontaneous remissions and relapses which make assessment of treatment difficult. Although uncommon, it is probably not so rare as the literature would suggest, for fewer than 180 cases have been described. The following case reports may therefore be of interest.

Case 1

A housewife first noticed that her right knee was painful and swollen in April, 1950, at the age of 41. The swelling disappeared after a few days, only to reappear five days later, and thereafter the knee swelled at intervals of 9–13 days for a year. The swelling developed gradually, reaching its maximum in two to three days, and disappeared after five to six days. There was no history of previous injury, arthritis, or venereal disease, and the patient had never lived abroad. The effusions were not related to menstruation (Fig. 2).

In May, 1950, one month after the onset of the effusions, the patient developed an irritant rash over the lower trunk and thighs, thought to be true lichen planus; this persisted for over six months despite treatment with antihistamines, penicillin, vitamins, and local applications.

The patient remained in good health, and subsequent examinations revealed no abnormality except periodic effusions in the right knee-joint, accompanied at times by transient pitting oedema of the legs. There were no local signs of inflammation, and disability was not severe, though the patient felt unable to take up part-time domestic work.

The results of investigations, which included radiographs of the knee, haemoglobin estimation, white-cell count, erythrocyte sedimentation rate, and estimation of plasma proteins, were normal.

Treatment with pressure bandages, quadriceps exercises, antihistamines, autohaemotherapy, and penicillin was ineffective. In April, 1951, a course of gold injections was started, and in June, 1951, the patient reported that the knee had swollen only twice following chrysotherapy. Sodium aurothiomalate was given, by intramuscular injection, in weekly doses of 0.05 g. After the patient had received 0.75 g., 0.05 g. was given monthly to a total of 1.35 g. Injections were discontinued in August, 1953, as the patient went out to work and could not attend the clinic.

There has recently been a recurrence of her intermittent hydrarthrosis after a remission lasting five years.

Case 2

A housewife first noticed a painless swelling of the right knee in 1941, at the age of 27, when she was awakened in the early hours of the morning by an air raid and the knee "gave way." After two weeks the swelling disappeared, but six weeks later the left knee became swollen. For the next two years she was troubled by pain and swelling of alternate knees at intervals of three to four weeks. A remission lasting one year followed appendicectomy for acute appendicitis in December, 1943. Intermittent joint effusions, affecting alternate knees at intervals of two weeks, then recurred, each effusion lasting about four days. A further remission, lasting 10 months, followed venous thrombosis of the left leg with subsequent pulmonary infarction in January, 1951. The effusions recurred in November, 1951, again affecting alternate knees at two-weeks intervals, and antihistamines appeared to diminish pain and swelling without affecting the periodicity of the effusions.

The patient was admitted to hospital in May, 1952. Her general condition was good and examination of the knee-joints revealed no abnormality. Results of investigations, including haemoglobin estimation, white-cell count, erythrocyte sedimentation rate, serum uric acid estimation, and examination of catheter specimen of urine were normal; Wassermann reaction, gonococcal complement-fixation test, and brucella agglutination test were negative; radiographs of chest and hands were normal, and radiographs of the right knee showed early degenerative changes only. A small effusion, which developed in the right knee-joint, was aspirated; it was sterile and contained endothelial cells and lymphocytes only. Neither bed rest nor a four-day course of corticotrophin by injection influenced the periodicity of the effusions.

In June, 1952, the patient was treated as an out-patient with radiotherapy. Treatment was given to four areas, 10 by 8 cm., on the medial and lateral aspects of the knee-joints, the total skin dose to each area amounting to 1,200 r. The effusion recurred only once after radiotherapy.

thyroid extracts (Pellet, 1946) and testosterone (Lièvre, 1947; Hiller 1952) are unconvincing.

There is no evidence that the condition is inherited, and a familial incidence has been reported only once before.

There have been few reports on pathological changes in the synovia. Ghormley and Deacon (1936) found slight thickening of the lining cells only. Krida (1933) performed a synovectomy during an acute attack; the synovial membrane was pale, pink, and thickened, and microscopy revealed hyperaemia, round-cell infiltration, and granulation tissue in the enlarged villi and subsynovial tissues. Similar findings were reported by Weiner and Ghormley (1956). Ragan (1953) also found changes indistinguishable from rheumatoid arthritis, although his patient had a normal erythrocyte sedimentation rate and a complete remission without significant joint changes. With one exception (Baker, 1929) the joint fluid has been sterile, but it may contain several thousand cells per cubic millimetre, with over 50% polymorphs (Collins, 1936). The hyaluronic acid in the synovial fluid of the cases seen by Ragan (1953) was normal, in contradistinction to the changes which occur in rheumatoid arthritis. In "idiopathic" intermittent hydrarthrosis the sedimentation rate, haemoglobin level, and white-cell count are normal; the Wassermann reaction and gonococcal complement-fixation and brucella agglutination tests are negative, as are blood cultures. When intermittent hydrarthrosis develops in a patient with a chronic rheumatoid type of arthritis the results of investigation are those usually found in that disease.

Although the characteristic feature of the condition is the periodicity of the effusions, the cycle of joint swellings is perhaps not so constant as May, Huet, and Barraud (1937) believe when they state that "at the beginning of the year the patients can mark on their calendars in advance the dates on which they will be indisposed." Garrod (1910) pointed out that when the effusions are charted for long periods the attacks are not so regular as they appear to be if only a few effusions are observed, and this was so in Case 1 (Fig. 2). In the idiopathic cases, signs of local inflammation such as heat, tenderness, and muscle spasm are lacking and there is no constitutional disturbance. Transient oedema of the legs, as in Case 1, was also noted by May and Robin (1947).

Spontaneous remissions frequently occur and may last 5-10 years, making assessment of treatment difficult. Relapses, for no apparent reason, are equally common and the condition may persist indefinitely. The great majority of cases reported in the literature have been followed up for less than three years. While some of the patients with "idiopathic" intermittent hydrarthrosis undoubtedly develop rheumatoid arthritis, there is no evidence that this is inevitable or a frequent occurrence. Cohen (1955) has even seen a patient whose attacks recurred for over 30 years without developing rheumatoid arthritis, and Ragan (1953) states the prognosis of these cases to be good with regard to eventual crippling, although attacks may continue without remission. None of the 47 patients described by Weiner and Ghormley (1956) developed rheumatoid arthritis.

Many of the early cases of intermittent hydrarthrosis were treated with quinine, for periodicity was thought to be synonymous with malaria. It rarely proved beneficial, and other treatments equally unsuccessful included tonsillectomy, autohaemotherapy, histamine desensitization, and the administration of arsenic, mercury, ovarian extracts, stilboestrol, chorionic gonadotrophin, antihistamines, and cinchophen; injections of adrenaline, calcium gluconate, and "para-thormone" proved useless. Bed rest, ice packs, mud baths, splints, and exercises have been ineffective.

Exclusion diets, following skin tests for allergens, were credited with remissions by Berger (1939) and Miller (1949), but the latter failed to help a further case, and Epstein and Edeiken (1940) were also disappointed. Weismann-Netter (1929, 1937) claimed success with ergotamine tartrate by injection and by mouth respectively. The period of follow-up in both cases was short, and the first patient had a severe

reaction to treatment. Perhaps more convincing is the report of a case treated by Cook (1937): a man of 43, with a 15-year history of intermittent hydrarthrosis, remained in remission for three years following a prolonged course of ergotamine tartrate, 1 mg. daily by mouth. Ragan (1949) and Railliet (1938) were less successful, and most authors stress the dangers of long-term administration of this drug.

Temporary remissions have been produced by intravenous T.A.B. vaccine, but Cohen (1955) emphasizes the danger of a severe reaction; a generalized arthritis may result.

Gold injections have not previously been advocated in the treatment of intermittent hydrarthrosis, which is surprising, as they have been found to benefit patients with palindromic rheumatism (Boland and Headley, 1949) and patients with an episodic or palindromic type of rheumatoid arthritis. The remission reported in Case 1 lasted more than five years, and this result is encouraging enough to suggest a further trial of chrysotherapy.

There are few reports on the use of steroids in treatment. Steinberg (1955) found oral cortisone, 25 mg. t.i.d., was ineffective, and intra-articular hydrocortisone, whilst having a temporary effect, may aggravate the condition. A short course of corticotrophin by injection failed to prevent the onset of an attack in Case 2.

Few patients have received chemotherapy. Case 1 had two courses of intramuscular "distaquine" (300,000 units daily for five days, and 600,000 units daily for 20 days) for minor skin sepsis complicating lichen planus, without affecting the effusions. Intra-articular injection of antibiotics has not been reported and might be more effective than systemic administration.

Temporary remissions have resulted from radiotherapy (May, Huet, and Barraud, 1937; Epstein and Edeiken, 1940; Ragan, 1953), but patients were followed up for less than two years, and Ragan (1949), Lièvre (1947), and Railliet (1938) found radiotherapy ineffective. Case 2 has now had a remission lasting four years following radiotherapy, and, whilst it is too early to decide that the remission is complete, the patient remains very grateful.

Synovectomy has been recommended, but Krida (1933) followed up his two cases for only a year, and Key (1940) gives no details of cases so treated. Ragan (1949) found that, while synovectomy prevented recurrence of effusions in a knee-joint for over five years, the operation was followed within a few months by recurrent effusions in both elbow- and hip-joints. Weiner and Ghormley (1956) found synovectomy was effective in a few patients, but noted recurrence of the effusions after an interval of one to two years in several joints.

Summary and Conclusions

Intermittent hydrarthrosis is characterized by periodic joint effusions, usually affecting one or both knee-joints.

The cause is not known. Some patients develop rheumatoid arthritis.

Spontaneous remissions and relapses are common and make assessment of prognosis and treatment difficult.

Three cases are described; in two, remissions were apparently induced by chrysotherapy and radiotherapy.

Intermittent hydrarthrosis may be an unusual variant of rheumatoid arthritis, but permanent joint damage is not inevitable. It could, however, be a syndrome accompanying various joint disorders, the periodicity of the effusions being related to normal but exaggerated cyclical changes in the tissues of the patient.

Treatment is, of necessity, empirical and usually ineffective; radiotherapy, chrysotherapy, and synovectomy may induce at least a temporary remission.

I am indebted to Dr. A. C. Boyle, of the Middlesex Hospital, for his help with this paper and permission to publish details of Cases 2 and 3, and to Dr. H. A. Burt, of University College Hospital, for permission to report Case 1.

ACUTE SCHÖNLEIN-HENOCH PURPURA TREATED WITH PREDNISOLONE

REPORT OF A CASE

BY

ALAN S. COHEN, A.B., M.D.

Lately Registrar in Medicine, Dundee Royal Infirmary,
Dundee

Schönlein-Henoch purpura is a disease associated with an increased permeability of the capillary endothelium permitting the passage of blood cells and plasma (Win-trobe, 1946). The specific aetiology is not clear (Davis, 1948), although evidence points to a hypersensitivity to an antigen which may be bacterial or non-bacterial (Gairdner, 1948; Jensen, 1955). Prognosis is dependent upon whether or not severe renal damage is caused (Ackroyd, 1953). Until recently it was generally believed that no medication had a favourable effect on the natural course of the disease (Davis, 1948; Gairdner, 1948). When the adrenal and pituitary steroids were found to exert favourable responses in various allergic disorders, several investigators studied their effect on Schönlein-Henoch purpura. The results have been variable, but a symptomatic response has been observed in at least half of the reported series (Stefanini *et al.*, 1950; Levinson *et al.*, 1951; Adamson *et al.*, 1953; Leese, 1955). It was therefore of interest to observe the effect on the course of the disease of prednisolone. Stefanini and Martino (1956) stated that this drug had caused striking remissions in two cases of the acute variety of Schönlein-Henoch purpura.

The following is a report of a typical case of this disease complicated by severe and progressive renal involvement. The downhill course was apparently unaffected by cortisone, but was dramatically reversed by prednisolone.

Case Report

A 10-year-old schoolgirl was transferred to the Dundee Royal Infirmary because of purpuric eruption and rectal bleeding. She apparently had been in excellent health until three and a half weeks previously, at which time she had an abrasion of her knee requiring no specific treatment. The following day she had had an uneventful dental extraction. Four days later she complained of abdominal discomfort and vomiting. Her family doctor found she had a fever and gave her 500,000 units of penicillin. Her symptoms continued, and, as she was also suspected of having tonsillitis, she was admitted to a fever hospital one week after the onset of her illness. At that time physical examination was negative except for enlarged tonsils. Her white count, sedimentation rate, haemoglobin, urinalysis, and chest x-ray films were all within normal limits.

Within several days of admission, however, scattered haemorrhagic spots appeared over her arms. These soon spread to involve her back, buttocks (see Fig. 1), and lower extremities. Two days after the appearance of the rash, gross blood was observed in her stools. She also complained of stiffness in her right knee and both shoulders and elbows, though no redness, swelling, or tenderness was noted in these areas. The following day she had pain in the joints

FIG. 1.—Haemorrhagic eruption on buttocks of a 10-year-old girl with Schönlein-Henoch purpura; second week of illness.

of the left hand and a small effusion was found over the dorsum. New crops of haemorrhagic spots were constantly appearing. Albuminuria occurred, and one week after the appearance of the bloody stools fresh blood was found in her urine. A diagnosis of anaphylactoid, or Schönlein-Henoch, purpura was therefore made, and the patient was transferred to the Royal Infirmary approximately three and a half weeks after the initial onset of her symptoms.

At this time she was an acutely ill, pale girl complaining of colicky abdominal pain, which came in spasms that lasted from five to ten minutes. A haemorrhagic eruption was present over buttocks, abdomen, and extremities; the face was clear. The rash varied from fresh spots to faded areas. Examination of heart and lungs was negative. Blood pressure was 130/80. Abdominal examination showed no enlargement of liver or spleen, and though some tenderness was present the abdomen was soft throughout. Neurological examination was negative. Joints were normal. Laboratory studies showed: haemoglobin, 8.8 g. per 100 ml.; white blood cell count, 16,000 per c.mm.; E.S.R., 35 mm. in 1 hour; blood urea, 20 mg. per 100 ml.; cholesterol, 120 mg. per 100 ml.; serum bilirubin 4 mg. per 100 ml.; while the serum sodium, potassium, chloride, and carbon-dioxide-combining power were all within normal limits. The platelet count was 851,000 per c.mm. The antistreptolysin titre (drawn four weeks after admission) was within normal limits. X-ray films of chest and abdomen and electrocardiograms were

FIG. 2.—Summary of pertinent clinical and laboratory findings and of treatment.

within normal limits. No organisms were found in blood cultures or throat swab. The stools were grossly bloody. The urine had albumin and red-blood cells but no casts.

After four days' observation the patient was treated with cortisone, 200 mg. the first day, 100 mg. the second day, and 50 mg. for five subsequent days. Despite this medication, abdominal pain persisted and new crops of haemorrhagic spots appeared. There were no changes in the character of the stool or urine. There was a slight rise in the diastolic blood pressure, but serum electrolytes were unchanged. On the seventh day of treatment the patient sustained for the first time in her life two grand-mal epileptic seizures, which left her with a transient paralysis on her left side for twelve hours. Cortisone was then discontinued and phenobarbitone given (which medication was continued for the remainder of her stay in hospital).

Several days later, owing to the persistence of all symptoms, a test dose (15 mg. daily) of prednisolone was given for three days. She underwent a prompt symptomatic improvement and became alert, co-operative, and cheerful for the first time during her admission. On the third day of this treatment a decrease in the bleeding into the bowel and urinary tract was noted. At this time, however, periorbital oedema appeared, although blood pressure, serum electrolytes, and blood urea were unchanged. Treatment was again stopped.

The patient continued to deteriorate, and by the next week hyaline and red blood cell casts were found in her urine. It was decided that in view of her previous response to a small dose of prednisolone she should be given a definitive course of therapy, and this was started two months after the onset of her original illness. She received 40 mg. of prednisolone for three days, 30 mg. for the next two days, 25 mg. for four days, and then was maintained on 15 mg. until she was

asymptomatic and showed laboratory evidence of improvement (a period of eleven days). The dosage of the drug was then further decreased in 5-mg. steps and finally omitted altogether.

The subjective response to treatment was marked. The patient again became cheerful and co-operative, her appetite improved, and the abdominal discomfort disappeared. Objectively, she showed no further evidence of skin eruption, the casts and then the red cells disappeared from the urine, and the blood from the stools. The only residuum was the mild but persistent albuminuria. She was discharged home ten days after the cessation of prednisolone therapy. A follow-up one month later showed no blood in the urine or stools and no rash. Her blood pressure, blood urea nitrogen, and electrolytes were normal, but a trace of albumin was still present. She had been fully active.

A summary of the pertinent findings in the clinical course is shown in Fig. 2.

Summary

A case of Schönlein-Henoch purpura treated with apparent success with prednisolone is presented. Clearly, in a disorder so prone to spontaneous remission, caution is necessary in the interpretation of treatment. However, the patient did not respond to cortisone but did give evidence of response first to a small dose and subsequently to larger doses of prednisolone. The dramatic remission is in accord with the few other reported cases so treated (Stefanini and Martino, 1956). Only a long-term follow-up will determine whether the patient has sustained permanent renal impairment.

I thank Professor Ian G. W. Hill and Dr. Kenneth G. Lowe for their aid in the management of this case and for permission to report it; and Dr. Thomas English and Sister McLee for their help in collecting the clinical data.

A brief review of current research in the U.S.A. on injuries to occupants of motor-cars in road accidents has been written by H. J. H. Starkes, Ph.D., and published by the Department of Scientific and Industrial Research (*Research on Injuries Sustained in Road Accidents*, H.M.S.O., 2s.). In the U.S.A. about three-quarters of all people killed on the roads are occupants of motor-vehicles, whereas the corresponding figure in Britain is about one-sixth; consequently the American data may be of rather indirect relevance to British problems, derived as they are from motor-cars and roads that differ appreciably from those over here. For instance, the doors of American motor-cars contribute notably to the death rate by bursting open in crashes and allowing the occupants to be ejected; this doubles the risk of serious injury or death.

TREATMENT OF MONILIAL VAGINITIS

A CLINICAL TRIAL OF NYSTATIN

BY

R. F. JENNISON, M.D., M.R.C.P.

Clinical Pathologist

AND

J. D. LLYWELYN-JONES, M.B., M.R.C.O.G.

Resident Surgical Officer

St. Mary's Hospitals for Women and Children, United Manchester Hospitals, Manchester, 13

Since the preparation of the antifungal antibiotic nystatin from *Streptomyces noursei* by Hazen and Brown in 1950, there have been reports of its use in the prevention of experimental infections with candida (monilia) in animals (Brown, Hazen, and Mason, 1953; Drouhet, 1955a) and also in the treatment and prevention of infections in humans, especially in patients undergoing treatment with the broad-spectrum antibiotics such as the tetracyclines (Drouhet, 1955b; Sarewitz, 1955; Childs, 1956; Stewart, 1956). The successful treatment of patients with primary infections with candida have been reported by Sloane (1955), Robinson (1955), and Stewart (1956). Recently vaginal pessaries containing nystatin became available, and we report here the treatment with these pessaries of 53 patients suffering from vaginal candida infections, and in order to assess the value of this treatment the results obtained are compared with those in 36 patients treated with gentian violet.

Clinical Investigation

We included in this investigation only those women who were complaining of a vaginal discharge and/or irritation, and who were found to have candida infection bacteriologically. Two positive cultures were obtained from most patients—one on the first attendance at the clinic and one immediately before the first treatment. The women were divided into two comparable groups—one group to be treated with nystatin, and the other with a 1% aqueous solution of gentian violet. All patients were seen by one of us (J. D. L.J.) and all had the typical lesions associated with candida infection. Anyone who had an associated trichomonal vaginitis was excluded.

Initially, treatment was carried out on three alternate days, on each occasion the vagina being inspected with a speculum for lesions before its commencement. Treatment consisted in the insertion of two pessaries containing 100,000 units of nystatin or, in the control group, in painting out the vagina with a 1% aqueous solution of gentian violet.

All patients were asked to attend one week after the completion of the treatment, when the vagina was inspected for lesions and a swab taken for bacteriological examination. In the case of a negative swab being obtained, the patients were asked to attend one month later for a final examination. If candida was still present on either occasion, treatment was continued for a further week, and a swab taken a week after completion, as before. Most of the patients in the gentian-violet series who did not respond after one week were transferred to the nystatin series, together with six women in whom gentian violet caused a severe local reaction necessitating termination of treatment. There were no adverse local reactions to nystatin.

Bacteriological Examination

All the swabs were inoculated on to blood agar and Littman's medium; smears were also examined microscopically. The Littman's plate was incubated for three to five

days before a negative report was given. All the strains of *Candida* isolated were subcultured on to corn-meal agar, so that the identification of *C. albicans* by chlamydospore formation could be made. Four strains not producing chlamydospores were further examined. Their fermentation reactions resembled *C. krusei*, but their morphological appearance was not typical. Sensitivity tests were carried out on all strains by serial dilution in broth and by blotting-paper disks (Jennison and Stenton, to be published). The average minimal inhibiting concentration at 48 hours in the broth was 3.6 µg. per ml. (2,800 units=1,000 µg.). No evidence of the development of resistance appeared in this series.

Results

In Table I the bacteriological findings after treatment with nystatin are compared with those obtained in the control group treated with gentian violet. The number of patients

TABLE I.—Comparison of Bacteriological Findings One Week After Treatment with Gentian Violet and Nystatin

	Gentian Violet			Nystatin		
	No. Treated	Candida		No. Treated	Candida	
		Present	Absent		Present	Absent
Pregnant ..	13	9	4	16	5	11
			($\chi^2=2.8$, $0.1 > P > 0.05$)			
Non-pregnant	23	10	13	19	0	19
			($\chi^2=7.3$, $P < 0.01$)			
Total ..	36	19	17	35	5	30
			($\chi^2=10.0$, $P < 0.01$)			

who were bacteriologically free from infection one week after the cessation of treatment was significantly higher in the nystatin series. Some of the patients from whom candida was grown after treatment were in fact free from symptoms, and no lesions could be seen on clinical examination. Three of the failures with nystatin were in pregnant women who were delivered before a second course could be given; the other two were re-treated, one being cured. Four of the failures with gentian violet were re-treated with gentian violet with no effect.

TABLE II.—Effect of Treatment with Nystatin on Patients not Cured by Gentian Violet

	No. Treated	Candida	
		Present	Absent
Pregnant ..	6	0	6
Non-pregnant	12	4	8

TABLE III.—Total Number of Patients Treated with Nystatin, Including Five after Second Course

	No. Treated	Cured	
		No.	%
Pregnant ..	22	18	82
Non-pregnant	31	29	93
Total ..	53	47	88

Table II shows the effect of treatment with nystatin on patients who failed to respond to or who had a reaction with gentian violet. All the latter group were cured by one course of nystatin. Three of the four failures were re-treated, with a successful result in two.

The results in all 53 women treated with nystatin are shown in Table III. A notable feature of this treatment has been the large number of patients who stated that their symptoms were relieved after the first day of treatment. The number of patients cured refers only to those who were bacteriologically negative one week after the cessation of treatment and does not include some patients who, although clinically cured, still harbour candida organisms.

All the patients apparently cured after one week were asked to attend four weeks later for reassessment. Some of

the patients had been delivered, but 11 out of a possible 16 of the gentian-violet series and 34 out of 47 of the nystatin series did attend, and the relapse rates are shown in Table IV. Three of the women who had been treated with nystatin were seen by colleagues at about the appropriate time and were free from obvious infection.

TABLE IV.—Relapse Rate in Patients Seen Four Weeks After Cessation of Treatment

	Gentian Violet			Nystatin		
	No. of Patients	Candida Present	Relapse Rate	No. of Patients	Candida Present	Relapse Rate
Pregnant	2	2	100%	14	4	29%
Non-pregnant	9	3	33%	20	3	15%
Total	11	5	46%	34	7	21%

Discussion

Although the patients treated with nystatin had only a short course of treatment the results have proved to be most promising and distinctly better than those in the patients treated with gentian violet in a comparable scheme. Moreover, treatment with the nystatin pessaries is much simpler and does not have the disadvantage of staining linen, etc., as does gentian violet. The insertion of the pessaries could be easily done by the patient, thus saving much time for the patient and for the nursing and medical staffs. Also, as nystatin acts mainly on fungi and yeasts and has very little effect on bacteria, it means that there is much less interference with the normal flora than is the case with gentian-violet treatment.

Relapses, which are probably reinfections, are less frequent after nystatin than after gentian violet. It has been shown that oral nystatin greatly reduces the yeast population of the intestinal tract (Sternberg *et al.*, 1953), and it may be that combined oral and local treatment may clear the more persistent or recurrent infections. Sarewitz (1955) reported five cases of genito-urinary infection with candida which were improved or cured by oral therapy. We have treated one patient with oral tablets alone (500,000 units thrice daily for one week) with an excellent result, there being no symptoms and the culture being negative after six weeks. However, as there is no good evidence that high blood levels can be obtained by oral therapy it is unlikely that better results would accrue from this method alone. In fact, Childs (1956) has noted that systemic treatment had little or no effect on the numbers of candida organisms in the sputum and throat. Stewart (1956) and Childs (1956) reported nausea as a side-effect of oral nystatin, and our patients also complained of nausea with some abdominal pain.

Summary

Of 53 women with monilial vaginitis treated with a new vaginal pessary containing 100,000 units of nystatin, 47 (88%) were free from infection one week after treatment, whereas of 36 treated with gentian violet, only 17 (47%) were cured.

Out of a group of 18 who had not responded to gentian violet, 16 were cleared with nystatin.

In the patients seen four weeks after treatment the relapse rate was 46% in those treated with gentian violet and 21% in those treated with nystatin.

No side-effects or local discomfort has occurred with nystatin, whereas six of the women treated with gentian violet had a reaction which made it necessary to stop treatment.

One patient was treated with oral nystatin only, with an apparent cure.

We thank the obstetric and gynaecological staff of St. Mary's Hospitals for permission to treat their patients, and in particular Dr. E. A. Gerrard and Professor W. I. C. Morris for help in the planning of the investigation. Mr. Peter Stenton carried out

a large proportion of the bacteriological investigations, and Messrs. Squibb and Son supplied the nystatin preparations.

THE BREATH IN ACUTE LEUKAEMIA

BY

E. K. BLACKBURN, M.D., F.R.F.P.S.

Consultant Haematologist, the Royal Infirmary and Hospital, Sheffield

It is well known that a fetid breath may be found in patients with leukaemia in association with lesions of the upper alimentary and/or respiratory tracts. These lesions may be gum hypertrophy, petechiae and ecchymoses, or oozing of blood, gingivitis and mucosal ulceration, and necrosis. The smell is presumed to arise from the bleeding and from secondary infection.

Over the last few years some patients have been seen in whom acute leukaemia was accompanied by a peculiar sweet odour of the breath resembling that of a freshly opened corpse, but not associated with clinical involvement of the gums, mouth, or upper respiratory or alimentary tract. As the smell of the breath was of assistance to me in the clinical diagnosis of some of these patients, the results are recorded of my findings from this aspect in 73 cases of leukaemia which presented in hospital practice. In each case the presence or absence of halitosis was confirmed by at least one other medically qualified observer.

The 73 cases comprised 51 cases of acute leukaemia (34 myeloblastic, 15 monoblastic, 2 erythro-leukaemic) and 22 cases of the chronic group (11 granulocytic, 11 lymphocytic).

Results

Of 51 cases of acute leukaemia, 12 (9 myeloblastic, 3 monoblastic) had the characteristic halitosis without obvious clinical involvement of the mouth or respiratory and alimentary tracts (see Table). In six of these (Cases 5-10)

Blood Picture in the 12 Cases of Acute Leukaemia with Characteristic Halitosis

Case No.	Sex	Age in Years	Type of Leukaemia	Hb (%)	Total W.B.C./c.mm.	Blast Cells/c.mm.
1	M	17½	Myeloblastic	82	3,000	1,230
2	F	49	"	70	4,000	1,040
3	M	71	"	58	1,000	520
4	M	24	"	35	4,000	2,000
5	M	18	"	40	200,000	198,000
6	M	29	"	88	5,000	600
7	M	41	"	47	23,000	12,420
8	M	9	"	35	13,000	9,880
9	F	46	"	45	5,000	550
10	M	28	Monoblastic	48	24,000	2,880
11	M	68	"	63	45,000	14,950
12	F	44	"	47	80,000	12,000

there were other signs and symptoms such as splenomegaly, etc., which suggested the true diagnosis. Clinical examination of the remaining six patients (Cases 1-4, 11, and 12) helped very little, for they had no sternal tenderness, haemorrhagic lesions, hepato-splenomegaly, or lymphadenopathy, and it was only after examination of the blood and bone marrow that a firm diagnosis could be made. One patient (Case 1) had had an appendicectomy followed by

treatment for suspected paratyphoid fever during the six weeks before admission to the Royal Infirmary, Sheffield, while another (Case 2) had shown features of erythema multiforme. Case 3, a medical practitioner, had been admitted on the surgical side with pain in the right hypochondrium radiating to the back, upward flatulence, distaste for fatty foods, and a positive Murphy's sign. So far as the haemopoietic system was concerned, the only physical sign was mucosal pallor. Case 4 had complained of lethargy and had shown mucosal pallor only for two months. The fifth patient of this group (Case 11) had had progressive loss of energy, dyspnoea on effort, flatulent dyspepsia, and pallor of the mucous membranes only for four months, while the sixth patient (Case 12) had had a six-weeks history of malaise and pallor only, with no other suggestive physical signs.

A further 26 of the cases of acute leukaemia (15 myeloblastic, 10 monoblastic, 1 erythro-leukaemic) had the well-known fetid breath associated with a variety of intra-oral leukaemic lesions. In addition, five of these patients had epistaxis, one haemoptysis, three melaena, and two haematemesis plus melaena.

The remaining 13 cases of acute leukaemia (10 myeloblastic, 2 monoblastic, 1 erythro-leukaemic) had no halitosis at all. Five of these patients had oral petechial haemorrhages, and, in addition, one had nasal petechiae with epistaxis.

None of the 11 cases of chronic lymphatic leukaemia had halitosis, and only one had oral lesions consisting of slightly swollen gums. Ten of the 11 cases of chronic myeloid leukaemia had neither halitosis nor upper respiratory or alimentary lesions. The other case had a fetid breath. This patient had, however, bled excessively into the gut and the abdomen following partial gastrectomy for a large chronic gastric ulcer five days previously, and had received repeated blood transfusions. His tongue was tender and enlarged, the surface being dry, cracked, and yellowish red in colour.

Discussion

In 6 out of 73 cases of leukaemia, the peculiar sweet-smelling breath was of value in reaching a tentative diagnosis of acute leukaemia after clinical examination only. So far as I am aware, this physical sign has not been described previously in its present context. This may well be due to the fact that halitosis is usually associated with obvious lesions in the upper respiratory and/or alimentary tract, and/or with abnormal physical signs elsewhere suggesting the diagnosis.

The abnormal breath at present under discussion does not appear to be related to enlargement of the liver, spleen, or lymph nodes, to the haemoglobin level, to the total leucocyte count, or to the blast-cell count (see Table). A sweet, slightly faecal odour likened to the smell of mice or to a freshly opened corpse has been described in hepatic failure (Sherlock, 1955), but in none of the present cases was there clinical evidence of such a state. Recent work has shown that, in both man and animals, the lung plays an active part in the removal (from blood and organs) and release (to blood and organs) of leucocytes and platelets under various stimuli (Bierman, 1955). The mechanisms whereby these changes are induced remain to be clarified. They may possibly play a part in the halitosis, but this is only conjecture. Finally, the odour in the above six cases may have been due to lesions in the alimentary and/or respiratory tract which were not found on ordinary clinical examination.

Summary

A physical sign is described consisting of a peculiar sweet odour of the breath found in relation to 73 cases of leukaemia (51 acute, 22 chronic). It was present in 12 of the cases of acute leukaemia without obvious clinical involvement of the gums, mouth, or upper respiratory and alimentary tracts. In six of these cases there

were signs and symptoms, such as splenomegaly, to suggest the true diagnosis, while ordinary clinical examination of the other six cases, halitosis apart, was unrewarding, and it was only after examination of the blood and bone marrow that a firm diagnosis could be made. Possible sources of the halitosis are discussed.

I am indebted to my medical and surgical colleagues in the United Sheffield Hospitals and in the Sheffield Regional Hospital Board area for referring their cases, and to the medical staffs who have confirmed the observations. I also thank Dr. H. T. Swan for reading the manuscript.

Medical Memoranda

Congenital Absence of Spleen Associated with Cardiac Abnormalities

Polhemus and Schafer (1952) described four cases of congenital absence of the spleen associated with gross cardiac abnormalities and reviewed the literature up to that time. Since then Ivemark (1955), Gasser and Willi (1952), Bush and Ainger (1955), Polhemus and Schafer (1955), and Nihoyannopoulos *et al.* (1956) have reported further cases. Bush and Ainger lay emphasis on the unusual peripheral blood picture which may be found in this condition—namely, normoblastaemia, reticulocytosis, leucocytosis, Howell-Jolly bodies, and a decreased osmotic fragility.

Details of a further case are given below. I have been unable to trace any previous report of this condition occurring in an infant born in Britain.

CASE REPORT

A male child was admitted to hospital 48 hours after birth because of an imperforate anus and possible upper intestinal obstruction. The mother's pregnancy and labour had been normal. The birth weight was 5 lb. 1 oz. (2.3 kg.). The two previous pregnancies had resulted in one miscarriage and one living healthy child.

On admission the infant's general condition was good. There was no cyanosis or dyspnoea. A precordial systolic murmur was detected at this time, but, despite repeated auscultation, was not heard again for 10 weeks. The abdomen was not distended, but there was a tight anal stenosis, probing of which produced a small amount of meconium. The anus was dilated and gave no further trouble. Straight x-ray examination of the abdomen showed gas shadows only as far as the duodenum. A laparotomy was therefore performed by Mr. A. Jolleys under general anaesthesia. An atresia of the third and fourth parts of the duodenum was found. The continuity of the lumen was restored by anastomosing the blind ends.

Progress was uneventful for the next 12 days, when the infant started passing loose green stools which became increasingly offensive. These were at first thought to be "starvation stools" because of the small feeds the child was taking, but the loose stools persisted when normal feeds were taken. The blood count at this time showed a haemoglobin of 96%. The total nucleated cell count was 19,000 per c.mm., with polymorphs 27%, lymphocytes 22%, monocytes 9%, eosinophils 2%, late normoblasts 40%. The reticulocyte count was 30%. In an attempt to account for the normoblastaemia the osmotic fragility of red cells was investigated and a slight decrease of fragility was found, 50% of cells being still present at a dilution of 0.36%, the indirect Coombs test was negative, and the urine contained no bilirubin or excess of urobilin.

When the infant was 5 weeks old, cyanosis appeared and gradually increased in intensity. In view of the absence of

a heart murmur at this stage the blood was examined for sulphhaemoglobin and methaemoglobin, with negative results. However, a systolic murmur was again heard at the age of 10 weeks, and soon after a precordial thrill also developed and the child became increasingly dyspnoeic. E.C.G. was within normal limits except for the presence of slight left axis deviation and a suggestion of left ventricular hypertrophy in the precordial leads. Radiological examination of the chest showed some widening of the upper mediastinum with a slightly globular heart shadow. The lung fields were clear. The diarrhoea, which had persisted throughout, now became profuse, and death occurred from uncontrollable dehydration at the age of 13 weeks.

At the post-mortem examination a bilocular heart was found with the aorta and pulmonary artery arising in the correct relationship from the common ventricle. The aortic arch was right-sided and the pulmonary artery was hypoplastic. On each side a superior vena cava and two pulmonary veins entered the common auricle. Each lung possessed three lobes. There was a complete absence of spleen and splenic tissue. The stomach was represented by a thick-walled widening of the gut embedded in the liver. The pancreas consisted of a small round mass of tissue.

COMMENT

In such cases as this the diagnosis of splenic agenesis might be suspected during life from the unusual blood picture and the presence of cyanotic heart disease.

I am indebted to Dr. G. M. Komrower and Mr. A. Jolleys for permission to report this case; to Dr. H. B. Marsden for the post-mortem findings; and to Dr. Komrower for his encouragement and advice.

Polyneuritis Caused by Antirabic Vaccination

Polyneuritis is one of the neuroparalytic complications of antirabic vaccination. The incidence of neurological complications during prophylactic treatment seems to vary widely, having been reported as 0.017% (Greenwood, 1945), 1.3% (Babés, 1912), and in India about 1 in 8,500 cases, or 0.012% (Ahuja and Brooks, 1951). The sexes are affected equally, but the extremes of age are generally immune. In my series of 2,455 patients receiving antirabic vaccination from August, 1954, to July, 1955, neurological complications occurred in five (0.2%), two of whom developed polyneuritis.

The pathogenesis of polyneuritis is controversial. Van Rooyen and Rhodes (1948) suggest that antibodies develop to the brain tissue, and that an antigen-antibody reaction occurs in the perivascular tissues, giving rise to inflammation and degeneration of the vessel wall.

With regard to its pathology, both mesodermal and parenchymatous toxo-degenerative lesions characterize the palsy. Either of these may occupy the foreground; they may also coexist, yet not develop in the same parts of the tissues.

The incubation period is between the tenth and fifteenth days from the first prophylactic dose of vaccination, with a limit of five weeks, the period being shorter than the incubation period of the disease itself, and dependent not on the interval elapsing after the bite but on the treatment.

Among the different forms of neurological complication—consisting of acute ascending paralysis of the Landry type; dorso-lumbar myelitis; cranial neuritis; polyneuritis; and meningo-encephalitis—dorso-lumbar myelitis is the commonest and polyneuritis is the rarest. The rarity of the latter condition warrants this report.

CASE 1

A Hindu peon aged 37 was admitted to the J.A. Group of Hospitals, Gwalior, complaining of weakness in all his limbs of three days' duration. The onset was gradual. As he had been bitten by a rabid dog, a course of antirabic vaccination (5 ml. for 14 days) was given. Three days after the last injection he felt weakness in all limbs, which gradually worsened. There was nothing significant in his personal and family histories. On examination there was lower motor neurone paralysis of the limbs, with severe weakness, loss of all tendon-jerks except the supinator, and tenderness of the calf muscles. There were no other subjective or objective sensory disturbances and no evidence of myelitis. Other systems were normal, and he had full sphincteric control during his illness. Laboratory investigations revealed no abnormality in any system.

He was treated in hospital for nearly four months with vitamins B₁ (100 mg.) and B₁₂ (100 µg.) parenterally on alternate days. For the first two months the condition deteriorated, and there was wasting of the distal muscles of the limbs. Subsequently he improved slowly. When he was discharged from hospital the limb weakness, loss of all tendon-jerks except the supinators, and the wasting of the distal muscles persisted, though there was slight improvement. At the time of writing he could walk about, but had very little power in his hand muscles.

CASE 2

A Hindu office superintendent aged 42 was admitted into the J.A. Group of Hospitals, Gwalior, having had pain and weakness in all limbs for 10 days. The onset was gradual, with fever. Two days after being bitten by a rabid dog he was put on a course of antirabic vaccination (5 ml. each dose). Following the seventh injection he had slight fever and felt weakness in his limbs. After an interval of four days two more injections were given. As the weakness increased the injections were stopped, and he was admitted to hospital. There was nothing significant in his family history. At the age of 15 he had received 14 injections (each 5 ml.) of antirabic vaccine after being bitten by a rabid dog. On examination there was lower motor neurone paralysis of all limbs, with marked weakness, complete loss of tendon-jerks except the supinators, and no muscle wasting. The calf muscles were tender. There were no other subjective or objective sensory disturbances and no signs of myelitis. Other systems were normal and sphincteric control was retained throughout. Laboratory investigations revealed no abnormality in any system.

He was treated with vitamins B₁ (100 mg.) and B₁₂ (100 µg.) parenterally on alternate days. About two weeks later there were signs of improvement. He gradually recovered after six weeks. After two months in hospital he was discharged with a fair degree of power in all limbs, loss of all tendon-jerks except the supinators, ability to write but inability to type, and no tenderness in the calf muscles.

COMMENT

The first case showed poor improvement even after four months, while the second case improved very well within six weeks. The difference in the degree of improvement could possibly be due to the difference in the amount of vaccine being injected. The persistence of the supinator-jerks, when all the other tendon-jerks were completely lost, was interesting. Sensory disturbances in both cases were very slight.

SUBARACHNOID HAEMORRHAGE

Subarachnoid Haemorrhage. By John N. Walton, M.D., M.R.C.P. Foreword by Sir Charles Symonds, K.B.E., C.B., D.M., F.R.C.P. (Pp. 350+xv; illustrated. 30s.) Edinburgh and London: E. and S. Livingstone Ltd. 1956.

Dr. Walton has based his monograph on the study of case reports of over 300 instances of spontaneous subarachnoid haemorrhage in Newcastle upon Tyne. He has, however, used all the more important published series of cases and isolated case reports to present as detailed and balanced a record of the disorder as is possible to-day. The work is a model of semeiological accuracy, in which the special difficulties which he has had to overcome are reflected in the fact that in over two-thirds of the Newcastle series the cause of the subarachnoid haemorrhage is unknown. That is really the justification for his researches into the literature, for this state reflects the situation as it was in the immediate past, whilst now, when every case should be fully investigated as soon as is safe and practicable, the causal lesion is more likely to be revealed in life.

The time of publication of this book is particularly opportune, for the immediate management of subarachnoid haemorrhage is a topic for formal and informal discussion in many centres, and most of the discussants need more facts upon aspects of the subject other than their own. All the facts seem to be here presented logically and without personal bias in interpretation, though with an occasional tilt at some who seem to have a little. The use of personal research and comment in this way enlivens a factual survey which might otherwise have become tedious.

It is useful to have the detailed supporting evidence for the statement: "A ruptured aneurysm is likely to be present in about 80% of cases of subarachnoid haemorrhage. In about another 10% angiomas may be demonstrated. The remaining 10% will be made up partly by cases in which it will be possible to attribute the bleeding to the many uncommon causes discussed hitherto." It is also valuable to read the evidence for the statement that "recurrent bleeding is most likely to occur in the 2nd and 3rd weeks" after the first haemorrhage, for this must be the guide to immediate management. It is equally important to see how selected have been some of the groups of patients upon which previous opinions are based.

The contemporary interest in the techniques of diagnosis of vascular disease and its medical and surgical treatment makes more than formal notice unnecessary. Great credit is due to Dr. Walton's industrious compilation, but that credit must also be extended to the multitude of workers whose observations he has documented and so faithfully integrated.

DENIS WILLIAMS.

ADVANCES IN PHARMACOLOGY

Recent Advances in Pharmacology. By J. M. Robson, M.D., D.Sc., F.R.S.E., and C. A. Keele, M.D., F.R.C.P. Second edition. (Pp. 501+xii; illustrated. 40s.) London: J. and A. Churchill Ltd. 1956.

The decision of Professor Robson and Professor Keele to combine in writing a book on *Recent Advances in Pharmacology* was fortunate for the first edition, and imperative for their second edition, which has recently appeared. The subject has grown and now covers the whole of experimental medicine in so far as that is concerned with the action of chemical substances. The reader will find in this second edition, which is to all intents a new book, discussions covering fields as varied as (1) that centring around noradrenaline; (2) the treatment of hypotension; (3) histamine and hydroxytryptamine; (4) the pituitary and adrenal cortex; (5) newer antibiotics; (6) the chemotherapy of tuberculosis; (7) nucleotoxic drugs; (8) radiation hazards; (9) haemopoietic substances; and (10) anticoagulant drugs. There

are other chapters also. Great care has been taken to deal with recent advances in all these fields, and there is no doubt that the book is of the greatest value, not only to students of pharmacology, but to all teachers of clinical medicine. Few things would do more to enrich clinical teaching in this country than a careful study of this book.

The subject-matter does not, however, become easier as years go by. Increasingly a knowledge of chemistry is required if a grasp of the advancing subject is to be maintained; increasingly, also, some idea of the action of cell membranes and of electrophysiological terminology; and now, as the analysis of cerebral processes becomes more detailed, a closer acquaintance with neuro-anatomy. We need to consider afresh the training of those who are to teach medicine in the future. That they should have spent a year in studying physiology at an honours level has till now been regarded as the essential element. Physiology is, however, now too narrow, and chemistry, biochemistry, anatomy, and pharmacology are also required. Let those who need convincing read this most valuable book.

J. H. BURN.

DISORDERS OF MENSTRUATION

The Management of Menstrual Disorders. By C. Frederic Fluhmann, B.A., M.D., C.M. (Pp. 350+xii; illustrated. 59s. 6d.) Philadelphia and London: W. B. Saunders Company. 1956.

This is a new book, and not a second edition of one on the same subject published by Dr. Fluhmann in 1936. Those to whom the title suggests another addition to the numerous accounts of sex hormone therapy by an over-optimistic enthusiast can take heart. It is nothing of the kind. The author obviously adopts the view that the proper management of menstrual disorders rests essentially on understanding them. He therefore devotes most of the work to a clear account of the function as well as the dysfunction of the ovaries and the uterus, and on allied matters such as puberty and the menopause. The hormones are there, of course, and so is endocrine therapy, but the latter is given its proper restricted and rational place. Empiricism is banned. The amount of information in this small book is quite remarkable; moreover, it is mostly factual, and any concepts not fully proved are clearly indicated with a summary of the evidence for and against. There are also many excellent photomicrographs. A critical sifting of the literature to reach a reasonable conclusion is apparent throughout, and the whole represents a masterly yet concise statement of the latest knowledge. This is introduced by an interesting and helpful review of the main historical steps which have led from the myths of the past to the reasonable certainties of the present, and by an explanation of the origin of some of the "old wives' tales" which still persist. The book is intended for undergraduates, but contains enough to satisfy the gynaecologist in practice or in training who needs an honest and logical account of these matters. It is highly commended.

T. N. A. JEFFCOATE.

Now that the laboratory has taken the place of the botanic garden as the prime source of materia medica, the study of botany has of necessity been relegated to a small and remote corner of the medical curriculum. But those medical men who in their spare time pursue this delectable science as a hobby—and doctors' names are usually prominent in the membership of natural history societies—those enthusiasts, in particular, who study the British wild flora will find Miss Stella Ross-Craig's *Drawings of British Plants* a fine aid to their pursuits. Part 9, concluding the Rosaceae and containing 39 plates, has now appeared (G. Bell and Sons, 8s. 6d.). Each plate depicts in a line drawing one species, showing the plant in natural size and some of its parts enlarged. With unique artistry Miss Ross-Craig has succeeded in portraying the plants in a manner that is at once beautiful, informative, and exact, and the superb quality of the drawings already published has everywhere evoked the highest praise. This is one of those rare works that deserve the name of masterpiece.

SATURDAY JANUARY 19 1957

ANTIBIOTICS GALORE

With the discovery of valuable new antibiotics at intervals of one or two years it has become progressively more difficult for the clinician to keep himself informed about the properties and uses of the drugs available to him. These intervals have now shortened, and the pace of increasing complexity in this subject has accelerated sharply during the past few months—indeed, in such a way as to cause positive bewilderment in many minds. Are these new antibiotics really new, and have they advantages over those available before? These questions cannot be fully answered, but the following appraisal may help to view these drugs in the right perspective.

This recently accelerated pace of discovery has produced a series of antibiotics all of which have a range of activity similar to that of penicillin: the species most sensitive to them are streptococci, pneumococci, staphylococci and other Gram-positive organisms, together with the feebler and more delicate Gram-negative genera, *Neisseria* and *Haemophilus*. Penicillin will therefore do most of what any of the new antibiotics will do unless the strain of organism is resistant to it (a problem almost confined to staphylococci) or the patient is sensitive. Only two of these antibiotics are genuinely and entirely new in the sense of being unrelated to any others. Of these vancomycin is not yet generally available in Britain, and is unlikely in its present form to be very widely used, since the only possible route of administration at present is intravenous. Its advantages are that very little bacterial resistance to it develops and that it is bactericidal. Its successful clinical use in severe staphylococcal infections is reported from the Mayo

Clinic¹: one of the patients, treated for acute endocarditis, had intravenous injections at 6-hour intervals for 3 weeks, then at 8-hour intervals for 4 days, and finally at 12-hour intervals for 3 days, totalling 102 injections in four weeks, a remarkable feat and perhaps a record. The other genuinely new antibiotic is novobiocin (known also as "albamycin" and by other names) on the value of which there are now several clinical reports.² It attains higher concentrations in the blood than any other antibiotic, perhaps in part because very little is excreted in the urine: for this reason the usefulness claimed for it in urinary infections is very doubtful. Bacterial resistance to it is acquired rather readily.

The other new drugs to be mentioned are all related in some way to erythromycin, and a question which will have to be answered is whether they possess any advantages over this well-tried and established antibiotic. At present there is very little indication that they do: indeed, in terms of such activity as can easily be measured they seem somewhat inferior. Spiramycin is the oldest of these,³ but has only recently appeared on the English market under the trade name "rovamycin." Against most bacteria it has only a fraction of the activity of erythromycin—one-sixteenth or less against staphylococci in the tests reported in this *Journal* by L. P. Garrod and P. M. Waterworth.⁴ Cross-resistance studies by these authors and others showed a close relationship with erythromycin, although there is some suggestion that this relationship may not obtain in strains found initially resistant instead of being artificially habituated in the laboratory,⁵ and one observation is claimed to have shown actual antagonism between them.⁶ This question clearly calls for further investigation, if the therapeutic properties of spiramycin are thought to make it worth while.

The other newcomer is oleandomycin, an agreeable name of obscure derivation for a substance originally described⁷ from the Pfizer Laboratories under the designation PA 105. This substance seems to have lain fallow for a time, perhaps because the preliminary view may have been that oleandomycin was too closely related to erythromycin, as well as somewhat inferior to it in antibacterial activity, to constitute a valuable discovery. That it exhibits cross-resistance with erythromycin is clear from the observations of H. E. Noyes *et al.*,⁸ who also credit it with an anti-staphylococcal activity *in vitro* which appears somewhat less than that of erythromycin. G. M. Needham and J. E. Geraci,⁹ on the other hand, found complete cross-resistance only in artificially habituated strains, a majority of initially erythromycin-resistant staphylo-

cocci being sensitive to oleandomycin. Cross-resistance with both erythromycin and carbomycin is also reported by B. Furst *et al.*,¹⁰ who nevertheless argue that oleandomycin is a distinct entity. It is said to be less toxic than erythromycin (as measured by the effects of very large doses in animals) and to display minor differences in therapeutic activity in mice: it is non-toxic to man in therapeutic doses. This paper is from the laboratories of Hoffmann-La Roche, who are now marketing oleandomycin as "romicil." There are two Swiss reports on its clinical use. A. Bernstein and M. Piller¹¹ report effects such as would be expected from any efficient drug of this class in bacterial pneumonia and acute streptococcal angina, more variable results in urinary tract infections, and failure in two cases of staphylococcal empyema (the organisms becoming resistant) and in one of osteomyelitis. A. F. Esselier and J. Keith¹² are far more sweeping in their claims: apart from acute and self-limited infections due to susceptible bacteria, they report successful treatment of staphylococcal sepsis including osteomyelitis, two cases of endocarditis lenta, influenza, ornithosis and Q fever, cholecystitis, appendicitis, diverticulitis, infectious mononucleosis, leptospirosis, and inoculation hepatitis. Further clinical study is evidently necessary before such findings can be accepted.

The other form in which oleandomycin has now appeared on our market is as a 1:2 mixture with tetracycline, under the name "sigmamycin" (Pfizer), the first product to be advertised—against a background of what seem to be perishing staphylococci—as having a two-dimensional "spectrum." The advertised claims made for this product rest on some clinical reports to the Fourth Antibiotics Symposium in Washington which are not yet in print, and on a single paper from the Pfizer laboratories by A. R. English, T. J. McBride, G. van Halsema, and M. Carlozzi.¹³ These authors' studies show that this combination of antibiotics obstructs the acquisition of resistance to either, which is to be expected, and that it is synergic, which is not so much in accordance with theoretical expectation. *In vitro* tests actually show a more than twofold difference between the activity of the mixture and that of either of its components on only 9 strains of staphylococci out of 22. Therapeutic tests in mice compared the action of a given dose of the mixture with that of the amount of each component contained in that dose: it would have been a fairer comparison to have given the same dose by weight of all three.

Before it can be accepted that this mixture has marked advantages much more work will evidently

have to be done. Further studies might include an inquiry into the combined action of tetracycline and erythromycin, a mixture which it has been open to anyone to use for some time past. The final task of assessing the relative clinical value of such closely similar products in even the commoner infections will daunt the most enterprising investigator. If antibiotics continue to be discovered which are merely first cousins or half-brothers of those already in use, to distinguish clearly between their merits will cease to be possible.

VOLUNTARY MUSCLES

That so much should have been learnt about the physiology of the voluntary muscles and so little about the disorders to which they are subject is at first sight a contrast so striking as to be almost paradoxical. Yet the explanation is probably simple. The physiologist has naturally been primarily concerned with how the muscle functions; how the impulse from the brain results in the contraction not only of the muscle fibre but of the individual protein molecules ultimately responsible for the contraction. His interest has been shaded by biochemists and biophysicists, and together they have displayed an ingenuity and achieved results unsurpassed in any other aspect of physiology. Our knowledge in this field has been admirably reviewed in a recent number of the *British Medical Bulletin*. It makes fascinating reading, but shows none the less the possibility, if not probability, that most of what has been learnt about the physiology of muscle, and much too of its biochemistry, is not directly relevant to the fundamental biochemical defect underlying human muscle dystrophy. The essential clue probably lies not so much in the mechanism of contraction as in those less well understood processes concerned with the synthesis, maintenance, and repair of the muscle protein and membrane. The nutritional approach to the study of experimental muscular dystrophy has indeed shed some light on this aspect of muscle biochemistry, and has been of undoubted value in studying the dystrophies occurring in animals. However, despite the histological similarities, the human disease is in some way fundamentally different, and at the moment it seems impossible to apply the knowledge

gained in animals to the cure of the human dystrophies.

But it would be absurd to suppose that the basic sciences have not helped to extend our knowledge of some, at least, of the disorders of muscle. Two obvious examples are those of myasthenia gravis and the paralysis associated with a low level of potassium in the extracellular fluid. In neither instance is the underlying cause of the paralysis fully understood, but such facts as are known can be interpreted only in the light of what is known of the physiology of neuromuscular conduction. Here there is a wealth of information.¹ The muscle membrane at rest is in a state of polarization, having a potential difference of 90 mV between the inner and outer surface. This is caused by the large individual differences in the concentration of certain ions, especially potassium, on either side of the membrane. A specialized region of the membrane, the motor end plate, lies in intimate apposition to the motor nerve endings. A nerve impulse reaching the nerve ending releases acetylcholine, which, on diffusing across to receptors on the end plate, has the property of inducing a local depolarization before being split by choline esterase. The area of depolarization results in a flow of current in the adjoining polarized membrane which, in turn, becomes depolarized. A. L. Hodgkin² has shown that this local current causes a transient increase in permeability of the membrane to sodium ions, which is limited to the region of depolarization. The sodium ions flow inwards through the membrane and thus regeneratively reinforce the initial potential change. Another local current results, and in this way a wave of depolarization travels along the muscle fibre, repolarization being effected by an initial outward flow of potassium ions, by the active extrusion of sodium from the cell, and by an inward movement of potassium. It is these propagated changes in membrane potential that constitute the muscle action potential. How it causes contraction of the muscle is not definitely known, but A. F. Huxley,³ with the ingenuity which is a feature of much of the work on muscle physiology, has shown that the initiation of contraction is in some way related to the I band. He believes that most probably "activation" of the muscle fibrils is conducted along the Z membrane, which can be convincingly shown by interference- and electron-microscopy to bisect the I band.

Recent work on myasthenia gravis has confirmed the widely held view that the essential defect is concerned with the chemical transmission of the nerve impulses at the motor end plate. H. C. Churchill-Davidson and A. T. Richardson⁴ have put forward the suggestion that the defect lies in an alteration of the

response of the motor end plate to acetylcholine, brought about by the persistence on the receptor protein of acetylcholine itself, or of a breakdown product, in an inactive form. They reached this conclusion largely by comparing the different effects of intravenous decamethonium in normal subjects and in patients with myasthenia, and considering these against the results of Zaimis⁵ in different species of animals. D. Grob, R. J. Johns, and A. McG. Harvey,⁶ as the result of detailed observations on the effects of intra-arterially injected acetylcholine, choline, D-tubocurarine, and anticholinesterases, do not regard the response of the myasthenic end plate to acetylcholine as abnormal. On the other hand they confirm the abnormal response in myasthenia to decamethonium, and find in addition that the predominant action of injected choline on myasthenic muscle, like that of decamethonium, is to produce a competitive type of block rather than the depolarizing type, which is the main action of these compounds in normal subjects. This holds true even for those muscles that clinically are unaffected. Two explanations are offered: either the end plate responds abnormally to these compounds, or else these compounds are themselves converted at the myoneural junction into competitive blocking agents. The position is further complicated by the suggestion that the block is not always of a competitive type; this type of block does not respond to neostigmine, and, if present, would explain the partial response and the danger of overdosage sometimes encountered in severe cases. These observations have also a direct bearing on the mode of action of the neuromuscular blocking agents now commonly used by anaesthetists, which have in recent weeks been the subject of a voluminous correspondence in this *Journal* (see annotation at p. 153).

The nature of the paralysis associated with the low serum potassium encountered in familial periodic paralysis and in severe potassium depletion still remains a subject for conjecture. The most plausible hypothesis is that it is analogous to the paralysis resulting from anodal stimulation of the motor end plate—that is, caused by a hyperpolarization of the end plate raising the electrical threshold to excitation. In one, the hyperpolarization is due to the anodal current, in the other to the marked increase in the ratio of potassium concentration on either side of the membrane. But whether the resting membrane potential is in fact raised has yet to be shown by applying the intracellular electrode technique to the study of human disease. This technique would also be of help in testing the theories advanced⁷ to explain the abnormal shift of potassium into the cells that initiates an attack of familial periodic paralysis.

NEOSTIGMINE-RESISTANT CURARIZATION

During the last few weeks a large number of letters in this *Journal* have focused attention on an apparently new condition—namely, neostigmine-resistant curarization. The contributors have expressed widely different views, and the subject is cloaked in some confusion. At the outset Dr. A. R. Hunter described six cases, all of them elderly and seriously ill patients, who failed to respond adequately to neostigmine after the previous administration of an anti-depolarizing myoneural blocking agent.¹ Since then many other authors have added to the total. In nearly every case cited the patient has died from circulatory failure some hours after operation, and the impression may have been created that D-tubocurarine or one of its substitutes was probably responsible. But the question must be asked: Is the evidence so far available sufficient to justify this assumption? This question is an important one, for the muscle relaxants represent the greatest advance in modern anaesthesia and it would be a pity to turn back the clock on a false assumption. On the other hand, to disregard informative clues is equally culpable.

From the data presented it appears that the risk is greatest in a particular type of case—for example, a seriously ill and elderly patient with abdominal distension after ileus or obstruction. It would be true to say that the post-operative mortality of these cases has always been high, and in the "good old days of ether" many patients were found at the end of operation to be breathing inadequately with severe tracheal tug. Recent advances in the recognition of low-blood-volume states and electrolyte imbalance in these patients have gone a long way towards reducing mortality. The distended bowel has always been a problem for both anaesthetist and surgeon, so that the temptation to try to produce just a little more relaxation is always present; yet these patients require hardly any anaesthesia, since their reflex activity is severely depressed by their toxic state.

Three theories have been propounded to account for the possible failure of neostigmine to reverse the neuromuscular block in these cases. First, that inadequate ventilation during the operation leads to an accumulation of carbon dioxide, with resultant damage to the respiratory centre. Secondly, that these patients may have a low intracellular potassium, which permits the relaxant drug to have a central depressant action on the brain. Thirdly, that the hypovolaemia and consequent low cardiac output are sufficient to prevent the neostigmine from being carried to the respiratory muscles. The last theory does not attract many supporters, and the small amount of evidence available suggests that this condition may occur irrespective of changes in the level of intracellular potassium. Whether this condition is central or peripheral is not known and it might be shown later that neostigmine had in fact reversed the neuromuscular block at the motor end-plate despite the inadequate respiratory movements. The part played by carbon dioxide at the neuromuscular junction has still to be elucidated. It is known that excessive dosage of

neostigmine in cases of myasthenia gravis can produce a neuromuscular block. It would therefore seem unwise to give large doses of this drug unless the intravenous injection of a short-acting anticholinesterase shows that some improvement in muscle power may be expected. One of the most difficult matters to explain is why these patients should die of circulatory failure if D-tubocurarine is the primary cause. Many sufferers from tetanus and poliomyelitis supply convincing proof that patients can be kept completely paralysed for many days by means of this drug without suffering any harm provided their lungs are adequately ventilated. Clearly more clinical data are needed before we can reach a conclusion. In the meantime anaesthetists who have to face this problem will be keenly aware of its dangers.

CONGENITAL ABSENCE OF SPLEEN

Congenital absence of the spleen is a rare anomaly. In a recent review of the literature W. G. J. Putschar and W. C. Manion¹ found 78 reported cases. As an isolated anomaly it is usually discovered in adults unexpectedly at operation or necropsy, but most cases are seen in young subjects, because associated developmental abnormalities are apt to shorten life. The most frequent of these are cardiac malformations and partial situs inversus of abdominal organs. These were present, separately or together, in 49 of the cases reviewed by Putschar and Manion. The cardiac anomalies are various and often complex. The commonest single defect seems to be ostium atrioventriculare commune. Especially in association with partial situs inversus, atrial septal defects and anomalies of distribution of the great veins are usual. Dissections of the vascular system in some cases have revealed abnormalities in the distribution of branches of the coeliac axis and mesenteric arteries, and anomalous connexions between the portal and pulmonary veins. Symmetrical lobation of the liver and lungs is often found. Dr. D. E. M. Plowman describes a case with some of these abnormalities at p. 148 in this issue of the *Journal*, and a further case in a 2-months-old girl has recently been reported.²

The origin of splenic agenesis and of all the commonly associated anomalies can be dated between the fifth and seventh week of foetal life. Putschar and Manion point out that the spleen is the only strictly unilateral organ in the body, and postulate that this asymmetrical development requires a special vascular or chemical stimulus. Several of the accompanying anomalies—symmetrical lobation of the liver and lungs, and situs inversus—are also regarded as disturbances in the development of "laterality," thus suggesting a reason for the frequent association. The vascular anomalies are explained as representing persistence of an embryonic vascular pattern, which may be due to absence of the splenic anlage or of the splenic vessels, or may be the cause of splenic agenesis.

⁴ Rowley, D. A., *J. Immunol.*, 1950, 64, 289.

⁵ Gasser, C., and Willi, H., *Helv. paediat. Acta*, 1952, 7, 369.

⁶ Hunter, A. R., *British Medical Journal*, 1956, 2, 919.

The effect of absence of the spleen in otherwise normal subjects is doubtful. R. M. Myerson and W. A. Koelle³ recently reported the case of a man of 36 who had frequent infections and recurrent episodes of Waterhouse-Friderichsen syndrome, in one of which he died with pneumonia and bilateral adrenal haemorrhage. The authors suggest that this history may indicate a lack of immune response owing to absence of the spleen. It is believed that the spleen plays a part in antibody production, and D. A. Rowley⁴ has detected a failure of antibody response to intravenously administered antigen in splenectomized human beings. The available evidence, however, is too slender to support a general conclusion that subjects with splenic agenesis are unusually susceptible to infection.

A possible means by which splenic agenesis may be diagnosed during life is provided by the discovery by C. Gasser and H. Willi⁵ that Heinz bodies may be found in 10% or more of the erythrocytes of infants with congenital absence of the spleen. Confirmation of this interesting observation, and its extension to older subjects, must await future investigation.

PAROXYSMAL IDIOPATHIC MYOGLOBINURIA

Among the various causes of myoglobinuria is the paroxysmal idiopathic disease in which muscle pigment is excreted in the urine in association with attacks of muscular pain and weakness. During severe attacks fever, vomiting, and circulatory collapse may occur, but after three to five days recovery is usually complete. Anuria may be a complication and is probably due to circulatory collapse. Various factors precipitate attacks in susceptible subjects; most common are exertion and cold, and occasionally infections. Although there is often a familial incidence, no definite genetic pattern has been found. L. R. Reiner and colleagues⁶ have recently reported two cases of this condition and reviewed the literature; only about 21 cases seem to have been documented. The condition has to be distinguished from other causes of myoglobinuria. These include crush injuries, electric shock, infarction of muscle, and rarely carbon monoxide poisoning. Myoglobinuria has also been described in association with dermatomyositis and muscular dystrophy, and it occurs in another rare disorder which has been reported in Germany and Sweden after eating fish caught in certain estuaries, Haff disease. Conditions likely to be confused in the diagnosis are those associated with haemoglobinuria and porphyria, but spectroscopy of the pigment gives certain differentiation. Idiopathic myoglobinuria may easily be confused with march haemoglobinuria, but the latter is usually painless.

It is improbable that myoglobin escapes from muscle cells in the absence of necrosis, and most reported cases in which biopsy specimens have been taken have shown

this change. Reiner and colleagues maintain that the microscopical changes differ from those of muscular dystrophy, a condition that may be simulated by the wasting that sometimes follows attacks of idiopathic myoglobinuria. M. C. Berenbaum and colleagues⁷ have suggested that the muscle pigment might be abnormal by analogy with abnormal haemoglobins, but T. A. J. Prankerd⁸ has investigated the electrophoretic properties of myoglobin and found no abnormality of the pigment in this disease. On the other hand, W. Dameshek and colleagues⁹ suggested that the abnormality might lie in the muscle membrane. There is a striking similarity between this disease and a disease of horses in which these animals are afflicted with pain and myoglobinuria when exercised after a period of rest on a high-carbohydrate diet. After a cab strike in Paris early this century large numbers of animals were affected on resuming normal work. B. Carlström¹⁰ has studied this condition and found raised levels of lactic acid in the blood during the attacks; he suggested that sudden liberation of lactic acid without normal dilatation of capillaries might lead to muscle necrosis. However, in man raised levels of lactic acid have not been detected. In spite of this it seems that the disease may be a manifestation of abnormal chemistry in the muscle cell. No specific treatment has yet been found to avert the attacks apart from the avoidance of precipitating factors.

TWO NEW HUMAN GENES

Few of the characters for which men commonly vary, such as stature, intelligence, skin colour, and eye colour, are simply inherited. This contrasts with the number of rare diseases and malformations which are largely due to affected individuals being heterozygous or homozygous for a single mutant gene. Common variations that are known to be unifactorially inherited are mostly those for qualities of the blood, and include the blood-group antigen systems such as the ABO, Rh, MNSs, and Lewis groups, the secrete character,¹ and haptoglobulins.² In certain parts of Africa and Asia variant forms of haemoglobin such as S, C, D, and E, determined by single genes, are common.³ In addition, variations in the ability to taste phenylthiocarbamide and related substances depend largely on a single pair of alternative genes. Possibly, too, the disposition of the venous drainage of the anterior chest wall is simply inherited. Claims for the unifactorial inheritance of other qualities have been made, such as eye colour, tongue-rolling, and left-handedness, but in all of these inheritance is more complex.⁴

It is therefore interesting that A. C. Allison and K. G. McWhirter,⁵ of Oxford, have been able to put forward preliminary evidence of two new common variations that are dependent on a single pair of alternative genes. These are the characters of excreting a distinctive smell-

ing substance, methane-thiol, after eating asparagus, and of excreting an unidentified red or brown pigment in the urine after eating beetroot. Excretion of methane-thiol after ingesting asparagus appears to depend on a dominant gene, for which the name "As" is suggested. In four families in which both parents were non-excretors all eleven children were found to be non-excretors. In families in which the parents were excretors or of mixed type the children were also of both types in about the proportions expected from the estimated frequency of the gene controlling excretion and of its allele (0.23 and 0.77 respectively). The excretion of red or brown pigment after eating beetroot appears to depend on a recessive gene, for which the name "bt" is suggested. For this character all six children of three pairs of parents who were both excretors were also excretors, while the children in other families were mixed in the proportions expected on the estimated frequency of the gene controlling excretion and its allele (0.31 and 0.69 respectively).

Like the genes for the blood groups, these raise interesting problems in evolutionary theory. Both conditions are controlled by a pair of genes, each member of the pair being common in the population. On general evolutionary theory it would be expected that if, for example, the dominant gene for methane-thiol excretion conferred even a small selective disadvantage it would be rare, and kept from extinction only by recurring mutations. On the other hand, if it conferred some advantage the alternative gene for non-excretion would be rare. Two possibilities are that the heterozygote with one of each gene is fitter than either homozygote, or that each gene confers an advantage under different circumstances. Both the "As" and "bt" gene and their alleles probably have more important functions than those they serve with compounds derived from asparagus and beetroot.

VAGINITIS

An outstanding phenomenon in gynaecology since the war is the remarkable increase in the incidence of non-bacterial vaginitis. This is not an artifact of more accurate diagnosis, for the symptoms are all too obvious. The increase has been variously ascribed to malnutrition, dietary imbalance, avitaminosis, alkalosis, and psychological factors; but, whatever the cause, a condition hitherto infrequent is now a major problem in both general and specialist practice. In the great majority of cases the patient is infected with either *Candida albicans* or *Trichomonas vaginalis*, but the reaction of each to treatment is so distinct that their clinical differentiation is of essential importance. Fortunately this is a fairly easy matter. Monilial infection occurs mainly during the latter half of pregnancy, though it is also closely associated with diabetes, vitamin deficiency, poor hygiene, and antibiotic therapy. It is characterized by a discharge of the consistency of a thick paste and by greyish-white spots on the vagina. Microscopically *C. albicans* is found in profusion. Trichomonad vaginitis presents as a foul, greyish-white, frothy, watery discharge; the vulvo-vaginal irritation is equally great, but

the vagina is of a much brighter red than in moniliasis. Again the offending organism is easily identified microscopically.

The diagnosis, therefore, is relatively easy. Treatment, on the other hand, presents formidable problems. The extent of them may be gauged from the multiplicity of chemicals advocated in the recent flood of publications on the subject. They include mercurials (phenylmercuric acetate), detergents (sodium lauryl sulphate), antimycotics (oxyquinoline sulphate and compounds of caprylic, propionic, and ricinolinic acids), dyes (Bonney's and methylene blue), and antibiotics (tyrothricin, nystatin). The last in the form of a pessary is the subject of a clinical trial reported by Drs. R. F. Jennison and J. D. Llywelyn-Jones at p. 145 of the *Journal* this week. The difficulty with all these preparations lies not in finding an effective fungicide—for they are all initially potent—but in overcoming the drug resistance which the organisms acquire with such rapidity and persistence. Their primary sensitivity is indeed a chief obstacle to cure, for symptoms in early cases clear so rapidly on treatment with any of the standard preparations that it is usually discontinued far too soon, and the remaining organisms, now insensitive, multiply and produce further attacks with impunity. The solution to this problem of recurrence would appear to lie, therefore, not so much in the choice of any particular chemical as in its vigorous and prolonged application. Each case should be regarded as potentially recurrent and, after differentiation into its primary type, treated thoroughly long after the cessation of the symptoms. Resistance is best avoided by large dosage, and recurrence by frequent changes of drug. In candida infections it is probably best to begin with a ten-day course of 1% methylene blue pessaries, followed by chlorphenesin ("mycil") pessaries for ten days, with nystatin pessaries for a further fourteen days. The last should be reinforced at the same time by the oral preparation, and both should also be prescribed during the subsequent three menstrual periods. For trichomoniasis two pessaries of the stovarsol-acetarsol type are inserted twice daily for ten days, reinforced by an oral trichomonicide such as aminitrazole, both being repeated during subsequent menstrual periods. The vagina is later insufflated with silver picrate thrice weekly for three weeks, with intermediate lactic acid douching. The commonly accompanying vulvitis is treated with calamine cream or lead lotion, and later with a mild fungicidal ointment. It is a mistake to risk stronger preparations in this type of dermatitis.

These measures will be found effective for most patients, but some will present with recurrences in spite of intensive and repeated courses of treatment. The explanation in these cases may lie in reinfection from the partner, for, though candida is rarely found in the husband, trichomonads are present, according to G. Peel and colleagues,¹ in the semen of 50% of contact males. These workers have also shown that the cure rate is doubled when husband and wife are treated simultaneously.

PSYCHOTHERAPY AND THE GENERAL PRACTITIONER—I*

BY

MICHAEL BALINT, M.D., Ph.D., M.Sc.

Psychiatrist, The Tavistock Clinic, London

I wish to start with the fact that I have to talk to general practitioners about things that each of them does every day practically with every one of his patients; I who am not a general practitioner have, in fact, done very little general practice, and for a short time only, and—I think it is better to admit in advance—not even very well. I have therefore to discuss topics about which I know very little, with people who know them intimately from first-hand experience. And on top of this I intend to tell them, not that they should do their everyday work differently—that would be really foolhardy and impertinent—but that they should do it *with a difference*.

What I mean is this: what the general practitioner does, the act itself, should remain outwardly the same: talking patiently with the patients, listening to their complaints, using his well-proved diagnostic skill to find out what they really need from their doctor, and giving them something as near as possible to what they really need. The difference I have in mind should be an internal affair; it concerns what the general practitioner thinks and feels while he is doing his work.

To begin, I wish to prove that hospital medicine and general practice are not identical—in fact, they are greatly different. Still—I repeat here only common knowledge—what the future general practitioner is taught is exclusively hospital medicine, and only after he has started his practice has he any opportunity to learn, at his own peril and at that of his patients, what general practice really is. Thus it happens that in some way he is always rather ashamed of what he is doing; he feels that his real duty is to be a minor, or even a full-grown, hospital scientist, and consequently considers his own work as a general practitioner a kind of second best, which could and even should be done better—that is, according to the standards of hospital medicine—if only there were more time and more facilities available. And lastly, because of this general atmosphere he hardly ever dares draw upon his own experiences and state confidently what he really knows, for in his mind his knowledge is neither as valuable nor as reliable as that of the hospital scientists.

Certainly you will ask now, where have I got this knowledge? The answer is that for the last six years or so we in the Tavistock Clinic have organized research seminars in which general practitioners and psychiatrists discuss as equals psychological problems arising in general practice. All the material used in this address stems from this source.

The Real Field of Study

We have only time to discuss one patient. This will be a chronic case—the real field of study for the general practitioner. It is fair to say that if the time of observation is comparatively short—from a few weeks to a few months—the findings of scientific or hospital medicine are

*Read in the Section of Psychiatry at the Annual Meeting of the British Medical Association, Brighton, July, 1956.

valid and relevant; but if the time of observation is extended to several years, new factors emerge which profoundly change the picture. Whereas hospital medicine only rarely finds opportunity and musters staff and facilities for this long period of observation, this is part and parcel of the daily work of a well-established general practitioner. Our case will clearly show this difference. I quote this case as it was presented by Dr. B. at one of our recent seminars: the shorthand record has had to be abridged for publication, but is otherwise unchanged.

An Illustrative Case

"Mrs. D., aged 42, married. One daughter of 20. She was seen in April for the first time in our practice by Partner No. 1, who made a note that she had had an operation for twisted bowel five years ago and she had had constipation and pains for 20 years; he gave her 'normacol' and liquid paraffin. Then she saw Assistant, who added that Mrs. D. was 'highly strung; severe emotional overlay,' and gave her 'drinamyl.' She saw the same doctor nine days later, and he wrote, 'Much improved. Continue treatment.' A month later she saw Partner No. 2 and told him that a fortune-teller predicted that she would have a long life but her husband a short life. She had been weeping ever since. He put down, 'Anxiety state.' She saw him again three days later. She felt faint in the morning, legs were weak; he continued drinamyl.

"About a week or 10 days ago she was brought into the surgery as she had collapsed near by. Partner No. 1 saw her, dialled 999, and sent her off to hospital with diagnosis '2 over-dose.' She was discharged from hospital about an hour later.

"I saw her first in mid-June. She is small, slight, has very grey hair, rather pale complexion, a lot of lipstick, and she smokes excessively. Was very retarded, moved slowly, took a long time to say anything, and was on the verge of tears all the time. She told me she had had a very hard life, looking after her mother, her daughter, and always going out to work. Though she didn't mind going out to work she really didn't think her husband appreciated how hard she had worked all these years.

"During the air-raids a bomb fell very near and she was badly shaken. Her husband sent her with the daughter to the country. Mother went somewhere else—to another relative probably. When evacuated she met an American soldier aged 24 (she was 26). She had intercourse with him once; she did not want to, but he persuaded her; she did not think there was anything wrong in it at the time.

"There are no hospital letters to support what follows, but she tells me that soon after she had trouble with her periods. She went to the local hospital and was told she was pregnant. A few months later she was told she was not pregnant but had an ovarian cyst, and this was removed. Meanwhile she had told her husband she was pregnant by this American soldier. Her husband was very shocked, was almost in a state of collapse at hearing the news; but they made it up, and she thinks they have been happier since.

"Between 12 and 20 she went to different fortune-tellers three times. Each one told her there would be a death in the family, and there followed a death in the family . . . the husbands of two of her sisters and her stepfather died. The fortune-teller she saw recently told her that her husband would live another two years, or would die within two years. She is quite convinced that this is going to happen.

"I saw her again this morning. She was worse, more retarded, more hopeless. One gets the feeling that she believes it is because she went to the fortune-teller that caused the chain of events. She also feels responsible for the death of the people in the family when she was young, though she does not actually put it into words.

"To-day the notes arrived from her previous doctor. There are a lot of consultants' reports. While attending an out-patient department for her bowel complaint she had a cold axillary abscess in January, 1948, which was successfully treated; chest x-ray normal. October, 1948: She was having difficulty with defaecation; nothing abnormal found and she was being treated with confection of senna. February, 1950: 'She must, I think, be suffering from spastic colon. I could find no abnormality clinically or on proctoscopy. Arranging barium enema, x-ray, and blood count. . . . March, 1950: Barium enema—no abnormality; blood count: 85% haemoglobin and 4,300,000 red cells; sigmoidoscopy—no abnormality. Symptoms must be largely

functional. . . . April, 1951: 'She was found to have second-degree piles, and these have been injected. She was given a sheet of instructions on bowel function, and some normacol. . . . July, 1951: 'Has signs suggestive of supraspinatus tendinitis. She has been put on treatment in the physiotherapy department. . . . October, 1951: 'This patient was admitted with incomplete intestinal obstruction. She had had a number of similar but less severe attacks. Laparotomy was performed and revealed the obstruction in the ileum. It was adherent to her previous scarring. The adhesions were divided and she made an uneventful recovery.' June, 1952: 'She gave a history of chronic constipation. Abdominal and rectal examination failed to reveal any abnormality. She was reassured about her condition and liquid paraffin was prescribed.' August, 1955: 'I was unable to find any haemorrhoids in this patient and although she tells me she is constipated she only has soft faeces in her rectum. Perhaps her previous history is significant in her acquisition of an exaggerated bowel awareness. She also says she feels blown up towards the end of each day, and I am wondering whether there is some stricture formation at the site where the adhesions were divided. I have arranged a barium meal and follow-through for this. She also complains of feeling depressed and requested a consultation with a psychiatrist. I am arranging this. . . . November, 1955—from the psychiatrist: 'The above-named patient of yours was referred to my out-patient department from the surgical department, where she was regarded as being over-preoccupied with her alimentary tract for no adequate physical reason. This is indeed so, but on further inquiry I find she is suffering from a moderate degree of depression, with the usual accompanying anergia, lack of concentration, excessive guilt, and irritability. She herself tends to blame her housing conditions for this, but as she has been there for 20 years this, I feel, can only be of partial aetiological significance. With your agreement I would like to see her further in out-patients in the hope of improving her general depressive condition.'

"She was seen then by the psychiatrist four or five times. There is no further letter, and I could not get much out of her about what sort of treatment she got from him."

Dr. B. then added that he thought there was no time to lose, and so he made an appointment with a psychiatrist, who was well known to him, to give the patient E.C.T. without any delay.

Points from the Case

There are a great number of important issues in this case, all well worth discussing. I shall pick out only a few. The first is diagnosis. Everybody will agree with the psychiatrist that the woman is suffering from depression. What the psychiatrist did not say in his letter is that the depression has been going on for many years. When it started it is difficult to say, but the case history suggests that its first symptoms may go back to puberty or early adolescence—when she first went and consulted fortune-tellers. Even the basis on which the depression had arisen can be approximately surmised; it must have something to do with her bad wishes towards her near male relatives, first stepfather and brothers-in-law, and recently her own husband. The fortune-teller, obviously, is only a mouthpiece of her own repressed desires. The little that we know about her does not allow us to go further and speculate why originally these desires had arisen in her and why recently they had developed to such intensity that she broke down. Remarkably, the psychiatrist's report did not even mention these problems.

Then there is another highly important aspect. When a patient presents symptoms strongly suggestive of psychological problems doctors in general feel uneasy and sooner or later—as did Dr. B.'s partners—resort to two kinds of wholesale medication. One kind is well-meant common-sense reassurance, and the other is prescribing some tonic or stimulant if the patient is depressed, or some sedative or—to use its recent fashionable name—tranquillizer if the patient is not. Drinamyl, being a combination of stimulant and sedative, is a happy solution of the doctor's dilemma.

This automatic prescribing of tonics and tranquillizers in cases suggestive of psychological problems has an unintended but highly important side-effect. When a patient comes to his doctor complaining—I leave the verb intentionally without an object—his attitude towards illness is

still "unorganized." What will happen in the future is determined partly by the nature of the illness, but partly—and especially so in chronic conditions—also by the doctor. I do not mean here faulty diagnoses or therapeutic errors, but the effects of clinically correct diagnoses and rationally correct therapy. What usually happens may be described as follows: the patient offers various symptoms to his doctor; the doctor, on the basis of his knowledge, experience, and diagnostic skill, decides which of the symptoms should be taken seriously and be treated, and which not. The "illness" to which the patient and the doctor settle down is thus a compromise, acceptable to both.

This agreement between patient and doctor about what to consider as the true "illness" can be described from another angle as the doctor helping the patient to organize an "illness" around certain symptoms. The present state of medicine, with its emphasis on organic diagnosis and the corresponding neglect of psychological factors, prompts the doctor to organize illnesses around anatomical or at least physiological—that is, around some concrete—pathology; in our case around intestinal functions, resulting in Mrs. D.'s "exaggerated bowel awareness," so poignantly described by one of the consultants. The awkward question arises, how much of this "exaggerated awareness" is due to her intrinsic illness or constitution and how much to her doctors' efforts. Our whole training is an incessant cautioning against the dangers of missing some organic sign. Although this is a well-founded attitude, I think doctors—particularly general practitioners—should be equally strongly warned against finding an irrelevant organic sign and concentrating their own and the patient's efforts towards treating it, while not paying due attention to the glaring psychological symptoms.

Although everybody hearing Mrs. D.'s whole history will agree that her psychological problems have been the most important "illness" offered by her, her doctors responded exclusively to other "illnesses" offered, and treated only those. Thus we hear of an ovarian cyst removed; from more recent years we have evidence that she was considered to be suffering from life-long constipation, a cold axillary abscess, spastic colon, piles, tendinitis, incomplete intestinal obstruction due to adhesions which were accordingly divided, a possible stricture due to further adhesions, etc.

Hospital surgeons performed four operations on Mrs. D.—all successfully—and so they closed her case, proudly improving their statistics. But what about the general practitioners? They had to go on attending Mrs. D., still suffering from exactly the same complaints as before or between the operations.

Collating the Evidence

Does this mean that the operations were not necessary? Or that treating her constipation was incorrect? Emphatically not. The four operations, as well as the treatment prescribed for her constipation, were rational therapy. It will be remembered that in the beginning of my address I said that I do not propose that doctors should do their work differently, merely that they should do what they are doing *with a difference*. Everything done in this case was correctly done; but now, looking back on the whole medical history, it appears as if the overall problem had persistently eluded the doctors. Instead of tackling the real problem, all doctors in unison joined hands with the patient to concentrate all attention on the function of her bowels.

Although the psychological problems—or, as Assistant noted on the patient's card, "the severe emotional overlay"—were glaring, no doctor, *not even the psychiatrist*, tried to piece the evidence together. For the whole duration of her "illness"—that is, at least since her ovarian cyst—Mrs. D. was described by all her many doctors as suffering from some entirely organic disease, and it was only in November, 1955, that a psychiatrist was consulted. All the records in the various hospitals or in the files of her

general practitioners list her under the various organic "illnesses" proposed by her and accepted by the doctors. Is this sensible "medicine" or only a matter of convenience, a kind of short-term, and perhaps short-sighted, thinking? And how many cases diagnosed and listed in our statistics as organic, might turn out—if properly examined—to belong to this category?

All these aspects of the case were thoroughly thrashed out in a long discussion at our seminar. The following week we learnt from Dr. B. that when he saw the patient on the day after the seminar her depression seemed more tolerable—perhaps it was better, or maybe the doctor was better. To cut a long story short, patient and doctor could talk to each other; a good deal more of her previous history was revealed which threw new light on the possible causes of the something "bad" collecting in her. In the end the emergency appointment with the psychiatrist for E.C.T. was cancelled, as neither patient nor doctor felt any urgent need of it. Let me add, drinamyl was neither prescribed nor asked for, but a psychotherapeutic relationship was started—it is true, somewhat late in the day, and so with only a very guarded though not absolutely bad prognosis.

The real change achieved at this point was that the doctor approached the patient in a different mood, in a different spirit; instead of trying to find some not quite relevant—or even irrelevant—organic change, he established a psychotherapeutic relationship with the patient, which may grow into something. Whether he himself will be able to continue the treatment or will have to refer the patient to a specialist is a matter of policy, not of principle. In other words, a tactical step, not a strategic decision. The strategic decision was taken when he sat down with his patient and listened to her. This kind of listening is an art, at least as difficult and subtle as using a stethoscope. Still, training for this kind of listening is not yet included in the medical curriculum. Maybe it will be in the future.

As you see, here is a vast field of research accessible, above all, to the general practitioner. It is he who knows intimately the patient's previous history, and it is he to whom the patient first turns with his fears, pains, or worries—with all that medicine calls complaints, symptoms, or signs. It is the general practitioner of all doctors—who can most easily get hold of and piece together the various bits of information about a patient, so that the picture should make sense. Moreover, his relationship with the patient is, as a rule, lasting, not ephemeral like that of a specialist. Thus he can conduct long-term observations extending over many years and can collect sufficient well-authenticated material on the basis of which the short-term achievements of hospital medicine can be more accurately assessed. Obviously this cannot be done so long as general practitioners are overawed by the unquestionably great successes of hospital science and cannot consider their own observations valid and reliable.

Help for the G.P.

Here we—psychologically minded psychiatrists—can be of considerable help. It will be remembered that Dr. B., after the second interview, found Mrs. D.'s depression so severe that he arranged for an immediate E.C.T. I do not wish to raise here the much-discussed problem of shock therapy; for our case this is a side issue. What is important, however, is that Dr. B. could not bear the woman's depression; it was too much for him. The more our experiences in our seminars grow, the more we become impressed by the amount of therapy prescribed—*sit venia verbo*—to help the doctor. Whether this kind of prescription helps the patient is another matter. The chief assistance that we psychiatrists can offer a general practitioner is to enable him to become aware of his own involvement in his patients and so help him to respond better, more freely, and more accurately to their needs, while being less encumbered by his own emotions.

This is by no means an easy task, and I am rather doubtful how far an individual general practitioner can achieve it on his own. One promising method for acquiring this self-awareness and with it a modicum of psychotherapeutic skill is participation in our research-cum-training seminars. I know that one case is not sufficient proof for such a peremptory announcement, but it was impossible to quote more here.

Conclusion

So may I sum up: The most important aspect of the problem "general practitioner and psychotherapy" is to understand the presenting complaints as symptoms of the patient's whole life history. In order to achieve this the general practitioner must become less dependent on—that is, more critical of—hospital medicine and with it more confident about his own observations. Further, an equally important condition, he must become aware of his own involvement in his patients' problems in order to control his responses more accurately. Whether this latter can be achieved without outside help must remain for the time being undecided.

PSYCHOTHERAPY AND THE GENERAL PRACTITIONER—II*

BY

P. R. SAVILLE, M.R.C.S., L.R.C.P.

I shall deal with only a few of the aspects of psychiatry as related to general practice, and it would perhaps be of most interest if I concentrate mainly on the influence which the research seminars at the Tavistock Clinic had on my work as a general practitioner and give some general idea of the nature of our group and its atmosphere.

Problems of the G.P.

It soon became apparent that the problems of general practitioners were different from those of the psychiatrists, in so far as we have large numbers of patients who have to be dealt with on the spot, so to speak. We cannot pick and choose; we cannot put them off; we cannot tell them to go elsewhere because we are too busy. They have to be dealt with there and then, and it becomes obvious that we must necessarily evolve different techniques to treat them. As, in the normal course of events, psychiatry in general practice does not exist at all, we had to work it out for ourselves over a period of a few years, and it is really the purpose of this contribution to demonstrate how valuable and rewarding was the time spent at the seminars, and how much it has helped me in my everyday work.

It must be remembered that we have originally been trained to think in terms of pathological processes and have in our minds a list of drugs which will alleviate these conditions. When I was a student it was a very small list, but it is much larger now; in fact, the advent of the antibiotics has enabled us to really cure people of certain inflammatory diseases. But in my early training disease of the mind (other than frank lunacy) was relegated to the diagnosis of patients after full investigation had revealed no organic cause. At that stage we produced a medical sneer, our attitude changed to one of contempt, and we labelled the patient "a neurotic"—a dreadful slur. We sometimes let the patient down more lightly by calling his condition "functional." We felt we had done a jolly good job at this stage

*Read in the Section of Psychiatry at the Annual Meeting of the British Medical Association, Brighton, 1956.

—no germs were found, no growths, and so there was nothing really wrong with him; therefore he could get on with it himself.

Unfortunately, the patient showed great reluctance to get on with it himself, and continued to plague us with his complaints. At this stage we got rid of him—to the psychiatrist, who, queer chap though he was, became rather useful after all. What he did with the patient was none of our business, but he performed his main function adequately—by keeping the patient away from us.

We learned that he was a kind sort of chap who sat down for half an hour or more and actually listened to the patient!

This was indeed a revolutionary idea, and, more surprising, it occasionally seemed to do some good. This made some of the more enlightened of us sit up and take note and attempt to follow suit, but it soon became apparent that one had to know how to listen. It was not all that simple; but how to acquire that valuable art was another matter—in fact, there was no practical way of doing it. The usual long and costly special training was out of the question for a busy general practitioner. One read a few books and attended the occasional lecture by a chap who seemed to have heard of Freud. But it did not really help.

Research Seminar at the Tavistock Clinic

At last the heaven-sent answer to our prayers arrived. The Tavistock Clinic attempted some solution to our problem, and, I think, succeeded very well.

A group of eight doctors met weekly to discuss our own cases, as a research seminar. We were a varied group, with only one thing in common—that we were all doctors in general practice. The sexes, ages, and nationalities were mixed. We had the usual tensions of any therapeutic group, for that is what we inevitably became (in a mild sort of way). We got to know each other really well and we recognized each other's patterns, idiosyncrasies, and weaknesses, and were fully conscious that everyone else was just as aware of our own deficiencies.

We gradually became more and more cognizant of the intricacies of the hackneyed doctor-patient relationship, and the traditional "bottle" was given a little extra meaning.

Listening to our colleagues relating their own cases (with some cunning and judicious guidance from the psychiatrist leader) it soon became apparent how varied and different we all were in our individual approaches to the patient, and how we all expected him to conform to certain patterns of behaviour, each of us taking it for granted that our own brand of expectation was the correct one.

Most of us learned to examine our own attitudes in the light of these discoveries, and our increasing ability to acknowledge and accept criticism was a very noticeable by-product.

Incidentally, we became highly critical of each other—not much was missed by us, and indeed we were often brutal. This was where the psychiatrist was called upon to exercise all his skill in keeping the temperature at a reasonable level. We began to understand what he meant when he spoke about the "apostolic function" of the doctor—one of his pet hobby-horses.

We were also given the opportunity of discussing difficulties concerning our own cases with one of the psychiatrists at the Tavistock Clinic (other than the seminar leader).

All this helped to increase our elasticity, so necessary in dealing with patients in general practice, reducing tension, and, most important, removing some of our own guilt feelings towards patients. We also noted that the patient responded favourably to our new type of approach and our new style of listening. We got to know something about what could be done for different patients, who could benefit by psychotherapy, and who should not be referred to a psychiatrist.

We even attempted psychotherapy ourselves. At first we looked for startling and dramatic cases, and in fact got what appeared to be amazing results—so much so that it made some of us over-ambitious. But after a bit we learned that beginners' luck did not continue to hold, and with some miserable failures we gradually dropped attempts at major psychotherapy and became more aware of our own limitations and more sensitive to what we could and should attempt, finally settling down to a type of therapy varying with our own individual skill and inclination. In my own case a combination of ventilation, reassurance, and counselling.

My personal development in the group was one of wonder at what was attempted and achieved by certain other members of the group, and then came a remarkable result in one of my early cases, a bit of magic which rather overstimulated me.

I was soon disillusioned by a dismal failure, and finally settled to my present level of treatment. I think I can best illustrate this development by relating a few details of three cases.

Case 1

The patient was a thin, pale, inoffensive man aged 26 who had been married three weeks. He complained of splitting headaches ("behind his eyes"), so severe that he could not walk and had to be taken to hospital in a taxi, where he was admitted there and then and investigated for possible cerebral cause or acute sinusitis. He reported to me immediately he left hospital, complaining that his headaches were still severe.

I knew his family set-up well—his blind father (now dead), whom he used to lead about; recent marriage; wife's healed tuberculosis; childhood in orphanage—and something clicked. I dived right in, spent an hour with him, took a full history, and with plentiful material made an immediate interpretation, tracing it back to his childhood in the orphanage, associating himself with his blind father, to whom he was greatly attached—and perhaps unconsciously resented, with headaches (always behind eyes). He was assured of the non-organic origin of the headache. There was a good deal more interpretation involving his wife, a newly acquired motor-cycle, his relationship with an elder brother, and his Cinderella-like role in life.

The patient accepted the interpretation fully. I saw him a few days later. He said he felt marvellous, "no headaches," and now understood that his symptoms were related to his abnormal childhood. He was no longer afraid of crowds, slept well, and was most grateful to me. This all happened in March, 1953. I think you will agree that he was suffering from a severe anxiety neurosis.

Over three years have elapsed. He is the proud father of a bouncing baby girl, aged 1; loses no time from work, and rarely reports to me, except for tonsillitis and such-like complaints. His wife tells me how well he is. I feel you might bear with me if I allowed myself to be carried away by this case.

Case 2

I was soon brought back to earth by my next case. A young man of 22, who could not report for his annual military training, was seized at the railway station with dizziness, apprehension, and near collapse. In a few sessions I was overwhelmed by a mass of homosexual material plus a rapidly developing positive transference. It was all there for the asking if one knew what to do with it. But I could not handle it; I was overwhelmed by the weight and content of the material presented to me, and I panicked—more or less ran away, or rather made the patient run away. He avoided me after that, with his problem unsolved. I understood from his mother, who was quite pleased about her son now, that he had a boy friend living with him and that he had settled down and was quite happy. So I nearly spoiled that romance.

This experience made me wary, and I developed more restraint and took on only the type of case I felt I could properly handle.

Case 3

My third patient was the sort of case I now feel I can do most for. She was a worried-looking married woman of 41, who had consulted me regularly for six to eight years, practically weekly, complaining of a multitude of symptoms, including sweats, headaches, "fibrositis," pain in the chest, "pins and needles," with never any abnormal physical signs. She also had waves of depression and crying bouts. It was always obvious that her symptoms were psychogenic in origin, but I had been disinclined to tackle them on that level, until the stimulating effect of the group influenced me to arrange an appointment with her, after surgery hours, so that I could really listen to her.

I spent an hour with her and listened. I heard about her drunken father, who used to beat her overworked mother, and about terrifying scenes with parents fighting and children in the street in the early hours of the morning; stitches put in mother's wounds; scenes at police courts; her mother's death followed by a stepmother in the house; and her own early marriage to get away from home.

Then came discussion of her own frigidity and memories of witnessing parental intercourse. I had to do little more than listen. The floodgates were opened, and for the first time in her life she spoke about those unmentionable things.

My interpretation was minimal, and I let her talk with only a little prompting here and there. This all happened in March, 1954, over two years ago. I see her only occasionally now, very much less than in the past. Her whole attitude is different and our relationship is especially good; we understand each other. We have friendly, encouraging chats, and we have both silently agreed not to go too deeply into it.

My heart no longer sinks as she walks into my consulting-room, and she no longer looks miserable when she walks in. In fact, the doctor has not only done the patient some good but the patient has also helped the doctor. She even brought me a new patient a few months ago.

I must emphasize that this case, so apparently simple in every way, would not have been possible for me in my pre-Tavistock Clinic days. I had learned to listen.

ORDER OF ST. JOHN OF JERUSALEM

The *London Gazette* has announced the following promotions in, and appointments to, the Venerable Order of the Hospital of St. John of Jerusalem:

As Knights: Surgeon Vice-Admiral Sir K. A. Ingleby-Mackenzie, K.B.E., C.B., M.R.C.S., L.R.C.P., Q.H.P., Brigadier Sir A. E. Porritt, K.C.M.G., C.B.E., F.R.C.S., and Colonel G. D. English, M.B. *As Commanders (Brothers):* Surgeon Vice-Admiral R. C. May, C.B., O.B.E., M.C., M.R.C.S., L.R.C.P., Q.H.S., Major-General F. K. Norris, C.B., C.B.E., D.S.O., M.D., Air Vice-Marshal P. B. L. Potter, C.B.E., M.D., Q.H.S., and E. A. Daley, C.B.E., M.B., Drs. R. Cauchi-Inglott, M.B.E., M.D., A. T. McKay, W. W. King-Brown, R. Chester, T. C. James, G. L. C. Colenso-Jones, A. J. Boase, O.B.E., and N. H. Ashton. *As Officers (Brothers):* Lieutenant-Colonels W. Windsor, M.R.C.S., L.R.C.P., and I. A. Walsh, M.B., R.A.M.C., Wing Commander W. O. Davies, M.R.C.S., L.R.C.P., Drs. W. E. Talbot, A. R. Shaw, Chang Hoey Chan, I. Mackenzie, A. K. MacRae, A. Kefaals, M. A. Watson, T. D., R. Brown, J. E. King, G. Walker, W. E. Lock, H. A. Korn, D. J. Turnbull, G. Thompson, N. J. Caldwell, A. M. Purves, V. C. Dyring, L. N. Gollan, J. A. Waycott, and E. O. Halliwell. *As Serving Brothers:* Mr. W. A. L. Tucker, F.R.C.S., Drs. Mohammed Ahmed, I. McCracken, H. H. Coulter, F. D. Morphy, M.C., J. T. Paranjothy, Kong Sau-Yui, W. Grima, J. Saliba, E. Cesario, E. H. B. Grey, A. Edwards, J. M. Sherriff, R. S. Abraham, T. F. Greenwood, T. Cullen, W. B. Ballenden, W. Kirkwood, J. F. Coates, A. St. C. R. de Costa, M.B.E., D. T. Gilbert, and F. E. Fletcher. *As Associate Serving Brothers:* Mr. I. B. Taylor, Drs. L. K. Luk, G. Frampton, and H. M. Wolfsohn. *As Serving Sisters:* Drs. Evelyn W. A. Churches, Stella C. C. Macdonald, and Catherine J. S. Sedgwick.

Correspondence

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

Smoking and Lung Cancer

SIR,—It is refreshing to read Dr. E. L. Wynder's new approach (*Journal*, January 5, p. 1) towards the solution of the tobacco-cancer problem and to see that, instead of trying to stop us smoking, he is pursuing his researches with a view to letting us continue to smoke while ridding the cigarette of its carcinogenic properties.

I think that most doctors in this country not only accept now the association between cigarette smoking and cancer but, moreover, assume that tobacco smoking is carcinogenic. One should, however, utter a word of warning to those who compute mathematically the increased risk at which smokers are in respect of cancer of the lung. There are several definite, and probably a still greater number of hypothetical, factors which may be associated with smoking. It is clear, for example, that there is some relationship between smoking and the consumption of alcohol. In the group of lifelong non-smokers are a number of persons who abstain from smoking as a matter of personal or religious principle, and most of these abstain also from alcohol. At the other end of the scale, men who drink spirits in excess nearly all smoke cigarettes too. In the small group of people who relapse after having stopped smoking drinking men bulk very large. The first cigarette is very often smoked at a party. It is therefore clear that an association does exist between alcohol and tobacco, and consequently it would be inevitable that an investigation of alcohol consumption would show a relationship between alcohol and cancer of the lung, even if there is a carcinogen in tobacco smoke. The association between alcohol and cancer of the lung would, in fact, be a false association, and false associations are the bugbears of those who conduct statistical research. Nor should we too lightly dismiss the effect that alcohol unquestionably has on respiratory function.

No one would make the absurd mistake of ascribing cancer of the lung to alcohol, but in fact that such an obvious association has not yet been reported or discussed by the authors of papers on this subject shows clearly how great a risk there may be of some factor other than tobacco smoking having a bearing on the problem of cancer of the lung. Additional associations of this kind, concealed in mortality statistics, should make us very wary of accepting calculations of the risk of cancer of the lung to which smokers are exposed. Moreover, now that cancer of the throat and gullet is being examined for a possible relationship with tobacco, extreme care will be necessary to exclude a possible causal relationship with alcohol. Such a relationship might occasion a false association between tobacco and cancer of these parts of the body, for cancer of the throat and gullet is certainly commoner in alcoholic subjects.

We have planned an investigation of the relationship between drinking and smoking, and when, in due course, your readers are invited to complete a short questionnaire, perhaps they would be good enough to co-operate with us.

I am, etc.,

London, W.12.

IAN AIRD.

Function of the Prostate

SIR,—I have been most interested in the correspondence on the function of the prostate. Dr. J. A. L. Magee (*Journal*, December 15, 1956, p. 1427) feels convinced that the prostate is the functionless remains, in the male, of the uterus and vagina. Surely this cannot be so, because it appears that the prostate depends for its development on the presence of functioning male gonads. In the immature male the prostate is small and hardly palpable,

and it grows with the development of the male gonad. If it were a vestigial remnant of the uterus and vagina, why should it do this? One would assume that the presence of male hormone in the circulation would inhibit the development of a purely "female" remnant.

Some years ago I had the opportunity of examining a number of elderly Turkish eunuchs, relics of the polygamous days of the Ottoman empire, retired seraglio guards. They were remarkably fit old people, lean and wiry, contrary to popular opinion. Their prostates were small and completely undeveloped, and could scarcely be felt per rectum. I was told that disorders of micturition were unknown among eunuchs, and that, on the whole, they lived longer than ordinary men. This proved to me that the prostate was dependent on the male gonads for its development, and must therefore be an essentially male organ with a specific function, presumably to add a fluid to the semen. One of these eunuchs, aged 76, told me that he had, in middle age, become capable of intercourse, and that he then ejaculated a small quantity of clear fluid.

I suggest that the prostate has a definite function, and that it is our civilized mode of life that leads to its giving trouble in old age. Veterinary surgeons tell me that prostatic troubles are common in pampered house dogs but unknown in foxhounds, working farm dogs, sheep dogs, etc. They treat prostatic enlargement and disorders of micturition in dogs by castration.—I am, etc.,

JOHN NESFIELD.

Whitstable, Kent.

Glycyrrhetic Acid

SIR,—I have read the letters of Drs. R. Hall and J. Jefferson (*Journal*, December 15, 1956, p. 1431), Dr. B. F. Russell, Dr. I. M. P. Smeed, and Dr. K. M. Tomlinson (*Journal*, December 22, pp. 1483 and 1484), and, although I am loath to burden any further the pages of your *Journal*, I feel it necessary to clarify certain cardinal points.

The work of Molhuysen *et al.*¹ deals with the oral administration of "succus liquoritiae" (a dried watery extract of the roots of *Glycyrrhiza glabra*), and these workers came to the conclusion that "the effect of liquorice extract by mouth is in almost all respects similar to that of injections of large doses of deoxycortone." However, I fail to see how the oral use of "succus liquoritiae" has any bearing on the topical use of glycyrrhetic acid. It is significant, as Dr. Nieman² states, that the characteristic group of deoxycortone acetate and cortisone, etc.—that is, the alpha, beta unsaturated ketone grouping—is also present in glycyrrhetic acid.

It appears to me that most of the correspondents who have written on glycyrrhetic acid have failed to examine the chemical aspects of this drug. They refer to glycyrrhetic acid as though it were a simple standard substance available from any chemist's shelf. Briefly, glycyrrhetic acid is a very complex triterpene, in the chemistry of which has still not been fully elucidated, in spite of the lengthy research work and many publications of the Ruzicka,³ Voss,⁴ Professor Spring,⁵ Kon and Ross,⁶ etc. The method of extraction from liquorice root varies considerably, as does the resultant product. Four isomers have already been described.⁷ Their melting points, optical rotations, physical and chemical properties vary. Under these circumstances it is impossible to class all the substances called glycyrrhetic acid under one heading. This is a most important point to be borne in mind when making trials with "glycyrrhetic acid."

I would also refer to the veterinary report on glycyrrhetic acid, where Mr. Brendan Halpin⁸ has demonstrated the anti-inflammatory properties of glycyrrhetic acid in veterinary practice.

The results published on my trials⁹ were obtained prior to July 5, 1956, and since that date many of my patients have been treated with "biosone G.A.," which preparation claims to contain the active isomers of glycyrrhetic acid. My results up to September of this year in selected subacute and chronic conditions of an eczematous pattern are:

Cleared	Improved	No Change	Worse
22 23%	56 58%	10 10%	9 9%

While I was fully convinced of the efficacy of this preparation, I did not find it necessary to enter into complex statistical analyses and controls. Nevertheless, after the Brighton meeting, when some colleagues suggested that this was necessary, I decided to control a few cases against the base. The figures shown only confirm my original convictions.

	Marked Improvement	No Change	Worse
"Biosone G.A."	14	1	2
Base	3	14	—

I should also like to draw the attention of your correspondents to the publications and patent specification¹⁰ of Drs. Cornforth and Long, of the National Research Development Corporation. They demonstrate, in the manner described by Long and Miles,¹¹ that products which they obtained from liquorice root had cortisone-like activity. In my opinion, it is completely unscientific to take the results of a number of independent dermatologists, add them together, and then draw conclusions for or against a particular drug. In the case of glycyrrhetic acid this is impossible, as the drug and the base used have been supplied by various manufacturers and would therefore vary. It is only after an extended clinical trial, where the dermatologist can gain experience with the drug and can select the cases, that he has any opportunity of assessing its efficacy. If this were done haphazardly it could readily alter the statistics. I cannot over-emphasize this fact.

Having used glycyrrhetic acid in several hundred cases, I feel that I can give a true opinion on this drug. Glycyrrhetic acid and hydrocortisone do not always act in the same fashion, but they can be complementary; thus I have used glycyrrhetic acid ointment with success where hydrocortisone has failed, and of course the reverse is equally true. The active isomers of glycyrrhetic acid should be the first choice in the treatment of the subacute and chronic conditions, bearing in mind its cost, and hydrocortisone can then be tried on the failures of glycyrrhetic acid.—I am, etc.,

E. COLIN-JONES.

Hove.

SIR,—May I be permitted to voice the experience of a G.P. who, in common with most of his colleagues, is too busy to read the ever-increasing volume of manufacturers' literature but endeavours to keep abreast of the "newer remedies" through the columns of your *Journal*? In the last few weeks I have read with interest many letters regarding the value of glycyrrhetic acid in a variety of inflammatory skin conditions, and my own experience with what is claimed to be the active isomers of glycyrrhetic acid as contained in "biosone G.A." preparations may be worthy of record in this connexion.

Having been aware of the high therapeutic efficacy but the prohibitive costs of the hydrocortisone preparations—which were not even released for general prescribing on F.C.10 until December, 1955—I gave vent to treating some of my patients suffering from acute inflammatory skin conditions, especially "contact dermatoses," with biosone G.A. ointment, with and without neomycin dependent on the presence of superimposed bacterial infection. Later I tried biosone G.A. rectal suppositories in anal piles, prolapsed with or without bleeding, and also biosone G.A. ophthalmic ointment in inflammatory eye conditions, and soon I was in no doubt that most of my patients benefited from this medication. It was gratifying to make a mental note at the same time that a substantial saving had resulted in the national health bill without loss of efficacy.

Admittedly, I had relied entirely on my clinical acumen, as most G.P.s do, and obeyed the simple rule that, if

SIR,—Following the interesting article by Dr. J. Basil Rennie on renal oedema (*Journal*, December 29, 1956, p. 1506) I felt the following observations on the progress of one patient with a type II nephritis of interest.

In October, 1956, because of increasing oedema (proteins 3.1 g.%, urea 60 mg.%), I decided to repeat cortisone therapy at home. Fluid input-output charts, along with weight, blood

The close association between stress (by infection) and urinary output is interesting, and perhaps a carefully watched naturally occurring infection (always more likely in a nephrotic subject) might be included as a capricious weapon in the armamentarium against nephrosis.—I am, etc.,

Eastwood, Essex.

EDWARD T. R. HOLT.

SIR.—Your leading article (*Journal*, December 29, 1956, p. 1531) on the treatment of this condition is bound to be of particular interest to general practitioners, for upon them, in most cases, responsibility falls for dealing with one of the really grave emergencies of medicine. There is, however, one strange omission in respect of the medicinal treatment of this condition. Can anyone doubt the value of combining atropine 1/75 to 1/50 gr. (0.9 to 1.3 mg.) with the morphine? Not only does it tend to lessen rapidly further bronchial secretion, but its effect in diminishing the risk of vomiting from the morphine is well known.—I am, etc.,

London. N.W.7.

A. H. MORLEY.

SIR.—The conclusions resulting from Drs. W. F. Tyrrell and J. Smith's article on tuberculosis in Glasgow (*Journal*, December 22, 1956, p. 1451) are sufficiently unusual and unexpected to warrant some comment, and I submit the following observations.

(1) The new cases of active tuberculosis discovered in the period under review were "practically all" sputum-positive. This is not the case in my own area, where only about 60% of new cases are positive. One wonders whether such matters as standard of diagnosis, laboratory facilities, or reluctance of patients to consult their doctors have anything to do with this finding: but, in view of the subsequent sections of the article, it may well be that this high proportion of positive cases is related to an undue susceptibility of the population dealt with.

(2) Approximately three-quarters of all the new patients were found to have a history of contact with tuberculosis. This is a much larger proportion than is usual in other areas, and, since "history of contact" is to a large extent synonymous with "family history," it follows that the Glasgow patients presumably have a subnormal resistance to tuberculosis on account of their family history. According to the article, this is not due to environmental conditions, such as poverty or overcrowding, and if one can exclude the possible factor of better-than-usual ascertainment of family history it would seem that we have here a further indication of undue susceptibility in the Glasgow patients.

(3) The examination of contacts appears to have been on a fairly normal scale—412 contacts of 125 new patients were examined (for comparison, in my own area, 519 contacts of 93 new patients were examined in 1955). It is remarkable, however, that 5.7% of the Glasgow contacts were found to have active tuberculosis (my own figure for 1955 is less than 1%). Again,

Like Dr. Alexander, I also have been harassed by anxious ship's captains who are always prepared to have a whole

Like Dr. Alexander, I also have been harassed by anxious ship's captains who are always prepared to have a whole

battery of engineers, electricians, carpenters, and plumbers standing by to "help," because to the lay mind an operation at sea is always more dramatic than an operation on shore. Actually, an inflamed appendix is no more dramatic than inflamed tonsils, and I find conservative treatment for the former as efficient as for the latter. I am, etc.,

London, S.W.7.

CHARLES W. LEECE.

Facial Palsy

SIR,—In reply to Dr. E. C. O. Jewesbury (*Journal*, December 22, 1956, p. 1488), who comments on the paper by Dr. Haynes and myself on facial palsy (*Journal*, November 24, p. 1197), I wish that we could produce a strictly controlled series of cases of severe and stubborn Bell's palsy in which alternate cases were submitted to decompression or left alone. We can, however, mention a group of 27 cases of Bell's palsy in which decompression was declined, though the patients remained under observation. In none of these patients was there any sign of returning function in under nine weeks, and in seven the final recovery was classified as poor because of contractures and limited movement. I agree that the classification of degree of recovery is not satisfactory, and I am now starting to control cases by cinematography.

May I once again stress the fact that in a significant proportion of the cases (in the group reported 46 out of 110) a return of facial movements was noted within a week of the decompression operation and we feel that this was more likely to be due to relieving pressure on non-degenerated axons than to coincidence.

As regards the time at which decompression should be undertaken, we quite agree with Dr. Jewesbury, and indeed with others, who say that if decompression is of value in Bell's palsy it should be undertaken as soon as possible after the onset of the paralysis. Unfortunately, we do not as yet have any means of telling within several days of the onset which nerves are going to degenerate. When we do, I have every hope that early decompression will reduce the proportion of incomplete recoveries. I am, etc.,

London, W.1.

TERENCE CAWTHORNE.

Tropical Pulmonary Eosinophilia

SIR,—Dr. Rosemary Davies (*Journal*, December 22, 1956, p. 1470) has performed a service in drawing attention to the occasional discovery of tropical pulmonary eosinophilia in this country. In a rapid survey by the records officer at the Seamen's Hospital it appears that my colleague Dr. Ronald Hartley and I have made the diagnosis in seventeen cases seen since 1951, and to these should be added another referred to me by Dr. David Erskine from his dermatological clinic.

After reviewing the case notes it seems that fourteen of these cases satisfy all diagnostic criteria. With one exception, a European who had spent most of his working life in Calcutta, the patients were Asiatic seamen. At the Seamen's Hospital the diagnosis is considered in all patients with cough, sputum, dyspnoea, and bronchospasm who are Asiatic or have lived for any length of time in that continent. Routine E.S.R., white blood counts, and W.R. and Kahn are done on all admissions, and differential white counts whenever the total leucocytes exceed 10,000 per c.mm. Fever at the time of admission usually calls for examination of blood films, and eosinophilia is sometimes discovered in this way.

We find that some of the patients have intestinal parasites which may have explained the eosinophilia, but almost all the definite cases had absolute eosinophil counts of 10,000 per c.mm. or more. The uniform feature of the series has been the satisfactory response to carbarsone 0.26 g. three times a day for four days followed by four days' rest in which exacerbation of symptoms sometimes occurred, after which 0.26 g. three times a day is again given for six days. Using this treatment all eighteen patients showed a remarkably swift and gratifying clinical response, and it seems probable that they can all be correctly classified in one

clinical group, although we have no positive proof of any single aetiological factor. In all cases eosinophil counts have fallen dramatically after treatment, but not always to normal. We have not observed relapse, but no conclusion can be drawn from this, since, with one exception, our patients were seamen and therefore nomadic.

In 1952 Dr. Ernest Soysa allowed me to examine the chest x-rays of a large number of his cases, and I then formed the opinion that there is no characteristic x-ray abnormality on which the diagnosis can be based, and that many of the patients have films which are essentially normal. Although the diagnosis is so simple and treatment so satisfactory much work still remains to be done before our knowledge of this syndrome is complete. I am, etc.,

London, W.1.

ALIC WINGFIELD.

Pregnancy Sickness

SIR, There has been correspondence recently on pregnancy sickness (*Journal*, December 22, 1956, p. 1487; January 5, p. 49), and I noted that no reference was made to the large part which might be played by the occurrence of acetonæmia. Surely in the vomiting of pregnancy, as in post-operative vomiting, one of the first investigations should be the examination of the urine for acetone, and the prompt administration by mouth, by rectal drip, or intravenously of glucose, possibly with the addition of insulin.

A vicious circle can be set up so quickly; early slight acetonæmia causes anorexia, with prompt diminution of intake of food, particularly starches and sugar. This can soon be followed by vomiting and further loss of intake, with consequent increase of the acidosis. The first thing is to break this cycle, and a day in bed with a rectal drip of 5% or even 10% glucose, or an intravenous injection of a relatively small amount of glucose, is often most efficacious. I am, etc.,

London, W.1.

J. LYLE-CAMERON.

SIR,—From time to time medically qualified women, like your recent correspondents and me, are privileged to bear children. Some of us attempt to analyse our reactions to this supreme experience, and if we differ at all from the countless generations of mothers before us it is surely only in this respect. So it happens that frequent bursts of correspondence appear in which numbers of trained personnel are constrained to confide to the press just how they, in their time, started to vomit or failed to relax. Doctor-mothers alone must surely number some hundreds at the present time. If we could collect and analyse their experiences we should gain, I believe, an interesting slant on the psychological effects of instruction on pregnancy and labour. This might influence our present trend of "education" of the pregnant lady. Meanwhile, ladies, I fear that our personal experiences, however absorbing, are simply not "statistically significant." I am, etc.,

S. Ockendon, Essex.

PRUDENCE TUNNADINE.

Allergic Response to Hyaluronidase

SIR, Dr. P. J. Joubert's report (*Journal*, January 5, p. 46) of a case of a severe allergic reaction to hyaluronidase prompts me to describe the following case.

A nurse, aged 19, had no history of asthma or eczema, but for the previous three years she had experienced watering of the eyes and nose when in proximity to horses. Hyaluronidase had never been administered to her. In the course of her duties she dissolved "hyalase," 1,000 units, in a few ml. of saline in a syringe and the solution was added to a bottle of saline for subcutaneous administration. The nurse then removed the needle from the empty syringe, and accidentally pricked her thumb with the detached needle. Within a few minutes the thumb was tensely swollen, and this was followed by intense conjunctival injection, oedema of the eyelids, and bronchospasm. Antihistamines were given and the bronchospasm was relieved in a few hours; the oedema of the eyelids persisted for three days. The amount of hyaluronidase causing this reaction must have been very small indeed.

It was shown by Holborow and Keech¹ that hypersensitivity to hyaluronidase develops rapidly on repeated administration to a given subject. The manufacturers feel that protein impurities in the preparations used at that time may have been responsible for their findings. However, it is evident that the danger of a very severe reaction still exists with modern preparations.—I am, etc.,

London, N.W.3.

Health of Refugees

SIR,—I am able to tell your correspondent Dr. Bertram Mann (*Journal*, January 5, p. 44) that the Hungarian refugees who passed through the transit camp at Aldershot were not x-rayed. We had arranged mass radiography for all refugees, but this was cancelled at short notice by orders from "a higher authority." This was a pity, because there was a tuberculous history in about 10% of all refugees we saw in the medical room. These Hungarians are now spread all over the country, and a job which was once very easy is now much more difficult.—I am, etc.,

Mudford, Hants.

WILLIAM ELDON.

Mild Endogenous Depression

SIR,—I would like to compliment Dr. C. A. H. Watts on his paper entitled "Mild Endogenous Depression" (*Journal*, January 5, p. 4). Depressive illness is so common, and, in its more mild degrees, so rarely diagnosed, that it is without doubt responsible for more rectifiable ill-health and misery, not to mention work hours lost, than any other disorder in this country. Anyone who attempts to draw the attention of the medical profession as a whole to this fact is indeed rendering a public service.

On one or two points I would beg to differ from Dr. Watts, and the chief of these is in regard to prognosis. It is my experience in general practice that depressive illness does not right itself nearly so readily nor so rapidly as Dr. Watts would seem to suggest, and it is my opinion that, for a reasonably quick and full return to lasting health, convulsive therapy is usually needed in these cases. The mild depressions respond just as dramatically to this treatment as do the more severe cases in hospital.

The only members of the profession who have the opportunity to become proficient at the diagnosis of these cases of mild depression are those in general practice. I would suggest that a number of general practitioners throughout the country, especially those engaged in practice outside the N.H.S., might well become expert in this respect. Having become so, they could then receive training so that they might carry out modified convulsive therapy in their patients' homes.—I am, etc.,

Paignton.

R. J. T. WOODLAND.

Aid to Motility

SIR,—Risking accusations of the grandmother-and-egg type, I feel that a simple idea of mine may be of some assistance to exasperated colleagues whose wheels may spin in the inevitable nippy weather to come. Attendance at rugger matches during my Army service in Austria usually involved professional assistance at some stage of the game. I grew wary and carried useful odds and ends. From this evolved the fact that a standard length of Kramer wire 40 in. by 4½ in. (1 m. by 12 cm.) fits comfortably and unobtrusively on the rear window-ledge of the average small car, and two are as easily carried as one. These are useful medically, but also when stuck may be placed in front of and in line with the rear wheels to make a track on which to crawl away. I hardly dare to add that a suitable length of bandage being tied to the wire and to the rear bumper will cause your wire to bound happily along behind until a suitable stopping surface is reached.—I am, etc.,

Stourport-on-Severn.

JOHN PARKES.

Simplicity in Anaesthetics

SIR,—In his review of analgesic supplements to nitrous oxide anaesthesia (*Journal*, December 8, 1956, p. 1326) Dr. Ephraim S. Siker points out that the parabolic curve of the incidence of use of intravenously administered supplements is almost completed. He mentions ether and cyclopropane, only to dismiss them because "diathermy could not... be safely used with these otherwise valid techniques." This is analogous to insisting that fuel oils should be carried in windjammers only and that the crews of these vessels should live exclusively upon cold tinned food. In your leading article (*Journal*, November 24, 1956, p. 1225) you pointed out that 6 million inflammable anaesthetic administrations led to only three deaths in a period of six or seven years, but Dr. A. R. Hunter (*Journal*, October 20, 1956, p. 919) reports six deaths from respiratory failure in a two-year period, and subsequent correspondents—for example, Dr. G. B. Burchell (*Journal*, November 3, 1956, p. 1054) and Dr. K. A. Stewart (*Journal*, November 17, 1956, p. 1174)—more than doubled this score.

This is perhaps a suitable time to re-emphasize the virtue of simplicity. The first duty of an anaesthetist is to relieve pain in his patient. Any other contribution he may make to the conduct of a surgical operation is subsidiary to that aim and should never be made with a view to facilitating his own or the surgeon's work without a careful assessment of the added hazards to the patient. After all, it is the patient who runs all the risks. Over 100 years of time have added volumes of useless print to library shelves and have witnessed a constant procession of whimsical methods and sorry substitutes for di-ethyl ether, the most powerful and one of the safest of anaesthetic agents, but they have shed virtually no light whatever on our ignorance as to where and how ether exerts its narcotic action. If all the efforts diffused in attempts to snatch a moment of limelight with "something new" were put solidly to work in attempts to elucidate the behaviour of this versatile drug and to improve the methods of using it, we should at least have a solid baseline from which to advance into the unknown. For when we know how and where ether acts we shall be very close to the secret of life itself.—I am, etc.,

C. S. JONES.

Domiciliary Treatment of Pneumonia

SIR,—Now that the high season for pneumonia is near its peak may I enter a plea for the more efficient domiciliary treatment of this condition? By pneumonia is meant the grave acute pulmonary infection, usually lobar in distribution, most frequently due to the pneumococcus, and met with in the average practice perhaps two or three times in a twelvemonth. Looking over recent editions of standard British textbooks on medicine one finds in many cases that sulphonamides are apparently still advised as first choice of treatment. One also gains the impression that, if it is not convenient to inject crystalline penicillin at frequent intervals, it will suffice to inject procaine penicillin once every 12 or 24 hours.

Pneumonia is a serious disease. According to the 1956 edition of Price's *Textbook of Medicine* the mortality rate in lobar pneumonia, even with sulphonamide and penicillin therapy, is still as high as 8%. Faced with a mortality figure of this magnitude it does not seem appropriate to rely on sulphonamides by mouth, since many patients tolerate them poorly in the relatively high doses necessary for success. Nor does it seem adequate, in the early acute stage, to inject a relatively insoluble penicillin compound to form a depot in muscle from which small amounts of the active substance are released into the circulation, never attaining a really high concentration. Once the diagnosis of pneumonia appears clinically certain it is essential that effective steps be taken at once to kill the offending organism with the greatest possible speed, and this can usually best be accomplished by injecting crystalline penicillin (benzylpenicillin B.P.) in large doses and at frequent intervals.

I suggest that the mortality rate could be markedly reduced by adopting the following measures. After obtaining a specimen of sputum for sensitivity tests, inject one million units of crystalline penicillin intramuscularly every four hours for the first day with one injection through the night. In many cases on this dosage schedule the temperature will have fallen sharply within 24 hours with accompanying marked subjective improvement. When this has been achieved, inject one million units crystalline penicillin every six hours during the next three or four days, omitting the night dose. With continuing improvement it is then permissible to carry on the treatment with procaine penicillin by daily injections of 900,000 units until the infection is at an end. What are the objections to these large and frequent doses of crystalline penicillin? Certainly not cost. A million units cost only 1s. 8d. Perhaps inconvenience? But pneumonia is a killing disease and the few extra visits which the use of crystalline penicillin entails should not count. Hypersensitivity reactions—about the only serious side-effects of penicillin—do not appear to be increased in frequency by adequate dosage.—I am, etc.,

Belfast.

Hydrocortisone for Buccal Ulcers

SIR,—I have read with great interest Dr. S. Hillman's letter (*Journal*, December 22, 1956, p. 1486) describing the use of hydrocortisone ointment for recurrent aphthous ulcers. For a year or so, on a similar hypothesis—that is, that some cases at least are due to a psychosomatic disorder—I have prescribed somewhat similar treatment with great success. I have used 1% hydrocortisone ointment, without any antibiotic addition, smeared on the ulcers after drying the mucous membrane with a clean handkerchief. This I find gives almost immediate relief of discomfort and heals the ulcers very rapidly if repeated frequently. Until I read Dr. Hillman's letter I was uncertain whether it might not have been the ointment base of the preparation ("cortril" in this instance) alone which did the trick, but his experience would seem to confirm mine. I have not had trouble with spread of infection. It is a pity that a method cannot be devised to bring local hydrocortisone into contact with peptic ulcers as Dr. S. C. Truelove (*Journal*, December 1, p. 1267) has in the case of ulcerative colitis.—I am, etc.,

North Berwick.

DERRICK MORTON.

Fluoridation of Water

SIR,—In a pamphlet from California entitled "Fluoridation Unmasked" the following statement about myself appears:

"Professor R. A. Peters, Biochemist, of Oxford, England, says: 'Fluoroacetic acid prevents the body from breaking down the citric acid created when sugar is burned into simpler compounds. Retention of waste citric acid acts as a violent poison on heart and nervous system. Fluoroacetic acid is used by African natives to murder their enemies. What will happen to the person drinking fluoridated water when he uses vinegar?' (acetic acid)."

I do not know upon what writing of mine this is supposed to be based, but I think it as well to point out that it gives entirely the wrong impression. Inorganic fluoride acts completely differently in the body from fluoroacetic acid, in which the carbon is linked firmly to the fluorine. Fluoroacetic acid is a rat poison which is much more toxic than fluoride. The suggestion in the last sentence that fluoride and acetic acid will combine easily to form fluoroacetic acid is very wide of the truth. It is, in fact, quite difficult to synthesize fluoroacetic acid, and certainly there is no evidence that it can happen in the body; furthermore, acetic acid (vinegar), if given early enough, is an *antidote* to fluoroacetic acid poisoning in some animals.—I am, etc.,

Cambridge.

RUDOLPH A. PETERS.

Obituary

Sir JOHN NEWMAN-MORRIS, C.M.G.
F.R.A.C.S., F.A.C.S.

Sir John Newman-Morris, consulting surgeon to St. Vincent's Hospital, Melbourne, and one of the most prominent medical men in the State of Victoria, died on January 3. He was 77 years of age.

John Newman-Morris was born in Melbourne on March 2, 1879, and was educated at Hawthorn College and at Melbourne University, where he graduated M.B., B.S. in 1903. Making surgery his career, he worked for many years on the staff of St. Vincent's Hospital. In later life he was a member of the advisory boards of the Royal Melbourne Hospital, Prince Henry's Hospital, and the Queen Victoria Memorial Hospital, Melbourne, and a member of the board of the Cancer Institute. In 1928 he was elected a Fellow of the Royal Australasian College of Surgeons and of the American College of Surgeons.

Newman-Morris was intensely interested in all matters affecting the health and welfare of the people and in the well-being of his own profession, and he held a remarkable number of offices in various organizations. Since 1945 he had been president of the Medical Board of Victoria, and was a member of the Federal Council and the first president (1936 to 1938) of the Australian Flying Doctor Service. At various times he was president also of many other bodies in the State of Victoria, including the Victorian Institute of Hospital Almoners (being also a member of its London council); the Voluntary Blood Donors Association; the Victorian Council of Social Training; the St. John Ambulance Association (1935-7 and 1946-7); the Old People's Welfare Council; the Medical Defence Association; and of the eighth session of the Australian Medical Congress in 1952, having been vice-president of the 1937 congress. He was also chairman of the Victorian Charities Board in 1936-7. An active and influential supporter of the Australian Red Cross, he was chairman of its national council, and visited Britain, Canada, and the U.S.A. as a member of a special wartime mission in 1942. Six years later he served as a vice-president of the seventeenth International Red Cross Conference held at Stockholm, and was vice-chairman of the general commission of the conference. During the second world war he was a member of the Central Medical Co-ordination Committee and the Commonwealth Alien Doctors' Board, under the National Security Regulations. He also served on the Standing Committee of Convocation of the University of Melbourne, and was deputy chancellor of the university from 1951 to 1953, and on the Victorian State Committee of the Royal Australasian College of Surgeons. In 1940 he delivered the Mackay Oration at Canberra and in 1945 the Stawell Oration at Melbourne.

Newman-Morris attained high office in the Venerable Order of St. John of Jerusalem, of which he was appointed a knight in 1945, being for a time treasurer of the Priory of St. John in Australia and, later, Receiver-General. A member of the British Medical Association for 50 years, he had been a member of the council of the Victorian Branch since 1918 and its chairman from 1922 to 1938, and president of the Branch in 1926-7. He was vice-chairman of the old Federal Committee of the B.M.A. in Australia from 1929 to

1932 and vice-president of the Federal Council from 1932 to 1938. Appointed C.M.G. in 1938 for public and social welfare services, he was created a knight 10 years later for outstanding services in Red Cross matters and voluntary hospital work. He married Miss Eleanor Jones in 1905 and had one son and one daughter. Lady Newman-Morris died in 1949.

H. VESEY WELLS, C.B.E., M.R.C.S., L.R.C.P.

Air Commodore H. Vesey Wells, who after some years in the Royal Navy had a distinguished career in the Royal Air Force, died on December 30, 1956. He was 79 years of age.

Hardy Vesey Wells was born at Bedford on January 30, 1877, the son of Mr. George Wells, J.P., and was educated at Bedford School and at St. Mary's Hospital, London, qualifying M.R.C.S., L.R.C.P. in 1900. Having joined the Royal Navy as a surgeon lieutenant, he was appointed to the Naval Wing of the old Royal Flying Corps in 1912 and had the unusual distinction of qualifying as a pilot in 1913. In the following year he was promoted surgeon commander, and served throughout the first world war. In 1919, having previously transferred to the newly formed Royal Air Force with the rank of lieutenant-colonel, he was granted a permanent commission in the R.A.F. as a wing commander. Promotion to group captain came in 1921 and to air commodore in 1930. During the course of his career he acted as assistant medical administrator in Ireland in 1918. Later he was principal medical officer, Inland Area (in 1920); with the British forces in Iraq (1924-6); with the Inland Area again (1927-32); and at the headquarters of the Air Defence of Great Britain (1932-4). Appointed C.B.E. in 1919, he was an Honorary Physician to the King from 1925 until he retired from the R.A.F. in 1934. Air Commodore Wells was president of the Mesopotamia Branch of the British Medical Association in 1925-6. He also served on the Central Council of the Association in 1937-8 as the representative of the Royal Air Force Medical Service, and was a member of the old Naval and Military Committee from 1935 to 1938. He contributed an article on the medical aspects of aviation to the *Journal of the Royal Naval Medical Service* in January, 1915, at which time he was serving in France as a staff surgeon in the Royal Navy, but the article was written in 1913, when he was in medical charge at Eastchurch Flying School. In 1916 he contributed an article, written jointly with Temporary Surgeon H. Graeme Anderson, to the *British Medical Journal* on injuries and destructive effects of aeroplane bombs, with suggestions on the precautions to be taken during hostile aerial raids.

Air Commodore Vesey Wells married in 1912 Miss May Justice, who survives him and by whom he had two daughters.

H. A. H. writes: "Hardy Vesey," as he was known to us in the Navy and Air Force, was a singularly attractive personality, vital and compelling. There are many who will be saddened by the news of his passing, despite his having been outdistanced the allotted span by almost 10 years. Although we had known each other it was not until the first world war had ended and Inland Area Command was formed that I had the good fortune to be appointed as his deputy. Well I had the good fortune at this move, because, having can I recollect my pleasure at this move, because, having been associated under Martin Flack, the physiologist, with the medical problems of flying, I was now to be on the staff of the man who from his personal experience as a pilot could guide those under him. For it was in May,

1913, when medical officer in charge of Eastchurch, that Hardy Vesey became the first British naval medical officer to obtain a Royal Aero Club certificate, No. 490 in fact. It is strange to look back to those times when, as he told me, he had to combine his medical duties with those of meteorological officer, "Met" forecasting being then in its infancy. The organization of Inland Area was a big task for him. There was no set pattern to follow and personnel was scarce in those days, but he surmounted all the difficulties with that wonderful resiliency, humour, and confidence to which we under him became accustomed both then and later, abroad and at home. And his human outlook and common-sense interpretation of regulations to meet their spirit rather than the written word was an example to us juniors and a happy one on many an occasion. His was truly a balanced outlook, and he believed in games as almost a necessity for the Service doctor, playing tennis and squash well above the average and getting much amusement from his determined sorties into the golfing world.

J. R. OWEN, M.R.C.P.

Dr. J. R. Owen, senior honorary physician to the skin department at the Royal Northern Hospital, London, died at a London hospital on December 23, 1956, at the age of 51.

James Roy Owen was born on March 28, 1905, and received his medical training at Birmingham, qualifying M.R.C.S., L.R.C.P. in 1929. After holding resident appointments at Queen's Hospital, Birmingham, he went into general practice at Bromsgrove in 1932. A few years later he moved to London and took the M.R.C.P. in 1937. Among the posts he held in the next few years were those of first assistant to medical out-patients at the London Hospital, honorary assistant physician at the Hospital for Diseases of the Skin, Blackfriars, and medical registrar at the Royal Cancer (now the Royal Marsden) Hospital and the National Temperance Hospital. During the second world war he served first as blood transfusion officer and acting assistant physician in the Emergency Medical Service at the National Temperance Hospital, and later in the R.A.M.C., attaining the rank of lieutenant-colonel. He was officer in charge of a medical division as a senior medical specialist, and in 1945 was mentioned in dispatches for gallant and distinguished services in Burma. On return to civilian life he decided to specialize in dermatology, in which he had always had a special interest, and he became honorary physician for diseases of the skin at the Royal Northern Hospital; the Ashford Hospital, Middlesex; Hampstead General Hospital; the Victoria Hospital for Children, Chelsea; the Queen Elizabeth Hospital for Children; and the Hospital for Diseases of the Skin, Blackfriars. At the time of his death he was senior honorary physician to the skin department of the Royal Northern Hospital. He contributed the chapter on toxic eruptions in *Modern Practice in Dermatology* (1950). Dr. Owen was a widower, his wife having died in 1953.

H. T. H. W. writes: Those who knew James Owen in former years will remember him as a man of immaculate appearance and debonair charm. He had a passion for adventure, and his past activities ranged from jumping by parachute to underwater exploration; with this passion was coupled a magnificent disregard for the trivialities of life. His essential kindness endeared him to colleagues, nurses, and patients, while his easy wit made him an excellent companion. To a man whose constitution had already been weakened by prolonged ill-health, the death of his wife a few years ago came as a profound shock from which he never recovered.

I last saw him a few days before I returned to the Middle East and perhaps two weeks before his death. He was completely composed and even cheerful as he gave me his advice and suggestions for disentangling some of the difficulties that now confront us in our Association activities in the Middle East. He must have been well aware of his approaching doom, but there was no word of complaint nor hint of any anxiety, and only a quiet determination to carry on as normally as possible to the end. We of the

Middle East Branch would like to record our gratitude to Louis Findlay both for his life of devoted service and for the calm courage of his end, and we also wish to offer our heartfelt sympathy and condolences to his wife and family.

W. G. CLARK, C.B.E., M.B., F.R.C.P.Ed., D.P.H.
The obituary of Dr. W. G. Clark was published in last week's *Journal* (p. 109).

I. A. G. M. writes: Recollection of W. G. Clark's constant kindness, and grief at the passing of that genial intellectual giant, make the penning of a tribute a difficult task. Dr. Clark—"George" to his contemporaries and "W.G." to those whom he affectionately termed his boys—was a great man, as well as a much-loved medical officer: a man big enough to acquire fame both in the old and in the modern brand of public-health work. Trained in the era of sanitation and environmental hygiene, he acquired in various posts in Glasgow a national reputation as an expert on housing, sanitary law, and hospital administration. In Edinburgh, in addition to maintaining and enhancing that reputation, he turned more and more to the newer aspects of public health. Realizing that further improvement in the health of the community would be possible only if the members of the community were prepared to co-operate actively, he developed health education on a scale previously unattempted in Scotland; he persuaded his council to appoint a medical officer and a lay assistant for health education; he gradually but steadily built up the health-visitor service, which he regarded as "the sheet anchor of the public health services"; and he organized health weeks and Sunday-evening film shows, never sparing himself in his efforts to make his city health-conscious. Appreciating that research was no less essential in preventive than in clinical medicine, he actively fostered research, and it is probably true to say that during his fifteen years as medical officer of health more papers were published from his department than from the health department of any other local authority. He devoted considerable attention to the health maintenance of the elderly and was chairman of the committee which drafted the report "The Ageing Population."

W.G.'s ability as a statesman and negotiator was almost proverbial. Sagacious, tactful, good-humoured, and persistent, he had the knack of converting opponents into allies; but when occasion warranted, or when the health of the community was endangered, he could be outspoken enough. Indeed, he often displayed not merely a powerful personality but moral courage of no mean quality. By his students at Edinburgh University (where he held the part-time post of senior lecturer in public health and social medicine) and by his staff W.G. was universally beloved. He was an inspiring chief, an excellent teacher, a brilliant administrator, and a man of boundless humanity. The whole profession is the poorer for his passing.

Dr. H. R. A. PHILP, medical missionary and minister of the Church of Scotland, died on November 14 at the age of 73. Horace Robert Andrew Philp was born at Pailton, Rugby, on February 1, 1883. From the Royal High School, Edinburgh, he went on to study medicine at Edinburgh University, graduating M.B., Ch.B. in 1909. After a period as house-surgeon in the Deaconess Hospital, Edinburgh, he became a member of the Church of Scotland's Mission to the Kikuyu people of East Africa (now the Kenya Colony Mission). Almost all his twenty years of service were at one station, Tumutumu, where he is remembered and loved to this day. Here, starting completely from scratch, he built up a simple yet efficient hospital which achieved a very considerable reputation in northern Kikuyuland. Part of the success of the hospital was due to the spectacular

treatment of yaws with arsenicals, but before Dr. Philp left much progress had been made in the treatment of leprosy and tuberculosis, as well as in general medicine and surgery. A well-developed system of training African dressers had been started, and for this Dr. Philp had prepared a simple textbook in Kikuyu, probably the first medical book in the language. Some of the men he trained are still at work in the hospital after forty years, a fact which says much for his training and inspiration. He also took a strong line against female circumcision, to this day a curse to the young womanhood of Kikuyuland. But he was above all an evangelist, his strong faith being an inspiration to many. Fine tributes to the esteem and affection in which he was held were paid at a memorial service at Tumutumu soon after his death. During the first world war he acted as medical officer for all the northern part of the Central Province. Retiring from missionary service in 1930, he became minister of the Church of Scotland in Newcastle. On the outbreak of the second world war he was appointed factory surgeon in Newcastle, and, among other things, re-organized the ambulance services in one of the largest engineering works there. Meantime he continued to act as minister. At the end of the war he gave up medical practice, but continued his work as pastor until he retired in 1955. At a memorial service held at Tumutumu soon after his death the tributes paid to his memory were evidence of the esteem and affection in which he was held.—W. M. B.

Dr. W. P. LOWE, honorary consulting radiologist to the Burton-on-Trent General Hospital, died at his home at Burton-on-Trent on December 10, 1956, at the age of 79. William Pickering Lowe, who was born on November 25, 1877, came of a well-known Burton family. Leaving Shrewsbury School in 1896, he went to Gonville and Caius College, Cambridge, where he took both parts of the Natural Sciences Tripos, and then, after a period of research in physiology, moved on to the London Hospital. After graduating B.Chir. in 1905 and M.B. in the following year, he held house appointments at the London and was for a time clinical assistant to out-patients at the Hospital for Sick Children, Great Ormond Street. Returning from voyages as a ship surgeon, he settled in Burton-on-Trent in 1909 in partnership with the late Dr. E. C. Salt. He was soon appointed to the staff of the General Hospital, and there began many happy years, with work in almost every department. He was a sought-after anaesthetist, he operated, and for some time he was in charge of the V.D. department. For many years he lectured on medicine to the student nurses, and, before joining the R.A.M.C. in 1917 for service in the first world war, even became a resident house officer once more when no junior men were available. The late Mr. C. T. Holford had introduced him to radiology, which gradually became his absorbing interest, and he worked hard to build up his department. He retired in 1948 as consulting radiologist to the hospital. In 1910 he became the first honorary medical officer to the "Babies Welcome" scheme, which was opened by voluntary effort in the town. He carried on this work for many years till the scheme grew up into the local infant-welfare service and was taken over by the local authority. At the same time he was taking his part in running a large general practice. He began this work if not in the horse-and-buggy days before the National Insurance Act of 1911, when there were large clubs as well as many private patients, and he worked on until two years after the inception of the National Health Service, when he retired, retaining only a small private practice. He was always anxious to attend clinical meetings at the hospital and meetings of the Burton-on-Trent Division of the British Medical Association, and was chairman of the Division in 1945-6. His knowledge of radiology was wide, and he kept up with the almost overwhelming advances in medicine during the fifty-two years his name was on the *Medical Register*. At Shrewsbury and Caius, William Lowe rowed with distinction, and went to Henley with his college boat. He was an

able musician, much influenced by Charles Wood in his Cambridge days, and his abiding interest was choral music and choir training. His golf was skilful, and he particularly enjoyed his many holidays at Machrihanish. He was friendly and gentle, diffident and most painstaking, always devoted to his patients and his beloved hospital, and he was a fine example of that past generation of practitioners who had the opportunity to serve in so many fields. His were the ability and the zeal to do good work everywhere.—E. G. F.

Dr. HARVEY GARDNER, of Birkdale, Southport, died in his sleep on December 23, 1956, at the age of 44. Harvey Gardner was born on August 10, 1912, and was a medical student at Liverpool University, qualifying M.R.C.S., L.R.C.P. in 1938. After holding resident hospital appointments in Liverpool he went into general practice at Brigg, Lincolnshire, for a short time before going into partnership with the late Dr. A. J. Lewis at Southport in 1942. Some five years later—after the death of Dr. Lewis—he was joined by Dr. D. MacDonald in the practice. Soon after settling at Southport Dr. Gardner became medical officer to the Post Office. Later he was appointed a Treasury medical officer and medical officer to Dr. Barnardo's Home at Birkdale. Ill-health forced him to give up general practice about eight years ago. However, he was able to serve as a member of a Ministry of Labour and National Service recruitment board for some years and as a boarding officer at Liverpool under the National Insurance (Industrial Injuries) Act. He was also medical officer to two industrial firms in the Southport district. His wife and daughter survive him.

E. G.-E. writes: The death of Harvey Gardner has robbed patients and friends of a "great and cultured gentleman" who had packed the 40-odd years of his life with selfless labour for others. His good sense, charm, wit, and painstaking interest in everything that he undertook earned affection and respect everywhere. The last eight years of his life were overcast by a serious cardiac lesion, but never once was this allowed to diminish the quality of such work as he was able to do. H. G. gave of his best or declined the attempt. His sense of humour, serious-minded conscientiousness, and utter loyalty marked him above other men. We who have been privileged to know him can never, will never, forget him.

Dr. HERBERT FOWLIE died suddenly at Aberdeen on December 25, 1956, one week after his 49th birthday. By heredity and environment Herbert Fowlie, who was born on December 18, 1907, should have been a farmer, but he turned to medicine, saying, as he often did, that he "hadna the brains for farming." He graduated M.B., Ch.B. at Aberdeen University in 1930, and, after house-appointments at the Cumberland Infirmary, Carlisle, and experience of general practice at Appleby, Westmorland, he settled in Aberdeen in 1940. He soon became one of the busiest, best-known, and best-loved family doctors in the city.

J. L. writes: "Hebbie" Fowlie was of great humanity and transparent honesty, of infinite patience when patience was needed, but of blistering impatience with incompetence or dishonesty. He made friends of all whom he met—in his practice, in his work for the British Medical Association, on the golf course, and on his beloved shooting and fishing excursions. If he had any enemies they were not of his making, and must have been folk of small account, for they were never heard of. For fifteen devoted years Hebbie Fowlie was honorary secretary of the City of Aberdeen Division of the B.M.A., but he was never proprietorial or dictatorial. To him the B.M.A. was like one of his patients, to be served and tended unsparingly and with scant regard for his own convenience. Hebbie was a wise and considerate colleague. He was also the family doctor of a number of medical households, including my own, and he paid us

a visit only a few hours before his death. He left us all laughing, for his gaiety was infectious and wherever he went he left laughter and lightened hearts behind him. We who were his patients can say with pride and gratitude, "He was our doctor, aye he left us cheered." For the last year of his life Hebbie knew that the illness which had already attacked him might strike again at any time. Mrs. Fowlie, an ideal wife for a doctor, comforted and sustained him in meeting the challenge of illness and in continuing with his work, and she was with him when his last call came. To her and to his daughter and two sons our sympathy goes out on the death of this very good man.

Major R. R. M. PORTER, I.M.S. (retired), writes: As one of Dr. Fowlie's patients, may I be permitted to put on record my great appreciation of his ability and of his unfailing kindness and understanding and my very real sense of personal loss on hearing of his death on Christmas Day? In my opinion Dr. Fowlie was one of the very best type of general practitioner, one whose unfailing care of his patients overrode any consideration of his personal convenience, and who never spared himself when they had need of his help. I feel sure I shall be expressing the feelings of his many patients, who knew they had in him not only a doctor but a friend, when I say that our sincere sympathy goes out to his widow and family.

Dr. A. P. HICK died at his home at Chippenham on December 26, 1956, at the early age of 44, after a long illness courageously borne. Alan Prowde Hick was born on May 2, 1912, the son of Dr. R. H. P. Hick, of Bracknell, Berkshire. Educated at Coatham School and at St. Thomas's Hospital, London, he qualified M.R.C.S., L.R.C.P. in 1937. He then held the post of house-surgeon at King Edward VII Hospital, Windsor, afterwards becoming medical superintendent of the hospital. After a short period at sea he volunteered for the R.A.M.C. in 1939 and went to France in that year, being evacuated from St. Nazaire in the summer of 1940. After serving in the Western Desert with the 7th Armoured Brigade he went with the same brigade to Burma and took part in the long trek back to India. In 1942 he was mentioned in dispatches for his gallant and distinguished services in Burma. After a short spell in England he landed with the 53rd Division in Normandy, and served with it, with the rank of major, until demobilization in 1945. In the following year he joined the partnership of Drs. G. W. Ayres, M. H. Evans, and R. S. Cox at Chippenham, where his cheerfulness and charm quickly won him many friends. His patients had the greatest confidence in him, for his manner was reassuring and he was an able diagnostician. He represented the Trowbridge Division at the Annual Meeting of the B.M.A. in 1955, and for some years he had been a divisional surgeon in the St. John Ambulance Brigade. He will be greatly missed both by his colleagues and patients in Chippenham and the surrounding district. He leaves a widow and two sons, to whom we extend our deepest sympathy in their tragic loss.

The obituary of Dr. C. E. BEVAN was published in the *Journal* of November 17, 1956 (p. 1181), and further tributes in the issue of December 22, 1956 (p. 1494). Dr. JOHN GUTHRIE and Dr. JOHN BREBNER write: The murder in Amiandos Hospital of Dr. Charles Bevan by a terrorist gunman was an act of such shocking and wanton brutality that one can still scarcely believe it to be true. Charles Bevan's work at Kyperounda Sanatorium was known and admired throughout Cyprus. He and his work were held in love and respect throughout the island, where he devoted the greater part of his professional life to the care of Cypriots suffering from tuberculosis. Many of his colleagues who knew him and his work more intimately than we did will be paying tribute to his skill, integrity, and devotion to his patients. Bevan's work did not end in the operating theatre or the wards. Because of widespread fear of

Vital Statistics

Infectious Diseases in 1956

The incidence of most infectious diseases in England and Wales during 1956 was relatively low. The chief features of the returns were the continued rise in the incidence of dysentery and the continued fall in the incidence of diphtheria. The incidence of dysentery was the largest on record. It was particularly high during the latter part of the first quarter, when a peak of 2,371 cases was reported in one week; this was 500 larger than the highest weekly total of previous years. The number of notifications of diphtheria during the whole of the year was less than one-half of the lowest weekly total in the pre-inoculation period. The largest numbers of notifications of diphtheria during the year were 63 in Lancashire, 54 in Warwickshire, and 38 in London. Only 8 cases were notified in Wales, and 20 English counties had no case at all.

A comparison of the returns for the past five years is given in the following Table:

England and Wales	1952	1953	1954	1955	1956
Scarlet fever	69,091	61,578	43,388	32,922	33,285
Whooping-cough	116,311	157,772	105,628	79,191	92,046
Measles	400,838	534,020	147,076	690,918	158,131
Acute poliomyelitis	4,504	5,251	2,388	7,305	3,853
Diphtheria	1,473	1,022	778	542	302
Meningococcal infections	1,687	1,783	1,569	1,423	1,478
Dysentery	15,665	19,540	33,976	41,414	53,006
Acute pneumonia	31,403	37,058	26,750	28,087	25,675
Typhoid and paratyphoid fevers	1,190	569	751	1,117	652
Great towns: Influenza deaths	1,019	3,381	947	1,591	1,216

Week Ending January 5

Notifications of infectious diseases in England and Wales during the week included: scarlet fever 572, whooping-cough 2,109, diphtheria 2, measles 10,970, acute pneumonia 644, acute poliomyelitis 63, dysentery 535, paratyphoid fever 3, and typhoid fever 2.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases (deaths for influenza) of certain diseases notified weekly in England and Wales (great towns for influenza). Highest and lowest figures reported in each week during the years 1947-55 (influenza, 1952-5) are shown thus ----, the figures for 1956 thus —. Except for the curves showing notifications in 1956, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

The largest variations in the notifications of infectious diseases in England and Wales during the week ending December 29, 1956, were decreases of 467 for whooping-cough, from 1,732 to 1,265, 348 for dysentery, from 696 to 348, 211 for scarlet fever, from 735 to 524, and 65 for acute pneumonia, from 465 to 400, and the only large rise was 303 for measles, from 6,575 to 6,878.

The largest rises in the incidence of measles were 176 in Lancashire, from 1,701 to 1,877, and 113 in Yorkshire North Riding, from 142 to 255; the largest falls were 87 in Surrey, from 216 to 129, and 87 in Yorkshire West Riding, from 503 to 416. The largest declines in whooping-cough were 63 in Yorkshire West Riding, from 137 to 74, and 55 in Durham, from 115 to 60. The largest fall in the number of notifications of scarlet fever was 30 in Lancashire, from 91 to 61. 3 cases of diphtheria were notified, being 7 fewer than in the preceding week.

49 cases of acute poliomyelitis were notified, and these were 3 fewer for paralytic and 8 fewer for non-paralytic cases than in the preceding week. The largest returns were London 10 (Lewisham 3, Islington 2, Wandsworth 2), Sussex 6 (Crawley U.D. 2), and Lancashire 5 (Clitheroe M.B. 2).

The chief centres of infection of dysentery were Warwickshire 66 (Coventry C.B. 62), Yorkshire West Riding 47 (Bradford C.B. 17), London 42 (Woolwich 10), and Lancashire 35.

Some Census Populations

The total of 43,757,888 persons enumerated in England and Wales at the 1951 census was 3.8 million more than the population enumerated in 1931, according to the latest book of tables on the census to be issued.¹ In 1801, at the first general census, the population of England and Wales was 8,892,536. It passed 10 million in 1811, 20 million in 1861, 30 million in 1901, and 40 million in 1951. Females have always been more numerous than males, but in the nineteenth century, when maternal mortality took a high toll, they were relatively less so than in the twentieth century. The proportion of females to males was highest after the first world war, when it was 1,096 to 1,000. It was lowest in 1821, at 1,036 to 1,000. In 1951 it was 1,082 to 1,000.

The number of people aged 100 or over at the census was 271, comprising 49 men and 222 women. Of the 49 men, 14 (29%) were single and 35 married or widowed; while of the 222 women 44 (20%) were single and 176 married or widowed. None had been divorced. These percentages of single people are higher than in any other age group from the age of 30 onwards.

On census day 0.8% of the population (349,058) were in civilian hospitals and nursing-homes; 0.5% were in institutions for the mentally ill or defective; and 0.2% were in homes for the permanently disabled or aged.

Of the persons enumerated in England and Wales, 6.0% were born elsewhere, as compared with 3.9% in 1931, 4.5% in 1911, and 4.3% in 1851. The greatest number not born in England and Wales were born in Scotland (1.3%), and the next after that in the Irish Republic (1.1%).

¹ Census, 1951, England and Wales, General Tables, 1957. H.M.S.O. (52s. 6d.).

England and Wales in 1955

The crude death rate in England and Wales from coronary thrombosis again increased in 1955, according to the Registrar-General's latest Annual Review.¹ It reached 1,589 per million living population, nearly double the rate for 1946, when it was 800. On the other hand, deaths from rheumatic fever and its cardiac sequelae diminished. In 1955 the rate was 5 per million for rheumatic fever and 188 for chronic rheumatic heart disease; the corresponding figures for 1946 were 19 and 243. The suicide rate has remained fairly constant since the end of the war. In 1955 it was 113 per million living, while in 1946 it was 106. But though the total rate has not changed much the deaths by soporific substances (chiefly barbiturates) and by domestic coal gas have notably increased—the drug suicides from 4 per million in 1946 to 13 in 1955, the gas suicides from 40 in 1946 to 53 in 1955. Compensatory diminution in the suicide rate is to be found among deaths due to drowning and to poisoning other than by soporifics.

A comparison with Scotland shows that, after allowance is made for differences in age and sex in the populations, England and Wales have had a slightly lower general death rate in each of the years 1951–5. In 1955 it was 11.6 per thousand as compared with Scotland's 13.1. The rate in England and Wales was the highest since 1951, when influenza caused many deaths.

¹ The Registrar-General's Statistical Review of England and Wales for the Year 1955, Part 1, 1956. H.M.S.O., London.

Medical News

Australian Research Fellowship.—The Royal Australasian College of Physicians has established a senior research fellowship—the Adolph Basser Research Fellowship—for research likely to contribute to knowledge in clinical medicine. The fellowship, tenable for five years and possibly renewable for a further term, is at the rate of £A.3,750 a year. A candidate must be a "trained research worker in a field related to the problems of clinical medicine," and the research during the tenure of the fellowship must be done in Australia or New Zealand. The closing date for applications is March 15. Full particulars may be obtained from the Hon. Secretary, Royal Australasian College of Physicians, 145, Macquarie Street, Sydney.

Influenza Vaccines.—During the past two winters (1954–5 and 1955–6) a Medical Research Council committee has been carrying out large-scale field trials of influenza vaccines, particularly of vaccines against virus A infections. The full results of these trials are expected in about a couple of months. In the meantime the 27,000 volunteers from industry and the R.A.F. who took part in the trials have been told, through their medical officers, the broad outcome. The results were disappointing. "Although some further evidence of the value of influenza vaccines was forthcoming," states the M.R.C. committee, "there was once more no virus A epidemic either sufficiently severe or extensive to show the true comparative value of the several vaccines under trial." However, the trials—together with the concurrent serological investigations—did apparently provide useful data on the comparative reaction rates of emulsified and saline vaccines, and about the antibody production by the various vaccines tested. In one of the main trials last winter (1955–6) two virus A vaccines, tested in 7,495 industrial volunteers against a virus B vaccine as a control, are said to have reduced the influenza attack rate by 26 and 30%, as judged by the experience of those inoculated with the control (virus B) vaccine; and during the more limited period of influenza prevalence within the total period of

observation they halved the attack rate. The same vaccines were also tested in 5,278 R.A.F. volunteers, but here the incidence of influenza was too low for a satisfactory comparison.

Olympic Award to the Stoke Mandeville Games.—The International Olympic Committee has awarded the 1956 Fearnley Cup to the Stoke Mandeville Games, in recognition of the outstanding services of the International Sports Movement for the Paralysed to the Olympic Movement. The Fearnley Cup is awarded annually to a sports organization in any country, and this is not only the first time the cup has been won by Britain but also the first occasion it has been awarded to a sports organization for the disabled. Previous winners have been organizations in Portugal, Iceland, Mexico, France, and Colombia. The International Sports Movement for the Paralysed was the creation of Dr. L. GUTTMANN, director of the national spinal injuries centre at Stoke Mandeville Hospital, Aylesbury. At the first Stoke Mandeville Games in 1948 there were 16 competitors, all from Britain; by 1952 the Stoke Mandeville Games had become international; and at the 1956 Games no fewer than 300 paralysed competitors from 19 different nations participated. Sir ARTHUR PORRITT, who is a member of both the International Olympic Committee and the British Olympic Council, is to present the trophy.

Advisory Council on Employment of the Disabled.—The National Advisory Council on the Employment of the Disabled, originally established in 1944 to advise the Minister of Labour and National Service, has been reconstituted by the Minister for a further period of three years. The medical members, all of whom have served before, are Dr. J. J. R. DUTHIE, Dr. MAXWELL JONES, Sir HARRY PLATT, Dr. D. STEWART, Dr. R. R. TRAIL, and Sir REGINALD WATSON-JONES.

Fellowships in Clinical Research.—The Medical Research Council invites applications for a further series of fellowships in clinical research, tenable at centres in the United Kingdom during the academic year 1957–8. These fellowships are open to suitably qualified medical graduates who wish to prepare themselves for a career in clinical research, and the intention is to give each fellow an opportunity to study methods of research in the basic subject most relevant to his particular clinical interest. The awards will be for one year in the first instance, and renewable annually up to a maximum of three years. Stipends will be at the rate of £950 per annum, rising by annual increments of £75 to £1,100 per annum, with superannuation provision in addition. Further details and forms of application may be obtained from the Secretary, Medical Research Council, 38, Old Queen Street, London, S.W.1. The closing date for these fellowships is March 1, but applications should be lodged earlier if possible.

Kathleen Schlesinger Fellowship.—The Medical Research Council invites applications for this fellowship, for which the closing date is February 9. Preference will be given to candidates proposing to investigate degenerative diseases of the central nervous system (including biochemical abnormalities). The stipend is between £700 and £1,000 per annum, and the fellowship is usually tenable at the National Hospital, Queen Square. The appointment is renewable annually up to a maximum of three years. Further details may be obtained from the Secretary, Medical Research Council, 38, Old Queen Street, London, S.W.1.

Fulbright Travel Grants.—The United States Educational Commission in the United Kingdom announces that, under the provisions of the Fulbright Programme, travel grants are available to citizens of the United Kingdom and Colonies to go to America for an academic or educational purpose, such as study, research, or lecturing. All awards are competitive. Recommendations are made by the Commission, but the final decision rests with the Board of Foreign Scholarships in Washington. There are two classes of grants

for applications for these grants, depending on the departure date: March 15 for those travelling between June 1 and July 31; and June 1 for those travelling after August 1. Full details are obtainable from the United States Educational Commission, 71, South Audley Street, London, W.1.

Royal College of Surgeons.—At the council meeting on January 10 Sir HENRY DAWSON, F.R.S., was elected to the Court of Patrons. A Moynihan lectureship was awarded to Professor R. M. JAMES, President of the Royal College of Physicians and Surgeons of Canada. Mr. M. J. SMYTH, surgeon to the Gordon Hospital, was appointed to give the first Gordon-Watson lecture.

Medical Society of London.—Sir GORDON GORDON-TAYLOR was unanimously elected an honorary fellow of the Medical Society of London at a meeting on January 14.

Dr. Hill in the Cabinet.—Dr. CHARLES HILL has become a member of the Cabinet, as Chancellor of the Duchy of Lancaster, in Mr. Macmillan's Government. Dr. Hill was previously Postmaster-General. Last month he was put in general charge of the Government's public relations (except in the field of Foreign Affairs).

Société Française de Médecine Psychosomatique.—This society, which was formed last summer in Paris with the aim of promoting scientific research in psychosomatic medicine, seeks to establish scientific collaboration with other societies, groups, and individuals interested in exchanging information in this field. Its officers are: president, Dr. F. MOUTIER; vice-presidents, Professor G. HEUYER and Dr. M. BOLGERT; secretary-general, Professor P. ABOULKER; secretaries, Dr. L. CHERTOK and Dr. M. SAPIR; treasurer, Dr. CH. BRISSET. Correspondence should be addressed to Dr. L. CHERTOK, Centre de Médecine Psychosomatique, 54, Avenue de la République, Villejuif (Seine), France.

Postgraduate Medical Studies at Oxford.—Dr. JANET VAUGHAN, Principal of Somerville, and Dr. G. E. F. CHILVER, D.Phil., have been appointed to the directorship of Postgraduate Medical Studies at Oxford until the beginning of the Michaelmas Term, 1960.

Edinburgh Postgraduate Prize.—The Lewis Cameron prize, valued at about £45, is offered to the Edinburgh graduate of not more than five years' standing who submits the best papers (published or not) on original work relating to the diagnosis of disease. The closing date for this competition is April 5. Further details may be obtained from the Dean of the Faculty of Medicine, Edinburgh University.

Food Standards Committee.—Professor B. S. PLATT, professor of human nutrition at the London School of Hygiene and Tropical Medicine, has been appointed a member of the Food Standards Committee by the Minister of Agriculture, Fisheries, and Food (with the agreement of the Minister of Health and the Secretary of State for Scotland). He fills a vacancy caused by the retirement of Professor S. J. COWELL.

COMING EVENTS

University of Liverpool.—Six refresher courses for general practitioners, March–July. All except one consist of four half-day sessions. Enrolment before February 7. Details from the Dean of the Faculty of Medicine, the University, Liverpool.

Chronic Rheumatic Diseases.—Concentrated week-end course at St. Stephen's Hospital, Fulham Road, London, S.W.10, March 9 and 10. Details from the secretary, Fellowship of Postgraduate Medicine, 60, Portland Place, London, W.1.

Royal Society of Health.—The annual congress will be held at Folkestone, April 30 to May 3.

Symposium on Ageing and Old Age.—Arranged by department of studies in psychological medicine, Liverpool University, March 23. Speakers, Dr. A. HERON, Professor A. B. SEMPLE, and Professor M. ROTH. Details from Dr. H. JARVIE, 77, Bedford Street South, Liverpool, 7.

American Trudeau Society.—52nd annual meeting, Kansas City, Missouri, May 6–9, in conjunction with the U.S. National Tuberculosis Association. Details from the association, 1790, Broadway, New York, 19, N.Y.

Second International Congress of Social Medicine.—In Vienna, May 31–June 2. Details from Professor T. ANTOINE, 23, Spitalgasse, Vienna, 9, Austria.

Fifth International Congress of Therapeutics.—Utrecht, June 4–6. Details from the general secretary's office, 6, Vondellaan, Utrecht, Holland.

NEW ISSUES

Medical and Biological Illustration.—The new issue (Vol. 7, No. 1) is now available. The contents include:

FRONTISPIECE.
THE B.M.A. SCIENTIFIC EXHIBITION.
CO-ORDINATE GRID MAPPING TECHNIQUE IN MEDICINE. Paul Zuckerman, William Regelson, and James F. Holland.
PHOTOGRAPHIC BACKGROUND CONTROL. Ralph Marshall.
DESIGN AND TECHNICAL INNOVATIONS IN A MEDICAL SCHOOL LECTURE THEATRE. C. A. ESKINE.
KINEMOGRAPHY OF LIVING BLOOD VESSELS. Brenton R. Lutz and George P. Fulton.
TELEVISION OF OPERATIVE SURGERY. David S. Ruhe and Michael R. Klein.
ANIMATION AND TITLING STANDARDS—I.B.P. MEDICAL GROUP.
EQUIPMENT AND METHODS:
PROJECTION CHARTS FOR LONGER THROWS.
ANTI-STATIC DARKROOM BRUSH.
ILFORD COLOUR FILM DUPLICATES.
VECTOGRAPHY.
ILFORD DIAPHRAGM TRIPOD HEAD.
STANDARDS OF PROCEDURE FOR THE PREPARATION OF 16-MM. PRINTING LEADERS.
BRUBAKER 35-MM. ENDOSCOPIC STILL CAMERA.
NEW DRAWING INSTRUMENTS.

Issued quarterly; annual subscription £2 2s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

Annals of the Rheumatic Diseases.—The new issue (Vol. 15, No. 4) is now available. The contents include:

GROWTH IN STILL'S DISEASE. B. M. Ansell and E. G. L. Bywaters.
STUDIES IN OSTEO-ARTHRITIS USING INTRA-ARTICULAR TEMPERATURE RESPONSE TO INJECTIONS OF HYDROCORTISONE ACETATE AND PREDNISONE. Joseph L. Hollander and Robert Moore.
ABSORPTION OF HYDROCORTISONE FROM THE JOINT CAVITY INTO THE CIRCULATION. Martti Oka.
LOCAL INJECTION OF HYDROCORTISONE AND PROCAINE IN OSTEO-ARTHRITIS OF THE HIP JOINT. V. M. Leveaux and C. E. Quin.
LABORATORY AIDS IN STEROID THERAPY. J. H. Glynn.
A HAND CORSET. H. Herschel.
PSORIASIS AND ARTHRITIS. V. Wright.
STUDIES OF HYALURONIC ACID IN RHEUMATOID ARTHRITIS. N. Egelius, E. Jonsson, and L. Sundblad.
RESPONSE BY ANTIBODIES TO TISSUE ANTIGENS IN THE COURSE OF RHEUMATIC FEVER. V. Wagner and V. Rejholet.
BOOK REVIEWS.
OBITUARY: MATHIEU-PIERRE WEIL.
AMERICAN RHEUMATISM ASSOCIATION. PROCEEDINGS OF ANNUAL MEETING, 1956.
HEBERDEN SOCIETY.
ARTHRITIS AND RHEUMATISM FOUNDATION.
ABSTRACTS.
INDEX.

Issued quarterly; annual subscription £2 2s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

British Journal of Ophthalmology.—The new issue (Vol. 41, No. 1) is now available. The contents include:

RADIOTHERAPY OF NON-MALIGNANT DISEASES OF THE EYE. M. Lederman.
AMORPHOUS SUBSTANCE IN THE TRABECULAR MESHWORK. F. Vrabec.
MUCINOUS LAYER COVERING THE CORNEAL ENDOTHELIUM IN THE OWL STRIX ALUCO. Ernst Bárány, Lennart Berggren, and Frantisek Vrabec.
POSTERIOR CONICAL CORNEA. H. B. Jacobs.
TRAUMATIC KERATOCONUS POSTICUS. H. B. Jacobs.
CHOROIDAL SARCOMA WITH A METASTASIS IN THE OPPOSITE ORBIT. J. Foster, W. Henderson, J. W. Cowie, and D. S. F. Harriman.
NEUROBLASTOMA. W. J. Levy.
RETINITIS PIGMENTOSA AND GAUCHER'S DISEASE. A. D. Charters.
NEW SUTURE NEEDLE FOR CORNEAL SURGERY. C. A. Pittar.
BOOK REVIEW, NOTES.
OBITUARY.

Issued monthly; annual subscription £4 4s.; single copy 8s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

ovaries the spring of the diaphragm may cause considerable discomfort. In such cases the use of an alternative type of cap, such as a vault-fitting Dumas or cervical cap, may be more suitable. The size of the cap required must be estimated. The diaphragm fits from the posterior fornix to the sub-pubic space, and a large range of sizes from which to select is required. Although fitting-rings may be used for this purpose, they are useless for instructing the patient.

It is important that the patient should be given careful instruction in locating her cervix and in placing the cap correctly. Instruction by diagrams or models alone is inadequate. Also instruction must be given in the use of a spermicidal jelly or cream with the cap—an essential part of the method. A subsequent examination must be carried out after the patient has practised placing the cap and returned with the cap in position. It is only at this examination that a final accurate estimation of the size of the cap required can be made. Subsequently routine checking of the satisfactory fit of the cap is advisable at six-monthly to yearly intervals. Post-natal refitting should always be carried out. From this it will be seen that it is impractical for a patient to fit herself with a Dutch cap.

"Petrified Men" of Pompeii

Q.—In "The Times" of October 8, 1956, a photograph was published of what was said to be "a petrified man found preserved in lava stone" at Pompeii. I have seen a number of these so-called "petrified men" in the museum at Pompeii in various attitudes which would suggest that they were fixed suddenly and rigidly where they were without even falling flat. Can you explain the mechanism by which a body could become petrified like this, or are they, as I suspect, fakes?

A.—The photograph in *The Times* is almost certainly of a plaster cast. The victims at Pompeii were overwhelmed by volcanic ash, not lava. (At Herculaneum the bodies were buried in lava.) After being moistened by rain, the ashes formed moulds round the bodies, which in the course of time disintegrated and left the moulds hollow. When these moulds are discovered they are filled with plaster to give a cast of the victim's body. All the "bodies" in the museum at Pompeii were produced in this way.

Sudden death probably accounts for the bizarre attitudes of the victims. Rapid death might have resulted from the inhalation of the hot dust and ashes, or from the inhalation of hydrogen sulphide. The first mechanism is in some ways comparable to the killing and fixation of machine-gunners by flame-throwers in the second world war. It is well known that "sulphurous fumes" accompany the eruption of many volcanoes, and, although hydrogen sulphide is not usually considered a very rapid poison, in high concentration it is said to be as dangerous as hydrogen cyanide.

Tab. Codein. Co.

Q.—What is the maximum safe daily dose of tab. codein. co. (B.P.) in an adult for the relief of an acutely painful condition likely to persist for a week or ten days? What toxic effects should be watched for? How should the dose be modified for children? Are there any special contra-indications?

A.—Tab. codein. co. (B.P.) are compound tablets each of which contains 7.5 mg. of codeine phosphate in addition to acetylsalicylic acid and phenacetin. The analgesic effect of tab. codein. co. is chiefly due to its aspirin and phenacetin rather than to its codeine content. There is no point in giving tab. codein. co. in large doses to relieve pain, for if the pain is so severe as to require very large doses of tab. codein. co. a stronger analgesic such as morphine, pethidine, or methadone is preferable. Doses in excess of two tablets of tab. codein. co. four-hourly, though possibly not dangerous, are undesirable as likely to cause nausea and vomiting. Constipation is usually the most troublesome side-effect of the drug, and in patients with prostatic hypertrophy or urethral stricture difficulty with micturition may

be encountered. Codeine may cause vomiting, and rarely abdominal pain may develop—probably due to pylorospasm. The risks of respiratory depression are very small and do not increase as the dose of codeine is increased. Rarely allergic skin reactions may be seen. The recommended analgesic dose of codeine phosphate for children is 0.4 to 0.7 mg. per lb. (1.54 mg. per kg.), and therefore half to one compound tablet of codein. co. may be given four-hourly with safety. Codeine should be used with caution in patients with obstruction of the lower urinary tract, and should be avoided in those known to be allergic to it.

Fluorides and Domestic Water-softeners

Q.—Is the use of a domestic water-softener likely to affect the fluorine concentration in drinking-water?

A.—No. The common domestic water-softener is operated with base-exchange material which removes only the cations which cause hardness—that is, calcium and magnesium. The anions—chlorides, sulphates, fluorides, etc.—are not affected by passing through a column of base-exchange material.

NOTES AND COMMENTS

Rudolf Steiner Movement.—Dr. P. ENGEL (medical officer, Camphill Rudolf Steiner Schools, Bielside, Aberdeenshire) writes: In your reply ("Any Questions?" December 29, 1956, p. 1560) regarding schools for handicapped children established by the Rudolf Steiner movement, it is stated that the availability of this accommodation is limited by cost. At this particular residential school, which is the largest of its type in this country, the present fees are £320 a year for children sent by local authorities (plus £36 for extra expenses such as clothing); private children pay 7 guineas a week and the same extra expenses. This compares favourably with other residential schools and institutions. Ever since local authorities have sent children to us we have had a considerable waiting-list, and many requests for admission had to be declined owing to shortage of accommodation of staff and of capital rather than by cost to parents or local authorities. In 1956, 65% of children at this school were paid for by local authorities in England and Scotland.

OUR EXPERT replies: Perhaps, if isolated, the remark that the availability of the accommodation is limited by cost may appear slightly ambiguous. But its meaning would surely have been quite clear to anyone reading the rest of the sentence, which ran as follows: "so that it (the accommodation) is in practice only accessible to those children whose parents can afford to pay for them, or in whose case public authorities are willing to pay for their tuition and care in one of the special schools or colonies." The correctness of this statement is borne out by Dr. Engel's letter.

Correction.—Dr. I. B. Sneddon asks us to correct an inadvertent error he made in his letter on varicose ulceration (*Journal*, January 5, p. 43). "The cause of varicose veins is chronic venous stasis" should have read "the cause of varicose ulcers . . ."

Books of "Any Questions?" and Refresher Course Articles.—The following books are available through booksellers or from the Publishing Manager, B.M.A. House. Prices include postage. *Any Questions?* Volumes 2 and 3 (8s. each); *Refresher Course for General Practitioners*, Volumes 2 and 3 (26s. 6d. each inland, 26s. overseas); *Clinical Pathology in General Practice* (22s. 3d. inland, 21s. 9d. overseas).

THE HORMONAL PRODUCTION OF NEPHROSCLEROSIS AND PERIARTERITIS NODOSA IN THE PRIMATE

BY

HANS SELYE, M.D., D.Sc., F.R.S.C., and PIERRE BOIS, M.D.

(From the Institute of Experimental Medicine and Surgery, University of Montreal, Canada)

[WITH SPECIAL PLATE]

Most of the experimental work on the possible participation of the adrenal cortex in the production of renal and cardiovascular lesions has been performed on the rat, because this species is especially sensitive to deoxycorticosterone, the most readily available mineralocorticoid. It had been clearly shown that overdosage with deoxycorticosterone can produce nephrosclerosis in rats, but many investigators considered it unwarranted to assume that, therefore, endogenous mineralocorticoids might participate in the pathogenesis of similar diseases in man. It was pointed out that rodents may occasionally develop periarteritis nodosa spontaneously and that the corticoid metabolism of the rat is fundamentally different in many respects from that of primates. (For literature see Selye, 1950, 1951; Selye and Horava, 1952, 1953; Selye and Heuser, 1954, 1955-6.)

In answer to these objections we attempted many years ago to produce renal and cardiovascular changes with deoxycorticosterone in rhesus monkeys, but found that even the highest tolerated doses of this steroid produced no periarteritis and only moderate degrees of nephrosclerosis in occasional animals. Besides, the renal lesions which occurred were invariably accompanied by often fatal spells of hypokalaemic paralysis. This high mortality precluded long-term experimentation and, in any event, clinical nephrosclerosis is not usually accompanied by muscular paralysis, so the experimental syndrome produced with deoxycorticosterone did not truly duplicate the disease as it occurs in man (Selye and Hall, 1943). Subsequently we learned that, in primary aldosteronism, nephrosclerosis and hypokalaemic paralysis do occur conjointly in patients (Conn and Louis, 1955-6), but this merely strengthened the view that if the disease produced by deoxycorticosterone in the monkey had a clinical counterpart it would be primary aldosteronism and not ordinary nephrosclerosis or periarteritis nodosa.

The recent discovery that the introduction of a methyl group at C² greatly enhances mineralocorticoid activity in certain steroids (presumably because it interferes with their normal metabolic destruction and activity) furnishes us with new tools with which to study this problem. It was found that 2-methyl-9(α)-fluorocortisol and 2-methyl-9(α)-chlorocortisol are more effective by far than aldosterone in producing sodium retention and

potassium excretion (Byrnes *et al.*, 1956) as well as in inducing nephrosclerosis and periarteritis nodosa (Selye and Bois, 1956 a-d) in the rat. In fact these two methylated compounds are the most active mineralocorticoids discovered up to now. It seemed to be of interest, therefore, to establish their toxicity in a primate before introducing them into general practice. We also hoped that such experiments would give us further indications concerning the possibility of reproducing nephrosclerosis, and perhaps even periarteritis nodosa, with comparatively small doses of a steroid, and that in an animal more closely related to man than is the rat. Of course, the success of such an experiment would depend upon the ability of 2-methyl-9-halo-corticoids to produce morphologic changes at dose levels that do not cause fatal paralysis. We hoped that this might be possible, as both these steroids possess some degree of glucocorticoid activity, in addition to their extraordinarily pronounced mineralocorticoid effects. These two activities of steroids are antagonistic in most respects (inflammation, lympholysis, catabolism), but synergistic as regards the production of renal damage.

In the present communication we wish to present data which show that, in fact, 2-methyl-9(α)-fluorocortisol (Me-F-COL) can produce marked nephrosclerosis and periarteritis nodosa in the rhesus monkey without causing muscular paralysis.

Materials and Methods

Eight young female *Macacus rhesus* monkeys, having an initial body-weight range of 1.8-2.7 kg., were divided into three groups whose mean initial body weight varied between 2 and 2.4 kg. On the first day of the experiment the right kidney was removed under sterile conditions through a sub-costal incision in all animals to sensitize them for the possible nephrotoxic actions of Me-F-COL. For the same reason a 1% NaCl solution was supplied as the sole source of drinking fluid, but the animals did not take much of this solution and tried to get their fluid mainly from the abundant amounts of vegetables (carrots, cabbage) and fruit (oranges, lemons) which were made available to them, together with a ground wheat and soy-bean meal diet as a source of nourishment.* Group I (two animals) was other-

*The basic diet was kindly adjusted with vitamin and mineral supplements by Dr. P. Marois as based on his experience with the feeding of the large monkey colony of the Institute of Microbiology of the University of Montreal.

wise untreated. In Group III (two animals) both adrenals and the right kidney were removed simultaneously through subcostal incisions. These adrenalectomized monkeys, as well as those of Group II (four animals), received Me-F-COL in the form of microcrystals in aqueous suspension, subcutaneously. The drug was administered daily in a single injection: 1 mg. in 0.5 ml. during the first week, 2 mg. in 1 ml. during the second week, 4 mg. in 1 ml. during the third week, 8 mg. in 0.5 ml. during the subsequent four days, 16 mg. in 0.5 ml. during the next ten days, and then 8 mg. in 0.5 ml. until termination of the experiment on the 80th day.

All animals recovered from the operations without complications, but soon the adrenalectomized monkeys of Group III became obviously ill, refused to take food, and exhibited signs of great weakness, especially in the muscles of the neck. This was thought to be due to hypokalaemic paralysis such as we had previously seen in monkeys overdosed with deoxycorticosterone (Selye and Hall, 1943). The animals were consequently given repeated intravenous injections of 1%–3% KCl solutions. They seemed to rally after each injection, but relapses continued, and, despite treatment with Me-F-COL, both the adrenalectomized animals died, one on the tenth, the other on the eleventh day after the operation. The remaining six monkeys were killed, under pentobarbitone sodium anaesthesia, by exsanguination on the 80th day, and their organs were removed and fixed in Susa solution for subsequent weighing and histological study.

Results

We shall discuss our observations on the two adrenalectomized monkeys first, because, as these animals died within the first fortnight, the results obtained were not comparable to findings in the other six monkeys, with which this communication is chiefly concerned. As explained in the preceding section, recovery immediately after adrenalectomy was uneventful, but in the course of the next few days repeated attacks of great muscular weakness developed in both animals, and intravenous administration of KCl was only partially successful in relieving these spells. Curiously, histological examination of the tissues in both these animals revealed an almost leukaemia-like infiltration of the hepatic stroma with mature and immature white blood cells; in many blood vessels (especially in those of the renal medulla and liver) there was a striking predominance of polymorphonuclear leucocytes in various stages of maturation. In the blood of the vessels we also found a great deal of strongly basophilic, amorphous material somewhat reminiscent of the so-called "haematoxylin bodies" of Klempner. At the same time oedema of the adventitia developed, sometimes accompanied by hyaline necrosis of the subintimal layers, in many arteries throughout the body. There was also some oedema and thickening of the endocardium with patches of hyaline necrosis. It was tempting to attribute this whole syndrome to some accidental infection, but the operations were performed under strict aseptic conditions, and, for the sake of greater security, 50 mg. of chloramphenicol was administered intramuscularly to all eight monkeys, both on the day of the operation and 24 hours later. Besides, no sign of infection was visible in any of the non-adrenalectomized animals. It is also unlikely that the syndrome could have resulted from mere adrenal insufficiency, since KCl did not aggravate it and treatment with the highly potent Me-F-COL had been initiated several hours before surgical intervention. Although neither of these possibilities can be excluded with certainty, it seems more probable that the adrenalectomized monkeys—noticeably sensitive to corticoid overdosage—merely exhibited a particularly acute syndrome of Me-F-COL intoxication. We intend to perform systematic studies on the response of adrenalectomized monkeys to 2-methyl-halo-corticoids as soon as these compounds become more readily available, so here it will suffice merely to mention these unexpected reactions.

Organ Changes in Treated Animals

The organ changes in the four non-adrenalectomized Me-F-COL-treated animals, which form the basis of this report, were essentially the same in all individuals and may therefore be discussed conjointly.

During the period of observation the untreated controls showed a mean gain corresponding to 12% of their initial body weight, while the monkeys treated with Me-F-COL lost 5% of their initial weight. Two of the monkeys in this latter group developed a moderate puffiness around the eyes and some bluish cutaneous striae around the abdomen.

At necropsy it was noted that all but one of the Me-F-COL-treated monkeys had abundant stores of adipose tissue underneath the skin of the abdomen and in the mesentery, despite the over-all loss of weight. In three of the treated animals chalky yellow patches of steatonecrosis were seen in the fat throughout the omentum and mesentery. In these foci histological examination revealed the presence of many foreign-body giant cells with needle-shaped intracellular spaces, which apparently corresponded to dissolved fatty acid crystals.

The most striking macroscopic changes occurred in the kidneys. These were definitely enlarged in all the treated animals (9.9–11.9 g.), as compared with the controls (6.3–6.7 g.). The renal surface was pale and mottled with numerous punctate light-grey or red spots. The outstanding characteristics of the renal lesions are illustrated in the Special Plate, Figs. 1–4. The minute red spots which were macroscopically visible on the surface of the kidney corresponded to focal glomerular haemorrhages. Many of the glomeruli were partially hyalinized, and on sections stained with the PAS technique the thickening of the basement membranes around Bowman's capsules and the proliferation of the glomerular stroma with "intercapillary glomerulosclerosis" were particularly evident. Some of the glomerular capillaries showed the "wire-loop" appearance due to accumulation of PAS-positive hyaline material underneath the endothelium. Often this progressed so far that large, pearl-like accumulations of hyaline material took the place of glomerular loops, and a picture indistinguishable from the renal manifestations of the Kimmelstiel-Wilson syndrome resulted. Many of the afferent glomerular arterioles underwent hyaline necrosis and numerous tubules were obliterated with hyaline casts. In a few areas the stroma of the kidney was infiltrated with leucocytes and showed some sclerosis; the stroma of the renal pelvis and papilla was oedematous in all the treated monkeys. None of the control animals showed any abnormality in renal structure.

The heart was manifestly enlarged (11.2–16.8 g.) as compared with the controls (10.2–10.5 g.), and even mere macroscopical inspection immediately revealed the presence of pronounced periarteritis nodosa in the coronary vessels of all four Me-F-COL-treated animals. The lesions were particularly pronounced along the anterior descending branch of the left coronary artery, which assumed a rosary-like aspect due to the inflammatory nodules. Histological examination showed that most of the branches of the coronary arterial system were affected. In some instances the periarteritic changes extended to all parts of the arterial wall and led to considerable hyaline necrosis, especially in the media and the subintimal layers. Occasionally the endothelium was totally destroyed, and thrombus formation occurred on the denuded surface. However, the aspect of the arterial lesions was quite polymorph, and within the same heart it was possible to find acute necrotizing and thrombotic arterial lesions as well as largely organized obliterative endangitis in different branches (Plate, Figs. 5–7).

The peripheral vessels were not systematically examined in all organs, but definite periarteritic lesions have also been noted in the gall-bladder, pancreas, kidney, and urinary bladder. Although the intensity of the lesions differed from case to case, all four Me-F-COL-treated monkeys exhibited signs of advanced periarteritis nodosa.

The arterial blood pressure had to be taken under profound pentobarbitone sodium anaesthesia by the direct intra-arterial (femoral artery) method, and therefore gave values which were probably much below the normal resting blood pressure. Yet it is noteworthy that, under identical conditions, the mean blood pressure in the controls was 62 mm. Hg (60–65 mm. Hg), as compared with 110 mm. Hg (75–135 mm. Hg) in the Me-F-COL-treated monkeys. These observations, as well as the already mentioned great cardiac hypertrophy, imply that the steroid did produce an elevation of blood pressure.

In the pancreas the most conspicuous changes were observed in the islets of Langerhans. In three of the four Me-F-COL-treated monkeys many of the islets (and in one animal almost all of them) contained cystic cavities filled with a poorly tingible homogeneous fluid. Some of the islets were almost totally transformed into cystic spaces. There was also a conspicuous hypertrophy and hyperplasia of the centroacinar cells, and throughout the pancreas there appeared to be transitional stages between proliferating centroacinar cell clumps and Langerhans islets (Plate, Figs. 8 and 9).

The adrenals of the treated animals underwent considerable atrophy (160–255 mg.) as compared with the controls (335–380 mg.). Histologically, all layers of the cortex participated in this involution. It is especially noteworthy that the glomerulosa—which many investigators believe to be independent of hypophysial regulation—was also very definitely involved in this compensatory atrophy. As an incidental observation it may be noted that in the cortex of the monkey adrenal comparatively large, homogeneous intercellular accumulations of strong PAS-positive material are frequently found. The origin and significance of this substance are not known, but in our series it was present both in the treated and in the untreated animals (Plate, Figs. 10 and 11).

The spleen underwent considerable atrophy in all the Me-F-COL-treated monkeys; its mean weight was 1.8 g. (1.3–2.0 g.), compared with 2.7 g. (2.3–3.1 g.) in the controls. Microscopical examination showed that the involution was principally due to a disappearance of the white pulp. Another striking histological change in all the treated animals was the deposition of PAS-positive hyaline material in the arteries of the white pulp. This was particularly conspicuous at the place of ramification into the penicilli, and often led to a complete obliteration of the lumen—with total loss of the vascular structure. PAS-positive material was also seen, free and within macrophages, in the interstitial spaces of the white pulp (Plate, Figs. 12 and 13). This process is presumably closely related to the hyaline changes of periarteritis nodosa, but, curiously, within the spleen infiltration with inflammatory cells was never conspicuous.

We saw no noteworthy changes in the thyroid and parathyroids of the treated animals. The anterior-lobe cells of the pituitary were perhaps somewhat atrophic, but hyalinization of the basophils, similar to that seen in Cushing's disease, was not observed. The thymus, on the other hand, became so atrophic in all monkeys treated with Me-F-COL that it was impossible to dissect the organ for accurate weighing. This involution, as well as the atrophy of the white pulp in the spleen, was presumably a manifestation of the glucocorticoid (lympholytic) potency of our steroid.

Discussion

These observations clearly indicate that Me-F-COL, a potent mineralocorticoid compound, can produce severe renal and cardiovascular changes in a primate. It remains to be seen whether the special "conditioning" which we used (unilateral nephrectomy and a comparatively high NaCl intake) is essential in order to obtain such effects in the monkey; however, our earlier work showed that in several other species (rat, hamster, fowl) such procedures sensitize but are not indispensable. The lesions in the monkey exhibited the histological characteristics of a

malignant nephrosclerosis, with changes typical of the Kimmelstiel-Wilson syndrome. At the same time there developed cardiac hypertrophy, an increase in blood pressure, widespread periarteritis nodosa, and a peculiar cystic transformation of Langerhans' islets. Since the last change was unexpected, we neglected to determine the glucose content of the blood and urine, and hence we do not know whether the monkeys became diabetic. Several earlier investigators observed minor changes in the Langerhans' islets of animals other than the monkey (rabbit, cat, dog)—especially after sensitization with alloxan or subtotal pancreatectomy—following heavy overdosage with cortisone, cortisol, the Δ^1 -corticoids, or A.C.T.H. (For literature see Houssay *et al.*, 1954; Penhos and Cardeza, 1956; Selye, 1950, 1951; Selye and Horava, 1952, 1953; Selye and Heuser, 1954, 1955–6.) But, so far as we are aware, this cystic change has not been previously produced with steroids in any species.

The average daily dose of Me-F-COL given to our monkeys during the 80-day observation period was 7.5 mg., and necropsy revealed that most of the injected hormone crystals remained under the skin, presumably because this steroid is very slowly absorbed. Consequently it is clear that only a fraction of the injected steroid was actually responsible for the production of these severe organ changes, although we cannot tell from our experiments the minimum amount required for the production of renal, cardiovascular, and pancreatic changes of this type.

Since in this experimental series the morphological organ changes were unaccompanied by signs of muscular paralysis, it is clear that the syndrome of malignant nephrosclerosis with periarteritis nodosa can result from overdosage with a steroid compound in a primate without the complicating signs of the periodic paralysis characteristic of primary aldosteronism.

There is no reason to believe that the adrenal cortex can produce steroids similar in their chemical structure to Me-F-COL. Still, we feel that our observations raise the question whether deviations from the normal pattern of steroidogenesis in the adrenal could result in the formation of corticoids having comparable biological actions. In any event, it is clear that the syndrome of generalized "hyalinosis" can occur in the primate as a result of corticoid overdosage, and that, contrary to common belief, periarteritis nodosa is not necessarily a manifestation of allergic hypersensitivity.

Summary

Experiments on unilaterally nephrectomized rhesus monkeys indicate that overdosage with comparatively small amounts of a new highly potent synthetic mineralocorticoid, 2-methyl-9(α)fluorocortisol (Me-F-COL), can produce severe malignant hyalinizing nephrosclerosis, with renal changes reminiscent of those seen in the Kimmelstiel-Wilson syndrome, cardiac hypertrophy, a rise in blood pressure, periarteritis nodosa, and a peculiar type of cystic transformation of Langerhans' islets.

This syndrome was not accompanied by the signs of periodic paralysis seen in monkeys overdosed with deoxycorticosterone and in patients with primary aldosteronism. It is concluded that a rather typical syndrome of malignant nephrosclerosis with periarteritis nodosa can be induced hormonally in the primate under conditions which bear no apparent relationship to allergic hypersensitivity.

Attention is called to the danger of producing similar changes by overdosage with 2-methyl-halo-corticoids in man, but further work will be necessary to establish with certainty whether endogenous secretion of corticoids can participate in the pathogenesis of malignant nephrosclerosis, the Kimmelstiel-Wilson syndrome, periarteritis nodosa, or Langerhans' islet changes in the human being.

As an incidental observation, it was noted that completely adrenalectomized monkeys given 2-8 mg. of Me-F-COL per day rapidly died showing a syndrome characterized by acute cardiovascular damage and leucocytic infiltrations, especially in the liver and kidney.

This work was supported (in part) by the Medical Research and Development Board, Office of the Surgeon General, Department of the United States Army, Contract No. DA-49-007-Md 186, and by a grant from the Muscular Dystrophy Association of Canada. The authors are also grateful to the Upjohn Company for their generous supply of 2-methyl-9(α)-chlorocortisol, and to Mr. Kai Nielsen for the preparation of the photomicrographs.

HYPERPLASIA OF THE ADRENAL MEDULLA

BY

W. DRUKKER, M.D.

P. FORMIJNE, M.D.

AND

J. B. v. d. SCHOOT, M.D.

From *Wilhelmina Gasthuis, University of Amsterdam*

[WITH SPECIAL PLATE]

In every case in which hypercorticalism is present the question arises whether the increased function is caused by a tumour of the adrenal cortex or by hyperplasia. The occurrence of hyperfunction of the adrenal medulla, causing permanent or paroxysmal hypertension, has long been known. In most cases a pheochromocytoma was thought to be the underlying cause. The number of cases in which such a tumour has been found and removed surgically is rapidly increasing.

In general, in discussing problems of the glands of internal secretion it can be stated that conditions which can be expected to exist as theoretical possibilities have a tendency to occur in practice. Such a theoretical possibility is clearly the existence of hyperplasia of the adrenal medulla as a counterpart to pheochromocytoma and in analogy to the conditions found in the adrenal cortex. However, the existence of a clinical syndrome corresponding with this possibility has been greatly neglected, and has even been emphatically denied in many recent articles and textbooks discussing adrenal disease and especially hyperfunction of the adrenal medulla. The following is a case in point.

Case History

The patient, an unmarried woman, first noticed that she had become nervous, irritable, and intolerant to heat in 1936, when she was aged 17. These symptoms disappeared gradually. In 1950 she had for the first time during the night an attack of occipital headache, palpitations, and severe diffuse sweating. Since then she has had similar attacks with increasing frequency, usually lasting two or three hours. Usually the attacks started without known cause, about twice a week. Dyspnoea developed, but there was no marked loss of weight. The patient was admitted to another hospital in 1951, where she was found to have marked tachycardia (150 per minute), an increased basal metabolic rate (+52%), and hypertension (220/100 mm. Hg). The presence of a pheochromocytoma was suspected. The usual tests for this disease gave no definite results, and treatment with antithyroid drugs had no effect. Perirenal insufflation with oxygen showed moderate enlargement of the left adrenal. On surgical exploration of the adrenals both glands appeared to be normal. No pheochromocytoma was found in the adrenals or in the para-aortic tissues, and a biopsy of the left adrenal was performed. The only finding was some hyperplasia of the adrenal cortex. The possibility of a diencephalic lesion was discussed, and treatment with methylphenobarbitone and hexamethonium was instituted without benefit.

First Admission

The patient was first admitted to our department in 1953. She again had marked hypertension (200/120 mm. Hg), tachycardia (120-140 per minute), and a very high basal metabolic rate (+90%), without other clinical signs of hyperthyroidism. The blood pressure fluctuated markedly. Investigation with radioactive iodine showed normal thyroid function.

The frequency of the attacks increased, and during each attack she felt acutely ill. The attacks consisted of severe occipital headaches, palpitations, and excessive sweating,

Record of blood pressure and pulse rate during period March 26 to April 9, 1953. Shows one severe attack on March 31 with rise in blood pressure and tachycardia, and two minor attacks on April 4 and 6 with tachycardia but no rise in blood pressure.

with a pulse rate reaching 196 per minute. Often there was an increase in blood pressure, especially the systolic pressure (see Chart). Other signs were red blotching on the face, neck, and chest, mild dyspnoea (25-30 respirations per minute), and occasionally tremor affecting the whole body. During two attacks the blood sugar was determined and found to be normal (105 and 106 mg. per 100 ml.). The duration of the attacks varied from 15 minutes to half a day. During mild attacks the blood pressure was not increased. Pharmacological tests with piperoxan, phentolamine, histamine, and hexamethonium gave no indications of the presence of a pheochromocytoma. Blood sugar tolerance was normal. Excretion of 17-ketosteroids was

FIG. 2.—Case 1 (cirrhosis). Double portal venogram complementary to Fig. 1 (diiodone of splenic venogram showing as pyelogram). Well-filled portal vein and less diversion; splenic vein not filled.

FIG. 3.—Case 2 (cirrhosis). Splenic venography by injecting 20 ml. 70% diiodone into substance of spleen percutaneously before operation. All dye is being diverted by way of large cluster of gastric varices into retroperitoneal veins which drain into inferior vena cava.

FIG. 4.—Case 2 (cirrhosis). Portal venography on same patient as Fig. 3, after abdomen opened, by injecting 25 ml. diiodone into radicle of jejunal vein. Almost all dye, admixed with blood in superior mesenteric vein, passes either to liver via a normal portal vein or to same clump of gastric varices by way of enlarged left gastric vein.

10 mg. in 24 hours, and of 11-oxycorticosteroids 0.1 mg. in 24 hours—values giving no indication of increased activity of the adrenal cortex. Kidney and adrenal function tests gave normal results, and serum electrolyte estimation did not show any abnormality. Perirenal insufflation again showed enlargement of the left adrenal, and it was decided to remove this gland. The operation was carried out in September, 1953, by Professor Boerema. This was followed by a decrease in frequency of the attacks and alleviation of the symptoms, especially the sweating; the blood pressure was reduced to 170/94 mm., and this level was maintained for some time. The palpitations and the tachycardia, however, persisted, while the B.M.R. remained high (+103%). It soon became evident that the operation had been unsuccessful. Treatment with hypotensive drugs, especially rauwolfia preparations, was tried without result, and the patient was discharged.

Second Admission

She was readmitted in 1954 with the same symptoms. Blood pressure, 190/130 mm. Hg; pulse 130 per minute; B.M.R., +96%. On treatment with chlorpromazine and reserpine there was a temporary lowering of the blood pressure and the B.M.R. to normal values, but a short time after her discharge from hospital both the blood pressure and the B.M.R. increased again.

Third Admission

In 1955 she was admitted for the third time. Her blood pressure was 230/130 mm., and B.M.R. +74%; the level of 17-ketosteroids in the urine was again normal; a cortisone suppression test showed a marked reduction in excretion of 17-ketosteroids. The condition of the patient became steadily worse.

The similarity of the clinical picture to that of pheochromocytoma was striking during every observation, but all special investigations to confirm the presence of such a tumour had been consistently negative. It was then thought that an explanation of this puzzling disease might be found in the existence of hyperplasia of the adrenal medulla, a condition which could be expected to give rise to a clinical picture resembling that of pheochromocytoma. The patient's condition necessitated reconsideration of the therapeutic possibilities, and finally it was decided to remove the remaining adrenal gland, which seemed to us a logical treatment if the diagnosis of hyperplasia of the adrenal medulla was correct. Although determination of the pressor amines in the urine, giving a value of 21 μ g. in 24 hours, did not support a diagnosis of hyperfunction of the adrenal medulla, this was disregarded on the assumption that this procedure could not be decisive, as even in true pheochromocytoma normal values are sometimes obtained. The possibility that the pressor amines in the urine have much lower values in medullary hyperplasia than in pheochromocytoma had also to be taken into account.

The right adrenal was removed in February, 1956, without difficulty. After the operation the blood pressure was kept at a normal level by noradrenaline intravenously, and the patient was also given cortisone orally, 75 mg. daily and later 37.5 mg. daily. The attacks, which had become very frequent before the operation, did not reappear, and the patient improved rapidly. The blood pressure was much lower, fluctuating between 145 and 160 mm. systolic and between 105 and 120 mm. diastolic. At the first and fifth months after operation the B.M.R. was +7% and +10% respectively. During these five months the patient remained well, except for slight arthralgia and a pulse rate of 130 per minute. These are possible signs of hypocorticalism in spite of a maintenance dose of 50 mg. of cortisone.

Pathological Findings

The pathological report on the left adrenal, removed in September, 1953, had been: "No pheochromocytoma is present. The adrenal medulla is clearly hypertrophic and has elongations between the cortex radiating to the sur-

face" (Special Plate, Fig. 1). At that time the significance of this report had not received enough attention. When the second operation was carried out, in February, 1956, it was decided to send the whole adrenal gland to the pathologist, as this offered the only possibility of obtaining a definite answer as to the nature of the disease. Re-entention of part of the gland for pharmacological investigation of the content of adrenaline and noradrenaline would have made it impossible for the absence of a pheochromocytoma to be proved anatomically.

The pathological report (Professor Deelman) on the right adrenal was: "Very marked local hypertrophy of the medulla. No tumour is present" (Special Plate, Fig. 2). This report confirmed the clinical diagnosis. The absence of a pheochromocytoma in the remaining adrenal gland was also proved; the presence of marked hypertrophy of the medulla made the existence of a tumour outside the gland very improbable. However, the significance of the hypertrophy of the adrenal medulla in the second gland is uncertain, in so far as some compensatory hypertrophy was to be expected following extirpation of the first adrenal gland in 1953.

Discussion

The case here described had the typical clinical picture of paroxysmal hypertension. The attacks were marked by a further rise of blood pressure, extreme sweating, and a high pulse rate. In the interval between the attacks there was persistent hypertension, with tachycardia, a very high basal metabolic rate, and normal thyroid function. The absence of other signs indicating the presence of a pheochromocytoma combined with this clinical picture suggested a diagnosis of hyperplasia of the adrenal medulla. This was confirmed by the report of the pathologist, who found marked hyperplasia of the medulla in both adrenals, especially the right, which had been removed in February, 1956.

From a study of the modern literature it seems that hyperplasia of the adrenal medulla is not regarded as a separate clinical entity, while Sprague *et al.* (1953) state that the condition is unknown. Soffer (1948) maintains that the complete classical picture of hyperadrenalism is not simulated by any other clinical condition, but he does not mention the possibility of hyperplasia of the adrenal medulla as a causal factor. Hartman and Brownell (1949) write that the proved cases of hypersecretion of the chromaffin tissue of the adrenals were due to a chromaffin tumour, and Goldenberg (1951) states that the only known instance of hyperfunction of the adrenal medulla in man was also due to chromaffin-tissue tumours. Further search in the literature has revealed, however, that the existence of hyperplasia of the adrenal medulla, either as an autonomic disease or as a consequence of renal disease, has been mooted before. Many years ago Vaquez (1904) suggested that the cause of the common type of essential hypertension may be found in the hypersecretion of adrenaline by the suprarenal gland. Vaquez and other investigators found a high incidence of diffuse cortical hyperplasia and of cortical adenomata in patients with hypertension. The fundamental difference between the cortex and the medulla was not clearly recognized at that time; moreover, critical investigations showed that there was no clear-cut correlation between the cortical changes and the presence or absence of hypertension.

Other authors have claimed the presence of medullary hyperplasia in essential hypertension, but this finding also has not been confirmed. The theory that increased secretion of adrenaline is the cause of the common type of essential hypertension has been generally abandoned. Treatment by unilateral adrenalectomy has been tried in a number of cases, sometimes with success, but on the whole the operation has been disappointing. Recently bilateral adrenalectomy has been investigated as a treatment for the more common forms of hypertension, though independent of the conception that hyperfunction of the adrenal gland may play an important part in the causation

of this disease. Other operations have been performed to eliminate the influence of the adrenal medulla. Riser *et al.* (1951) have devised a method of destroying the major portion of the medulla by sclerosing injections of salicylic acid. This treatment does not cause permanent damage to the cortex. They combined this procedure with the operation of Smithwick in cases of hypertension, sometimes of malignant type. Durante (1952) carried out curettage of the adrenal medulla, without destroying the cortex, in many cases in which he assumed there was increased activity of the adrenal medulla. His main indications were hypertension (sometimes of malignant type), Raynaud's disease, Buerger's disease, and sclerodermia.

Several authors have claimed that renal diseases can cause a secondary hyperplasia of the adrenal medulla. Sometimes the clinical picture of paroxysmal hypertension was found. An interesting case was that described by Giraud (1952). A woman of 50 had had paroxysmal hypertension for 18 months. The B.M.R. was +20%. At operation a right-sided hydronephrosis with abnormal arteries was found, and the right adrenal was also abnormal. After removal of the right kidney and adrenal the blood pressure became normal and the attacks disappeared. The adrenals contained a central cyst filled with haemorrhagic fluid, and there was hyperplasia of the medulla and cortex.

Apart from the presumed hyperfunction of the adrenal medulla in the common type of essential hypertension, cases have been presented in which hyperplasia or hyperfunction of the adrenal gland without primary renal disease was considered to be the specific cause of the hypertension. Many of these cases have been operated upon either without a clear-cut diagnosis or with a pre-operative diagnosis of phaeochromocytoma which was not confirmed at operation. Most of these cases had permanent hypertension. Unfortunately, in many of the cases the histological description of the changes in the adrenal has been incomplete.

Piotrowski and Ody (1935) observed a woman of 45 years with severe headache and hypertension, the highest systolic pressure being only 180 mm. Hg. Pain in the right lumbar region suggested the possibility of a right adrenal tumour. At operation no tumour was found, however, but the right adrenal was removed. The pathologist considered the condition to be one of hypersecretion of both cortex and medulla rather than of marked hypertrophy. After the operation the patient's condition improved. Leriche *et al.* (1935) described a similar case. A 44-year-old woman had severe headache and a hypertension of 200/100 mm. The B.M.R. was not mentioned. The right adrenal was removed and found to contain 6.3 mg. of adrenaline, which was considered to be higher than normal. Histological examination showed a central haemorrhage in the medulla. Here again improvement followed operation. Neither case is very convincing, and both could be considered as cases of common essential hypertension.

Bergstrand (1947) observed a case of severe permanent hypertension in a woman of 25 years who died from uraemia. At necropsy both adrenals were found to be greatly enlarged, weighing 90 g. together (normal 10-12 g.). Histological examination showed only small islands of medullary tissue, the glands consisting mainly of cortical tissue.

The presence of paroxysmal hypertension, presumably caused by medullary hyperplasia, has been found in only a few cases. Rowntree and Ball (1933) observed a man of 40 years (B.M.R. was +20% to +10%) in whom a diagnosis of phaeochromocytoma was not confirmed at operation. The patient died shortly afterwards, and histological examination showed hyperplasia of the adrenals. The authors do not mention whether this was a hyperplasia of the medulla or of the cortex, and in any case their opinion was that the changes were not sufficient to explain the clinical syndrome.

Schwab and Denniger (1952) describe a case in which surgical exploration for a phaeochromocytoma was made in a woman of 53. B.M.R. +9%. No tumour was found, but the left adrenal was excised. It weighed 12 g. At necropsy a central haemorrhage was found. Histological

examination showed marked hyperplasia of the adrenal medulla. Part of the adrenal investigated pharmacologically contained 49.5 µg. adrenaline and 48.5 µg. noradrenaline per gramme of tissue, which are very low values.

Lian *et al.* (1946) observed a woman of 42 years with paroxysmal hypertension in whom radiological examination showed the left adrenal to be slightly larger than the right. The left adrenal, which weighed 8.6 g., was removed. Histological examination showed a normal medullary zone and some increase of spongiocytes in the cortex. After the operation there was some improvement and the attacks disappeared. The B.M.R. is not stated. The same authors described another case, in a woman of 43 years, with a similar history. In this case the excised adrenal showed slight medullary hyperplasia, and again considerable hyperplasia of the spongiocytes. Four other cases with transient elevations of blood pressure are mentioned briefly, and are described as a minor form of paroxysmal hypertension caused by hyperplasia of the adrenal gland without tumour. In these cases also the hypertension was considered to be due to a sudden secretion of adrenaline in the blood as in phaeochromocytoma.

Our own case presents a number of features which distinguish it from other cases reported in the literature, especially: (1) the frequency and severity of the attacks, with marked tachycardia, hyperhidrosis, and general malaise; (2) the persistently high basal metabolic rate, with values of up to +100% and normal thyroid function; (3) the failure of unilateral adrenalectomy to influence the condition; these features, combined with the negative results of tests for phaeochromocytoma and the failure to find a tumour at the first exploration, led us to the diagnosis of medullary hyperplasia. Other aspects are: (4) the complete anatomical investigation of the adrenals showing the presence of medullary hyperplasia in both glands and the absence of tumour and of cortical hyperplasia; and (5) the complete disappearance of the attacks and the return of the B.M.R. to normal after removal of the second adrenal.

In conclusion some reference should be made to the differential diagnosis of paroxysmal hypertension. Although many conditions giving rise to this clinical syndrome have been mentioned in the literature, most of them appear to be rare. Mackeith (1944) mentions symptomatic paroxysmal hypertension in lead intoxication, eclampsia, tabes dorsalis, aortic insufficiency, angina pectoris, angina pectoris vasomotoria, tumours of the thalamus, and diseases of the vagal nerves. Rogen (1947) described an interesting case of paroxysmal hypertension caused by a glioblastoma in the right hemisphere in which the thalamus and hypothalamus were not affected. The blood pressure was normal (110/70 mm. Hg) between the attacks, but rose to 260/140 mm. Hg during attacks. At necropsy the absence of a phaeochromocytoma was proved. The connexion between renal disease and paroxysmal hypertension has already been referred to.

Summary

A case of hyperplasia of the adrenal medulla which gave rise to a clinical picture closely resembling that of phaeochromocytoma is described. The left adrenal was removed without effect. The diagnosis of medullary hyperplasia was made clinically before a second adrenalectomy, and this was confirmed by histological examination.

The main clinical features consisted of repeated attacks with tachycardia, excessive sweating, and an additional rise in blood pressure, the blood pressure already being permanently elevated, and the B.M.R. very high (up to +100%) without signs of hyperthyroidism.

After removal of the second adrenal all the symptoms and most of the clinical signs disappeared. The attacks did not reappear, the B.M.R. became normal, and the blood pressure fell. This improvement has now been maintained for five months.

Marsden Hospital, London

[WITH SPECIAL PLATE]

Radiological demonstration of the portal vein is a useful investigation which materially assists in the surgical treatment of portal hypertension. Its purpose is to demonstrate the presence and nature of the main channels in the portal tree, especially the portal vein itself. Accuracy is essential, otherwise it will be misleading. Two methods of obtaining portal venograms are commonly practised. In the first, which may be referred to as splenic venography, 20-30 ml. of 70% diodone is injected into the substance of the spleen itself. In the second the dye is injected into a radicle of the portal vein after the abdomen has been opened. Both methods have their advantages and disadvantages, but neither can be depended upon to demonstrate more than half the portal tree. Much has been written on the subject recently, most articles stressing the value of one or other method. It is our purpose in this brief communication to emphasize that both are sometimes necessary in order that the portal vein may be completely delineated.

Splenic Venography

Splenic venography is carried out as a diagnostic method or as a preliminary to operation (Abeatici and Campi, 1951; Dreyer and Budtz-Olsen, 1952; Walker *et al.*, 1953; Atkinson *et al.*, 1955). It is performed under local analgesia or general anaesthesia, and provides information which may be a valuable guide to the nature of the disease process and to the type of operation required in the particular case. Discomfort is minimal if the injection is well conducted in a suitable patient. Unfortunately splenic injection is by no means foolproof, for the following reasons. It is difficult to inject the diodone accurately into a spleen which is not grossly enlarged. It is unsafe to puncture a spleen when the clotting power of the blood is reduced by a deficiency either of platelets or of prothrombin. Sometimes the spleen can be damaged with consequent haemorrhage, and a few deaths have occurred as a result of this accident (see, for example,

Gvozdanovic *et al.*, 1953; Reynolds *et al.*, 1955). We have often noticed a material perisplenic haematoma at laparotomy following splenic injection (see Cooper *et al.*, 1953). For some patients the investigation, when carried out under local analgesia, is an ordeal and should therefore be avoided. Lastly, venography by the splenic route is out of the question for patients whose spleen has been removed. We have had experience of 20 such "post-splenectomy bleeders."

Portal Venography

When the above contraindications to splenic venography apply to patients who have been selected for surgical treatment, the portal vein can be demonstrated only by the direct method. Apart from this regarding it as an alternative technique, direct portal venography is applicable to all patients undergoing abdominal exploration for portal hypertension and allied diseases. It is the older and more elastic method, in that any suitable radicle of the portal vein can be used (Blakemore and Lord, 1945; de Sousa-Pereira *et al.*, 1949; Santy and Marion, 1951). It is far more certain to provide an accurate picture of the anatomy of the portal vein (Special Plate, Figs. 2 and 4), whether this vein is normal or not. A negative finding on splenic venography may mean nothing (Plate, Fig. 3), whereas such a finding on portal venography is proof that no portal vein exists. When this is the case the splenic vein is often delineated. It is not so important to show the splenic vein when a large and normal portal vein is present, because we usually prefer to use the portal vein for shunt operations. Portal venography is the safer method.

When it is our intention to demonstrate the trunk of the portal vein we use a jejunal vein for the injection. On other occasions we have used the left gastro-epiploic, left gastric, or even a branch of the splenic vein itself. The simplicity, speed, and safety of the method have recommended it to us (du Boulay and Green, 1954; Kemp Harper, 1955). However, it has two great disadvantages—it cannot be used until the abdomen has been opened and it does not usually demonstrate the splenic vein. It is less likely to show up the anastomotic vessels draining blood from the spleen. Lastly, an x-ray apparatus of high output is not usually available in the operating theatre, so that the number of serial radiographs of good quality which can be obtained from one injection is limited. When splenic venography is done in a department of diagnostic radiology, however, this limitation is less likely to apply.

In discussing the two methods, the haemodynamics of the blood flow must be considered in addition to details of technique.

"Streamlining" and Diversion of Portal Blood

Radio-opaque solutions injected into the spleen will delineate only vessels or parts of vessels which drain off splenic blood. It has been recognized for very many years that "streamlining" is a phenomenon commonly encountered in the portal vein (McIndoe and Counseller, 1927; Helps and McDonald, 1954). It has often been suggested that in some animals blood coming from the spleen and inferior mesenteric vein travels more to the left lobe of the liver than to the right, while blood from the right colon and small intestine travels to the right lobe of the liver. We have on many occasions been able to demonstrate "streamlining" in the portal vein giving preferential supply to the right lobe of the liver, but good filling of the left lobe of the liver from splenic injection has not often been an outstanding feature. Sometimes "streamlining" has prevented diodone from fully delineating the portal vein, and has thus given a false picture easy to confuse with partial thrombosis (Hunt, 1956).

When intra- or extra-hepatic obstruction is present, blood is diverted through other channels into the systemic circulation. Blood from the spleen and from the stomach seems to be the first to be side-tracked up oesophageal varices or back through the veins of Retzius into the retropancreatic, paracolic, and para-splenic veins. The diaphragmatic veins may also play a large part in this diversion of portal blood.

On three occasions recently diodone injected into the spleen has failed to reach a normally patent portal vein, having been totally diverted. (For an example see Special Plate, Fig. 3.) In such circumstances it is possible to build up a picture of the portal tree only by using both methods one after the other as required, thereby filling the complementary parts of the portal system.

Serial Radiography

In all methods of angiography in which radio-opaque material is injected into a flowing stream of blood an accurate representation is more likely to be obtained by multiplicity of pictures—the method of serial radiography. The greater the number of exposures made—that is, the more cinematographic the technique—the more complete will be the picture of the system being investigated. In the portal tree, however, multiplying photographs is not going to alter "streamlining" or diversion of portal blood along adventitious channels. Leger (1955) attempts to circumvent the misrepresentation due to these causes by the injection of a large quantity of contrast medium and the taking of many serial films, but even he illustrates a case in which this method failed to prevent a misdiagnosis of portal thrombosis.

Combined Splenic and Portal Venography

Our own experience of portal venography dates back to early 1949. In every case of portal hypertension that has been operated upon since that date the portal tree has been investigated radiologically. Other cases of splenic disease have been similarly investigated. We have used the method as a technical aid to operation rather than as a diagnostic procedure. Altogether we have more than 40 percutaneous splenic venograms and nearly 150 portal venograms available for study. On about 15 occasions both methods were carried out. We have arrived emphatically at the conclusion that in certain cases a combination of the two methods is the best way of obtaining accurate information (Rousselot, 1953).

The decision whether or not to operate is arrived at on clinical, biochemical, and radiological assessment. The patient is anaesthetized and placed on the operating table in such a position that venograms can be obtained by both methods. The patient's arms are folded across the upper chest and fixed so that they do not interfere with the operation or with serial radiography (Hunt *et al.*, 1956). The skin over the spleen is sterilized and 20–30 ml. of 70% diodone is injected directly into the spleen by the most convenient route (proportionately smaller quantities are used for children). If the spleen is very large, this is usually done through the abdominal wall; if not very large, through a convenient intercostal space. The anaesthetist maintains absolute apnoea during the course of the investigation, so that damage to the spleen is minimal and there is no risk of capsular tear. The films are developed during the next few minutes while the field of operation is being sterilized and the final arrangements for operation made. They are thus available in time to guide the surgeon in placing the incision. Sometimes the portal vein is clearly demonstrated and there is no need for further radiological investigation. If the portal vein is indistinct or appears to be absent, portal venography is performed after the abdomen has been opened. We use a standard mobile x-ray apparatus and take two pictures, one at the exact finish of the injection of diodone and another 1½ seconds later (du Boulay and Green, 1954). In addition, we usually estimate the speed of flow in the portal or the splenic vein, using the method described by Hunt (1954), and this sometimes provides information of great value.

The dual approach to the radiological demonstration of the portal tree, when it has been possible, has not so far failed us. To illustrate our thesis we have selected the radiographs obtained in two patients with cirrhosis of the liver who were operated upon for massive recurrent haematemesis from oesophageal and gastric varices. The splenic venogram in Case 1 (Special Plate, Fig. 1), shows a well-filled splenic vein and diversion of splenic blood up the left gastric vein. The portal vein and its main branches is no more than out-

lined by the diodone—a good example of laminar flow which could easily be mistaken for thrombosis. The portal venogram (Plate, Fig. 2), on the other hand, demonstrates that the portal vein is normal and suitable for porta-caval anastomosis, which was duly constructed without difficulty. In the splenic venogram from Case 2 (Plate, Fig. 3), the dye can be seen to have been injected well into the substance of the spleen. There is no real splenic vein, but there are two large channels draining the blood into an enormous mass of gastric varices. Fig. 3B shows that this blood percolates away from these varices into retropancreatic channels which communicate with the inferior vena cava, which is distinctly though faintly shown. Drainage of the portal into the systemic system can thus be seen, and yet the patient suffered from massive haemorrhages. It was evident that all splenic and much gastric blood was being diverted away from the portal vein, and that further venography would be necessary once the abdomen had been opened. In Fig. 4 of the Special Plate are reproduced the pictures obtained by portal venography. Traces of the dye from the splenic injection still remain within the spleen. The portal vein is beautifully shown together with the left gastric vein draining blood back into the same mass of varices as demonstrated by splenic venography. On studying the four radiographs it was adjudged that the oesophageal and gastric varices would be most directly decompressed if a porta-caval anastomosis could be successfully constructed. This was therefore done, and the patient has had no further haemorrhage.

For some years we have considered a natural development of the double method by connecting splenic and jejunal needles to a single syringe containing the diodone and obtaining venograms by both methods simultaneously. Unfortunately it is complicated and time-consuming, and adds to the risks of technical fault in that it is necessary to watch two needle-points instead of one. We therefore prefer the simpler methods as described above.

Summary and Conclusions

Radiological demonstration of the portal tree is a valuable method of investigation. It can be achieved by the injection of contrast medium into one or other, or both, of the two main radicles of the system: into the spleen to delineate the flow of splenic blood, which may be partially or completely diverted from the portal vein; or into a jejunal vein to delineate the flow of mesenteric blood to the portal vein itself. The former may be carried out pre-operatively, the latter must be done at operation. It is often essential to perform both before a composite and complete picture of the portal blood flow can be obtained. The laminar flow of blood in such veins may also give rise to deceptive appearances which should be guarded against by using both methods.

MITRAL REGURGITATION WITH MOBILE VALVE CUSPS

BY

D. M. DOUGLAS, M.S., Ch.M., F.R.C.S.

Professor of Surgery, University of St. Andrews

[WITH SPECIAL PLATE]

The essential pathological difference between mitral regurgitation and stenosis as gauged by the gloved finger at operation lies in the damage done to the cusps by the inflammatory process. In pure stenosis, though the free edges of the valve have fused except for an area of about 1 cm. in the middle (Brock, 1952), the cusps are soft, pliable, and mobile, so that they can come into apposition above the aperture during ventricular systole (Fig. 1). In regurgitation, on the other hand,

FIG. 1.—Diagrammatic representation of movements of mitral valve in mitral stenosis and regurgitation. Note that the aperture remains open in each case, closure of the valve taking place above the aperture in stenosis. Very little movement of the cusps takes place in regurgitation, the cusps being converted into a shallow rigid cone with a central aperture.

the cusps are so damaged by rheumatic endocarditis that the resultant rigidity and contracture, with or without calcification, holds the orifice in a gaping position and prevents apposition of the supravulvar area (Fig. 1).

The rigidity of the cusps, together with the gaping orifice, may reasonably be taken to account for the classical heart sounds of mitral regurgitation. The soft quality of the first sound is due to the lack of movement of the cusps in ventricular systole, and the pronounced systolic murmur to the retrograde flow through the gaping orifice, which is often irregular because of calcification. Conversely, the classical heart sounds of mitral stenosis may be attributed to cusp mobility, the loud, abrupt quality of the first sound being due to vigorous propulsion of the cusp, particularly the anterior cusp,

into the atrium by the thrust of ventricular systole (Sellors *et al.*, 1953). From the experiment of palpating the movement of the anterior cusp in cases of pure stenosis while at the same time carrying out direct auscultation with a sterile stethoscope placed over the atrio-ventricular ring I find that the loud ringing first sound coincides exactly in time with the vigorous "ballooning" of the anterior cusp. However, there must clearly be another element responsible for the loud first sound of mitral stenosis, since the most mobile cusps of all are those of the normal heart, and the apical first sound of the latter is less loud than that of mitral stenosis. Wood (1954) suggests that the additional element in stenosis is the pressure gradient across the valve in diastole. This "balloons" the cusps deeply into the ventricle right up to the moment when that chamber contracts. In the normal heart, however, the left ventricle fills quickly, so that towards the end of diastole the mitral cusps tend to float into apposition, and therefore shut more quietly when the ventricle contracts. In other words, the cusps in pure stenosis move from ventricle into atrium in a more explosive fashion than do the normal cusps.

A consideration of these facts points to the conclusion that cusp mobility rather than valve closure is the cause of the characteristic first heart sound in mitral stenosis and that aperture size is only indirectly concerned.

Three cases are now presented which are exceptions to the general rule. In each instance quite gross mitral regurgitation was detected at operation although the valve cusps were soft and mobile. In each case a confident pre-operative diagnosis of pure stenosis was made because of the loud, abrupt first heart sound and the diastolic murmur.

Case 1

A married woman aged 30 years presented with increasing dyspnoea for six or seven years. She had a child at 27 years, and during the pregnancy had been very distressed. A spontaneous delivery occurred, but she had a severe attack of pulmonary oedema on the third post-natal day. She recovered a good deal for six months, but increasing dyspnoea with attacks of nocturnal dyspnoea necessitated admission to hospital. Her exercise tolerance was as follows: walking on the level, 25 yards (22.86 m.); upstairs, 4 steps; no hills; very light housework; no shopping. Pulse, 100 per minute, regular in time and force. Blood pressure, 110/75 mm. Hg. Lungs: widespread crepitations at both bases. Heart: apex beat in 5th interspace in mid-clavicular line; impulse diffuse; no thrill. Heart sounds, mitral area: first sound clear-cut; mid-diastolic murmur with presystolic accentuation; faint systolic bruit not conducted. Radiological examination (Special Plate, A) showed the heart to be enlarged in its general size, but no definite increase in vascular markings in the lung fields. The left atrium was enlarged, the aorta of normal type. A pre-operative diagnosis of pure mitral stenosis was made.

At operation the following findings were noted. A forceful regurgitant jet was palpable coming through the mitral valve. The aperture itself was quite large, measuring 2 cm. in its transverse axis. There was very little induration of either commissure and the anterior cusp was mobile. With a sterile stethoscope placed on the atrioventricular region the same findings were noted as in the ward—namely, a loud, abrupt first sound and a low, rumbling diastolic murmur with presystolic crescendo. The soft systolic murmur noted pre-operatively was not audible at operation. A note to the cardiologist concerned contained the following comment: "The anterior cusp, though shortened, was still mobile, and this was the reason we were led astray. It could be felt to 'flap' with each ventricular systole marking the typical loud first sound."

The functional result in this case has been poor. After initial improvement dyspnoea again became severe, and the patient has recently been admitted to hospital in congestive failure during a pregnancy.

Case 2

A married woman aged 32 complained of increasing breathlessness over five years. On admission her exercise tolerance was: walking on the flat, 100 yards (91.44 m.) slowly; stairs, one flight slowly; light housework. Sleeps with three pillows. An attack of pulmonary oedema with haemoptysis precipitated her admission to hospital. Pulse, 85 per minute. Blood pressure, 130/80 mm. Hg. No cyanosis or venous distension. Lungs clear. Heart: regular rhythm; apex beat in 5th interspace inside mid-clavicular line; no heave. Mitral area: presystolic-diastolic murmur; first sound abrupt and loud; soft systolic bruit not conducted. Radiography of heart (Special Plate, B) showed mitral configuration and marked enlargement of left atrium.

At operation a considerable degree of regurgitation was found to be present. The valve was also stenosed, the aperture measuring about 1 cm. and being ovoid. The anterior cusp was quite mobile, but was apparently unable to occlude the orifice. After splitting the commissures a finger was passed into the ventricle and the area of the chordae tendineae explored. The impression was gained that the free edges of the cusps were tacked down to the ventricular wall and thus prevented from closing.

The functional result in this case has been better. The patient has returned to work in a factory and has walked four miles (6.4 km.) on the flat.

Case 3

This patient, a married woman aged 37 years, complained of fatigue and dyspnoea for a period of six years. She had had one severe attack of nocturnal paroxysmal dyspnoea for which she was admitted to hospital in 1949. On the present admission her exercise tolerance was: walking on flat, one mile (1.6 km.); walking up hills, very breathless. Sleeps with one or two pillows. Pulse, 78 per minute, fibrillating. Blood pressure, 160/90 mm. Hg. Lung fields normal. Heart: apex beat in 5th interspace 4½ in. (11.5 cm.) from midline. Mitral area: diastolic murmur of low intensity; loud ringing first sound terminating in harsh systolic murmur conducted to axilla. Radiological findings are shown at C on the Special Plate.

At operation the mitral orifice was found to be gaping wide open, measuring 2 cm. by 1 cm., and there was free reflux of blood during ventricular systole. The anterior cusp was freely mobile, and it was difficult to be sure of the cause of the regurgitation. It was considered possible that the chordae tendineae attached to the anterior cusp were so shortened that, although the cusp was not itself contracted, it was restrained from coapting with the posterior cusp.

In this case the result has been indifferent. The patient's exercise tolerance has increased somewhat, but she still has precordial compression and a good deal of bronchitis.

Discussion

These three cases demonstrate exceptions to the rule that mitral regurgitation is due to rigid and contracted valve cusps, and that mobile cusps enable the valve to close adequately. They have proved to be the only exception to this rule in a series of 183 valves palpated at operation. In each case a fairly confident diagnosis of pure stenosis was made pre-operatively, because of the loud ringing first sound at the mitral area.

The cause of regurgitation in these cases is uncertain. Belcher (1956) described four similar cases, and suggested that spontaneous rupture of a chorda tendinea was responsible for the regurgitation. However, it was my own impres-

sion on palpating the subvalvular area in the ventricle in these cases that shortening rather than elongation of the chordae had occurred and that "tacking down" of the free edges of the cusps to the papillary muscles was present. Thus the cause of regurgitation may be disproportionate damage to the chordae tendineae with lesser damage to the cusps. The excessive shortening of the chordae would lead to fixation of the free margins of the valve and prevent apposition, but it would not interfere with the sudden "ballooning" of the anterior cusps into the atrium during ventricular systole (Fig. 2).

Fig. 2.—Diagrammatic representation of movements of the valve cusps in the three cases of regurgitation with mobile cusps. Note that disproportionate shortening of the chordae tendineae prevents apposition above the aperture and so allows of regurgitation.

The findings in these three cases raise the question of the cause of the typical heart sounds of mitral stenosis. There is no dispute about the apical diastolic murmurs, but the abrupt quality of the first sound has been taken to be due to violent closure of the valve at the beginning of ventricular systole. The findings here would suggest that it would be more accurate to attribute it to the cusp movement than the valve closure.

As a corollary, it may well be that the opening snap (Rouchès, 1888; Mounsey, 1953) has a similar basis and that it indicates cusp mobility rather than opening of the aperture. Of course, in the majority of cases the two are the same, and from a clinical viewpoint the distinction is academic.

Summary

Three cases are reported in which mitral regurgitation was detected at operation though both valve cusps were soft and mobile. In each case the cusps appeared to be prevented from coming into apposition by disproportionate shortening of the chordae tendineae, and in each case the loud, abrupt first mitral sound characteristic of pure stenosis was present and a pre-operative diagnosis of pure stenosis had been made.

This evidence supports the view that the loud mitral first sound in mitral stenosis is not due to valve closure, but to cusp, and particularly anterior cusp, movement. The opening snap may have the same basis.

I am grateful to Professor I. G. W. Hill, Department of Medicine, University of St. Andrews, for referring these patients for valvotomy.

LYMPHANGIOSARCOMA FOLLOWING POST-MASTECTOMY LYMPHOEDEMA

BY

JOHN H. KETTLE, F.R.C.S., F.R.A.C.S.
Surgical Registrar, Royal North Shore Hospital of
Sydney, Australia

[WITH SPECIAL PLATE]

Oedema of the arm has always been regarded as one of the most troublesome complications of radical mastectomy. It is not generally realized, however, that it can, if long continued, be complicated by the development of a lymphangiosarcoma, which has proved rapidly fatal in almost every case observed.

Lymphangiosarcoma occurring in a lymphoedematous arm was first described in 1948 by Stewart and Treves. These authors reported six cases, and since then single case reports have brought the total to not more than 20. Nevertheless, it is considered that this rarity is more apparent than real, and that many of these tumours go unrecognized or are misdiagnosed as recurrences of mammary carcinoma.

Onset and Course

The tumour has a characteristic appearance and develops in the skin of an arm affected by long-standing oedema. Awareness of the condition, the patient's history, and the physical findings enable one to make a firm clinical diagnosis. In all case reports there is a history of carcinoma of the breast which has been treated by radical mastectomy. Some patients have had in addition a course of deep x-ray therapy. All have developed a persistent oedema of the arm soon after treatment. The shortest interval between the onset of oedema and the appearance of the tumour has been five years, the longest 24 years.

The first sign of the disease is the appearance of a dark reddish-purple nodule usually in the skin of the upper arm, though occasionally of the forearm. As this enlarges, other nodules arise around it with a tendency to centrifugal spread. Many of them fuse so that a patchy discoloration develops. The affected areas feel thickened, rubbery, and may be tender. Ulceration sometimes occurs, and the larger lesions may become cystic. On section of the tumour the discoloration is shown to be confined to the surface. The nodules lead to great thickening of the skin, and some of them may show areas of haemorrhage, necrosis, or cyst formation. Growth extends into the subcutaneous tissue and later involves the deep veins. Ultimately distant metastases, usually pulmonary, bring about the patient's death.

Histology

The histological appearance varies, so that many stages in the malignant process may be observed in the one section. The dominant pattern is a proliferation of lymphatic vessels, some lined with apparently normal cells, others with definitely neoplastic cells. In parts are seen circumscribed masses of undifferentiated cells. The changes are most marked in the corium and subcutaneous tissue, and the tendency is for the process to spread by involving the larger lymphatics accompanying the veins. Actual invasion of the veins is common and accounts for the frequency of embolic pulmonary metastases.

Relationship with Oedema

The nature of the relationship between the prolonged oedema and aetiology of the tumour is discussed by Stewart and Treves (1948), who postulate a circulating carcinogen

capable of acting on tissues already modified by a pathological process. It is of interest to note that one of their patients who had undergone left radical mastectomy for carcinoma of the breast subsequently had a similar operation performed on the right side for a benign lesion, with development of lymphoedema and later lymphangiosarcoma on the right side. McCarthy and Pack (1950) draw attention to the similarity in gross and histological appearance between lymphangiosarcoma and Kaposi's disease, which is a sarcoma arising from blood vessels usually in the lower limbs and having a racial predilection for Jews and Italians.

Treatment

In treatment both surgery and irradiation have been employed. Neither has met with conspicuous success. Clearly the case reports are too few to allow of any definite conclusions about the merits of a particular method of treatment. General opinion favours early radical surgery, preferably interscapulo-thoracic amputation. However, the sole reported five-year survival was treated with deep x-ray therapy only, and it would seem that this method should be given priority unless the oedema is already the cause of extreme disability (Southwick and Slaughter, 1955). The best result with surgery has been achieved by McCarthy and Pack (quoted by Marshall, 1955), with a survival of three years and five months following interscapulo-thoracic amputation. In most other cases, treated with either irradiation or surgery, or both, death has occurred within twelve months.

Case Report

In November, 1946, at the age of 63, a woman had had a radical mastectomy for carcinoma situated in the upper outer quadrant of the right breast. Microscopically the tumour had the structure of carcinoma simplex, and no metastases were found in the lymph nodes. The wound was slow to heal and required skin-grafting. On February 25, 1947, a course of deep x-ray therapy to the right supra-clavicular and axillary areas was begun, and very soon thereafter the whole of the right arm became moderately oedematous. The oedema persisted with little change until about July, 1955, when it became more marked coincident with the appearance of a reddish-purple nodule in the skin of the antero-medial aspect of the right upper arm. The nodule gradually increased in size and others developed in satellite fashion, the more centrally situated of these becoming confluent.

Clinical photograph showing the gross appearance of lymphangiosarcoma

On January 22, 1956, the patient was admitted to hospital with a provisional diagnosis of recurrent mammary carcinoma. Examination revealed oedema of the right arm extending to the hand, and marked scarring and telangiectasis of the right pectoral region and axilla, the result of deep x-ray therapy. On the antero-medial aspect of the right arm was a patchy discoloration affecting an area 7 by 5 cm. and made up of multiple dark nodules slightly elevated above skin level and varying in size (see photograph). Ulceration had not occurred and there was no tenderness. There was no clinical or x-ray evidence of metastases elsewhere. Being made aware of the possibility of lymphangiosarcoma presenting in this way by Dr. George Pack, of New York, who was visiting the hospital at the time, we were able to make a pre-operative diagnosis which was confirmed by biopsy.

From previous reports of this condition then available to us it seemed that radical surgery offered the best chance of survival. Interscapulo-thoracic amputation was therefore advised, but the patient would not agree to this. Local excision was performed on February 7, 1956, an oval of skin 15 by 9 cm. being removed together with the underlying fat and deep fascia. Closure of the wound was effected with the aid of a split skin graft, and healing proceeded satisfactorily.

Further examination of the excised tissue revealed that the skin was three to four times the normal thickness and that the discoloration was confined to the surface. Microscopical study showed that the thickening of the skin was due to an increase in the width of the corium. In this, and to a less extent in the upper subcutaneous tissue, neoplastic cells were scattered either singly or in groups of a few cells (Special Plate, Fig. 1), but sometimes as small masses (Plate, Fig. 2). Frequently these cells were lining spaces and channels. Some of the channels, especially those in close proximity to blood vessels, gave the impression that the lining of pre-existing lymphatics had become neoplastic; in other places they occurred as a seemingly purposeless network of vessels. Both the growth pattern and appearance of the cells were quite different from those of the original carcinoma of the breast, and were consistent with a diagnosis of lymphangiosarcoma occurring in post-mastectomy lymphoedema of the arm.

On April 1 the patient was readmitted with further nodules appearing at the lateral margin of the graft. Amputation was reconsidered, but again the patient was not agreeable. Accordingly a course of deep x-ray therapy was started, the final treatment being given on July 5. This led to a marked regression in the growth of the local recurrence, but, unfortunately, when the patient was last seen on July 9 nodules were detected in the area of old post-irradiation scarring in the right axilla. It was generally felt that this development must destroy any hope of controlling the tumour with irradiation. Nevertheless an attempt will be made to treat these metastases, there being at present no evidence of more distant spread.

Comment

The history and findings in this case are in accord with those previously described as occurring in lymphangiosarcoma following post-mastectomy lymphoedema. The natural history of this disease distinguishes it from other varieties of angiosarcomata. Of special interest is its association with lymphoedema in a patient who has previously been treated for carcinoma of the breast, though the nature of this relationship is obscure.

The risk of such a tumour developing is greatest in those who have survived radical mastectomy by at least five years and who may thus be regarded as having a very good chance of cure of their mammary carcinoma. The frequency of lymphangiosarcoma in this group is unknown, but its recognition as a possible fatal complication emphasizes the importance of the prevention and treatment of the swollen arm.

Summary

Lymphangiosarcoma has recently been recognized as a complication of post-mastectomy lymphoedema. Unless there is awareness of the condition it is likely to be confused with recurrent carcinoma of the breast. The characteristic features of the tumour are described and illustrated by a case report. It is hoped that appreciation of this new hazard to those who have survived a mammary carcinoma will stimulate further studies in the prevention and treatment of post-mastectomy lymphoedema.

I am indebted to Mr. Eric Langley for permission to publish this case. I wish to thank Dr. Colin Graham, who reported on the sections, and Dr. P. Corlette, of Sydney Hospital, who supervised the patient's radiotherapy.

NATURAL HISTORY OF OBSESSIONAL STATES

A STUDY OF 150 CASES

BY

JOHN POLLITT, M.B., M.R.C.P., D.P.M.

Senior Registrar, Department of Psychological Medicine,
St. Thomas's Hospital, London; formerly Registrar,
Department of Psychiatry, St. George's Hospital, London

(From the Department of Psychiatry, St. George's Hospital,
London)

The literature on obsessional states is mainly concerned with psychopathology and treatment by psychotherapy. Curran (1952) drew attention to an ignorance of the "natural history" of these illnesses. After pointing out that with increasing age a decreasing number of these patients were, in his experience, referred for a psychiatric opinion, he continues: "What happens to severe obsessional states as they get older? I have asked a number of experienced psychiatrists, and after humming and hawing they have, in the end, come clean and confessed that they did not know."

It has been possible to find only three follow-up studies based upon reasonably extensive material—namely, those carried out by Lewis (1936), Müller (1953), and Rüdin (1953). Rüdin has contributed a study of 130 cases, referring to the natural history, but places particular emphasis on the hereditary relationships of the illness. Lewis and Müller reported the progress of 50 and 57 patients respectively after discharge from hospital. These writings constitute the only follow-up studies based on reasonably large series of cases, and reports on the obsessional state from its onset have not been found.

Further, the information available in current textbooks on the course of obsessional states is often meagre and a striking pessimism may be noted. For example, Cecil and Loeb (1955) limit their observations on the outcome of the obsessional states to the sentence: "The prognosis of the obsessional state is poor." The present study is an attempt to provide fuller information on the natural history of the obsessional illness as a whole.

Lewis (1936) has emphasized that the essential element of an obsessional symptom is the sufferer's wish to resist the feeling of compulsion. In the present inquiry an obsessional symptom has been regarded as a recurrent or persistent idea, thought, image, feeling, impulse, or movement, which is accompanied by a sense of subjective compulsion and a desire to resist it; the event being recognized by the individual as foreign to the personality and into the abnormality of which he has insight. An obsessional state or illness is taken as one in which such defined symptoms are the dominant feature of the case.

In this study two main groups, often labelled "obsessional," were excluded. The first group consisted of patients with obsessional personality traits (the "anancastic personalities" as they are sometimes called) who developed a reaction other than that of obsessional illness, most commonly, perhaps, an anxiety state. The second group were cases in which obsessional symptoms occurred in the course of another mental illness, such as depression or schizophrenia. The differential diagnosis between obsessional illness proper and depression with obsessional features is often difficult. In this study doubtful cases were excluded, as were all cases in which the illness responded to E.C.T.

Material and Methods

The material for study, thus selected, numbered 150 patients. Of these, 69 (18 males and 51 females) had been in-patients at the psychiatric unit of St. George's Hospital at the Atkinson Morley Hospital, Wimbledon, the preponderance of female patients being due to the larger number of beds that were available for females during the relevant period. The remaining 81 patients (45 male, 36 female) had been seen and diagnosed by Dr. Desmond Curran in private practice as "out-patients." These "out-patients" had, on the whole, milder illnesses than the in-patients. Most of the severely sick out-patients seen were sent into hospital and were included in the hospital group.

It may be held that the inclusion of both out-patients and in-patients in this study helps to form a representative sample of these obsessional illnesses, but, since many of the hospital patients were admitted to the Atkinson Morley Hospital for leucotomy by Mr. Wylie McKissock, the bias here is probably in favour of severely ill patients. As is shown below, very few cases of obsessional state are admitted to or resident in mental hospitals.

Information was collected from case records, from reports kindly sent by other psychiatrists, and from data provided by psychiatric social workers; when possible, patients were interviewed personally. A questionnaire was designed for the follow-up. After modification in the light of a pilot run, this was sent to all patients. The obvious objection to any follow-up by means of a questionnaire is less valid when this was sent to all patients. The obvious objection to any follow-up by means of a questionnaire is less valid when considering obsessional illnesses rather than any other diagnostic category; most of the forms were filled in accurately and were found to be reliable in almost all cases in which an objective check-up was available from other sources. It seems a reasonable assumption that reliable information was provided in those cases in which an objective check-up was not available; but, in order to avoid a possibly optimistic bias, in no instance was a favourable outcome assumed solely on the basis of the patient's reply to the questionnaire.

Age of Onset of First Symptoms

Fig. 1 shows the distribution of 141 patients according to the age at which they experienced obsessional symptoms for the first time. Owing to the episodic course of the illness, the age when the first symptoms were shown must be distinguished from the age of onset of the present illness, and this age must be distinguished from the age at which the patients sought help. In 68 patients who had had no

previous attacks the first symptoms formed the present illness. The majority of patients (68%) experienced their first symptoms before the age of 25 years, and only four after the age of 45. As age increased, fewer and fewer had their first symptoms. The mean age when first symptoms developed was 21.58 years in females (standard deviation 14.46 years, standard error 1.63) and 20.16 years in males (standard deviation 11.09 years, standard error 1.41).

FIG. 1.—Age range in which first symptoms began.

Previous Attacks

Frequently the patient's history revealed that attacks of obsessional symptoms had occurred before the present illness, each attack ending in recovery. Of the 150 patients considered, 100 had reported previous episodes of obsessional symptoms and 82 of the latter had been sufficiently ill at the time to seek medical advice. The total number of attacks experienced by the 82 patients was 162, the approximate mean number of attacks being 2; the extremes of the range were 1 and 10 attacks (mean 1.98 attacks, standard deviation 1.56 attacks, standard error 0.17). Fig. 2 shows the numbers of patients who had one or more attacks in each age range. Ignoring the number of patients that experienced them, 28% of the previous attacks occurred between the ages of 11 and 15, 23% between 16 and 20, and 17% between 21 and 25, the peak being from 11 to 15 years of age, with its developmental associations of puberty. In general, the previous attacks were in childhood, adolescence, or early adult life rather than later.

FIG. 2.—Age range in which previous episodes occurred.

Duration and Frequency of Attacks

The approximate duration of the previous episodes and the number that occurred in each patient were determined, and the results recorded to show distribution (Tables I and II).

TABLE I.—Duration of Episodes

Approximate Duration	No. of Episodes Before Present Illness Began
Months	
0-3	44
3-6	30
6-12	54
Years	
0-1	128
1-2	9
2-3	8
3-4	6
4-5	4
5-6	2
6-7	1
7-8	1
8-9	1
9-10	0
10-20	2
	162

TABLE II

No. of Episodes	No. of Patients	No. of Episodes	No. of Patients
1	44	6	2
2	18	7	1
3	12	8	0
4	3	9	0
5	1	10	1

II). It is seen from these tables that 79% of the previous episodes lasted less than a year, and that in 88% of the 82 patients one to three attacks of symptoms occurred before the present illness. Mean duration of an episode is 1.09 years, standard deviation 2.1 years, standard error 0.17.

No simple relationship was found between the total duration of previous episodes a patient had suffered and his prognosis. No correlation was found between the number of previous episodes and the type of obsessional symptoms present, such as motor, sensory, etc.

Age of Onset of Present Illness

The present illness is regarded as the unremitting train of obsessional symptoms for which the patient sought advice at St. George's or privately. Fig. 3 shows the frequency distribution of patients according to their age when the present illness began. In 68 patients who had had no previous attacks this was also the age of onset of first symptoms. Half the total number of patients began their illness in late adolescence or early adult life, between the ages of 16 and 30 years, and only 7.3% began their illness after the age of 45 years. Mean age of onset of the present illness was 28.4 years, standard deviation 13.7 years, standard error 1.1. The relative expectation of developing an obsessional illness is shown in Table III.

Disablement

The age at which the patient was incapacitated by his illness is known in 121 cases. The criterion used was inability to carry out accustomed work or social duties which were a significant part of the patient's life. In the hospital series, if no other evidence was available, admission to hospital was taken as the time when the patient was incapacitated. Fig. 4 shows the distribution of patients according to the age when they were incapacitated. Three-quarters of the 121 patients were incapacitated before the age of 40. Very few were disabled after 50 years of age. (Mean age of disablement 33.2 years, standard deviation 12.6 years, standard error 1.1.)

FIG. 4.—Age range in which incapacity occurred.

Table IV shows the distribution of patients according to the duration of their present illness before they were incapacitated. Approximately half the total number of patients became disabled within a year of the onset of the illness; the remainder were incapacitated only after a considerable number of years elapsed. (Mean duration of illness to incapacity 4.7 years, standard deviation 8.1 years, standard error 0.73.)

Precipitation of Obsessional Symptoms

The events leading to the onset of the present illness were known in 93 of the cases reviewed. These were the events considered significant by both patient and doctor and were

elicited in the course of routine history-taking. Table V shows the incidence of precipitating factors in 93 obsessional patients and 90 non-obsessional admissions, the latter being selected at random from the patients admitted to the psychiatric unit at St. George's Hospital, and having an age distribution similar to that of the obsessional patients. The preponderance of sexual precipitating factors in the obsessional group is highly significant statistically.

Duration of Present Illness before Patient Attended for Advice

Table VI shows the distribution of patients according to their period of suffering in the present illness before they

were seen for the first time, privately or at St. George's. Approximately half the total number of patients were seen within two years of the onset of the illness. Almost a quarter were seen after ten years of suffering. (Mean period between onset of illness and attending for advice 7.5 years, standard deviation 9.3 years, standard error 0.77.)

Patient's Progress

It was not possible to follow up all the patients of the series owing to the fact that a number had been seen only for an initial interview and some of these failed to return the questionnaire. In the following quantitative assessment of the patient's progress, the number of cases included in each particular aspect of the study is given.

Fig. 5 shows the distribution of patients according to the period of follow-up (101 patients). The length of follow-up is variable; the range was 3 months to 15 years, and the mean follow-up period was 3.44 years; standard deviation 2.70 years, standard error of the mean 0.27.

FIG. 5.—Duration of follow-up period.

whose symptoms have improved. Group II, those whose symptoms are worse or as severe and incapacitating as when they were first seen. Group III, those whose obsessional symptoms have been replaced by other phenomena.

Table VII shows the number of patients in each of the above categories at the termination of their follow-up period

TABLE VII

	I	II	III	IV	V	Dead	Suicide	Total
Non-leucotomized	16	24	8	17	1	0	0	67
Leucotomized	15	6	7	5	0	1	1	34
Total	31	30	15	22	1	1	1	101

(101 patients). Sixty-one of the patients followed up reached a state of social adaptation, 31 of them becoming free of symptoms. Fewer than a quarter showed no improvement and were worse.

To define more clearly the progress of patients after a definite period of follow-up, Table VIII shows the patients categorized according to their state after one or more years

TABLE VIII

	I	II	III	IV	V	Total
Progress after 1 Year or More						
Non-leucotomized	19	18	6	9	1	53
Leucotomized	12	6	7	4	0	29
Total	31	24	13	13	1	82
Progress after 4 Years or More						
Non-leucotomized	12	9	3	5	1	30
Leucotomized	4	4	4	3	0	15
Total	16	13	7	8	1	45

and four or more years of follow-up. Although after four years the sample of patients is much smaller, 21 of the 30 non-leucotomized patients had become socially adapted and 12 of these 21 were free of symptoms. The high proportion of patients who did well even after four years of follow-up is noticeable.

Duration of Illness and Prognosis

In order to show the influence on prognosis of the duration of the present illness at the time of seeking advice at St. George's or privately, the mean duration of the illness was estimated for the group of patients in each follow-up category (Table IX).

TABLE IX.—Mean Duration of Illness in Years

	Category at End of Follow-up Period			
	I	II	III	IV
Non-leucotomized (65 cases)	3.0	6.1	6.8	8.1
Leucotomized (33 ")	10.0	15.0	11.1	18.6
Total (98 ")	6.2	7.9	8.8	10.5

A relationship exists between the duration of the illness before seeking advice and the prognosis. It is significant statistically ($P=0.05$) that in the non-leucotomized group those who became symptom-free had shorter illnesses before they were seen than those who showed no improvement. It would therefore seem that the longer they are ill before being seen the worse the outlook. The two categories compared in the non-leucotomized group had mean follow-up periods of 3.9 and 3.3 years respectively.

Recovery in Early Years.—Further evidence to support the finding of a good prognosis in patients with relatively short illnesses is obtained from estimation of the total duration of the illness in the 61 patients who became socially adapted (Table X). The majority of those who reached this state of improvement had endured symptoms for five years

TABLE X.—Duration of Illness and Number of Patients Reaching Social Adaptation

Duration	No.
0-2 years	21
2-5 " "	16
5-10 " "	11
10-20 " "	7
20-40 " "	6
Total	61

or less. As the duration of illness increases fewer patients with a good prognosis are found. Direct inquiry into the patient's mode of improvement reveals that the intensity of symptoms gradually lessens until they become unobtrusive or are present only when the individual is fatigued or anxious.

Mental Hospital Admissions.—Inquiries at two mental hospitals, with a total of 2,545 beds, revealed that only four of the patients were diagnosed as obsessional; they were voluntary patients, and two of them had been previously leucotomized. In the series of patients studied, only four are known to have become voluntary patients. It is an interesting fact that very few obsessionals end up in mental hospitals. If they do become mental hospital patients they rarely need to stay long.

Suicide.—Only one of the 101 patients followed up committed suicide. This was a female who developed an endogenous depression four years after leucotomy for a severe obsessional illness. This patient did not entertain fears of suicide during her obsessional illness. Only two other attempts at suicide were reported in the remainder of the patients.

Schizophrenia.—The only case falling into group V after follow-up was a female patient who later developed schizophrenia.

Discussion and Summary

Incidence

Many individuals have obsessional components in their personality. It is also not uncommon for psychiatric patients to show obsessional symptoms. Obsessional illnesses as defined here, however, are rare. The 150 patients studied (69 in-patients and 81 out-patients) formed respectively under 4% of the admissions to the psychiatric unit of St. George's Hospital and fewer than 2% of the patients seen

in private practice as out-patients. This low incidence indicates to some extent the degree of selection employed. Miller (1950) comments on the rarity of extreme degrees of obsessional illness.

Age of Onset

Owing to the episodic course, the age when the first symptoms were shown must be distinguished from the age when the first symptoms of the illness for which the patient sought help began.

In 68% of 141 patients studied, the first symptoms appeared between the ages of 6 and 25 years, the mean age being 21.58 years in females and 20.0 years in males. As age increased above 20, fewer and fewer patients developed symptoms for the first time; only four did so after the age of 45 (Fig. 1). After the age of 20 there is a decreasing risk with increasing age. Either increasing age protects against the start of obsessional symptoms or the population from which patients come must diminish with age at the same rate. The age of onset of the attack which brought the patient under observation at St. George's or privately was later, the greatest frequency being between the ages of 16 and 45 (Fig. 3). Greenacre (1923) confirms these findings and states that obsessive-compulsive disorders arise usually during the active, striving periods of life and only rarely in the later years.

Episodic Course

This has been commented on by a number of authors (Greenacre, 1923; Gordon, 1926; Bumke, 1929; Lewis, 1936; Ibor, 1952), but precise figures are lacking. In no less than half the patients studied the illness ran an episodic course, with an average of two previous attacks per patient before the attack which brought the patient under observation. A history of up to three attacks was obtained in 88% of the patients who had attacks, and a history of more than three was relatively uncommon, occurring in eight patients only. The majority of these episodes occurred in childhood, adolescence, or early adult life. They were frequently short-lived, 79% lasted a year or less.

Reactivity

Reactivity to environmental factors was striking; the attacks often seemed to be precipitated by stressful situations or events. Interestingly enough, overt sexual traumata were significantly more common than in a control group of the neuroses and psychoses. The reactivity of the illness to the environment was shown by many patients throughout; thus the symptoms became more severe and prominent when anxiety and tension increased from whatever cause or when the patient's resistance was lowered by debility or fatigue. A corresponding improvement could be observed when tension was reduced by environmental or other means. In milder cases, simple reassurance alone was sometimes followed by remarkable improvement. It was also interesting to observe that patients were often less troubled by symptoms when they had to face new external difficulties in their lives. The sensitivity to external stress often seemed highly specific.

Follow-up Results

An objection may justifiably be raised when the "natural history" of an illness is said to be studied in a series of patients, many of whom have had hospital in-patient care and most of whom have had treatment of some sort or another. This objection is valid if treatment is thought to influence the long-term course of the disease. Rüdin (1953), who followed up 130 patients, thought that in only nine cases did therapy contribute towards the apparent improvement in the illness. From the present series, the impression is gained that only leucotomy, in some cases, influenced the natural course of events. It is for this reason that the leucotomized patients have been considered separately in the follow-up study.

It proved possible to follow up 101 patients for a period of from 3 months to 15 years. Of the 82 patients followed for a year or more, 55—that is, 67%—had become either

free of symptoms or able to carry on a normal life. Excluding the leucotomized patients, 37 out of a total of 53 (70%) had demonstrated a similar degree of improvement or recovery.

After four or more years of follow-up, 29 out of 45 patients (64%) became either free of symptoms or able to carry on a normal life. Of the 30 non-leucotomized patients followed for this period, 21 showed this degree of improvement or recovery.

Lewis (1936) followed up 50 cases of obsessional neurosis for five or more years after treatment in hospital and found that approximately half did well. Müller (1953) found that out of a total of 57 obsessional cases followed up for 15 to 35 years 28 became symptom-free or socially adapted. Rüdin (1953) reports that 50 out of a total of 130 patients followed up for periods up to 20 years were either notably improved or apparently cured. In the light of this evidence, the obsessional state has a much better prognosis than is usually thought, and the view that it has an inevitable, gloomy outcome can no longer be held. The fact that few are admitted to mental hospitals, and that the number of patients attending for the first time falls off gradually after the age of 25 and rapidly after 40, provides indirect evidence of a favourable outcome.

When recovery took place it occurred far more commonly in the early years of the illness and much less frequently after many years had passed since the illness began. This observation, viewed with the recovery after a year or so from the previous episodes, suggests that the prognosis of the obsessional illness is related to the duration of symptoms in the present attack, the patient with a shorter period of suffering having a better prognosis than one who has been ill for many years. There is also a relationship between the prognosis and the time a patient has symptoms before seeking advice. Those who did not improve or were worse had been ill for longer periods than those who recovered.

Mode of Recovery.—With the possible exception of leucotomy, treatment was rarely followed by immediate, sustained recovery. The mode of recovery usually consisted in a gradual lessening of symptoms. The progress to recovery was seldom smooth, but was marked by a great deal of variability of symptoms during periods of anxiety and fatigue.

Development of Psychosis.—Only one patient is known to have developed schizophrenia in the present series; possibly the failure to follow up all the cases may account for this low incidence. Müller found that 10 out of 57 patients with obsessional neurosis developed schizophrenia later. Stengel (1945) has discussed and illustrated the transition of obsessional state to schizophrenia but does not indicate the frequency of this event.

It is hoped that this attempt to learn something more of the facts regarding obsessional illnesses is of more than academic interest. It is perhaps a small step towards providing a yardstick with which one may more easily compare the profound effects of modern treatments with the comparatively small influence on the disease of the more conservative methods.

I am grateful to Dr. Desmond Curran for generously allowing me the opportunity to conduct and complete this work. I thank Dr. E. Stengel for his criticism and help in translating the relevant literature. Dr. Eliot Slater and Dr. Fraser Roberts gave me their expert advice on the presentation of the figures. I am grateful to those, too numerous to mention individually, who have helped me in collecting data.

THROMBOCYTOPENIA AND LEUCOPENIA FOLLOWING CARBUTAMIDE

BY

J. C. PHEMISTER, M.B., Ch.B., M.R.C.P.Ed.

Registrar in Clinical Medicine, Department of
Therapeutics, University of Edinburgh

In a recent paper Duncan, Baird, and Dunlop (1956) gave an account of their use of N-butyl-N'-sulphanilyl-urea (carbutamide; BZ 55) in the control of a selected group of diabetics. Among toxic effects they reported thrombocytopenic purpura in two patients and a symptomless thrombocytopenia in several others, while throughout the group many patients showed depression of platelet or white-cell counts. They did not provide details of the blood findings or of the investigations which were being undertaken, and it is the purpose of the present paper to give them in full.

Methods

Platelet Counts.—These were made by the method of Oettle and Spriggs (1951), using a diluting fluid containing 1.2 g. of cocaine hydrochloride and 0.08 g. of sodium chloride in 40 ml. of distilled water. Normal platelet counts by this method lie between 210,000 and 400,000 per c.mm., and are commonly around 300,000 per c.mm. Counts of under 200,000 per c.mm. are regarded as abnormally low.

Tests of Capillary Fragility.—A positive-pressure test was used, and is described here as "Hess's test," though this is not strictly correct. The sphygmomanometer cuff was inflated round the upper arm to a pressure of between 90 and 100 mm. Hg, and left at this pressure for five minutes. It is notoriously difficult to classify the degree of response to such tests, and methods which pretend to numerical accuracy are misleading. Where tabulation has been required, the simple descriptive method of Ackroyd (1949) has been used, and this is explained in the legend to Table 1.

Patch Testing.—A piece of white lint approximately 1 cm. square was soaked with a suspension of pure carbutamide in a saturated solution in propylene glycol, and applied under a larger square of "cellophane" for 48 hours.

Platelet Agglutinins.—Simple examinations were made for the agglutination or lysis of platelets by the methods recapitulated by Ackroyd (1953). Platelet-rich plasma was prepared from the blood of the patient under investigation, and this was examined for agglutination or lysis of the platelets in the presence of a small amount of pure carbutamide. The effect on clot retraction of adding carbutamide to the clotting blood was investigated.

Preliminary Considerations

Carbutamide is a sulphonamide, and might be expected to have toxic effects on the blood similar to those of the chemotherapeutic sulphonamides. So far, however, there have been few published notices of such effects. Kinsell *et al.* (1956) described severe leucopenia in one patient after heavy dosage, and Ridolfo and Kirtley (1956) and Walker *et al.* (1956) each report one case of neutropenia occurring during the more usual administration of the drug. German workers (Bertram *et al.*, 1955; Franke and Fuchs, 1955; Robbers and Speck, 1956) have stated that carbutamide

has no effect on the blood picture, but do not report what examinations were made. In the present study, toxic actions of carbutamide have proved to be similar to those described for other sulphonamides.

Two aspects of the investigation of bleeding disorders in the diabetic have required special consideration. First, capillary fragility may be altered in diabetes itself, so that tests of capillary resistance may have little diagnostic value and be misleading. Secondly, there is no very satisfactory information on platelet levels in "normal" diabetics, and control studies have therefore been necessary.

Leucopenia, Thrombocytopenia, and Purpura due to Sulphonamide

Agranulocytosis is a well-recognized occasional complication of sulphonamide therapy, and leucopenia is common in patients receiving heavy or prolonged dosage (Britton and Howkins, 1938).

Thrombocytopenic purpura is rare, but has been reported following the use of all the common sulphonamides: more than 30 cases are described. Kracke and Townsend (1943) and Hurd and Jacox (1943) have reviewed the literature, and Ackroyd (1953) gives later references. A case of non-thrombocytopenic purpura due to sulphapyridine has been described by Sherlock and White (1944).

Kracke and Townsend record platelet estimations made in a group of 61 patients receiving sulphathiazole or sulphadiazine for a variety of infections. No significant alteration in the platelet counts was found during the course of treatment, but there was an abrupt rise in the count on the day after sulphonamide was stopped, with a later fall to the previous level. In some of the younger patients the "rebound" count reached 700,000 per c.mm. The authors offer this as evidence of a toxic effect on the marrow, but it is as probable that it indicates destruction of circulating platelets with a compensating overproduction by the marrow.

Capillary Fragility and Thrombocytopenia in Diabetes Mellitus

Capillary fragility may be increased in diabetes, and Hess's test may become positive. Comparatively little attention has been paid to this aspect of diabetic vascular disease, but it is of obvious importance in the investigation of thrombocytopenia and bleeding disorders in such patients. Several papers deal with the subject, notably those of Beaser *et al.* (1944), Rodriguez and Root (1948), Barnes (1950), and Hines *et al.* (1953). There is general agreement that positive tests are common and that the incidence is related to the duration of the diabetes rather than to its severity or to the age of the patient. All authors stress that with accompanying hypertension capillary fragility is increased. An association with retinitis is close but not absolute, for Barnes found 15% of his patients with frank retinitis to have negative tests. From the figures given by these authors it would be reasonable to expect that about half the patients in the present trial would have positive tests.

It may be seen from Table II that, of the 22 patients in whom initial blood examinations were made, three had platelet counts of under 200,000 per c.mm. By the method used, these are abnormally low. Carbutamide had not been given when the counts were made, and it became of importance to find out whether low platelet counts were to be expected in some diabetics. The literature makes no reference to this aspect of the subject.

A control group of 50 patients was therefore examined. Platelet counts were made and Hess's tests carried out. Forty of the patients were middle-aged or elderly diabetics having small doses of insulin, comparable to the patients who formed the trial group. Ten were of similar ages and types of diabetes, but had never received insulin. The findings are given in Table I. It will be seen that of the 50 patients 9 had platelet counts of under 200,000, one count being as low as 135,000. Low counts were found both in patients receiving insulin and in those not receiving it. There was no relationship between a low

Response to Hess's test: N, indicates 0-10 petechiae in the antecubital fossa (normal). sl. +, indicates up to 50 petechiae in the antecubital fossa. +, indicates over 100 petechiae in the antecubital fossa and just below. ++, indicates numerous petechiae extending to junction of upper and middle thirds of forearm. +++, indicates very numerous petechiae extending right down forearm (after Ackroyd, 1949).

platelet count and the age of the patient, the white-cell count, or the response to Hess's test, but low counts were more common in patients who had had diabetes for some years.

Thirty-two patients had positive Hess's tests. The positive response in diabetes was found to differ from that in thrombocytopenic purpura. In the latter the petechiae are purple and rapidly coalesce to small blotches as the pressure is maintained, while in diabetes the petechiae are red and pin-point, remaining discrete even when the test is strongly positive. The mechanisms may perhaps differ, or it may be that in the diabetic platelets limit the haemorrhage. Five patients showed very strongly positive responses, and it is of interest that three of these were not receiving insulin.

Clinical Observations

The selection of the patients and the conduct of the trial have been described elsewhere (Duncan *et al.*, 1956). It is sufficient to say that the majority of the patients were middle-aged or elderly women with mild diabetes of some years' standing. Carbutamide was given in a dose of 1.5 g. per day for the first seven days, and thereafter control was maintained on 0.5-1.5 g. daily. Average blood sulphonamide levels are given in Table III.

The trial had been in progress for five months, and only mild side-effects of the drug had been noted, when one of the patients developed thrombocytopenic purpura. This patient had only recently joined the trial and had received 24.5 g. of carbutamide over three weeks: she had shown some signs of intolerance after two weeks. Her case is considered in detail below. From the first it was probable that the thrombocytopenia was due to carbutamide, and thorough haematological examinations were at once undertaken on all the other patients.

At this time 34 patients were receiving carbutamide. Six others, who had not responded satisfactorily, had had a full fortnight's trial, with blood examinations both before the drug was given and at the end of the fortnight. The other patients of the group had either never received carbutamide or had had it for only a very short time: they have been excluded from the present study.

The 40 patients fell into two groups. In the first, full blood examinations had been made both before starting treatment and at intervals afterwards. In the second, no blood examinations had been made. Although from this time examinations were made regularly on all patients, it has remained convenient to consider the two groups separately, since the information each yields is different. No important changes in the haemoglobin levels or the red blood cell count were found in any patients, and for clarity these observations have been omitted from the Tables and are ignored. Changes in the differential white-cell counts are considered below.

Group 1

The 22 patients of this group were included in the trial at its inception or very soon after. All had had full blood examinations (haemoglobin, red-cell count, white-cell count, platelet count, and differential white-cell count) both before the administration of carbutamide was begun and two weeks later. When satisfactory control of the diabetes was achieved (in 16 patients) a further examination was made one month later while treatment was continued.

From this group, therefore, direct information may be obtained of changes in the blood picture during carbutamide therapy. The findings are given in Table II. Weekly counts made after the first check count have been omitted, as significant changes occurred only in those patients whose cases are considered separately.

Many of the patients showed a substantial fall in the white-cell count soon after carbutamide therapy was instituted, though usually the count rose again as treatment was continued. In one patient (Case 6) the count remained very low, and did not rise until some time after treatment with carbutamide was stopped: this patient also developed purpura, and her case is given in detail below.

Several patients showed depression of the platelet count. This was not marked, and took some time to appear: only in one patient (Case 8) was there any significant change in the platelet levels when the examinations were made two weeks and six weeks after the start of carbutamide therapy. By the time check counts were being made, however, an appreciable fall was shown in Cases 3, 12, and 14, while in Case 8 the platelet count had a further fall to 90,000 c.mm. Except in this last case, the changes were not alarming.

There were two other important observations. One patient (Case 3), who had latterly shown a considerable fall in the platelet count, complained of severe vaginal bleeding and said that this had been present for several weeks. Another (Case 6), the patient who had developed leucopenia but whose originally low platelet count had not altered during carbutamide therapy, was found to have spontaneous purpura. These two patients and the third (Case 8), whose platelet count had declined steadily to thrombocytopenic levels, require brief separate consideration.

Case 3

This woman showed good control of her diabetes with low blood carbutamide levels. Nothing untoward occurred until she had been receiving carbutamide for 15 weeks, when she developed vaginal bleeding, which became severe and persistent. The check count made at this time showed that her platelet count had fallen from an original 320,000 to 180,000 per c.mm. Hess's test was strongly positive and the bleeding-time prolonged to 12 minutes. Treatment with carbutamide was stopped and gynaecological examination arranged. This showed no abnormality, but after dilatation and curettage the bleeding stopped. Three weeks later her platelet count had risen to 300,000 per c.mm., and Hess's test gave a barely positive response. It is probable that carbutamide caused a haemorrhagic tendency which precipitated the uterine haemorrhage, whatever the local cause.

Case 6

This woman has presented the most difficult problem of all. It will be seen that her platelet count was low before carbutamide was given, but that there was no further fall during treatment. The white-cell count, however, fell steadily until, by the time the first check count was made,

she had a leucopenia of 2,450. At this examination she was found to have a fine purpura. The petechiae were very small and spidery rather than punctate. It is probable that in other circumstances they would not have been noticed, and the patient herself was unaware of the rash. Her platelet count was 180,000, Hess's test was only slightly positive, and there was no change in the bleeding- or clotting-time.

She was admitted to hospital for observation, and during her stay the purpura faded and disappeared. Her platelet count remained unaltered, and the white count did not rise. The differential white count showed a marked neutropenia, but mature neutrophils were present. The marrow was very fatty, though there was a fair amount of haemopoietic tissue which showed an eosinophilia. Megakaryocytes were probably diminished in numbers. Myelocytes were plentiful, but took stain badly and showed a poverty of granulation.

The mechanism of the purpura was obscure. It seemed probable that it was related to the carbutamide therapy and was allergic in type, as she had previously had a skin reaction, for which treatment had been interrupted. In view of the very low white-cell count it was thought inadvisable to give her a test dose of the drug. One month after her discharge from hospital the white-cell count had returned to normal, the platelet count remaining at its previous level. The purpura had entirely disappeared.

Her story has been given at this length for a purpose. She had found great subjective benefit from carbutamide, and was anxious to continue on oral therapy. She was given tolbutamide (D 860), to which she responded well, as she had done to carbutamide. She attended regularly as an out-patient for blood examination, and showed no significant change until, one month after starting tolbutamide, she came up with very extensive purpura, far more marked than previously and causing frank blotches on her arms and chest. On this occasion her platelet count was lower at 115,000, but again Hess's test was only slightly positive, and the bleeding-time, clotting-time, and prothrombin activity were normal. She did not have leucopenia. The time sequence of these complications is important. It was one month after she had first started to take carbutamide that the allergic rash appeared. After an interval of two months the administration of carbutamide was cautiously resumed, and it was after a further month that the first purpuric rash appeared. She had been having tolbutamide for one month when the second purpuric eruption was noted. It seems very probable that an allergic purpura, with little affection of the platelets, was caused by both carbutamide and tolbutamide. Only carbutamide caused depression of the white-cell count.

TABLE II.—Group 1. Effect of Treatment with Carbutamide on Platelet and White-cell Counts

* Therapy interrupted for two months because of skin allergy. Carbutamide was ineffective in Cases 17, 18, 19, 20, 21, and 22.

Case 8

This patient had a low platelet count before treatment with carbutamide was started, and showed a decline in the count during therapy until, when she had been receiving the drug for 12 weeks, it had fallen to 90,000 per c.mm. Hess's test was strongly positive and the bleeding-time prolonged. Marrow examination showed a great infiltration of fat, with scanty haemopoietic tissue and a diminution of the number of megakaryocytes: there was a moderate eosinophilia when the administration of carbutamide was stopped; her platelet count rose slowly without a "rebound," reaching a figure of 180,000 per c.mm. after two weeks and remaining constant. Hess's test, which had been very strongly positive indeed, became barely positive, and the bleeding-time became normal.

It is suggested that here a hypoplastic marrow was being steadily exhausted and was unable to compensate for the thrombocytopenic action of carbutamide.

Group 2

The patients of this group were included in the trial later. Their initial stay in hospital was short, and blood examinations were not made until the discovery of thrombocytopenic purpura in a member of the group made them imperative. Thereafter, examinations were made weekly. The findings are given in Table III, with a statement of the duration of therapy and the total dose of carbutamide which had been received at the time the first count was made.

When blood examinations were made, it was found that four patients (excluding the patient with thrombocytopenic purpura) had low platelet counts. It was tempting to attribute this to the carbutamide, but the several low initial platelet counts in Group 1 had to be borne in mind, and in the absence of any information on the original blood pictures attention was directed rather to the effect of stopping the administration of the drug and to *in vitro* experiment.

From Table III it may be seen that throughout the group, stopping the administration of carbutamide was followed by an abrupt rise in the platelet count, which in the course of the next few weeks returned to its previous level. Broadly, the lower the original count the higher was this "rebound." In the five patients (Cases 23, 25, 29, 30, and 40) with very low platelet counts, the "rebound" was followed by a return to the previous low level, and it must be considered probable that in these patients the count had been low before carbutamide was given. This "rebound" is discussed below. It is obviously similar to that which Kracke and Townsend (1943) found to follow sulphathiazole and sulphadiazine.

The patient who developed thrombocytopenic purpura belonged to this group, and her case is given in detail below.

Case 35

An otherwise healthy woman of 68 who had had diabetes for 14 years. For the first 11 years this was controlled by diet alone, but latterly she had been having 24 units of zinc insulin suspension daily. She was hypertensive (blood pressure 190/115 mm. Hg) and showed early hypertensive retinal changes. There was no evidence of diabetic retinopathy, albuminuria, or neuropathy. Her only serious illness had been a pneumonia two years previously. She gave no history of any blood disorder or bleeding tendency, but a son died at the age of 4 years (in 1918) of "internal bleeding" which was said to have been due to haemophilia. There was no other history of such disease in her own or her husband's family. Another son and a daughter are alive and well, and have shown no haemorrhagic tendency. A nephew suffers from diabetes.

She was given carbutamide, 1.5 g. daily for the first week, with an excellent response. Thereafter, as an out-patient, she received 1 g. daily. Two weeks after starting treatment she noticed a red bumpy rash on her arms and shoulders, but thought little of it and did not mention it when she attended at the clinic. During the next week she had a further crop of spots, and then, when she had been receiving carbutamide for three weeks, she showed spontaneous purpura. Administration of the drug was stopped at once and she was admitted to hospital for investigation.

No blood examinations had been made previously. The findings on admission were: platelet count, 60,000 per c.mm.; haemoglobin, 74%; red blood cells, 4,000,000; white-cell count, 7,200. The blood film was normal except that platelets were rare. Hess's test was strongly positive. The bleeding-time (Ivy) was 12 minutes. The clotting-time (Lee and White) was 9 minutes. Thrombin generation tests and prothrombin consumption tests were normal. The marrow had an unusual appearance: each smear showed a fenestration of small fat globules, sprinkled with a great number of megakaryocytes. These were intensely basophilic and granular, and where nuclei could be distinguished they were multilobular. Other haemopoietic tissue was very scanty but normal in appearance. There was no eosinophilia.

On the day after admission her platelet count had risen to 250,000 per c.mm., Hess's test was quite negative, and the bleeding-time was three minutes.

It was decided to give her a test dose of carbutamide, and for two consecutive days she received 1.5 g. in the morning. There was a slight drop in the platelet count on the first day, but no further change. On the second day there was a further fall in the platelet count, and in the evening she

developed a hot urticarial rash on the face and arms. She described this as being exactly similar to the first rash, which had developed two weeks after the course of carbutamide was started. By the next day the platelet count had fallen a little further, but thereafter it climbed again. The Chart shows the changes in her platelet count from the

Case 35. Effect of stopping administration of carbutamide, and effect of a test dose. A, Administration of carbutamide stopped. B, 1.5 g. carbutamide given. C, 1.5 g. carbutamide given.

time of her admission, and the varying response to Hess's test. Since there could be no doubt that her thrombocytopenia had been caused by carbutamide, a unique opportunity was presented of comparing the action in this respect of tolbutamide. Therefore, two months after the purpura had cleared and the platelet count had returned to normal she was admitted to hospital and started on a course of tolbutamide, receiving 1.5 g. daily. Her platelet count on admission was 275,000 per c.mm. and Hess's test negative. Platelet counts were made hourly during the first day, and thereafter daily. Within six hours of giving tolbutamide the count had fallen to 190,000 per c.mm., Hess's test remaining negative. During the following three weeks the platelet count continued to be between 170,000 and 200,000 per c.mm. There is no doubt that tolbutamide caused a significant fall in the platelet count, but there is no evidence that sensitization to carbutamide had produced cross-sensitization to tolbutamide.

Special Investigations

Differential White-cell Counts.—These had been included at each haematological examination of all patients in Group 1, and in those of Group 2 where there was alteration in the white-cell count. In all cases of leucopenia the fall was found to be predominantly at the expense of the neutrophils, though complete agranulocytosis never occurred.

Bone-marrow Examinations.—The marrow findings in the patient with thrombocytopenic purpura have already been described in detail. Examinations were made on four other patients (Cases 6, 8, 30, and 40) with low platelet counts. Their marrows resembled one another closely in appearance and were quite different from that of Case 35. Each showed a great increase in fat, and, except in Case 6, very scanty haemopoietic tissue. Megakaryocytes were diminished in numbers but had a normal appearance, and there was an appreciable eosinophilia and an increase in the number of plasma cells. As noted previously, there was an unhealthy appearance of the white-cell precursors in the marrow in Case 6.

Hess's Test.—It is not possible to present in tabular form the changes which occurred in the response to Hess's test. Insufficient attention was at first paid to this point, for their significance in a diabetic was not appreciated. Positive Hess's tests during carbutamide therapy were seen in Cases 3, 7, 8, 25, 26, 27, 30, 34, 35, 37, and 38. When the administration of the drug was stopped recovery followed. It will be noted that six of these patients had shown no depression of the platelet count. Conversely, three patients (Cases 6, 29, and 40) with low platelet counts (and in one instance spontaneous purpura) had only slightly positive Hess's tests.

Patch Tests.—Eight patients (Cases 3, 6, 8, 25, 29, 30, 35, and 40) were patch-tested with carbutamide in propylene glycol. No reactions were seen.

Clot Retraction and Platelet Agglutinins.—Clot retraction was very poor in Cases 6 and 35, and there was no appreciable change on adding carbutamide to the blood. Cases 8, 25, and 30 probably showed some impairment of retraction, while in Cases 3, 29, and 40 it was normal. In none of these patients was there any appreciable lessening of retraction after the addition of carbutamide to the clotting blood. There was no agglutination of platelets in platelet-rich plasma after the addition of carbutamide in any of these eight patients, nor was a significant reduction found in the number of the platelets after incubation with carbutamide for two hours, four hours, or overnight. This was unexpected, for in Case 35 at least it had been anticipated that agglutinins would be found. This patient did have strong agglutinins both to pooled platelets from group O blood and to platelets from several donors of the same blood group as her own: it was not possible to demonstrate an increased titre in the presence of carbutamide. No such agglutinins were found in the blood of the other seven patients.

Discussion

These findings demonstrate the common occurrence of neutropenia during carbutamide therapy. It is of interest that the white-cell count often rises again while administration of the drug is continued, a point noticed previously by Downie *et al.* (1956). The harmful effect on the white cells is now well attested and is similar to that of other sulphonamides. In this discussion, therefore, attention is directed primarily to the toxic effects of carbutamide on the blood platelets and the capillaries.

In the immune thrombocytopenic purpuras caused by certain drugs the drug acts as a hapten, combining with platelets to give a complex which is antigenic. There is growing evidence, particularly from experiments in passive immunization, to suggest that such a loose platelet-drug combination occurs in all patients receiving the drugs, but that it is only rarely that the antigenic effect is strong enough to cause trouble. When the complex is strongly antigenic, not only will the immune reaction cause platelet destruction but the megakaryocytes may be affected, producing the changes thought previously to be those of a primary toxic effect on the marrow. Capillary endothelium being antigenically very similar to blood platelets, damage to this may occur. The present observations are considered in the light of this concept of a toxic immune reaction.

The mild depression of the platelet count which occurs in some patients during therapy, and the remarkable "rebound" in most after the administration of carbutamide is stopped, can be explained satisfactorily in this way. Supposing there was to be a slightly increased rate of destruction of platelets following the creation of a weakly antigenic carbutamide-platelet complex, most patients would be able to maintain the level of circulating platelets by an increase in production. Where the marrow reserve was small and the platelet count would fall. Where the marrow was already depressed and the platelet count low, frankly thrombocytopenic levels might be reached. The actual occurrence of each of these possibilities can be demonstrated in the present study. Conversely, once the administration of carbutamide is stopped, peripheral destruction of platelets ceases and for a short time continuing overproduction by the marrow gives a high platelet count.

There is good evidence, therefore, that some degree of sensitization is common during carbutamide therapy. Control studies suggest that hypoplasia of the bone marrow may occur in diabetes, and this may be a further reason why depression of the platelet and white-cell counts has happened so readily. Little information is, however, available on the marrow changes which may occur in diabetes. These require full investigation, for all the drugs at present under trial in the oral treatment of diabetes are potentially haemotoxic.

Of the two patients who developed purpura, one exemplified in extreme degree such an allergic thrombocytopenia

* Indicates point at which treatment with carbutamide was stopped.

as that described above, while the other had capillary damage without alteration in the platelet count. The thrombocytopenia of the first was clearly shown to have been due to carbutamide, and an unusual feature in her case was the very rapid rise in the platelet count when the administration of the drug was stopped. This is strongly suggestive of peripheral destruction of platelets rather than of a toxic effect on the marrow, though *in vitro* evidence of sensitization was lacking. It is noteworthy that both patients had shown signs of intolerance, in the form of allergic skin manifestations, some time before the purpura appeared.

These two patients were later given tolbutamide. The patient who had developed thrombocytopenic purpura while receiving carbutamide showed a slight but significant fall in the platelet count when tolbutamide was given, but there was no further fall while the administration of the drug was continued, and Hess's test remained negative. There was therefore no good evidence that sensitization to carbutamide had produced cross-sensitization to tolbutamide. On the other hand, the patient who had developed non-thrombocytopenic purpura one month after the administration of carbutamide had been resumed, following its long interruption, developed purpura again after she had been receiving tolbutamide for one month. No conclusions can safely be drawn from these isolated findings, but they at least suggest that though tolbutamide is not a sulphonamide its toxic actions may be similar to those of carbutamide.

An effect of carbutamide on the capillaries was seen. In many patients capillary resistance was found to be increased when the administration of carbutamide was stopped, even when the platelet count had been high. The point was not fully investigated, but it seems probable that carbutamide accentuates the increased capillary fragility which is due to the diabetes itself. When the antigenic similarity of platelets and capillary endothelium is borne in mind, this is an understandable effect of a drug which has been shown to cause thrombocytopenia. It is clearly an unwelcome attribute, for such diabetic complications as retinopathy and nephropathy will presumably be influenced adversely. It must, however, be emphasized again that these observations were not adequately investigated, and require confirmation.

The toxic effects of carbutamide on the blood are therefore those which might have been anticipated in the extensive use of any sulphonamide. However, when in a group of only 40 patients it has been possible to show so many instances of harmful effects on the white cells and the blood platelets, it is obvious that the drug is dangerous. Added to this, there is the possibility that it may accentuate any damage to small blood vessels. Carbutamide cannot be regarded as a safe substitute for insulin in the routine control of diabetes.

Summary

A haematological study was made of 40 patients who were receiving carbutamide for the control of diabetes mellitus. Leucopenia was common soon after this treatment was instituted, but usually the white-cell count rose again as the administration of carbutamide was continued: one patient, however, developed a severe leucopenia which persisted until treatment was discontinued.

Many patients showed a mild depression of the platelet count, and two developed spontaneous purpura. In one case the purpura was thrombocytopenic, and was shown conclusively to have been due to carbutamide. In the other the purpura was non-thrombocytopenic, and was probably due to carbutamide. Both these patients were later given tolbutamide, and the possible toxic effects are discussed.

Clinical observations suggested that carbutamide accentuates the increased capillary fragility which may occur in diabetes, but this point was not fully investigated and the findings require confirmation. It is concluded

that carbutamide is not a safe drug for use in the routine control of diabetes.

I wish to thank Professor D. M. Dunlop for his encouragement and advice, and I am indebted to him and to Drs. Joyce D. Baird and L. J. P. Duncan for giving me the opportunity of carrying out these investigations on their patients.

EFFECTS OF "PACATAL" ON SYMPTOMS IN CHRONIC PSYCHOTIC FEMALE IN-PATIENTS

BY

P. H. MITCHELL, M.D., D.P.M.
Consultant Psychiatrist and Deputy Medical Superintendent,
Lancaster Moor Hospital, Lancaster

P. SYKES, M.B., Ch.B.
Registrar, Lancaster Moor Hospital, Lancaster

AND

A. KING, M.B., B.S.
Registrar, Saxondale Hospital, Radcliffe-on-Trent

"Pacatal," or pecazine, is one of eight different ring derivatives of phenothiazine synthesized by Schafer and Nezel in Hamburg. It is N-methylpiperidyl-(3)-methyl-phenothiazine, and has the following formula:

It was tested in animals by Nieschulz *et al.* (1954) and found to be well tolerated and to have various actions, including a tranquillizing effect on all animals, with somnolence in larger doses; an antisymphathetic-mimetic reduction of blood pressure; a potentiation of analgesics and narcotics; and an antiperistaltic action. Werenberg (1955), from whom the above information is derived, describes other effects of the drug in animals.

The therapeutic investigation described in this paper was devised in an attempt to determine whether pacatal was effective in the control of certain symptoms in chronic psychotic female patients—namely, incontinence, aggression, and noisiness—without the toxic side-effects which have sometimes caused anxiety when chlorpromazine, another phenothiazine compound, has been used.

Method

For the purpose of the investigation, 76 female patients suffering from chronic psychosis, of age range 32 to 75 years (average 59.5 years), were accommodated in one large ward. They were all long-stay patients, the duration of hospitalization ranging from 6 to 46 years (average 21 years). All were regressed in varying degrees and none had received any recent significant treatment. Most were suffering from schizophrenia (Table I).

TABLE I.—Age and Diagnosis Distribution of the Groups

	Pacatal	Control
No. of patients	37	38
Age { Minimum	32 years	35 years
Maximum	75 "	74 "
Mean	59.5 "	59 "
Diagnosis on admission { Schizophrenia	26	26
Manic-depression	9	4
Others	2	8
Duration in hospital { Minimum	6 years	10 years
Maximum	42 "	46 "
Mean	19.5 "	23.3 "

The patients were divided into two clinically random groups, which were, as Table I shows, similar in age and diagnostic distribution. The patients in one group received throughout the experiment active tablets of pacatal, for the first 12 days of the trial, in a dosage of one tablet three times daily (75 mg. daily); for the next 28 days two tablets three times daily (150 mg. daily); and for the final 12 days three tablets three times daily (225 mg. daily). Thus each patient in this group received a total of 7.8 g. of pacatal. The patients in the other group received equal numbers of inert control tablets which were identical in appearance with the active tablets. The identity of the tablets was known only to the hospital pharmacist.

For statistical purposes, with one exception (a patient in the pacatal group who had to be moved out of the ward for administrative reasons) those patients who were unable to complete the course of active tablets were regarded as having done so.

In an effort to make the investigation as objective as possible, only three symptoms were recorded throughout; the numbers of incidents of incontinence, aggression, and noisiness being recorded by the nursing staff against the patients' names on a large wall chart. Incontinence, either urinary or faecal, is self-explanatory. Aggression was defined as striking another individual or attempting to do so, and noisiness as a vocal outburst sufficient to warrant segregation of the patient because of her disturbing effect on other patients.

In addition, the blood pressure of each patient was recorded twice weekly by two of us (A. K. and P. S.), on each occasion at the same time of day, without change of instrument, posture, or investigator. At the same time any toxic effect was looked for and recorded. Apart from this, no detailed clinical appraisal of the patients was attempted, either before or during the investigation.

Results

Control of Symptoms.—Thirty-seven patients received pacatal and 38 were controls. In the pacatal-treated group there were 61 occurrences of incontinence, 31 aggressive acts, and 101 noisy outbursts, compared with 145, 96, and 206 respectively in the control group. In each case the difference is significant beyond the 1 in 20 level of probability. Thus there are significantly fewer incontinent, aggressive, or noisy incidents in the pacatal-treated group than in the control group.

Statistical Method.—In each case the incidence of acts of incontinence, aggression, or noisiness is expressed as a proportion of a hypothetical normal, this being the number of acts that would have occurred if each patient had been incontinent, aggressive, or noisy once weekly. The difference

TABLE II.—Symptomatic Incidents in Groups, With Statistical Analysis

	Pacatal-treated Group	Control Group	Difference Between Rates	Standard Error Difference
No. of patients	37	38		
Incontinent incidents	61	145		
Rate of incontinence (% if each patient incontinent once weekly)	22	51.5	29.5	10.6
Aggressive incidents	31	96		
Rate of aggression, %	11.3	34.0	22.7	10.7
Noisy incidents	101	206		
Rate of noisiness, %	36.7	73	36.3	10.6

between the proportions so determined in the two groups is then compared with its standard error (Table II). As a further control, the rates of occurrence of the three symptoms in the first 26 days of the investigation were compared with those in the second 26 days. In the group receiving pacatal the rates of incontinence and noisiness were significantly less in the second than in the first period, and that of aggression less, but not significantly so. In the control group there was no significant difference in the rates of incontinence. The rate of aggression showed an increase which just failed to be significant, while the rate of noisiness showed a significant increase in the second half of the period (Table III).

TABLE III.—Comparison of Symptomatic Incidents in First and Second 26 Days of Treatment

	Number of Incidents		Rates % of 1 Incident per Patient per Week		Difference in Rates %	Standard Error of Difference
	1st 26 Days	2nd 26 Days	1st 26 Days	2nd 26 Days		
Incontinence: Pacatal group	50	11	36.4	8.0	28.4	9.1
Control " "	75	70	53.1	49.6	3.5	11.5
Aggression: Pacatal group	23	8	16.7	5.8	10.9	7.2
Control " "	34	62	24.1	43.9	19.8*	10.6
Noisiness: Pacatal group	72	29	52.4	21.1	31.3*	10.6
Control " "	84	122	59.5	86.4	26.9*	9.9

* Increase.

Toxic Complications

Serious toxic complications of three types—jaundice, hypotonia, and neutropenia—occurred in a total of 16 (43%) of the patients receiving pacatal (Table IV).

TABLE IV.—Analysis of Toxic Effects in 37 Pacatal-treated Patients

	Jaundice	Neutropenia	Hypotonia	Total
No. of cases	2	4*	10	16
% of total	5.4	10.8	27	43.2
Age { Minimum	43 years	49 years	35 years	35 years
Maximum	56 "	63 "	74 "	74 "
Mean	48.5 "	58 "	59.4 "	57.8 "
Drug taken { Minimum	1.5 g.	6.8 g.	2.9 g.	
Maximum	3.9 "	7.8 "	7.3 "	
Mean	2.7 "	7.2 "	5.6 "	

* Includes one fatal case.

Jaundice.—Two patients developed mild jaundice; one after taking 1.5 g. and the other after 3.9 g. of pacatal. Both recovered spontaneously after withdrawal of the drug.

Hypotonia.—Ten patients developed a state of unilateral hypotonia. All showed a similar picture, differing only in degree. The syndrome consisted of a marked flaccidity of the extensors of both limbs of one side of the body and a concomitant flaccidity of the ipsilateral erector spinae muscles. The patients walked with semiflexed arm and leg, tilting to the hypotonic side. All had unsteady gait, two to such an extent that they fell, injuring themselves. Because of mental regression, detailed neurological examination was difficult, but it appeared that co-ordination was normal apart from the effects of the hypotonia. Those able to understand the

instructions could perform the finger-nose test with accuracy and without tremor. There was no nystagmus or signs of extrapyramidal or pyramidal motor lesions. Sensory examination was impossible because of the mental state, but there did not appear to be any posterior column involvement, gait being co-ordinated, allowing for the abnormal posture. One case of this condition occurred after 2.9 g. of pacatal; then towards the end of the trial nine cases occurred within a few days. The first case continued to receive pacatal to the end of the trial without any worsening. After withdrawal of the drug all cases recovered within seven days.

Neutropenia.—Four patients developed neutropenia late in the trial. In the first case, a woman of 61 presented with a small local infection of the thumb and, despite blood transfusion, penicillin, and cortisone, died of agranulocytosis 15 days later. The remaining three cases which were detected by routine white-cell counts, all occurred after the administration of between 7 and 7.8 g. of the drug. Two showed white-cell counts of 3,500 per c.mm., with 40% neutrophils. Pacatal was immediately withdrawn and the blood counts returned to normal within seven days. In the fatal case and one of the others, bone marrow biopsy confirmed an agranulocytic reaction.

Minor toxic effects in the patients receiving pacatal included dryness of the mouth and disturbances of vision, but these were not serious enough to seriously inconvenience or endanger the patients concerned and have not been tabulated.

Effect on Blood Pressure

It was found that many patients in both groups had labile blood-pressure recordings, sudden falls and equally rapid recoveries occurring at frequent intervals. Falls in the systolic pressure of 20 or more mm. Hg were recorded in 16.1% of the patients receiving pacatal and in 15% of the control group. The difference is not significant.

Discussion

The necessity of subjecting any new drug to adequate controlled clinical trials, so that its field of usefulness can be exactly determined before it is used generally, has been recently stressed (*British Medical Journal*, 1956). At the same time, psychiatric investigations present particular problems of objectivity, quantitative measurement, and adequate controls. It seems that a measure of the number of occurrences of particularly easily detected symptoms is one relatively simple way of meeting these difficulties (Mitchell, 1956). By this means, patients taking a new drug can continue to live in the same environment as previously, as they are not subjected to unusual prolonged clinical interviews by medical staff or others. Measurement of symptoms becomes a simple recording on a wall chart of each episode (in this investigation) of incontinence, noisiness, or aggression. As the individuals in a clinically similar and numerically equal control group, given an identical-appearing tablet, have similar recordings taken it is not necessary for every occurrence of a symptom to be recorded, as the final analysis is one of the relative frequency of each symptom. Thus there is a minimal change in environment, such change as there is being identical in control and the test groups, and it can be claimed that numerical differences observed in the objectively recorded symptoms are due (subject to statistical analysis) to the drug administered.

It might be argued that an initial observation period in all groups, prior to the administration of any active tablets, might have been desirable in reducing still further the effect of chance in the rather small clinically random groups chosen. It was felt, however, that the enthusiasm of the observers, on whom the success of the investigation depended, might quickly wane without positive results, so it was decided instead to compare incidences in the first half of the experimental with those in the second half as an additional statistical control, for not only were the patients on a bigger daily dosage of the drug in the latter part of the investigation, but it was presumed that pacatal, like chlorpromazine, would show some delay in developing its full effects. It

was interesting that the control groups showed an increase in aggressiveness and noisiness, due, presumably, to increasing reluctance to take tablets.

It must be noted here that no attempt has been made to restrict the investigations to patients with one type of psychosis, though, as might be expected, despite the diagnosis distribution (on admission) as shown in Table I, nearly all were suffering from chronic schizophrenia. Whatever the diagnosis, the symptoms chosen for enumeration are those which make the nursing of the chronic regressed patient a difficult and often thankless task. Any drug which will safely help to make the patients more accessible, by reduction of these symptoms, is thus of great value in these days of serious nursing shortages.

Our findings concerning the effectiveness of pacatal in the control of these symptoms—incontinence, noisiness, and aggressiveness—are similar to those reported by Werenberg (1955) in an uncontrolled experiment. It seems likely that the significant reduction in the incidence of incontinent acts may well be due, in part at least, to the inhibitory action of the drug on the smooth muscle of the intestine and bladder, rather than to increased co-operation on the part of the patient.

It has already been reported by many observers that another phenothiazine compound, chlorpromazine, is effective in the control of turbulent chronic psychotic female patients (Elkes and Elkes, 1954; Andermann and Lindsay, 1955), but, as already stated, toxic side-effects occur with this drug. These, though not usually serious, often give trouble and have been widely reported. Lomas *et al.* (1955) give a very full account of them. Jaundice, dermatitis, and Parkinsonism are the most troublesome; but Pollack (1955) describes one fatal case of agranulocytosis in 500 patients treated with chlorpromazine. At Lancaster Moor Hospital we have found that skin sensitivity to chlorpromazine amongst the female nursing staff has been our greatest cause of anxiety. No fewer than 21 female and 2 male nurses who have handled the drug have developed dermatitis, which in some cases has been of long duration. Moreover, the sensitivity appears to be long-lasting, four of the female nurses showing strong reactions to patch testing nine months after the original attack (Seville, 1956).

Unfortunately, in this investigation, pacatal has proved to be even more toxic than chlorpromazine—so much so that the investigation was terminated prematurely. The occurrence of one fatal case of agranulocytosis and three cases of neutropenia in the relatively small number under treatment, apart from the postural complications already described, made it unjustifiable to continue.

Toxic complications of the drug have previously been described. Thus Werenberg (1955) found seven cases of leucopenia in his series of 100 patients undergoing treatment with pacatal, including one fatal case of agranulocytosis in a woman of 46 who also suffered from mild diabetes mellitus. She had had a total of 7.5 g. of the drug. Of the other six cases, one had to have the drug discontinued, the remaining five exhibiting a return of the blood count to normal without stopping the drug. A case of fatal agranulocytosis, not firmly established as due to pacatal, has also been described by Wenderoth and Lennartz (1955) after a total of 13 g. of the drug. C. S. Parker (1956, unpublished communication) reports one fatal case of agranulocytosis in a patient receiving pacatal.

Kline and Jacob (1955) described five cases of postural difficulty apparently similar to those found in this investigation. Because of this and other complications, they found it impracticable to continue giving the drug. In our series it will be noted that almost 25% of the patients developed postural difficulties, two severely. Although the symptoms resolved rapidly on termination of the drug, it is clear that they could prove serious and incapacitating to an out-patient undergoing treatment.

There do not appear to be any reports in the literature of jaundice occurring in patients undergoing pacatal therapy, other than those found in this experiment.

Other serious toxic effects in patients taking the drug have been described by Kline and Jacob (1955), three of whose group developed atonic bladders and bowels when on intramuscular therapy. One of these actually showed symptoms of an autonomic bladder and required catheterization.

Finally, Werenberg (1955), in his series, reports three further deaths: one apparently from cardiovascular collapse; one from embolism of the pulmonary artery, thrombosis of the common iliac vein, and myocardial degeneration, associated with severe constipation; and the third from embolism of the pulmonary artery and thrombosis of the plexus parametralis together with a large uterine fibroma.

On the other hand, Bowes (1956) reports no serious toxic results in a series of 50 cases, some of whom received up to 600 mg. of pacatal daily.

However, the findings of Werenberg (1955), of Kline and Jacob (1955), and of the present investigation suggest that pacatal should be used only with extreme caution. Chlorpromazine is equally effective in the treatment of chronic regressed female psychotic patients and its toxic effects are much less serious. It seems to us that if either drug is to be used chlorpromazine is the drug of choice.

A reference to the pharmacology of phenothiazine itself shows that liver damage and jaundice, tachycardia, and sensitization of the skin to ultra-violet light are amongst the side-effects which brought it to be regarded as too toxic for use in humans (Martindale, 1952). It is clear that the derivatives of phenothiazine at present in use have toxic side-effects which are by no means negligible and which in some respects are similar to those of the parent substance. Further research is required in an effort to eliminate this unfortunate toxicity in drugs which otherwise seem to be valuable in mental hospital practice.

Summary and Conclusions

A controlled investigation into the effectiveness of "pacatal" in reducing the incidence of incontinence, noisiness, and aggression in chronically regressed psychotic female in-patients is described.

Pacatal was effective in reducing the number of noisy, aggressive, and incontinent acts in these patients, most of whom were suffering from schizophrenia.

Unfortunately, the high incidence of toxic side-effects in this group of patients suggests that the widespread use of pacatal is unjustifiable, at least until considerable evidence to the contrary is available. The toxicity of chlorpromazine, while not negligible, does not seem to be so serious, and it would appear to be the drug of choice. But where sensitivity to chlorpromazine has developed and where a drug of the phenothiazine type is strongly indicated, it would seem justifiable to use pacatal so long as close supervision of the white-blood-cell picture and of bowel and bladder function is maintained.

Acknowledgment is due to William R. Warner and Co. Ltd., who made supplies of pacatal freely available; to Dr. J. D. Silverston, medical superintendent of Lancaster Moor Hospital, for permission to perform the investigation; to Mr. H. Lewty, hospital pharmacist, for his assistance; and to the nursing staff, without whose help this investigation could never have been made.

NICOTINYL ALCOHOL TARTRATE IN INTERMITTENT CLAUDICATION

BY

R. O. GILLHESPY, M.D., F.R.C.P.Ed.

Physician, Dudley Road Hospital, Birmingham

The purpose of this investigation was to assess the value of nicotiny alcohol tartrate ("nicotol") in the treatment of patients suffering from severe intermittent claudication secondary to generalized arteriosclerosis.

Nicotiny alcohol tartrate is the alcohol corresponding to nicotinic acid, and has essentially the same vasodilator properties as the latter. However, its action is more sustained than that of nicotinic acid, probably because, in addition to the vasodilator properties of the alcohol itself, partial metabolism of it in the body results in the gradual release of nicotinic acid. The vasodilator effect of nicotiny alcohol tartrate is mainly on the small arteries and arterioles. A number of investigators in the United States and in Europe have reported encouraging results with its use in the treatment of peripheral vascular disorders.¹⁻¹⁰ However, although the drug is widely used in Great Britain, no report has yet been published describing a controlled investigation of its use in intermittent claudication.

Plan of Present Trial

The investigation was carried out on the "blind" principle; the majority of the patients had previously been admitted to hospital for full investigation and all had been treated previously with other compounds alleged to be of value in intermittent claudication. For inclusion in the trial, patients had to fulfil the following criteria: (a) There had been present for at least two months a severe gripping pain lasting for more than one minute in one or other of the calf muscles, coming on after a constant amount of exercise and relieved by a few minutes' rest. (b) Pulsation was absent in one or other of the palpable arteries in the affected limbs. (c) The skin of the extremity was blue or gangrenous and distinctly colder than that of the less affected limb.

Patients were excluded from the series if they were suffering from any other serious disease, correction of which might have influenced the assessment of the results. Congestive heart failure, when present, was always corrected by appropriate treatment in hospital before the patient was included in the series.

Once the diagnosis had been established all treatment was withheld for a period, in order to prevent any "overlap" of therapeutic effects. Patients were then treated with either nicotiny alcohol tartrate, one 25-mg. tablet four times daily, or with dummy tablets of identical appearance. Treatment was allotted by random selection by an independent person in the pharmaceutical department and I did not know the distribution of the patients until after the results of the trial had been assessed. The treated and control groups were comparable in respect of age and sex.

The series originally contained 50 patients, but by the end of the trial only 30 remained for final assessment. Of the remaining 20 patients, 15 died before the end of the trial, three moved to another area, and two refused to complete the course of treatment. It must be appreciated that, when organizing a trial using such poor clinical material over a fairly prolonged period, deaths from coronary thrombosis, cerebral haemorrhage, or renal complications, as a result of the generalized arteriosclerosis, are inevitable. All the case records of patients who died were studied, and it was decided to exclude them from the assessment of results because the duration of their treatment was too variable for useful assessment. The losses by death did not affect the comparability of the treated and control groups.

Assessment of Results

In order to achieve a high degree of standardization a form was prepared and completed for each patient. In each case the results were assessed, after at least 18 months' treatment, by analysis of the information contained in these forms. The results of treatment were classified as follows: "No benefit" means that the patient's condition had remained stationary or had become worse, as shown by a significant reduction in the walking distance before the onset of claudication, progression of the skin changes, or the presence of gangrenous ulceration. "Slight improvement" was considered to have taken place if the progress of the disease appeared to have been halted and if there was a slight but definite increase in the number of yards traversed before the onset of claudication. "Moderate improvement" means that after treatment the patient was able to walk at least half a mile further than had been possible before treatment.

The measurement of walking distance was carried out by the patients themselves, because experience has shown that this type of patient knows fairly accurately the distance that can be walked before claudication begins. It was impressed on all these patients that they must measure this distance (at their ordinary walking speed) in paces, each pace being taken as one yard.

After the trial had been in progress for about two and a half years, and all patients had received at least 18 months' treatment, it was closed and the result in each patient was assessed. Only then was I given the key to which patients had been on nicotinyl alcohol tartrate and which on placebo therapy. The results are shown in the table.

Results of Trial

Treatment	No. of Patients	Moderate Improvement	Slight Improvement	No Benefit
Nicotinyl alcohol tartrate	17	10	3	4
Dummy tablets	13	0	4	9

Side-effects.—The only side-effect observed was mild flushing of the face in two of the 20 patients excluded from the final assessment of results.

Discussion

Intermittent claudication marks the beginning of the final stages of a slowly progressive arterial disease. After a given amount of exercise the intensity of the pain is so impressive and its onset so constant that the alleviation of this symptom is an obvious way of assessing the value of any drug used in treatment.

Because of the difficulty of making an unbiased assessment of "improvement" in such a chronic condition, it was felt to be essential to carry out a "blind" control trial, comparing the effect of nicotinyl alcohol tartrate with that of a placebo. In this disease it is difficult to compare the effect of any one drug with that of another by the application of the "blind" method, because of the large number of patients who would be required, so no such attempt was made. Further, with the use of such poor clinical material a large percentage of "rejects" can be expected, and thus relatively large numbers must be included initially, even when comparing one drug with placebo therapy, in order to obtain final figures which are sufficient for analysis. In the present trial it was found possible to include 50 patients within a relatively short time, and by these means it was hoped that a sufficient number would remain at the end of the trial to give significant results.

When comparing the numbers of patients who improved on nicotinyl alcohol tartrate with those on dummy tablets there can be no doubt that the patients on the active drug improved to a greater extent than did those on the placebo. The converse was also true—that is, the number of patients failing to derive benefit from the active tablets was significantly smaller than the number of those who failed to receive benefit from the placebo.

It should be noted that statistical analysis takes no account of the fact that this is a progressive disease and is therefore no substitute for clinical experience. In the eyes of the clinician, a drug which halts the inevitable downward progress of the patient would be considered "beneficial," although, in the eyes of the statistician, a patient whose condition was unchanged at the end of 18 months would be considered to have received "no benefit."

Summary

A "blind" controlled trial is described in which 50 patients with severe intermittent claudication secondary to generalized arteriosclerosis were treated with nicotinyl alcohol tartrate or dummy tablets. Patients whose condition was complicated by the presence of other pathological processes were excluded. By the end of the trial the results of at least 18 months' treatment with nicotinyl alcohol tartrate (17 patients) and dummy tablets (13 patients) were available for comparison.

It was found that the results in those patients on the active drug were significantly better than in those who had received the placebo. It is therefore concluded that nicotinyl alcohol tartrate is a useful drug in the control of intermittent claudication.

The value of the "blind" method in a trial of this nature is discussed.

INTRAMEDULLARY NAILING FOR
RECENT FEMORAL SHAFT
FRACTURES

BY

A. E. STEVENS, M.B., F.R.C.S.Ed.

Consultant Surgeon, Redhill County, Horsham, and
Dorking Hospitals

AND

J. PETT TURNEY, M.B., F.R.C.S.

Formerly Senior Surgical Registrar,
Redhill County Hospital

During the past 16 years the insertion of intramedullary nails into the shafts of long bones has been done with increasing frequency. The method is not a new one, and in an extensive review of the difficulties of this form of treatment Watson-Jones and others (1950) discussed medullary nailing "after 50 years." They point out that Nicolayson in 1897 writes of the method, and Hey Groves (1918-19), in this country, described a number of cases, mostly of battle casualties from the first world war, treated in this way in 1916 and 1918. More recently, Küntscher (1940) has reintroduced the method, and there is now a vast amount of literature on the subject both on the Continent and in America. Böhler (1948) published his monograph on the method, dealing with 600 cases treated in his clinic, and the American Academy of Orthopaedic Surgeons (1951) surveyed 700 cases treated by 15 surgeons.

Few reports, however, have been published in this country. Lloyd-Roberts (1951) reported 20 cases, and although many surgeons use the method the recorded cases are few.

Material

At the Redhill County Hospital in the past few years we have been making increased use of the method in recent fractures of the femoral shaft, and we here present a series of 41 cases which have been dealt with since December, 1948, although 30 have been treated since January, 1953, the most recent in February, 1956. There were 26 men and 15 women. The age distribution is shown in Table I. The site of the fracture in 8 cases was the

TABLE I.—Age Distribution

Age No. of cases	-19	20-29	30-39	40-49	50-59	60-69	70-79	80+
	3	13	1	4	2	5	5	8

upper third, in 28 cases the middle third, and in 5 cases the lower third. Six were open fractures and 35 closed. Ten were pathological fractures, of which eight were due to Paget's disease of the bone and two to secondary carcinomatous deposits. All these patients were over 60 years of age. One patient who was operated on in June, 1954, had secondary carcinomatous deposits and two other deposits lower down the femur, without fracture. She is walking and the fracture has united. She has been treated with testosterone.

Union has occurred in all cases that were treated 12 or more months ago, except in one case, and we believe that the more recent cases will also unite satisfactorily.

Knee movements in cases which have united have also been very satisfactory. Table II shows the degree of knee

TABLE II.—Knee Movements in 34 Surviving Patients

Degrees of movement No. of cases	<30	30-59	60-89	90+	Full
	5	5	4	6	14

movements obtained in the 34 cases that have been traced out of the 37 surviving patients. It is interesting to note that in the group of 10 patients who obtained indifferent knee movements—that is, less than 60°—there were five of the eight cases of Paget's disease. Two more had ipsilateral fractures of the tibia, but in three no adequate reason was found for the limitation. In only two cases were hip movements restricted at all.

The average stay in hospital for all cases has been 84 days, which compares favourably with other forms of treatment, particularly when it is remembered that 18 of our patients were over the age of 60 and eight over the age of 80. One patient who had facilities for being nursed at home was allowed out of hospital after 10 days, and started to walk six weeks after the operation.

It is interesting to note that the average stay in hospital of the last 12 patients operated upon was only 32 days and that three of them were octogenarians.

Four of our patients died in hospital. All were over the age of 70. One of these deaths was due to pulmonary embolus the day after operation; one patient with a pathological fracture due to secondary carcinoma died on the logical fracture due to secondary carcinoma and 37th day; and two patients died of bronchopneumonia and 37th day; and two patients died of bronchopneumonia and 37th day. The cause arteriosclerosis on the 37th and the 130th day. No of death in all cases was confirmed by necropsy. One patient has died since June, 1954, and all suitable cases admitted to hospital have undergone operation.

Illustrative Cases

A lorry driver aged 25 had a comminuted fracture of the mid-shaft of the left femur. Some difficulty was experienced in inserting the nail, but eventually good immobilization was obtained. He left hospital eight weeks after operation and, against advice, drove his two-ton lorry

12 weeks after the fracture. He eventually made a good recovery.

A factory hand aged 31 had a transverse fracture of the mid-shaft of the femur which was operated upon on July 30, 1953. He was in hospital for about 12 weeks and returned in May, 1954, complaining that he had slight limitation of abduction of the hip. On May 4 the nail was removed and it was found that consolidation was not complete and the leg bent in bed the next day. On May 6 another nail was inserted, using a guide, and he eventually made a good recovery, although he did not regain full knee movements.

A woman of 80 had an oblique fracture of the upper third. She was very agile for her age and started to walk six weeks after operation. She regained full knee movements, and union occurred within six months.

Operation

We have had no experience of the closed method of inserting the intramedullary nail, with x-ray control, as practised by Küntscher, but have exposed the fracture in all cases, and inserted the nail by the "retrograde" method described by Key and Connell (1951) and also used by Lloyd-Roberts. We have not used the modifications mentioned by Watson-Jones (1955).

If the fracture is a closed injury it may be convenient to immobilize the limb temporarily on a Thomas splint. Pre-operatively it is important to have a knowledge of the length of nail required. A reasonably accurate working method is to hold one end of the nail against the sound greater trochanter and note how far short the other end is from the knee-joint. The width of the medullary canal on the film should also be observed, as occasionally it is abnormally narrow, especially in the middle third, and one of the complications is that the nail impacts into the medullary canal. This can be avoided by taking an x-ray picture of the femora with the nail strapped to the outside of the thigh and measuring the respective width of the nail and medullary canal. A more accurate method is to take scanogram measurements of the medullary canal, but this requires special apparatus.

Blood should be cross-matched in all cases, as in one case hammering on the nail caused shock profound enough to interrupt the progress of the operation. Blood transfusion has not, however, been necessary in every case, but it is wise to remember, as Ogilvie (1955) has stated, that "a man can bleed to death into the thigh muscles round a fractured femur without any free haemorrhage occurring."

It is advisable to have two assistants. If the fracture is an open one, operation within a few hours of the accident is imperative, and undressing and preparation of the patient may be deferred until anaesthesia is induced.

The patient is placed supine, with the injured side as near the edge of the table as possible. A flat sandbag is put under the buttock to tilt the patient towards the uninjured side. After skin preparations, the thigh is painted with "mastisol," and a sterile piece of tubular stockinet is rolled up the limb, which is then passed through the hole of an abdominal sheet. We find that this is a satisfactory method, insuring stable sterile cover while retaining maximum mobility.

If the tibia on the same side is fractured, we plate the tibia first, and then proceed to nail the femur. This occurred in four cases.

The ideal approach to the femur is that described by Henry (1945). An incision is made along the appropriate part of the line from the anterior superior iliac spine to the outer edge of the patella. The rectus and vastus lateralis muscles are identified by the V-shaped interval between them, a handbreadth below the trochanter, and are separated. The vastus intermedius muscle is divided lengthwise, cutting down to the bone. Often the incision can be modified to allow the routine treatment of the wound, but it may be more convenient to explore and close the wound before the normal approach is made.

The upper fragment is then grasped with lion forceps by the operator and delivered from the wound in an adducted position. The first assistant controls the lower fragment while the second assistant adducts the leg strongly across the other. When full adduction has been gained the nail is inserted in the upper fragment and tapped upwards. Should it tend to become impacted it is wise to substitute a narrower nail.

FIG. 1.—A: Showing slight comminution at fracture site and comminuted fracture of patella, which was excised. B: Same case, showing amount of callus formation eight weeks after operation. Patient had returned to work in an office.

We use a nail with an "eye" at both ends to facilitate its later removal. A sterile hacksaw is said to be a face-saving instrument if the nail becomes irretrievably impacted, but we have not had occasion to use one.

The resistance suddenly diminishes as the nail passes through the trochanter. The upper end of the nail can then be felt through the skin and glutei muscles, and a 1-in. (2.5-cm.) vertical incision is made over it. The nail is then tapped further upwards, and guided out of the upper incision with a blunt gouge, rather in the manner of a shoehorn, until the lower end is flush with the distal end of the proximal bone fragment. Full relaxation is now needed. The fracture is accurately reduced by temporarily diminishing the degree of adduction, and a large Lowman clamp, preferably with four blades, is applied. This, in the absence of much comminution, holds the fragments rigidly. The nail is then driven down into the distal fragment until no more than $\frac{1}{4}$ in. (1.3 cm.) protrudes from the trochanter. Careful watch is maintained that the fragments do not become distracted. Only the deep fascia and skin need to be closed, and the wound is covered with a non-encircling adhesive dressing.

Post-operatively the limb needs no external fixation as a rule, but if in comminuted cases it is felt that the internal fixation does not give complete immobility it is then

FIG. 3.—Transverse mid-shaft fracture; showing callus formation 12 months after operation.

FIG. 2.—A: Fracture of lower third of femur. B: Same case, showing amount of callus 12 weeks after operation.

FIG. 4.—A: Transverse pathological fracture due to Paget's disease. B: Same case showing union 12 months after operation.

necessary to rest the leg on a Thomas splint for some six weeks. Active exercises are enthusiastically encouraged and the patient is allowed to sit in a chair on the first post-operative day. Normally a young adult can lift his limb off the bed at the end of the first week, and can be discharged home when he is confident in the use of crutches. Weight-bearing is not generally allowed until there is good callus formation, but some of our patients with transverse fractures have borne weight after a fortnight.

Complications

Although Küntscher says "there is no complication of this method," both Böhler (1948) and Stuck and Thompson (1951), in addition to Watson-Jones, list a formidable number of complications and possible difficulties, ranging from instability of fixation to death from fat embolus. We have met with some but by no means all of these difficulties. Slow union has occasionally occurred, possibly because of slight distraction of the fragments. When one of our patients was seen nine months after the operation, he was complaining of pain on abduction of his leg, so the nail was removed. The next day the femur angulated in bed. The following day a larger nail was reinserted along a guide wire from above, and in a few days he was walking and working.

In another case of severe comminution of the femur it was found on x-ray examination after the operation that the nail had not penetrated the distal comminuted fragment, and a further exploration had to be done to correct this. The patient eventually made a satisfactory recovery.

In three other cases nails were removed because of upward displacement, but satisfactory union was obtained in all of them. One of these patients developed some sepsis in her wound, but this eventually cleared up completely. She was an obese diabetic, but did not develop any bone infection.

In the first case in our series the nail bent six weeks after insertion, and was removed at another hospital and a bone-grafting operation done. This case was poorly selected in that the fracture was too near the knee-joint.

In one patient with Paget's disease the nail bent during its insertion when its advancing end encountered sclerosed bone at the site of a previous fracture.

In one patient with Paget's disease, who was allowed to walk before the fracture was completely consolidated, the increased bowing of the femur has caused the nail to break in the centre. He is an old man of 80; he has been given a walking calliper, and manages to get about reasonably well. In other cases of Paget's disease the fracture has united satisfactorily.

In two cases calcification has occurred around the top of the nail above the great trochanter, presumably at the site of a previous haematoma. In both these cases a little pain was experienced, but after removal of the nail (in both cases about two years after the fracture) the pain has been relieved. Removing the nail was not a difficult procedure.

Although we do not advocate insertion of an intramedullary nail in children, we have used it in one case, with a satisfactory result, the nail being removed six months later. The fracture had united satisfactorily.

We have had two cases of wound sepsis; one necessitating removal of the nail, the other being a very superficial infection which did not delay progress.

Discussion

What are the indications for this method? We think that in adults all transverse fractures of the femoral shaft to within 4 in. (10 cm.) of the condyles can be treated with an intramedullary nail. Oblique fractures are not so well controlled as the transverse, but are satisfactory if the obliquity is not more than 3 to 4 in. (7.5 to 10 cm.) in length. Comminuted fractures are also suitable, although the insertion of the nail is more difficult. Eight of our cases showed comminution, two to a serious degree.

The ideal patient is the young healthy adult man with a simple transverse fracture of the midshaft of the femur. In this type recovery is rapid, discomfort and immobilization are less than with other methods of treatment, callus formation is good, and knee movements often return to normal. The method is also of value in old people: in our series eight were over the age of 80. Their nursing is facilitated by the absence of apparatus and splints.

We regard an open fracture seen six to nine hours after the causative accident as suitable for the insertion of a nail. Six of our cases were compound, and on no occasion have we regretted the treatment. In fact, in our hospital the only case of very delayed union after a fracture of the femur in the period under survey was early in this series when we were hesitant to use the technique on a compound fracture.

There is also a place for this method in the treatment of pathological fractures, and in our series there were 10 such. In cases of secondary carcinoma this method gives the patient an easier convalescence than is possible by other methods.

In difficult cases where the femur, tibia, and fibula are fractured on the same side, this is the ideal form of treatment if the tibia is plated at the same time. Four of our cases came into this category, one of them having compound comminuted fractures of the femur and of the tibia and fibula. He was able to return to work as a salesman in a multiple store 24 weeks after his accident.

Conclusion

Our experiences gained from the study of 41 cases of fracture of the shaft of the femur are presented. Watson-Jones gives a salutary warning that "this technique, if applied to improperly selected cases, or if inefficiently or unskillfully carried out, carries more possibility of trouble than any other." We would, however, like to add that we consider that in suitable cases it is at present the ideal form of treatment, and the overwhelming advantages outweigh the disadvantages, some of which we think have been exaggerated.

We are grateful to Mr. N. E. Pitt for allowing us to use the notes of one case operated on by him; to Dr. J. C. Cuthbert, medical superintendent of Dorking County Hospital, for the use of the notes of two cases which were treated at that hospital by one of us; and to Dr. E. Goldsmith for help in the translation of German papers.

The Annual Report of the Institute of Almoners for 1955-6 records that during the year 9 students qualified as almoners through the course in medical social work at the University of Edinburgh, 11 through the Carnegie course in applied social studies at the London School of Economics, and 64 through the Institute's course. All 84 registered with the Institute, and 66 were already in permanent full-time employment when the report was prepared. In 1956 there was an increase of 28 in the total number of almoners employed. There has been a marked increase also in the number of hospitals employing almoners—530 compared with 496 a year ago. The number of vacant posts for almoners is still very high, and the report remarks that it is a serious matter that many senior posts remain unfilled. It is hoped that the Whitley Council will have regard to this when considering almoners' salaries.

Medical Memoranda

Two Children of Same Family Showing Features of Mongolism

Mongolism occurs in all races, though most descriptions have come from Europe or America. It is not uncommon among the Chinese population of Singapore, and we have recently seen two mongols in a single Chinese sibship.

CASE REPORTS

Case 1.—A 2-year-old Chinese girl was admitted to hospital on November 14, 1955, for bronchopneumonia. It was noticed that she had the typical mongoloid facies (Fig. 1). Her eyes were slanting, with prominent epicanthic folds, and a squint was present.

FIG. 1.—Case 1. Mother with her 2-year-old mongol baby. Note the mongolian facies, flat bridge of nose, slanting eyes with squint, and small ears.

The small ears, the flat bridge of the nose, the protruding tongue, and the foreshortened mouth were all characteristics of a mongol. There was a general hypotonia of all muscles. Moist sounds were heard over both lungs. The abdomen was soft, but an umbilical hernia was not present. The liver was enlarged two fingerbreadths. A wide gap was present between the first and second toes and she had a single crease across the palm. The milestones of the child were very delayed. She was first able to lift her head at 10 months and to sit with support at 1 year. The first tooth appeared at 1 year. She was able to stand with support at 2 years but was unable to talk.

Whilst being questioned, the mother casually remarked that her youngest child was also "very soft," and had similar features to the patient. Her three older children, aged 10, 8, and 7, were normal and attending school. The mother is now 44 years of age and the father 46.

Case 2.—The mother was asked to bring her youngest child, a boy aged 1 year. He was noted to have the features

of a mongol, but was even more hypotonic than his sister. He had a small head (circumference, 15 in., 38 cm.) with a very flattened occiput. His eyes were slanting, with marked epicanthic folds; the bridge of the nose was very flat and the tongue protruding (Fig. 2). This child had a large umbilical hernia. No murmur was heard over the heart and the lungs were clear. Although 1 year of age he was unable to lift his head.

Both the mongols were lovable pleasant children and the parents were very fond of them.

COMMENT

The aetiology of mongolism is not fully understood. The relationship of mongolism to twinning indicates that the origin is in the germ cell (Jenkins, 1933). But the association of mongolism with diminished maternal fecundity, as suggested by the age of the mother and the long interval before the birth of a mongol, supports the theory that the mongol is a product of fertilization of the ovum the viability of which is diminished.

This is a rare example of two mongols occurring in the same family.

I thank Dr. C. Elaine Field, paediatric specialist, for her assistance and Dr. R. H. Bland, the Director of Medical Services, Singapore for permission to publish.

Acquired Diverticulum of the Mitral Valve

A woman of 63 sought advice because of severe inflammation of both eyes. She attributed this to putting her head out of the window a fortnight previously in an attempt to obtain relief during an attack of dyspnoea. She was admitted immediately to an eye and ear hospital and treated for seven days for acute iridocyclitis. She returned home and for a time was able to go out for walks, but vision was rapidly lost, and she was certified blind four months after the onset of the disease. During the next year a massive oedema of the legs and ascites developed and she became increasingly breathless. A loud blowing systolic murmur was heard in the mitral area. A diagnosis of mitral incompetence was made, palliative treatment was given, and at the end of the year she died.

Before these disturbances she had been in excellent health, and had never suffered from sore throats or any form of acute rheumatism. The appearance of a severe mitral lesion so abruptly and at such a late age was difficult to explain, and would in fact have remained unexplained had she not died when one of us (J. R.) was on holiday. No certificate could be issued and a necropsy was ordered by the coroner.

NECROPSY REPORT

A thin elderly woman with gross pitting oedema of the lower limbs and vulva and gross swelling of the abdomen. The oedema extended to the back, where extensive blebs were present. Each pleural cavity contained about 30 oz. (750 ml.) of clear fluid and there were dense adhesions at the right base in proximity to an ancient calcified focus in the lower lobe of the lung. The lungs were oedematous.

The heart muscle was pale and flabby but showed no zones of fibrosis. The left coronary artery was partially obstructed by a calcified zone 1 in. (2.5 cm.) from its origin, and the right coronary artery showed confluent fatty patches without obstruction. The heart valves, generally, showed senile opacity and fibrosis. The anterior cusp of the mitral valve was distorted by a pouch large enough to accommodate the tip of the little finger to a depth of over 1 cm. The pouch was directed backwards so that during ventricular systole it would impinge on the posterior cusp as a

rounded ball, leaving a triangular orifice on either side. The texture of the pouch was identical with that of the remainder of the valve cusp.

The liver showed advanced nutmeg change, the peritoneal sac contained 5 pints (2.8 litres) of clear fluid, and there was a cluster of tiny cysts in the head of the pancreas, forming a mass 1 in. (2.5 cm.) in diameter. No other abnormality was found in the abdomen.

COMMENT

Various diverticula have been reported in the left ventricle. Skapinker (1951) describes a congenital diverticulum arising from the apex of the heart and presenting as a pulsating swelling above the umbilicus. A successful excision was carried out. He cites 12 other cases in the literature.

The acquired diverticulum of the muscle wall, the so-called "aneurysm of the ventricle," is due to the progressive expansion of a fibrotic patch derived from obstruction of a branch of the left coronary artery. These lesions may be 4 in. (10 cm.) in diameter, and the condition is termed "bag heart." A full description is given by Friedburg (1950).

The described diverticula of the mitral valve seem to be limited to the pouches occasionally resulting from the destructive inflammation in acute bacterial endocarditis. These are usually mentioned in the formal descriptions given in textbooks of medicine and pathology.

In this case it is clear that the pouch was acquired and not congenital. It can hardly be thought that a woman could pursue an active life for 63 years and only then present symptoms. It is equally clear that she was not suffering from an ulcerative endocarditis. Her illness was protracted and afebrile, and at necropsy the valves were free from vegetations.

There may be an association between the eye condition and the diverticulum. The first symptoms of cardiac disorder appeared during the first days of the iridocyclitis, and it is possible, though it cannot be proved, that the weakening of the valve cusp and the iridocyclitis had a common origin, perhaps infective.

We are indebted to H.M. Coroner for the Craven District, Mr. Stephen E. Brown, for permission to publish this case.

Unilateral Haematocolpos Haematometra

Imperfect canalization of the lower end of the Müllerian duct is the commonest cause of haematogynauios. The latter designation, derived from the Greek forms meaning blood, female, and tube, has been suggested by Alders (1953) as a collective term for the accumulation of blood in a portion or in portions of the Müllerian ducts.

The combination of failure of fusion of the Müllerian ducts resulting in a double uterus and vagina, and unilateral atresia with haematocolpos, haematotrachelos, and haematometra, must be very rare. Few such cases have been described (Purslow, 1922; Wilson, 1925; Simon, 1928; Brown and Brews, 1930; Martindale, 1935; Embrey, 1950). A further case is recorded here.

CASE REPORT

A girl of 12 was referred to the out-patient department of Swanage Hospital because of increasingly severe dysmenorrhoea. Her periods had started six months previously and for the first three months had occurred at two-weekly intervals, and the loss, which lasted five days, was described

as heavy. For the last three months they had occurred at monthly intervals and were associated with pain, chiefly referred to the back, which was increasingly severe with each period.

She was an intelligent well-developed girl. General examination revealed no abnormality of significance. Nothing abnormal was discovered on abdominal palpation, but on rectal examination a tense cystic swelling was found to fill the pelvis. No attempt was made to examine her vaginally. A tentative diagnosis of ovarian cyst was made and a laparotomy advised.

A few days before the planned date of admission she developed difficulty in starting micturition, which was relieved on lying down. She was therefore admitted as an emergency case to the Royal Victoria Hospital, Bournemouth.

Under general anaesthesia the abdomen was opened through a median subumbilical incision. A symmetrical, tense cystic swelling was seen to be rising out of the pelvis. On its top were perched two uteri of approximately normal size, though the left was somewhat larger than the right. Both Fallopian tubes and ovaries were normal. The vesico-uterine fold of peritoneum was incised and the bladder was dissected off this swelling. The latter was incised transversely; about 10 oz. (284 ml.) of viscid dark fluid was evacuated, and it was seen that there were two separate vaginae. The left vagina ended blindly below and was grossly distended. The left cervical canal was gaping, and similar tarry fluid was seen emerging from it. The slightly larger size of the left uterus was obviously due to haematometra. The right vagina was quite narrow, and ended below at a normal hymen. The right cervix was small and admitted a probe. The septum between the two vaginae was resected throughout its length, and the incision in the now single vagina was closed with catgut sutures. The incision in the vesico-vaginal fold was sutured and the wound closed in layers. Vaginal examination whilst the patient was still anaesthetized revealed the presence of a wide single vagina into which two cervixes dipped.

The patient made an uneventful recovery apart from a transient pyrexia (which was thought to be due to the presence of some of the contents of the haematocolpos in the pelvis).

In view of the frequent association of renal with genital malformations an intravenous pyelogram was taken while she was still in hospital. This showed complete absence of excretion on the left side and a slightly enlarged right kidney. The right renal pelvis, ureter, and the bladder appeared normal.

The patient was seen six weeks after the operation, when she had had a painless period of five days' duration.

COMMENT

The diagnosis of haematocolpos was missed because of the absence of the leading symptom of cryptomenorrhoea, the two uteri were not felt on rectal examination because of the presence of the large cystic tumour, and the imperforate hymen on the left side was not seen as no attempt at vaginal examination was made because of her youth.

I should like to express my thanks to Mr. N. Alders, under whose care the patient was admitted and who performed the operation, for permission to publish this report.

Reviews

THE THYROID GLAND

The Thyroid. Edited by Sidney C. Werner, M.D., Sc.D.(Med.). (Pp. 789+xxii; illustrated. £7 7s.) London: Cassell and Co. Ltd. 1956.

This is unquestionably the best book on the thyroid gland which has so far been published. Despite the fact that 60 authors have contributed, excellent editing has seen to it that the discrepancies and overlapping are few and unimportant. Among the names of the contributors are found those of most of the American experts best known in England, such as Astwood, Bartels, Dobyns, Frantz, Lerman, Naffziger, Rawson, Riggs, Sloan, Smelser, Stanbury, and that of the editor himself. Dr. E. E. Pochin is the sole English contributor, and one of the few criticisms which might be levelled at the book as a whole is that there is, perhaps, a slight tendency to neglect un-American activities in this field.

Here and there the English worker will find himself at variance with his American colleagues. The value of anti-thyroid drugs in the preparation of patients for thyroidectomy is, he will think, insufficiently stressed; and he may be surprised at the high incidence quoted of post-operative vocal-cord paralysis and of permanent hypoparathyroidism—an explanation, perhaps, of the greater popularity of definitive treatment of thyrotoxicosis with antithyroid drugs in some American hospitals. The use of carbimazole is not mentioned, but when the book was written experience of the drug was almost entirely British, and short at that. The rather low quoted incidence of post-operative hypothyroidism pairs with the rather high relapse rate, and might not differ greatly from as wide a survey of British hospitals, but it is curious that there is no mention of the paramount importance of lymphadenoid changes in determining this complication. One is surprised at the high incidence of thyroid "storm" in some hospitals, perhaps resulting from a neglect of preparation with antithyroid drugs; and by the curious statement that "toxic nodular goitre is resistant to all forms of therapy including surgery." But these are niggling criticisms of an outstandingly good book which, despite its high price, is a necessity to everyone interested in thyroid disorders.

RAYMOND GREENE.

PRICE'S MEDICINE

Price's Textbook of the Practice of Medicine. By Various Authors. Edited by Donald Hunter, M.D., F.R.C.P. Ninth edition. (Pp. 1,774+xiv; 63s.) London, New York, Toronto: Oxford University Press. 1956.

Every clinician requires to own one large comprehensive textbook of the practice of medicine—not to read through, but to use as a work of reference. *Price's Medicine* has been regarded for a long time as the standard British work of this type. Many a senior physician, battling with the gathering mists of a middle-aged memory and humiliated by the superior erudition of his registrar, must have made excuses to allow him to be closeted for a time alone with his "Price," confident thereafter of being able to restore the balance of power. The ninth edition of this famous book contrasts very favourably with its immediate predecessor, which had many defects: it is handsome in its proportions; it is well bound and well printed on good paper; and the information which it contains is comprehensive, accurate, and on the whole modern. The work has always been representative of the London School of Medicine, and this tradition has been followed in the present edition. Twenty-four of the twenty-seven contributors (eleven of whom are new to the book) have charge of beds in the London teaching hospitals. The inclusion of a single contributor from St. Andrews (or should it be Dundee?) just enables the book to claim a British rather than a purely

English qualification. The clinical descriptions of the various diseases are almost invariably excellent.

The lack of illustrations is a drawback, particularly in the section on cardiology, for it is very difficult to describe electrocardiograms without giving illustrative examples; but, on the other hand, it must be remembered that there is no comparable work which is so inexpensive, and illustrations would have greatly increased its cost. It is pleasant to find that drugs are almost always referred to by their official names, the proprietary equivalent often following in brackets. The same uniform system might have been adopted with advantage in regard to dosage: a lead should have been given by using the metric system throughout, and when, as in the case of the older drug, use and wont have habituated us to the apothecaries' system, the dose in grains or drachms could have followed the metric dose in brackets. Occasional reversion to Latin—for example, *injectionis insulini protaminati cum zinco*—have a nostalgic bouquet of the '48 rather than of the '53 *Pharmacopoeia*. Here and there the recommended treatment is a little out of date: for example, the emphasis on A.T.S. and the failure to refer to curariform drugs in the treatment of tetanus; the administration of *rectal* salines six-hourly in correcting the electrolyte disturbances of pyloric stenosis; and the lack of any guidance on the indications and contraindications for thymectomy in myasthenia. In the admirable section on diabetes it is surprising to find that several litres of half-normal saline are recommended to be given by *mouth* before emergency operations on dehydrated diabetic patients, and that the foetal loss rate in diabetic pregnancies is still put as high as 40%. These minor criticisms may, however, merely reflect the reviewer's personal prejudices, and Dr. Donald Hunter—the new editor—is very much to be congratulated on producing a work of which British Medicine can once more be proud.

D. M. DUNLOP.

KRETSCHMER UP TO DATE

Medizinische Psychologie. By Ernst Kretschmer. Eleventh edition. (Pp. 382+viii; illustrated. D.M. 29.60.) Stuttgart: Georg Thieme. 1956.

This is a revised and enlarged version of the previous edition. The author has done his best to keep successive generations of readers up to date about progress made in the fields of physiology and medical psychology which he regards as relevant for them. Kretschmer's "Medical Psychology" has from the beginning been a doctor's psychology, written by a physician for physicians, and the author has remained faithful to this purpose ever since this book made its first appearance 35 years ago. He always endeavours to discern the workings of the brain behind the mental activities, and he has a strong tendency to "physiologize" in his psychological concepts. New topics included in this edition are the experimental studies by K. Lorenz and Tinbergen, recent work on constitutional physiology of development, on the biological basis of temperaments, on motor patterns and preformed automatisms, on correlations between body-build and autonomic regulations, and on analysis of psychomotor behaviour with the aid of the writing scales, to name only the most important subjects. A considerable part of the additions refer to work carried out by Kretschmer himself and his co-workers. There is a new chapter on projective tests jointly written with C. Schick; also a brief presentation of the author's views on psychosomatics.

To the medical man this book makes satisfying reading. It demonstrates how much physiology and clinical medicine have already contributed to the basis of mental science. Psychiatrists and psychologists may at times find it somewhat parochial and unduly dogmatic, but it is not primarily addressed to them. This book is unsurpassed as a courageous and consistent presentation of mental activities by a clinician of catholic orientation whose attitude to current trends in present-day medical psychology has been constructive and positive, and who has himself made outstanding contributions to medical psychology.

PREDNISONE AND PREDNISOLONE

The value of cortisone and hydrocortisone in the control of a wide variety of diseases is now firmly established,¹ but the search has continued for more effective substances with fewer undesirable side effects. Prednisone and prednisolone, which become available to general practitioners on February 1, are the outcome of this search and are synthetic compounds which do not occur in nature. Initially called metacortandracin and metacortandrolone, prednisone and prednisolone are analogues of cortisone and hydrocortisone respectively, from which they differ by having an unsaturated bond between carbon atoms 1 and 2 (Δ^1) in addition to the double bond between atoms 4 and 5. Hence the name delta-steroids, but this and the innumerable trade names are best avoided.

The anti-inflammatory and anti-rheumatic effect of prednisone and prednisolone is about equal to that of cortisone, but weight for weight these compounds are four or five times more active.^{2,3} They are therefore supplied in 5- and 1-mg. tablets so that the smallest effective dose can be prescribed, and this is usually one-quarter or one-fifth that of cortisone. Although more potent, prednisone and prednisolone do not influence conditions unresponsive to cortisone or hydrocortisone, and there is no convincing evidence that they are significantly more effective. Occasional patients respond to the newer steroids after showing little improvement with cortisone or hydrocortisone. This is probably related to the dosage used, though a case of Schönlein-Henoch purpura was reported by A. S. Cohen⁴ in this *Journal* last week in which striking improvement followed administration of prednisone despite the previous failure of cortisone.

In 14 patients with rheumatoid arthritis F. Dudley Hart and his colleagues⁵ found that 9 preferred prednisone or prednisolone to cortisone, 5 were indifferent, and none favoured cortisone.

The indications for using the new steroids are the same as for giving cortisone or hydrocortisone,⁶ and satisfactory results have been achieved in some cases of collagen disease (rheumatoid arthritis,^{2,5,7,8} scleroderma,⁹ rheumatic fever, disseminated lupus erythematosus), asthma,^{9,10} sarcoidosis, the nephrotic syndrome, blood diseases (leukaemia,³ thrombocytopenic purpura, haemolytic anaemia), ulcerative colitis, and acute gout. Prednisolone has been used topically in the treatment of eye and skin disease,^{11,12} but does not seem to have any clear advantages over the older compounds.

The side effects of prednisone and prednisolone are the same as cortisone and hydrocortisone with the important exception that they cause little or no retention of sodium^{3,13,14} and therefore do not give rise to oedema and hypertension. This makes them less beneficial in the treatment of adrenal insufficiency, but enhances their value in the treatment of patients with coexistent hypertension or incipient heart failure in whom cortisone or hydrocortisone would be contraindicated or would require a stringent reduction in the intake of dietary salt. This failure to induce retention of sodium may make prednisone or prednisolone particularly useful in the treatment of the nephrotic syndrome and of patients with intractable cardiac or cirrhotic oedema unresponsive to mercurial diuretics. While absence of this liability to cause oedema may encourage the prolonged administration of these steroids in high dosage, this will inevitably give rise to undesirable side effects unless care is taken to prescribe the minimum effective dose. Some investigators believe that prednisone and prednisolone are more apt to cause gastric complications (peptic ulceration, haemorrhage, or perforation) and mental disturbances, but this again may be largely a question of dosage. Except to save life, or as a calculated risk, adrenocortical hormones should not be given to patients with a history of peptic ulcer, and all patients should take their main meals at regular intervals and have milk drinks in between. Some authorities recommend the concurrent use of antacids, and a controlled trial to assess the value of this measure in preventing gastric complications is urgently needed.

Treatment with these compounds has its risks, and doctors might feel inclined in most cases to obtain specialist advice first. They are potent inhibitors of the pituitary,¹⁵⁻¹⁵ and by suppressing the release of corticotrophin induce inactivity of the patient's own

adrenals. Hence when treatment is stopped the dosage must be reduced gradually over a period of one to two weeks if dangerous adrenocortical insufficiency is to be avoided. If a patient on adrenocortical therapy needs an operation the dose of hormone must be increased, not decreased. Fear that the wound will not heal is largely unfounded.

PERINATAL MORTALITY

In 1955 stillbirths in England and Wales numbered 15,829, or 23 per thousand live and stillbirths; and there were 9,750 deaths of babies during the first week after birth, or 15 per thousand live births. These figures are a great improvement on those reported in the earlier years of the present century, but they are still a challenge, demanding further study and inviting action. The problem is many-sided; the father, the mother, the placenta, and the foetus all have to be considered, separately and in relationship to each other. And in addition to the medical aspects, whether obstetric, paediatric, or pathological, there are economic, social, nutritional, and human influences to be taken into account. In all the highly civilized countries many studies of the problem have been made, especially during the present century, and it is probable that the further development of modern laboratory techniques will add much information about placental function and the conditions of foetal life. This would indeed be an advance, for the placenta is a dead organ when it comes into the light of day, and the baby has had nine months of active life before he can be subjected to the standard methods of medical examination. It is no wonder that even the most experienced observers sometimes disagree about the significance of their findings, both clinical and pathological.

The usual pattern of recent studies on stillbirths and deaths in the first week after birth—perinatal mortality—has been to correlate the obstetrical condition of the mother during her pregnancy and labour with the clinical and pathological findings in the child, and so to reveal, whenever possible, the sequence of events leading up to the death of the child. As V. M. Crosse and J. M. Mackintosh¹ emphasized, the situation in a whole community should be studied over a period of years if we are to get a true picture of what is happening. But a detailed review of

perinatal mortality occurring in a single maternity unit can supply valuable information, and the recent survey in this *Journal* by J. P. Bound, N. R. Butler, and W. G. Spector² of 406 necropsies performed on babies stillborn or dying within a week of birth is to be welcomed. The cases were in two groups, the larger consisting of 337 babies (185 stillbirths and 152 neonatal deaths) born at University College Obstetric Hospital between January, 1948, and September, 1955; while the remaining 69 necropsies were on babies which had been admitted to the U.C.H. Premature Baby Unit from outside sources. As the total number of births during the period was 10,028 it must be assumed that the stillbirth rate at University College Hospital is unusually low or that about 50 stillbirths did not come to necropsy.

The results of the investigation emphasize certain facts which are now generally recognized. For instance, maternal toxæmia and hypertension, antepartum haemorrhage, and high maternal age are considerable threats to the child before birth; premature birth, multiple pregnancy, complicated vaginal delivery, and perhaps post-maturity carry danger during the baby's birth and in the neonatal period. In order to combat these potential threats to the child's life we need to understand the nature of the obstetrical conditions mentioned, how they arise, and the mode of their influence on the child before, during, and after birth. It is with this aspect—the effects upon the foetus and baby—that Bound and his colleagues are mainly concerned, and they introduce a classification comprising eleven groups of "causes of death," which are subsequently correlated with the mothers' clinical state and certain features of their pregnancies and labours. Anyone who has attempted a study of this kind will appreciate the problems that the authors had to face, not only in interpreting their clinical and pathological findings, but in deciding which of several potential threats was to be regarded as the most probable cause of death.³ A pertinent letter from Professor Dugald Baird appears at p. 224 this week. Any significant reduction in perinatal mortality will be achieved mainly by concentrating attention on (1) stillbirths and premature births occurring unexpectedly during a pregnancy that is apparently normal; (2) the prevention of anoxia and birth trauma; (3) the treatment of neonatal asphyxia; and (4) the prevention and treatment of antenatal and intra-natal infection, especially pneumonia.

Bound and his colleagues favour the hypothesis of placental insufficiency to account for some at least of the unexplained intrauterine deaths. P. Malpas⁴ has recently criticized this theory, and there can be no

firm conclusion until more is known of placental physiology and pathology. But this should not interfere with measures to improve and extend antenatal care, especially in regard to toxæmia and hypertension, which in Bound's series were associated with 44% of the antepartum deaths with maceration only and 42% of the antepartum deaths showing evidence of asphyxia. Perhaps more could be done, through the various social services, to ensure that medical advice given to the pregnant woman who remains at home can be put into effect. Moreover, multiparae who are aged 40 or over and women who have lost previous children have a perinatal mortality rate twice as great as that of other mothers; but they have their babies in hospital less often than the average.⁵

There is still much confusion about the interpretation of the various pathological changes found in the lungs of the premature, birth-injured, and asphyxiated babies, and their clinical differentiation is most difficult, as Bound and his colleagues point out. The treatment of neonatal asphyxia has improved in recent years, but emphasis must still be placed on its prevention, and on such steps as may be taken to lessen the danger of infection of the child during birth.^{6 7}

Even when unavoidable causes of perinatal mortality are omitted—for instance, congenital deformities and stillbirths due to haemolytic disease—we are left with a considerable problem not only of mortality but of morbidity in some of the survivors. In no field of medical work is it more necessary to secure full co-operation, as Clement Smith⁸ has indicated. There must be, he said, joint obstetrical and paediatric responsibility for the foetus and infant, not obstetrical interest and responsibility merely until the infant is born, and paediatric interest and responsibility only after birth. "One of the best ways of promoting this joint interest is by regular foetal mortality conferences employing good autopsy studies of both stillborn and neonatally dead infants, and never evading the question: How could we have done better?"

THE BLACK SHEEP

Readers who like to look at the weekly notifications and graphs of infectious diseases in the *Journal* have in recent years been greatly puzzled by the paradox of an intestinal infection with a spring prevalence and an ever-increasing incidence despite steady improvements in housing, nutrition, and hygiene. This infection, bacillary dysentery, attracted attention in our editorial column in 1937¹ when the first considerable increase in notifications occurred and the name Sonne

dysentery began to be used. The 4,119 notified cases of that year have been multiplied nearly tenfold to become over 36,000 in 1955, and the yearly notifications have looked like the successive epidemic waves of an incoming tide which gets bigger and bigger² with no indication that the peak has yet been reached. Dr. Ian Taylor, in his presidential address to the Section of Epidemiology and Preventive Medicine of the Royal Society of Medicine, had a curious story to tell of this "black sheep," as he called it, because of the embarrassment it causes to its guardians—the medical officer of health and his colleagues. The increase appears to be real and not just apparent. It has been said by a sceptic that the incidence of various infectious diseases has steadily increased with the growth of the Public Health Laboratory Service, which might mean that the bacteriologist is helping to uncover infections which before were not officially noticed. This cannot explain the epidemiological behaviour of Sonne dysentery with its peaks of prevalence and intervening troughs. The P.H.L.S., besides filling other gaps in the epidemiological picture, has shown that nowadays over 95% of the notified cases of bacillary dysentery are due to the Sonne bacillus. Moreover, it is certain that despite improvements in diagnosis only a fraction of the total cases are being officially notified. Other curious features of Sonne dysentery, discussed by Taylor, are the shift in prevalence from rural to urban areas, the disappearance of an earlier autumn hump, and the change in age incidence from the pre-school to the young school child. The shift from country to town, which has been noted in some infections with a declining incidence, was not due to the post-war return of evacuated children, but may be related to a change in the mode of spread of Sonne dysentery from a food-borne to a direct-contact infection. Although explosive food- or water-borne outbreaks of Sonne dysentery have never been common, the incrimination of food as a vehicle has been less frequent in the past ten years (six reported episodes) despite increasing prevalence than in the previous decade, when 41 food-borne outbreaks were reported. During the earlier period there was, besides the main peak in March, a secondary peak of prevalence in the autumn, which is the traditional season for the enteric food-borne infections. This secondary peak has now disappeared.

So we come to the principal paradox of an intestinal infection with a winter prevalence, resembling

measles epidemiologically rather than enteric fever. But this paradox is not perhaps so strange and certainly not unique, for, while respiratory infections occur predominantly in the winter and intestinal infections in the summer, there are many exceptions, and we are learning that each specific infection has its own mode (or modes) of spread. Thus it seems unlikely that, despite their seasonal correlation, measles and Sonne dysentery are spread by the same routes while, on the other hand, poliomyelitis and Sonne dysentery have epidemiological features in common and may be similarly spread, though they are seasonally distinct. Taylor showed that for the country as a whole and for London in particular the distribution of Sonne dysentery is correlated to some extent with industrialization and overcrowding, which fits the view that close contact is an important factor in the spread of the disease. It should be noted, however, that the incidence in any town may vary considerably in different years, which may be related to the development of immunity, an aspect of Sonne dysentery about which little is known.

What of the changing age incidence? Sonne dysentery used to be predominantly an infection of the age group 1-5 years. As Alison Glover has said, "The scourge of armies had become the bane of nurseries."³ But to-day it causes most trouble in the primary departments of schools. In 1955 more than half the total notified cases were in the age group 5-14 years, and the rate in this age group has now risen to about half that in the pre-school child. There is no evidence that this increase is related to the increasing provision of school meals, since school outbreaks do not occur explosively. Rather it may be a reflection of the poor sanitary arrangements in many schools and the likelihood of transmission via contaminated water-closets for which there is now good laboratory evidence.⁴ That the school is a breeding-ground for this as for many other infections is supported by the sharp fall in incidence during the Easter vacation with a secondary rise in the summer term. Can it be that this rising incidence in the school years is an indicator of improving hygiene in the home while school sanitation lags sadly behind? An analogy might again be sought with poliomyelitis.

What are the medical authorities to do about this increasing nuisance? The good advice and training to wash the hands after use of the lavatory is of little value to schoolchildren when facilities for hand-washing are so woefully inadequate; and in any case the child may have become infected from handling a contaminated lavatory seat before he (or she) can perform this good social custom. Improved designs of W.C.s to prevent the upward splash and the use of plastic seats which might themselves be antiseptic need consideration. Spread of infection occurs most readily from the acute case, and both the family and the

family doctor might be taught to regard the case of diarrhoea in the young child more seriously and urgently so that early treatment with sulphonamides or streptomycin or both is given. Here the bacteriologist with his enrichment and selective-culture media has perhaps done a disservice by attracting too much attention to the convalescent and symptomless carriers. For example, a recommendation that 6-12 consecutive negative cultures should be obtained before a patient with bacillary dysentery is discharged from hospital⁵ is hardly a practical proposition; indeed it would be better not to send children with Sonne dysentery to hospital at all except where home conditions warrant it. The sulphonamides had major victories against epidemic meningitis and bacillary dysentery in the second world war. Perhaps they or some other intestinal antiseptic could stem the rising tide of Sonne dysentery in times of peace.

CANCER OF THE BLADDER AND TOBACCO

Interest in the aetiology of cancer of the bladder has recently been renewed by the observation that it is one of the few organs in which cancer appears to be becoming more frequent. The most convincing data have come from Denmark, where J. Clemmesen and A. Nielsen¹ reported that the incidence of carcinoma and papilloma of the bladder among men almost doubled between the years 1943-7 and 1948-52 in the capital, but that in provincial towns and in the rural areas the increase in incidence was slight; among women, on the other hand, no increase was observed at all. In Britain data are not available in such detail, but R. A. M. Case² has shown that the male mortality from the disease has been steadily increasing while the female mortality has been practically constant. Such trends might readily be explained if it were shown that there had been a marked increase in the industrial uses of β -naphthylamine and of the other dye-stuffs known to produce cancer of the bladder, but the trends, though less marked in degree, are so similar in type to those which have been reported for cancer of the lung that it is natural to ask whether they might not be in part explained by the existence of a common cause for the two types of cancer. This concept is supported by the experimental data of L. R. Holsti and P. Ermala,³ who found that 75% of mice which had been treated with tobacco tar intraorally developed papillomas in the urinary bladder, while no such tumours were found in an untreated control group.

Direct evidence of an association between tobacco smoking and bladder cancer in man has now been reported by A. M. Lilienfeld, M. L. Levin, and G. E. Moore⁴ from an analysis of the records of the Roswell Park Memorial Institute, Buffalo, U.S.A. At this institute smoking histories have been taken as a routine

¹ Clemmesen, J., and Nielsen, A., *Danish med. Bull.*, 1956, 3, 33.

² Case, R. A. M., *Brit. J. prev. soc. Med.*, 1956, 10, 172.

³ Holsti, L. R., and Ermala, P., *Cancer*, 1955, 8, 679.

⁴ Lilienfeld, A. M., Levin, M. L., and Moore, G. E., *Arch. intern. Med.*, 1956, 98, 129.

⁵ Hamtoft, H., and Lindhardt, M., *Danish med. Bull.*, 1956, 3, 188.

on admission from all patients since 1945, and data are therefore available for comparison between patients with many different diseases. In their study the smoking histories of 321 men with bladder cancer were compared with those obtained from 39 men proved to have benign bladder diseases, 337 men without any recognized pathological lesions, 287 men with prostatic cancer, and 306 men with lung cancer. After making allowance for differences in the age distribution of the groups it was found that more of the men with bladder cancer had been smokers than of the men with benign bladder disease, no disease, or prostatic cancer (85% against 78%, 71%, and 78% respectively); that more of the bladder cancer patients had smoked cigarettes (61% against 37%, 44%, and 42%); and that more of the cigarette smokers with bladder cancer had smoked for 30 or more years (49% against 36% each for men with no disease and men with prostatic cancer). These differences are all statistically significant, but in no case were the proportions of the various types of smokers as high as those found among men with cancer of the lung—75% of whom, for example, had smoked cigarettes for 30 or more years. Among women, on the other hand, comparisons between the smoking habits of patients with and without bladder cancer failed to show any appreciable differences at all.

The data, taken in conjunction with the results of the animal experiments and the observed trends in the incidence of the disease, are certainly suggestive of a cause-and-effect relationship between cigarette smoking and bladder cancer. Such a relationship might, moreover, explain some of the greater incidence which has been reported in Copenhagen compared with the rural districts of Denmark, since cigarette smoking in Denmark is much commoner in the capital than in the countryside.⁵ Nevertheless, it would be premature to conclude that a relationship had been established. It will be necessary to explain why no relationship is observed in women and why cigarettes should be more harmful than other forms of smoking. Explanations for both these anomalies are possible, but first it would be desirable to check the findings with other series and, in particular, to see whether a similar relationship is found in prospective studies.

HEART-LUNG MACHINES

Progress in the development and application of the mechanical pump-oxygenator or artificial heart-lung apparatus continues, and experience with its use in the human subject is being gained, principally as an aid to open cardiac surgery. Most reports have come from the United States, where many machines are in use and where an appreciable number of human operations have been reported, as well as innumerable animal experiments. In Britain the apparatus described by D. G. Melrose in this *Journal* in 1953¹ has been further developed and is now in commercial production. It is still to be considered a piece of research equipment. In several British centres many operations on animals have been performed, and a very few on human patients. Many problems remain to be solved; a considerable proportion of the animals die

from unexplained causes, for instance, but as experience increases the proportion lessens.

The pumps replace the heart and the oxygenator the lungs. In Melrose's apparatus the pumps are soft plastic tubes which are squeezed between metal plates with an undulating motion. This is imparted by cams, which are shaped so as to imitate the time intervals of the heart with a filling period longer than the ejection period. The speed and stroke volume can be varied as necessary. Valves which open for appropriate periods ensure flow in the right direction. Other machines have different pumps, but the principle of pressure on soft tubing is usually invoked because it causes less haemolysis than other forms of pump. The venous pumps withdraw blood from cannulae in the great veins and from the interior of the right atrium, and pass it to the oxygenator. In Melrose's machine this consists of a tilted cylinder which rotates; blood enters the upper end and flows by gravity, coming into contact with moistened oxygen. The surface area in contact is made large enough by numerous projecting baffles of a special shape. Other types of oxygenator are the stationary vertical screen of J. H. Gibbon,² where the blood flows smoothly down screens, and the bubble type, where oxygen is bubbled through the blood, no large surface being necessary. The oxygenated blood is then returned to the patient's circulation by an arterial pump through a cannula, usually inserted in a subclavian artery so as to supply the aorta and coronary arteries. To ensure coronary flow the aortic valve must be competent. Electronic devices control the pressure in the hydraulic circuit and keep the blood volume constant.

A valuable aid to the use of extracorporeal circulation is the ability to arrest and restart the heart at will.³ Injection of potassium citrate solution into the coronary vessels causes immediate arrest in diastole. Normal beat is restored by washing out the potassium. Full recovery can probably take place after a period of arrest of up to about twenty minutes. While the heart is arrested no coronary circulation is necessary.

One possible field of use for the pump-oxygenator⁴ is in the treatment of reversible acute heart failure, in the same way as the artificial kidney is used for acute renal failure. No doubt death could thus be averted in certain cases of coronary thrombosis. The great practical difficulties remain of recognizing the suitable case and of bringing and attaching the machine to the patient. So far extracorporeal circulation has largely been used to allow operations on the open heart under direct vision, particularly for the correction of congenital defects not amenable to closed cardiac surgery. J. W. Kirklin, D. E. Donald, and their colleagues⁵ from the Mayo Clinic, Minnesota, have briefly reported forty human operations with the aid of a Gibbon-type pump-oxygenator. In every case the perfusion was maintained satisfactorily for as long as was necessary for the intra-

⁴ *British Medical Journal*, 1954, 1, 1310.

⁵ Kirklin, J. W., Donald, D. E., Harshbarger, H. G., Hetzel, P. S., Patrick, R. T., Swan, H. J. C., and Wood, E. H., *Ann. Surg.*, 1956, 144, 2.

⁶ Dubost, Ch., et al., *Brit. Heart J.*, 1957, 19, 67.

cardiac procedure—in one case forty-five minutes—and in every case except one the heart resumed its normal function immediately the extracorporeal circulation was discontinued. In the one, ventricular fibrillation occurred; normal rhythm was restored after further perfusion. The apparatus is apt to cause haemolysis and excessive post-operative bleeding, but this was seen in only one of these forty patients. There were no other serious sequelae. Twenty-four of the patients survived; they had a variety of cardiac lesions and some were critically ill with intractable heart failure. Twenty-one of the forty patients had ventricular septal defects; seventeen of these survived. Another recent report,⁶ from a team of French workers, describes open-heart surgery with the help of a pump-oxygenator in five cases of septal defect. Two of the children survived.

It seems likely that in the near future the artificial heart-lung machine will allow certain cardiac operations to be carried out which at present are not feasible. These include the complete correction of Fallot's tetralogy—one of the commonest congenital lesions, which present operations either add to (Blalock's operation) or partially correct (pulmonary valvotomy); the repair of other forms of ventricular septal defect and of certain atrial septal defects; and perhaps the correction of the less common abnormalities such as transposition of the great vessels. Open cardiectomy offers greater promise for the repair of incompetent rheumatic valves than present techniques.

LUMP IN THE THROAT

Most patients who complain of a lump in the throat refer to a subjective sensation somewhere in the cervical viscera or in the midline of the neck, though occasionally one who uses the expression refers to what is an obvious lump in the neck. Among those who complain of this symptom in the throat is a minority in whom it may be the only warning of serious organic disease in the upper respiratory or alimentary passages, and it is not difficult to underestimate the significance of the symptom in this group. Consequently every case requires careful interpretation, followed by a diligent examination until a precise diagnosis can be made. If this cannot be established with confidence by simple means, patients of an age when they are subject to cancer are best referred to a specialist department for further clinical, radiological, and direct endoscopic examination without delay. The sensation of a lump in the throat, often accompanied by other paraesthesiae and a variable degree of dysphagia, may indeed be the first symptom in cancer of the tongue, tonsils, pharynx, extrinsic larynx, oesophagus, or thyroid gland. Early diagnosis is thus essential. Too often these patients present themselves for treatment with what has become a lump in the neck, when both treatment and prognosis are altered.¹

While the occasional benign tumour or foreign body may also cause this type of pharyngeal discomfort, there are many more patients with the same sensations derived from lingual tonsillitis, chronic pharyngitis, and similar conditions producing an excess of mucus or mucopuru-

lent secretion in the hypopharynx. Chronic suppuration in one or more of the paranasal sinuses is well known to be often associated with any of these troubles. In a recent paper C. P. Mills has drawn attention to this,² stating that six out of ten patients who attended hospital complaining of a lump in the throat were found to have pus in their maxillary antra on proof puncture. All symptoms disappeared when the sinusitis was cured.

Finally comes a large group of patients whose complaint of a lump in the throat is an expression of some form of neurosis. It may often be aggravated by chronic ailments such as tuberculosis, anaemia, or dyspepsia.³ Hysterical symptoms of the same type may also develop in patients subjected to particular physical or emotional stress, sometimes in women at the menopause, and in many people as an expression of cancer-phobia. In a few of these patients it may even be possible to demonstrate actual spasm of the pharyngeal muscle or more rarely of the glottis. The correct treatment in some of these cases may amount to no more than sympathetic explanation and reassurance.

HUNGARIAN REFUGEES

Among the many thousands of Hungarian refugees who have reached Great Britain are 61 members of the medical profession, among them two medically qualified dental specialists. Doctors here have been generous in their response to help, and in addition the B.M.A. has acted on behalf of its members by permitting the expenditure of over £500 on the 53 of these doctors who sought its aid. The Association's International Medical Visitors Bureau, apart from helping financially, is keeping in constant touch with the doctors, either personally or by post, arranging for their accommodation and in some cases for them to attend hospital so that they can keep in touch with their professional work. A few have been able to obtain temporary hospital appointments while awaiting passage to another country. About twenty have so far expressed a wish to remain in Britain; twenty-six wish to go elsewhere, usually one of the Dominions or the U.S.A.; and the intentions of the remaining thirteen are at present unknown. Permanent registration to practise in this country nowadays presents considerable difficulties to the foreigner, especially to one who must also learn our language and support himself and perhaps a family meanwhile. Apart from passing at least one set of examinations, he is bound by law to spend a year in pre-registration house appointments. The Ministry of Health, among other bodies, is considering how best to help the refugees over these obstacles. Doctors individually can help mainly by offering accommodation, for it is naturally hard to come by. If it is in the London area, so much the better; the refugees are then enabled more easily to attend lectures and keep in touch with organizations assisting them. At present a few are fortunate enough to be living with relatives, but most are condemned to a makeshift existence. A temporary home can do much to relieve their plight, and offers will be welcomed by Brigadier H. A. Sandiford, Director of the International Medical Visitors Bureau, B.M.A. House, Tavistock Square, London.

CELLULAR BIOLOGY, NUCLEIC ACIDS, AND VIRUSES

CONFERENCE IN NEW YORK

[FROM A SPECIAL CORRESPONDENT]

In New York, from January 7 to 9, the New York Academy of Sciences held an international conference on cellular biology, nucleic acids, and viruses. The conference, made financially possible by anonymous friends, was a 65th-birthday tribute to a notable American—Mr. BASIL O'CONNOR—for his services to science, medical education, and human health and welfare. Mr. O'Connor has been president of the National Foundation for Infantile Paralysis since 1938. During this time he has accumulated princely sums for work on poliomyelitis and other viruses. Appropriately, therefore, pride of place on the first day of the conference went to poliomyelitis.

In its scope the conference programme illustrated the view, expressed by Burnet,¹ that virus investigation is now at a point where virology is ripe for integration into the structure of general biological theory. First to be discussed at the meeting was the latest triumph of applied virology in relation to poliomyelitis; then the programme committee clearly had it in mind to educate virologists and point them to the future by reviewing present biochemical knowledge of nucleic acids, the conditions of cell life in the test-tube, and the promising results of the application of tissue-culture methods to the study of human viruses. Only the future will reveal the success of bringing together workers from such different fields.

Prevention of Poliomyelitis

The conference opened, under the chairmanship of Dr. J. ØRSKOV (Copenhagen), with a review of the present position of work on immunization against poliomyelitis. After a comprehensive account of the pathogenesis of the disease by Dr. D. BODIAN (Baltimore), whose work has so fruitfully provided much of the theoretical approach to artificial immunization, Dr. J. E. SALK (Pittsburgh) spoke at length on the principal factors concerned in the preparation of his vaccine. He described the influence of changes in methods of culture, inactivation, and filtration on the final production of a safe and potent inactivated vaccine, and the effect of different doses of it in those both with and without previous experience of the virus. Dr. Salk mentioned attempts to substitute monkey-heart cells maintained by continuous artificial cultivation for the present wasteful use of monkey kidneys, with all its attendant disadvantages. Current progress in the use of inactivated vaccine in the U.S.A. was reviewed by Dr. A. D. LANGMUIR (Atlanta), who stated that their experience in 1956 indicated continued effectiveness and safety. A sharp outbreak of the disease in Chicago with 1,100 cases led to mass inoculation with over a million doses of vaccine. There was no sign that this had provoked disease, but nor had it clearly interrupted the course of the epidemic. The principles that should govern a field trial of polio vaccine were enunciated by Professor T. FRANCIS (Ann Arbor). Experience in Canada, Denmark, South Africa, and Great Britain was referred to by Dr. R. D. DEFRIES (Toronto), Dr. H. VON MAGNUS (Copenhagen), Dr. J. H. S. GEAR (Johannesburg), and Professor A. BRADFORD HILL (London). Dr. J. E. SMADEL (Washington) commented that even after two doses of present-day commercial vaccine antibodies sometimes failed to appear in children with no pre-existing antibodies to any of the three polio-viruses. This might be due to the current tendency to render vaccine safe by emphasis on repeated filtration, with consequent loss of antigenicity. Steps were now being taken to replace Mahoney with a less virulent type I virus,

¹ Burnet, F. M., *Principles of Animal Virology*, 1955. Academic Press Inc., New York

but these were not yet complete. A potency test using chicks appeared more promising than the usual monkey test.

Live Vaccines

Living attenuated polio virus was the subject of papers by Dr. A. B. SABIN (Cincinnati), Dr. H. KOPROWSKI (New York), and Professor G. W. A. DICK (Belfast). Dr. SABIN referred to the latest ways of purifying attenuated viruses by terminal dilution and by passage from single plaques on monolayer layers of tissue cultures. He considered that highly attenuated strains of all three types of virus were now available for study in man by oral feeding. The antibody formed as a result of natural infection or after such feeding appeared qualitatively different from that produced by inactivated vaccine. Professor DICK referred to the studies of Dr. Koprowski's attenuated rodent-adapted types I and II virus recently performed in Belfast and described in the *British Medical Journal* on January 12, p. 59. The viruses went in like lambs and came out via the stools like lions. They underwent an increase in capacity to produce paralysis in monkeys, and became not far removed from wild viruses. One family group had suffered contact infection from a child excreting the type I virus. There were no adverse clinical effects in these trials. Dr. KOPROWSKI, on the other hand, had obtained no evidence of altered virulence of his type I virus after three serial passages by oral feeding and recovery from the stools.

Professor J. R. PAUL (Yale) then referred to the oral use of Dr. Sabin's attenuated viruses as a method of boosting immunity in subjects previously immunized with Salk vaccine. The ease with which alimentary infection could be established in Salk-vaccinated subjects suggested that the Salk vaccine induced a different type of immunity from that following natural infection. Spread of excreted virus had occurred among children in an institution for the mentally defective. Other speakers, including Dr. R. DULBECCO (California), Dr. R. E. SHOPE (New York), Dr. P. LÉPINE (Paris), Dr. J. P. FOX (New Orleans), and Professor C. H. STUART-HARRIS (Sheffield), discussed the hazards and benefits from the oral use of living attenuated virus, and agreed that there was probably still much to be learnt on the subject.

Nature of Viruses

Nucleic acids now held the centre of the stage, and Dr. F. H. C. CRICK (Cambridge), Dr. M. H. F. WILKINS (London), and Dr. A. RICH (Washington) gave a masterly exposition of the structure of both deoxyribonucleic acid (D.N.A.) and ribonucleic acid (R.N.A.), as shown by x-ray crystallography. The double-chain helical configuration of D.N.A. was also thought to hold for R.N.A. and for synthetic ribopolynucleotides synthesized by Professor S. OCHOA (New York), using enzymes derived from bacteria. Tobacco mosaic virus (T.M.V.), being separable into nucleic acid (R.N.A.) and protein moieties, is a particularly fruitful source of material for investigating the relation between nucleic acid and virus activity. Dr. H. L. FRAENKEL-CONRAT (California) has now succeeded in showing that the nucleic acid alone, without the protein, carries not only the genetic information required for the replication of T.M.V. but also its infectivity. The smallest infective particles have a molecular weight of about 200,000–300,000. Improved methods of reconstituting T.M.V. from segregated R.N.A. and protein were now possible. In the presence of pyrophosphate or other metal chelating agents, as much as 30 to 50% of the viruses' original infectivity could be obtained in its reconstitution from R.N.A. and protein. Meanwhile the position of the R.N.A. within the rod-like protein particle was described by Dr. ROBLEY C. WILLIAMS (California) as a coaxial core. Infectivity experiments with sonically dispersed T.M.V. suggested that the R.N.A. did not extend throughout the whole length of the rod. Dr. B. COMMONER (St. Louis) suggested that the protein exerted an influence on the infectivity of R.N.A., perhaps because it created a strong configurational

¹ Martin, H., and Romieu, C., *Postgrad. Med.*, 1952, 11, 491.

² Mills, C. P., *J. Laryng.*, 1956, 70, 530.

³ Thomson, St. C., and Negus, V. E., *Diseases of the Nose and Throat*, 6th ed., 1955, London.

effect. He showed that the lesions produced by R.N.A. alone might be recognizably different from those of the complete virus. Discussion of these fascinating findings by Dr. N. W. PIRIE and Dr. F. C. BAWDEN, of Rothamsted Experimental Station, led to the conclusion that Nature was not designed for the convenience of biochemists, but they agreed that the segregated ribonucleic acid was infective.

Papers dealing with the nucleic acids of bacteriophage and of the mammalian cell by Dr. A. D. HERSHEY (New York) and Dr. A. E. MIRSKY (New York) brought D.N.A. to the fore, and led to an account by Dr. G. B. BROWN (New York) of attempts to block nucleic-acid biosynthesis by the use of purine and pyrimidine analogues. Metabolic analogues incorporated into the virus during synthesis sometimes succeeded in blocking infectivity, but unfortunately they were often toxic for the host cell.

Malignant Change in Tissue Culture

The mammalian cell as studied in cultures derived from single cells by Dr. T. T. PUCK (Colorado) now received the attention of a number of speakers who introduced the subject of malignancy. Under the able chairmanship of Dr. E. W. GOODPASTURE (Washington), speakers, including Dr. R. C. PARKER (Toronto), Dr. R. S. CHANG (Boston), Dr. J. T. SYVERTON (Minneapolis), Dr. L. L. CORIELL (New Jersey), and Dr. ALICE E. MOORE (New York), reviewed evidence for and against the suggested malignant transformation *in vitro* of epithelial cells derived from normal tissues. In addition to their resemblance to malignant cells in rate of growth, morphology, and biochemical characters, the chromosomes of the altered normal cells numbered 70-80 instead of the usual 42-46. Inoculation into rats treated by x-ray irradiation and cortisone led to the formation of tumours. Unlike the tumours induced by Hela cells originally derived from carcinoma, the normal tissue-culture lines underwent central necrosis and regression. They would not grow as did Hela cells in the peritoneal cavity of rats.

Dr. MOORE described the results of inoculating human volunteers with cells derived from Dr. Chang's normal conjunctiva and liver cells, and also with seven lines of cultures derived originally from malignant tumours. Patients with cancer supported the growth of implanted cancer cells, and subcutaneous nodules were also obtained with the cultures of normal cells. The latter nodules were morphologically similar to epithelial carcinoma, but did not form in as high a proportion of instances as with the cancer lines. On the other hand, normal human volunteers without cancer did not support the growth of Dr. Chang's cell cultures; any nodule which formed underwent subsequent regression; and only known tumour lines yielded growths. The reassuring results of these researches were somewhat dashed by Dr. H. S. GINSBERG (Cleveland), who reported on rats inoculated with cells derived from the epithelial-like outgrowths from human adenoids and tonsillar tissue. Serial passages for 14 months maintained cell-cultivation, and tumours were obtained with these cells in rats which underwent growth as rapidly as those from Hela cells. Regression did not occur, and subcutaneous tissue or glands were sometimes invaded.

Tissue Culture in Virology: E.C.H.O. Viruses and the Adenoviruses

The final session was devoted to virus studies in man which owed their inspiration to the tissue culture as the basic cultural technique. This has led to the recovery of the so-called orphan or E.C.H.O. (enteric-cytopathogenic human-orphan) viruses from human stools during studies on patients with poliomyelitis and on normal populations. Dr. J. L. MELNICK (Yale) said that similar orphan viruses existed in monkeys, cows, and swine; fourteen different antigenic types of human E.C.H.O. virus were now known. They were small agents resembling poliomyelitis virus. They passed filters with an average pore-size of 38 m μ , but were held back by 30 m μ . He had attempted to classify the

viruses with the aid of different monkey cells and plaque formation. The E.C.H.O.-9 virus recovered in England by Tyrrell and by observers elsewhere had caused outbreaks of human disease, particularly in children with an exanthem and sometimes with aseptic meningitis. Strains of this virus produced lesions in suckling mice which allowed its classification as a Coxsackie A virus. Other E.C.H.O. viruses appeared to be related to aseptic meningitis. Type 10 was pathogenic for mice. Dr. A. J. RHODES (Toronto), Dr. H. A. WENNER (Kansas), Dr. D. T. KARZON (Buffalo), and Dr. G. J. DALLDORF (New York) extended these findings with remarks on classification, on human outbreaks involving these agents, on clinical effects in monkeys, and on the confusing antigenic propensities of E.C.H.O.-6. Dr. Melnick's attempts to obtain genetic recombination between an E.C.H.O. and a polio virus emphasized the basic relationship between the new agents and older enemies. There was agreement that much hard work lay ahead.

The adenoviruses were now considered by Dr. R. J. HUEBNER (Bethesda). He reported on 14 established serotypes and several others whose antigenic relations were still doubtful. An association existed between clinical syndromes and antigenic types such that acute respiratory disease in Army recruits was more often associated with types 4 and 7, and to a lesser extent 3 and 14, than with any of the other types. Type 14 was originally derived from a chimpanzee, but was identical with strains recovered in Holland from human respiratory cases by van du Veen. Types 1 and 2 were most commonly recovered from the adenoids of children, but illnesses in children such as pharyngo-conjunctival fever or non-bacterial pharyngitis were commonly associated with types 3, 5, and other types. Kerato-conjunctivitis was linked with type 8. A high proportion of the more severe clinical forms of acute respiratory disease in children were probably associated with adenovirus infection. However, a long-term study of an orphanage had shown frequent recovery of viruses from throat swabs, and the exact relationship between virus recovery and clinical phenomena still had to be worked out. Over a period of time 11% of throat swabs taken once a week and totalling 2,066 specimens yielded adenoviruses, and 35% of stool specimens similarly studied yielded adenoviruses, E.C.H.O., or Coxsackie viruses. Such is the harvest of the tissue-culture technique.

Adenovirus Vaccine

Dr. M. R. HILLEMANN (Washington) reviewed acute respiratory disease in U.S. Army recruits, in whom the adenoviruses appeared responsible for as much as 80% of the total infections. The clinical picture of the disease was that of febrile catarrh as originally described in England. It was a serious cause of wastage in time and money in the Army. Tests with a mixed type 4 and 7 inactivated vaccine had been carried out and some 600-odd persons had been vaccinated. 78% of the illnesses during the subsequent few months had been due to types 4 or 7 adenoviruses in this community. The vaccine was serologically active, and induced antibodies against type 3 as well as against the homologous types. Protection against clinical strains became apparent one week after giving the vaccine, and the attack rate was lowered dramatically. Similar tests in the U.S. Navy had shown a protective effect with a mixed type 3, 4, and 7 vaccine, but the level of protection afforded was less than that obtained in the Army. However, Dr. GINSBERG warned against the view that an adenovirus vaccine would be of importance in civilian groups, in whom infection appeared much less frequent than in the armed Forces. The major role of the adenoviruses appeared to be that of latent agents, yet, as pointed out previously by Dr. Huebner, the full extent of clinical disease produced by them in babies and infants was still unknown.

The meeting closed with a sense of achievement, voiced by Dr. J. E. SMADEL (Bethesda), who echoed the opinion of the last sessional chairman, Professor J. R. PAUL, of Yale, that had the conference been held on Broadway it would have been hailed as a smash hit.

NEW MINISTER OF HEALTH

MR. D. F. VOSPER APPOINTED

One of the consequences of the reorganization of the Government under Mr. HAROLD MACMILLAN has been the appointment of a new Minister of Health. Mr. D. F. VOSPER, formerly Parliamentary Secretary, Ministry of Education, succeeds Mr. R. H. TURTON. His appointment was announced in the list of departmental Ministers without Cabinet rank and Ministers of State published on January 17. On the same day correspondence exchanged between the

[Universal Pictorial Press and Agency]
The Rt. Hon. Mr. D. F. Vosper, T.D.,
M.P.

he took an honours degree in natural science and political economy. In 1938 he joined the firm of ships' store and export merchants, Wilson, Vosper, and Coltart, of Liverpool, to which he still belongs. In April, 1939, he enlisted in the Territorial Army, and subsequently served throughout the war with the Cheshire Regiment. He was adjutant and later second-in-command of the 5th Battalion. He was demobilized in 1946 with the rank of major. In 1950 he was awarded the Territorial Decoration.

Mr. Vosper's political career began on his return to civil life in 1946. He became agent to the Knutsford Division Conservative Association, and in 1949 he was adopted as Conservative candidate for Runcorn. In the 1950 General Election he won this seat with a majority of 8,082 in a three-cornered contest. He was appointed a Conservative Whip in November, 1950, and was a member of the British parliamentary delegation to Israel in 1951 and to Turkey in 1953. At the 1951 General Election his majority rose to 9,841 in a straight fight. He was appointed a Lord Commissioner of the Treasury after this Election, and in October, 1954, became Parliamentary Secretary, Ministry of Education. His responsibilities here were the schools for handicapped and educationally subnormal children, school medical services, and the school meals service. He also paid special attention to problems arising from village schools and the Youth Service. At the last General Election, in May, 1955, Mr. Vosper increased his majority to 10,830.

Mr. Vosper is married, and his wife is also active in political matters. There are no children. Mr. Vosper gives his recreations as tennis, travelling, and gardening.

Parliamentary Secretary

Mr. J. K. VAUGHAN-MORGAN succeeds Miss PAT HORNSBY-SMITH as Parliamentary Secretary to the Ministry of Health, while Miss Hornsby-Smith goes as a Joint Parliamentary Secretary to the Home Office. These appointments were announced on January 19. Mr. Vaughan-Morgan, who will be 52 next week, has represented the Reigate Division of Surrey since 1950. In public life he has three main interests: social services, especially the wel-

fare of the elderly in industry; local government; and Commonwealth affairs. A company director himself, he is chairman of the Conservative Party's parliamentary committee on health and social security, and he is joint author of a Conservative Political Centre pamphlet, *Care of Old People*. He was member of the L.C.C. for Chelsea from 1946 to 1952, and was for four years vice-chairman of the London Municipal Society. He visited the British West Indies in 1953 as one of two Conservative M.P.s on the Commonwealth Parliamentary Association delegation, and is chairman of the West Indies Subcommittee of the Commonwealth Affairs Committee. He is also deputy chairman of the British Commonwealth Producers Organization.

Mr. Vaughan-Morgan has been a joint honorary secretary of the "1922" Committee (1949-50), and is at present a member of the executive committee of the National Union of Conservative and Unionist Associations.

Nova et Vetera

COMMON LODGING-HOUSES IN GLASGOW

Dr. Stuart Laidlaw died in June, 1955, a few days after learning that he had been awarded the degree of Doctor of Philosophy for his thesis on "The Common Lodging-Houses of Glasgow"; now, on the instructions of the City Health and Welfare Committee, the thesis has been published,* and probably Dr. Laidlaw would not have wished for a better memorial. His account of Glasgow lodging-houses through the ages is indeed a treasure trove for the historian, not merely for its recital of what the early sanitarians thought of these places, but for its introduction to people like Molly and that other Robert Burns who brought some distinction to the lodging-house keeper's craft; or to "Hawkie," with his description of the "flea barracks," or Roger Quin, who in later days was driven to write of the lodging-houses of his time, from first-hand experience, as "plague spots. . . Here are no touches of colour . . . one drab nocturne of hopeless torpid inanity." But, faithful and accurate as is this work in detailing the lodging-houses of the city as they are and as they were, the book owes its main charm to an intimate knowledge of the people in them. Laidlaw interviewed over a thousand of these people; he learned their stories, their background, the factors that brought them to live in a "model," what they thought about it all, and how they lived in this curious world in which they found themselves.

They were in the main an elderly population, more than half of them over 55 years of age and more than half incomers to the city. Half of them had now no contact whatever with any relatives; more than half were dependent, in part at least, on National Assistance. Comparatively few were in employment—more than one-third were "unemployed," more than one-third "retired," and the "normal" occupation of most was that of unskilled labourer. About one-half of them were in good health, the others presenting a catalogue of almost every conceivable cause of chronic incapacity, physical and mental. Nearly 30% of the women and 44% of the men had been living in "models" for upwards of 10 years, one of the men for upwards of 50. Many bore evidence of neglect. It is in some ways a changed picture from that of 70 years ago—a population some 20 years older nowadays, and of much longer common lodging-house attachment. But many—perhaps the majority—of "modellers" still have prison records, and the majority, as of old, have a liking for drink, though from considerations of cost the good wholesome whisky of other days has been largely replaced by things more objectionable—methylated spirits, eau-de-cologne, and a variety of odd cocktails prepared from such things as metal polish.

Perinatal Mortality

SIR,—Like Mr. W. G. Mills (*Journal*, January 12, p. 103), I feel that the classification of causes of perinatal mortality put forward by Dr. J. P. Bound and his colleagues (*Journal*, November 24, 1956, p. 1191, and December 1, p. 1260) will not prove very helpful to clinicians wishing to study their cases with a view to prevention. As he rightly points out, many asphyxial deaths arise from multiple causes the relative importance of which, in my experience, may be assessed more accurately by a careful study of the clinical history than of the necropsy findings.

In a reference to a paper published by myself and others in 1954,¹ Dr. Bound and his colleagues state that we challenged the value of post-mortem examination and rather gave the impression that we advised against routine necropsies. This was certainly not our intention, and, in fact, a necropsy was performed on all our cases except those in which permission was refused. We did, however, agree with Morison² that the main justification for routine necropsy is that it enables the obstetrician to recognize or to exclude such "anatomical" causes of death as birth trauma and congenital malformation.

The signs of asphyxia at necropsy show how, but not why, the baby died. The clinician is more concerned with the events which led up to asphyxia than with the terminal condition. For most of us, young and old, the ultimate cause of death will be failure to oxygenate the tissues. The classification of causes of perinatal death which we used took note of the necropsy findings, but was based chiefly on the train of clinical events which led to death, asphyxial or otherwise. We have found this approach useful, since it has enabled us to see more clearly the influence of such important factors as the mother's age, parity, and state of general health upon the incidence of complications of pregnancy and labour and upon the vitality of the foetus. The cause of a particular stillbirth may be that the foetus could not withstand some stress, physiological or mechanical, which would not have harmed a foetus of higher vitality. Depression of foetal vitality may be due to defects in the mother's development, which may have occurred many years before the pregnancy. In order to understand the prime causes of death we must therefore study the condition of the mother and the nature of the pregnancy and labour, as well as the state of the dead baby. Our data showed, for example, that asphyxial deaths occur more commonly in primiparae than in multiparae, in elderly than in young primiparae, and in post-mature pregnancies than in pregnancies at or before term, and often before the rupture of membranes has exposed the foetus to mechanical stress. Similarly, deaths due to prematurity are many times more common in ill-grown, generally unhealthy mothers than in tall, healthy mothers.

Although a post-mortem examination should be performed in all stillbirths and neonatal deaths, such examinations are unlikely to lead to great advances in our understanding of the causes of breakdown in maternal physiology which are incompatible with foetal survival.—I am, etc.,

Aberdeen.

SIR,—It is well that the subject of perinatal death should be brought before us both by the Registrar-General and by the recent circular to all general practitioners. The excellent article by Dr. J. P. Bound and his colleagues (*Journal*,

November 24, 1956, p. 1191) and the valuable criticism of Dr. A. L. Woolf (*Journal*, December 29, p. 1542) have sent me once again to Barcroft's invaluable *Researches on Pre-natal Life*,¹ even though, as he emphasizes (pp. 144 and 209), he deals mainly with sheep and not humans. I think some points are worth repeating. First of all (pp. 200 and 209), he shows that while the carotid blood about half-way through pregnancy is about 75% saturated with oxygen, just before term this has fallen to about 40%, while the venous return is about 25%, so that the foetal brain before birth is conditioned to anoxia, which must be even more severe than these figures suggest while the head is compressed in the pelvis. Furthermore, the graph on p. 98 shows how very small is the oxygen uptake of the brain compared with other tissues, and that even this drops decidedly just before term. This makes it unlikely that foetal death is commonly due to cerebral anoxia. The fatal anoxia is much more likely that of the heart, which not only requires oxygen to keep itself beating but has to supply the rest of the body, which takes so much more oxygen than the brain. Furthermore, the size of the body relative to the head is increasing rapidly at term, which may be one reason why post-maturity is so important in perinatal death, as the body is taking an ever-increasing proportion of the diminishing amount of oxygen available from the placenta.

This is not to say that cerebral anoxia is unimportant, for Barcroft (pp. 261-2) showed that it was all-important in determining the type of respiratory response. This is not, as is so commonly assumed, a response to lack of oxygen, for the brain is normally hypoxic anyhow. He showed how the respiratory response develops from a single gasp to a succession of gasps and so to a proper rhythm. Occlusion of the cord, by producing anoxia, would change these responses in the reverse order so that eventually stimulation would produce but a single gasp and finally none at all; but that did not mean that the foetus was dead. And the response was not elicited by lack of oxygen but by a tactile stimulus—i.e., it was nervous and not chemical. Anoxia, in fact, puts out first of all the response most recently acquired, and, as he showed on p. 266, this corresponded to the higher centres of the brain. When, therefore, Dr. Woolf writes so interestingly about cerebral irritation and "the expression of excessive activity of primitive mechanisms removed from the control of those more recently acquired" he is expressing almost exactly what Barcroft proved to be the effect of anoxia on the brain.

This may seem theoretical, but it has some very practical bearings on perinatal mortality. First of all, unless there is some fatal injury (which Dr. Bound's figures show is relatively uncommon) it should be possible to revive any baby born with a beating heart. The immediate need here is not to pump in oxygen but to apply that nervous stimulus which will elicit the fundamental respiratory response. As regards this, Barcroft says (p. 269): "Among specific sensations acting outside the body, pain (if such a word can be applied to the experiences of an organism so anoxaemic that it can have no real consciousness) can have a dramatic effect. A striking specific reaction is that of the gasp in a refractory rabbit's foetus when the ear is firmly pinched." This would seem to give some justification for the traditional slapping—though I think there are better ways. Among internal stimuli he mentions (p. 270), "A foetus with its placental circulation intact, alternately taken out of and replaced in its bath of saline, exhibits muscular tone to the point of shivering when it is taken out of the bath and relaxation when replaced." This would seem to give some support to the old-fashioned method of resuscitation by putting the baby into hot and cold water alternately. If these normal stimuli fail, the logical thing to do, as I have often stated, is to give some convulsant which will raise the threshold of the brain to such a pitch that it will respond to the stimuli which are reaching it, and 20 years' experience has taught me the safety and effectiveness of cardiazol-ephedrine for this purpose.

The other practical conclusion I draw is that, as it is the heart that finally gives out from lack of oxygen, it is important to diminish the demand for oxygen by keeping the baby cool until oxygenation is established, as I mentioned in a recent letter (*Journal*, December 8, p. 1368). Even if the heart has stopped beating it may still be possible to revive the infant. It is easy to stick an ordinary hypodermic needle into the left ventricle, prove that it is there by withdrawing a little blood, and then rapidly inject 1 ml. of cardiazol-

ephedrine. This sudden distension of the cavity may possibly restart the heart beating, but, if not, it is easy to massage the heart quite effectively through the soft foetal chest wall, and I have done this successfully on two occasions.

There is much more to be said, and unfortunately the second volume of Barcroft's researches was never published, but I trust that what I have written will send obstetricians and others to study the first volume for themselves. They will soon find that the brief précis which is given in most midwifery textbooks does not represent in any way the mind of the master. Some points are rather difficult to follow, largely because he was trying to assimilate his findings to clinical experience which he freely admitted he did not understand, but by and large it gives us physiological data on which alone a rational approach can be made to a most important aspect of the problem of reducing perinatal mortality.—I am, etc.,

Winsford, Ches.

Treatment of Acute Appendicitis

SIR,—Mr. Eric Coldrey's paper (*Journal*, December 22, 1956, p. 1458), advocating the conservative treatment of acute appendicitis of over 24 hours' duration and, latterly, of even less than 24 hours' duration, is certainly revolutionary, and, were it not for the astonishingly low mortality, one's natural reaction would be one of condemnation. The memories of the past are stirred and a few comments are called for.

In my younger days I had, like every resident surgical officer at the General Hospital in Birmingham, a wide experience of treating cases of acute appendicitis, and by 1928 had operated on over 2,000 cases with a mortality of just under 3%; and this, of course, long before the sulphonamides or antibiotics. Taught by such chiefs as Leonard Gamgee, Frank Barnes, and Seymour Barling, these cases were treated, except for 2-3 hours' rest and preparation, by immediate operation. At about this time the Ochsner-Sherren principles of "delayed treatment" for cases between the 2nd and 5th day had been underlined by several papers from the London Hospital analysing nearly 2,000 cases, and showing that where the case did not settle under Ochsner-Sherren treatment there was a mortality of 6.4%. Birmingham remained unmoved; and I well remember the late Professor Gemmill rebuking a visiting London physician [sic] for advocating such methods. Perhaps this was not to be wondered at in the city where the first appendicectomy was performed—that is to say, in 1880 by Lawson Tait—and Gamgee had proudly told us this in his vivid lectures.

To-day, nearly 30 years later, we all have the modern advantage of good anaesthesia, a variety of antibiotics, and some considerable understanding of fluid and electrolyte balance, and the results should indeed be better. In spite of Mr. Coldrey's very low mortality rate, one cannot help feeling that it has been obtained at the expense of a rather frequent incidence of pelvic abscess and abscess pointing in the right iliac fossa. In any case, I should regard delayed operation in a child of under 12 years as taking a serious risk. In spite of these objections, Mr. Coldrey's remarks with respect to the environment in which a surgeon works is of fundamental importance, and it is well that young surgeons-in-training should realize that their destiny may be to work (not just in the night, as Mr. Coldrey instances) where the amenities of their Alma Mater—such as good and adequate assistants, anaesthesia or laboratory services—are just not available. It is then that conservative treatment, as Dr. George L. Alexander's letter (*Journal*, January 5, p. 46) suggests, is likely to prove the safer course, and the more primitive the environment, as on board ship or in the villages of backward countries, the more important it is to avoid what might then become the dramatic or heroic. Much, of course, depends on the experience of the surgeon. Nevertheless, again must be stressed the potential dangers

of using antibiotics where intra-abdominal sepsis exists. Pus that has been sterilized by antibiotics remains a foreign body and an irritant. Two to three years ago Mr. Norman Lake¹ quoted a case treated by antibiotics where some 8 to 10 isolated sterile abscesses lay among the coils of small intestine, causing a most complicated form of subacute intestinal obstruction: and during the past six months there have occurred in the teaching hospitals in Birmingham two cases where pelvic abscesses had been converted into granulation tissue by antibiotic treatment, leading to a "frozen pelvis" with consequent stricture of the rectum.—I am, etc.,

Birmingham, 15.

Translumbar Aortography

SIR,—Mr. H. Gaylis and Dr. J. W. Laws in their excellent paper (*Journal*, November 17, 1956, p. 1141) have performed a most valuable service by drawing attention to the danger of dissection of the aorta as a complication of translumbar aortography. Similar lesions with serious and even fatal results have previously been described in the carotid artery following attempts at cerebral arteriography.^{1,2} Radiologists with extensive experience of arteriography are aware of this complication and take steps to avoid both it and the more frequent, but less dangerous, mishap of perithecal injection of the contrast medium. There is no doubt that the aorta is the site where such mishaps are most likely to occur. Mr. Gaylis and Dr. Laws review several methods of avoiding the mishap, but say that these are not uniformly successful. They describe their own technique in detail. This technique seems to me to require further discussion because (1) it does not seem to include adequate precautions against the mishaps they describe, and (2) it advocates doses of the contrast medium which I would now regard as excessive (30-40 ml. of 70% diodone).

Personally, I always use the test-dose method to localize the needle point during aortography because I believe it to be essential to know where my injection is going to go, instead of injecting "blindly." In an experience of some 400 aortograms performed in the last four years this precaution has on several occasions prevented an injection of the whole quantity of contrast directly into a renal artery or other major branch of the aorta. It has also rendered perithecal injection an extremely rare phenomenon. Despite theoretical objections, therefore, the method has proved its value in practice. The needle point is adjusted or a re-puncture made if the initial injection of 5 ml. of contrast medium is seen to be in an unsatisfactory position (incidentally, only about 3 ml. enters the aorta, as some 2 ml. is held in the plastic connecting system). We have also found plastic (vinyl) connecting tubes much more satisfactory than the rigid "polythene" used by Mr. Gaylis and Dr. Laws, and we inject by hand and not by pressure apparatus.

The use of as much as 40 ml. of 70% diodone at a single injection is, in my opinion, undesirable, particularly where it is not known in advance exactly where the material is going to go. There have been over 30 cases of anuria, including six fatalities, reported in the literature.³ In nearly all these cases similar large quantities of contrast medium were used. We have personally encountered a case where two separate hand injections, one of 30 ml. and one of 25 ml., of sodium acetrizoate ("diaginal") 70% produced a temporary anuria. The second injection was made with some reluctance because the first series of films were technically unsatisfactory, and after an interval for film processing. In our case a catheter was used, and there was no question of damage to the wall of the renal artery as suggested by Mr. Gaylis and Dr. Laws. We no longer use more than 25 ml. of sodium acetrizoate 70% or diodone 70% at a single injection for lumbar aortography, and we always use hand injection rather than a pressure pump. This technique in my experience gives adequate and satisfactory results for most practical purposes. Where renal function is suspect we now restrict ourselves to a single injection of 20 ml. only.

Mr. Gaylis and Dr. Laws suggest that other previously reported complications of aortography have been due to dissection, and they bring forward evidence that the cases of paraplegia reported by Boyarsky⁴ and by Antoni and Lindgren⁵ may have been contributed to by aortic dissection. This suggestion cannot be refuted, but I think toxicity of the medium when given in excessive doses is the major factor in such accidents. Hare,⁶ of

Melbourne, has recently reported (with excellent aortogram pictures) another case of paraplegia following aortography. His case was further complicated by a temporary anuria. After a test dose of 7 ml. of "urokon" two separate injections, one of 45 ml. and one of 32 ml., of urokon were made. There was no evidence in his case of the contrast being injected outside the lumen. However, a large quantity of contrast medium injected by a pressure apparatus was used by him, and the technique was similar to that of Mr. Gaylis and Dr. Laws. Incidentally, pressure pumps have, judging from the literature, often been used to inject the medium at far too high a rate. The speed suggested by Mr. Gaylis and Dr. Laws (10 ml. a second) is of course a safe one, but such instruments which are capable of very high injection pressures can be extremely dangerous in other and unskilled hands.

Hare demonstrates that the main blood supply to the lower lumbar cord usually comes from one of the upper lumbar arteries, and attributes the accident to the direct toxic effect of the contrast medium on nervous tissues or to trauma to the lumbar artery by the needle. Recently Tarazi, Margolis, and Grimson⁷ have shown by experimental work on dogs that the contrast medium used at aortography can damage the spinal cord by a direct toxic action. Previous experimental work has also demonstrated a direct toxic action of organic iodine preparations on animal cerebral tissue.⁸ Similarly, Idbohrn⁹ attributes the reported renal accidents to a direct toxic action produced by excessive doses of the contrast medium. Toxicity of the medium was undoubtedly the mechanism in our own case. In conclusion, while offering these further points for consideration, may I again congratulate Mr. Gaylis and Dr. Laws on producing a most valuable paper, and so beautifully demonstrating and explaining one of the dangers of aortography?—I am, etc.,

London, W.2.

Mild Endogenous Depression

SIR,—In common no doubt with very many others, I have read the very able article by Dr. C. A. H. Watts on the mild endogenous depression (*Journal*, January 5, p. 4) with great interest. I do not, however, feel satisfied that he has made good his claim that such depression is a distinct medical entity, nor in fact can I see any advantage in thus giving the condition a place to itself. Under the heading Dr. Watts himself subsumes such a variety of symptoms that it appears to me that, like Molière's M. Jourdain with regard to speaking "prose," I have been treating such depression for over 50 years of psychotherapy without knowing it.

According to Dr. Watts, the main thing which distinguishes this form of neurosis from others is its tendency to spontaneous cure, and it may be that this tendency has led me to claim successes in the past to which I was not entitled. I think, however, that a classification of nervous illness which includes under one column such widely different ages as 31 and 84 is *ipso facto* somewhat suspect. It is apparent that Dr. Watts follows his own excellent advice and establishes a good rapport with each individual patient; but even then it may be that he does not allow sufficiently for the natural ebb and flow of human spirits which made our ancestors conclude that we are all under the influence of "the inconstant moon."

External causes of present-day stress acting on the individual predisposed to neurosis by circumstances of early childhood determine whether such natural phases are unduly prolonged or pass quickly, and in elucidating and evaluating such stress the psychotherapist may need to look beyond the obvious. The typical neurotic is one who has "too much ego in his cosmos" and readily regresses to the child's attitude that "it isn't fair—this should not be happening to me." Psychotherapy finds its chief justification in

elucidating such regression and explaining the failure of childish patterns of behaviour. In my experience, analysis has rarely to be taken beyond the conscious memories, and these become more vivid and profuse once the patient starts thinking back and finds a patient listener. An analysis which dips into the unconscious is often asked for by the intelligent client who realizes that there is something lacking in his technique of living which mars his success, and who seeks help on that account.

History repeats itself. The psychotherapist must be by temperament and training a humanist. Half a century ago he had to contend with the "neurologist," who sought to interpret maladjustment to living in terms of minute anatomy. Now he finds himself superseded by the psychiatrist, whose interest is in achieving cure of symptoms by drugs and physical means rather than in finding out in each case where the shoe of life pinches. In congratulating Dr. Watts upon his research, may I express the hope that he will remain spiritually on my side of the fence?—I am, etc.,

Scarborough.

R. MACDONALD LADELL.

Benactyzine in Psychoneurosis

SIR,—We were interested in the paper by Drs. C. P. Seager and A. Leitch (*Journal*, December 15, 1956, p. 1407) recording their finding that benactyzine was no better than a placebo in the treatment of anxious neurotic in-patients. We have recently carried out a controlled trial upon 60 psychoneurotics, treating alternate cases with benactyzine and control tablets of identical appearance. The identity of these tablets was known only to the pharmaceutical departments of the hospitals concerned. Most of the subjects were out-patients; seven of the benactyzine and five of the control subjects were in hospital. All cases had some anxiety; it was the most prominent symptom in 90%. The dosage of benactyzine was 1 mg. four times a day for one to three months. An identical number of control tablets were administered. Results were as follows:

	Benactyzine	Control
Symptom-free	2	1
Improved	13	16
Unchanged	10	10
Worse	5	3

Side-effects appeared in eight of the benactyzine cases and five of the controls. They were as follows: *Benactyzine*.—Slowing of thought, weakness, and trembling; weakness and trembling; palpitations, cold feeling, erythema of scalp; generalized papular rash; headache, dizziness, nausea, and sweating; fainting, palpitations, insomnia; giddiness, dry mouth; eczematous rash. *Control*.—Thought block, giddiness, and nausea; papular rash of arms and face; frontal headache and loss of interest; trembling, sensation of unreality; headache, nausea, and confusion.

Our results would seem to indicate that benactyzine has little or no advantage over control tablets in the treatment of psychoneurosis in which anxiety is the main problem. A further point of interest is the number of what appeared to be side-effects which were attributed to the control tablets.

We would like to thank Messrs. Glaxo Laboratories Ltd. and the pharmaceutical staff of Wexford, Torbay, and Royal Devon and Exeter Hospitals.—We are, etc.,

Exeter.

H. SCOTT FORBES.
B. V. EARLE.

Care of Discharged Mental Defectives

SIR,—As you are aware, during the last six months a large number of mental defectives who have been on prolonged licence have been discharged from the order. Certain local authorities have the impression that, because these defectives have been discharged, they no longer need care, control, and supervision. This, of course, is not true, as many of the defectives concerned are of imbecile grade. I would suggest that it would be in the interest of these defectives if local authorities were informed that in the

case of the lower-grade defectives re-ascertainment should be carried out. This would then enable the local authorities legally to carry out their responsibilities concerning the supervision and training of these defectives.—I am, etc.,

Driffield, E. Yorks.

J. NEWCOMBE.

Sharpening Needles

SIR,—With reference to your annotation on sharpening needles (*Journal*, December 29, 1956, p. 1535), in 1916, knowing that sometimes Army needles had to be sent home from Salonika to be resharpened, I took out with me a No. 89 "carborundum" slip to be used for the purpose, either by a fiddle-bow or a scooping-out stroke. The needles for intravenous use then were of a larger gauge than they are to-day and clearing the burr on the outside rim helped. To-day the scooping-out method is easier and better against a support of glass or china and may be done with the small blade of a pocket-knife used longitudinally downwards. Clear the outside rim gently and test on a piece of chamois leather stretched tightly.—I am, etc.,

London, W.1.

G. H. COLT.

SIR,—I read with interest your annotation entitled "Sharpening Needles" (*Journal*, December 29, 1956, p. 1535). Personally I have found that there is less discomfort to the patients after using the same needle 20 or 30 times, as long as the arm or buttock is well relaxed and the skin well stretched. A few light strokes of the fine-grained oilstone can be used alternatively to remove the sharp point. The prick of a pin is less unpleasant than that of a fine sewing-needle. One never gets tired of being complimented on having given a painless injection.—I am, etc.,

London, S.W.1.

A. L. LANKESTER.

Vaccination Technique

SIR,—May I suggest to Dr. Neville Davis (*Journal*, December 29, 1956, p. 1545) that no covering of any sort is necessary over the vaccination area? After making two scratches through the drop of lymph I wait for about one minute and then wipe off the excess lymph. When I see the weals through the scratches I assure the mother that the vaccination has taken, and advise her that no special measures are necessary against infection and that at no time must she use a dressing over the area. Since adopting this method I have never had a failure to take, or any secondary infection, or any accidental infection of the child's mother.—I am, etc.,

Topsham, Devon.

GRACE H. WALKER.

Continuous Suxamethonium

SIR,—Dr. C. Langton Hewer (*Journal*, January 5, p. 45) disapproves of continuous suxamethonium. Perhaps we have been lucky, but, since reporting its use in 289 patients (*Journal*, August 8, 1953, p. 317), we have used this technique in some 1,500 cases of abdominal surgery. In only four instances has post-operative apnoea lasted more than a few minutes, while in the great majority the patient was breathing fully by the time the last stitch was tied. In the four exceptions mentioned, apnoea lasted 60 minutes (1), 40 minutes (2), and 30 minutes (1). No ill effects followed.

In using this technique we believe it essential, after the initial dose for intubation has been given, to keep the drip rate at "dead slow" until respiration starts again, and then rate at "dead slow" until the patient is always to so adjust it from time to time that the patient is always on the point of breathing. Constant supervision is therefore necessary, but the results seem to justify it, and, in our view, if this procedure were strictly adhered to we should hear much less of "succinylcholine apnoea," while the use of curare and neostigmine in abdominal surgery would be largely unnecessary. Moreover, if the concentration of suxamethonium is adjusted to the needs of the individual patient there should be no fear of overloading him with unwanted fluid.

Instances of slow recovery of breathing, as distinct from complete apnoea, following large doses of suxamethonium

have been reported by both British and American writers. Without discussing the theories advanced to account for these cases, we feel that this difficulty can be largely avoided by strict economy in the use of suxamethonium. Where, in exceptional cases, larger doses such as 1,500 mg. or over are given, the less well-defined type of recovery may be expected, but here no special treatment is necessary beyond careful observation and the avoidance of hypoxia in the immediate post-operative period.—We are, etc.,

Romford, Essex.

Neodymium 3-Sulpho-isonicotinate and Blood Coagulation

SIR,—Since the publication of our paper (*Journal*, November 24, 1956, p. 1214) we have found haemoglobinaemia in all of four patients who received daily injections of neodymium 3-sulpho-isonicotinate 5 mg./kg. for more than five days. One of these patients had haemoglobinuria which lasted for three days after the drug was stopped. None of these patients showed any other signs of blood destruction, or any other bad effects whatever, but this finding obviously calls for great caution in further clinical trials, or preferably the complete suspension of clinical trials until really adequate toxicity studies have been carried out in animals.—We are, etc.,

Dundee.

Corticotrophin and Cortisone Therapy in Dermatomyositis

SIR,—In Dr. Morgan McElligott's most interesting article on the treatment of dermatomyositis with corticotrophin and cortisone (*Journal*, December 29, 1956, p. 1509), he rightly points to some of the clinical differences between acute and chronic cases. I would like to draw attention to a letter I wrote on this subject¹ in which I suggested that the diagnosis of dermatomyositis at present includes three quite separate entities, and that most of the acute fulminating cases—including some which he cited from the literature² and at least case 1 of his own series—are of a polymyositic form of polyarteritis nodosa.

Typically, this hyperacute illness occurs in young adults, seemingly as a hyperimmune response to an infection which is usually of the upper respiratory tract, with or without sulphonamide treatment, and, given the same circumstances, it may recur.³ The distinctive features are: (1) hyperpyrexia; (2) pleomorphic skin lesions, which vary from erythema multiforme to peripheral gangrene; (3) exquisite tenderness of wasting muscles, to which polyneuritis contributes; (4) frequent visceral lesions from ischaemia or infarction; (5) a high polymorphonuclear leucocytosis, with or without eosinophilia; and (6) albuminuria and microscopic haematuria. A negative muscle biopsy does not exclude this diagnosis in these cases, which are an urgent indication for cortisone or corticotrophin, which can tide the patient through to virtually complete recovery. As with systemic lupus erythematosus, the initial dosage is that which controls the activity of the process and may well be up to 300 mg. of cortisone daily, with slow subsequent reduction.

In the second group of cases associated with malignant disease, which I have discussed elsewhere,⁴ it is a diagnosis of awareness when presented with a febrile patient in the relevant age group who has skin lesions like a disseminated—not systemic—lupus erythematosus, and weak oedematous muscles which proceed to waste rapidly, without great tenderness. As a palliative measure in these cases, cortisone and corticotrophin have been shown to be effective, but any success so achieved should not be allowed to hinder the exhaustive search for a neoplasm—the removal of which can, incidentally, lead to resolution of the dermatomyositic process.

In the third group of cases of true chronic progressive dermatomyositis—a variant of progressive systemic sclerosis—cortisone and corticotrophin appear to afford temporary

subjective relief only, except in the early, sometimes quite acute, oedematous phase. But, in the absence of any other certain remedy in this potentially crippling condition, one would agree with Dr. McElligott that these drugs should never be withheld.—I am, etc.,

Aberdeen.

Burns and Hydrocortisone

SIR,—My experience of hydrocortisone-antibiotic ointment in first- and second-degree burns agrees with that of Dr. E. L. Lonbay (*Journal*, December 29, 1956, p. 1547). During the course of a recent lengthy correspondence on the treatment of burns and scalds, I reported¹ that a 1% greasy hydrocortisone ointment incorporating neomycin had proved, on dermatological advice, an effective and safe application for use in a busy casualty department. Subsequent experience has confirmed this earlier impression, though no controlled trial has been carried out.—I am, etc.,

Hove.

Otitis Media

SIR,—I had the unusual opportunity recently in a boarding-school of seeing a child with acute otitis media within one hour of the onset of symptoms. At that time there was acute unilateral otalgia with no temperature or other signs or symptoms. The ear-drum was absolutely normal in all respects. Four hours later the drum had begun to become injected and red, and was distinctly different from the other normal drum. My object in writing this letter is to draw attention to the danger of discounting a normal ear-drum if seen very early after the onset of symptoms, and the necessity for reviewing such a case the following day.—I am, etc.,

Hatch End, Middlesex.

MARTIN STRATFORD.

Tobacco-cancer Problem

SIR,—Dr. E. L. Wynder's masterly deployment of the evidence in support of the carcinogenicity of smoking (*Journal*, January 5, p. 1) contrasts with the timidity of his "practical aspects of solving the tobacco-cancer problem." There is, of course, but one "practical aspect," one solution, as he must know, but, like Doll and Bradford Hill, he has avoided—very wrongly, in my view—stating plainly that tobacco-smoking should be stopped and that it is our duty to stop it, quickly. Instead, we continue to fiddle while Rome burns. "All a physician can do," says Wynder, "is to present the facts to the public." He can do much more. He can state plainly what action should be taken and crusade his utmost for that action. Moreover, the mode and frequency of the presentation of the facts are important. Because of the inaccessibility of smokers to the facts against smoking, nothing less than their very frequent and blunt presentation by a non-smoker over a long period using every modern publicity device would be effective in eliminating tobacco-smoking, and in the end there would have to be compulsory prevention of smoking to cure a considerable hard core of addicts.

A filter which would remove most of the carcinogens and most of the "equally important" nicotine, if one could be made, would be unacceptable to most smokers, who smoke mainly to obtain a satisfying dose of nicotine, just as smokers of opium and hashish smoke to obtain a dose of morphine and cannabis indica respectively. For this reason it is unrealistic to speak of "tobacco taste" and "satisfactory pressure drop" (though I am not clear what this means) as though they were the main considerations in smoking.

Economic considerations should weigh little with us. The saving of £55 million in dollars annually would go a long way towards compensating us for our economic upheaval.

Taxation would have to be equitably redistributed, present-day smokers paying much less, and non-smokers much more, than in the past; and the tobacco labour force, buildings, and equipment would have to be redeployed and put to socially valuable work. Individuals can stop smoking, so also therefore can nations. Notwithstanding my criticisms, I recognize fully and gratefully Dr. Wynder's pre-eminent contributions to the cause of non-smoking.—I am, etc.,

Wallasey, Cheshire.

LENNOX JOHNSTON.

Herpes Zoster and Chicken-pox

SIR,—After nearly half a century of semi-rural practice, I find Dr. R. M. McGregor's article on herpes zoster, etc. (*Journal*, January 12, p. 84), of great interest. I have never seen two cases of zona in one house together or even in succession, but I once had seven cases in adjacent houses simultaneously; zona, very severe, accompanied by chicken-pox in the third week; and one parent developing zona about three weeks after family varicella, several times. And, of course, the reverse. I have noticed repeatedly that zona comes in crops; there may be two or three cases in our country town; and in the same week, in scattered hamlets over about sixty square miles, perhaps half a dozen cases well apart; and chicken-pox may be expected very shortly, or vice versa. All very predictably haphazard.—I am, etc.,

Kington, Herefordshire.

G. W. DRYLAND.

SIR,—Dr. R. E. Hope Simpson (*Journal*, November 10, 1956, p. 1115), in commenting on my memorandum (*Journal*, October 13, p. 864), questions my statement that adjacent roots were often affected, and draws attention to the classical paper by Head and Campbell.¹ In my series the distribution of the rash was taken to indicate the roots involved. A drawing of the distribution of the rash was made in each case and compared with the sensory charts of R. Bing.² Sir Francis Walshe,³ and Gray's *Anatomy*.⁴ For instance, rash 2 in. (5 cm.) above Poupart's ligament, and on the anterior upper third of the thigh and on the upper half of the buttock, was taken to indicate L1-2. Supra- and infra-mammary rash extending posteriorly to the inferior angle of the scapula was regarded as D3-4. Rash above the iliac crest spreading over the buttock to the mid-thigh posteriorly was taken to indicate L2-3, as was rash over the upper part of the buttock and from Poupart's ligament to the upper border of the patella. Dr. D. G. French (*Journal*, December 29, p. 1545) confirms my findings that prolonged severe post-herpetic pain is comparatively infrequent in this common disease.

Dr. Hope Simpson has shown me the age incidence of his series of 79 cases of zoster, which differs considerably from mine in that, whereas in my 72 cases 56 were over 50 years old, in his there were more under than over 50. Dr. R. M. McGregor (*Journal*, January 12, p. 84) in a series of 81 cases found 61 over 45 years old. Owing to the nature of my practice, I see more patients in the older age groups and only few children, which may account for the discrepancy.—I am, etc.,

Redhill, Surrey.

SIR,—I cannot allow the article on herpes, chicken-pox, and cancer by Dr. R. M. McGregor (*Journal*, January 12, p. 84) to go unchallenged. In our practice we have an unusually high proportion of young children, and we find that epidemics of chicken-pox are frequently accompanied by an increase in the number of cases of herpes zoster. Herpes zoster occurs frequently in youth, and I trust one must not be classified as old when attacked. I personally contracted chicken-pox as a schoolboy and herpes zoster as a fourth-year student of Edinburgh. While serving as S.M.O. at the R.A.F. station, Drigh Road, Karachi, in 1946-7, I experienced an epidemic of chicken-pox in the married quarters.

In this closed community a young child with chicken-pox spread the infection rapidly, as the mother refused to co-operate. About three cases of herpes occurred in this small group.—I am, etc.,

Watford.

A. SCOTT.

Polycythaemia Vera

SIR,—In your leading article on polycythaemia vera (*Journal*, December 8, 1956, p. 1354) it is stated that "sporadic venesection, while contributing to the blood banks, is of little benefit to the patient. . . ." From this it might be inferred that such blood could be used for routine blood transfusions. Since the cause of the malady is still uncertain, such a course would appear highly undesirable.—I am, etc.,

Scarborough.

KENNETH FROOME.

Rapid Transfusion in Children

SIR,—I was interested to read the article on rapid transfusions in children by Dr. Leslie G. Andrews and David J. Coleman (*Journal*, January 5, p. 19), but would like to add a word of warning.

Knowing my interest in transfusion therapy during the war years, a friend in 1947 reported to me two fatal cases in babies due to cardiac failure caused by rapid transfusion therapy. In neither instance was anything found amiss with their hearts; it was a case of rather too much blood given too quickly. I well appreciate that marked apprehension may develop in young children from frequent transfusions, and the need to avoid interference with schooling where this applies, but I suggest the former is not necessarily reduced by frequent general anaesthetics, and that slower transfusion techniques need not incur a week's absence from school. Back in 1939 the French gave top-up transfusions in the out-patient clinic, and I submit that 24 hours in hospital should provide ample time to do the job as safely and satisfactorily as any transfusion can be. Treatment of medical conditions by rapid infusions under general anaesthetics should, I submit, be reserved for very exceptional cases.—I am, etc.,

Oxford.

HUGH ELLIS.

Sign of Wind in Infants

SIR,—After my fourth child I have again observed a sign which might be of some help if it were more generally known. This is a pallor of the area between the nose and upper lip in infants, which is present when the baby has "wind" and disappears immediately on eructation. When my first baby was born five years ago I observed this sign. I searched paediatric textbooks but failed to find any mention of it, although since then one eminent paediatrician¹ discusses in a recent textbook pallor of the complete face in infants with wind. I have never observed this, but I should be interested to hear of a physiological reason for the sign.—I am, etc.,

Glasgow, E.3.

Cervical Myelopathy

SIR,—Your annotation (*Journal*, January 12, p. 96) on cervical myelopathy ends by recommending that a means to arrest the vertebral disease should be sought. I agree. Prevention of a major displacement obviously consists in reducing it when it is minor. This should be undertaken at the outset of the disorder, years before there is any question of myelopathy.

When disk-protrusion begins at a cervical joint, it is the established practice to leave the displacement where it is. If, instead, logic were followed and the displacement were reduced at once by manipulation, the best possible would have been done to ensure that myelopathy never developed. When these displacements are small and recent they can nearly always be reduced by manipulation. When they press on the spinal cord enough to cause numbness and pins-and-needles in the upper and lower limbs without

objective signs of interference with cord function, they may still prove reducible, sometimes with permanent result. By the time that a root-palsy or a spastic paresis has supervened, manipulation comes too late.

Is it not time that we took the possibility of myelopathy to heart and refused to subject patients with cervical displacements either to heat and massage at the resultant area of referred pain or to a collar applied with the displacement unreduced? These too frequent evasions must result in enhanced likelihood of crippledness later. This is best obviated by reduction carried out at the early stage. Provided anaesthesia is avoided and traction is applied during each manoeuvre, there is neither risk nor difficulty.—I am, etc.,

London, N.W.1.

JAMES CYRIAX.

Unusual Cause of Obstruction

SIR,—The following case report records an unusual cause of acute intestinal obstruction.

A man, aged 69 was admitted to hospital at 5.30 p.m. on November 29, 1956, moribund. He was vomiting faeculent material profusely, and he died very shortly after admission and before effective treatment could be instituted. At necropsy there was no relevant abnormality except in the alimentary tract. He was edentulous and had marked dilatation of the stomach and small intestine down to within 8 in. (20 cm.) of the ileo-caecal valve. At that level there was a ring of oedematous thickening encircling the gut for 1½ in. (3.7 cm.) of its length, and wedged across the proximal margin of that ring was a thin bone 1 in. (2.5 cm.) long which was beginning to soften at its ends. Firmly pressed against the bone was an unmastered and undigested whole raw fig completely occluding the lumen of the bowel.

It appeared later that the patient had eaten rabbit on November 25 or 26 and figs on November 28. He was previously of good health, but complained of acute abdominal pain during the morning of November 29. He had dentures, but never used them.—We are, etc.,

Cardiff.
 B. J. STEPHENS.
 J. N. BODGER.

Increase in Scabies

SIR,—Dr. Margaret S. M. McGregor has raised again the question of aetiology of papular urticaria (*Journal*, December 15, 1956, p. 1427). I am quite certain that there is no evidence of scabies or similar infestation in the vast majority of cases of papular urticaria. There is an urticarial response in some cases of scabies, but in these the scabies mite can be isolated. I do this in my scabies clinic by simple needling as advocated by Mellanby, and it is quite a simple procedure. A very credible explanation of the cause of papular urticaria has been put forward in an article by Drs. A. Rook and W. Frain-Bell.¹ They state that "there is strong evidence that most cases of papular urticaria are the result of an acquired sensitivity to the bites of certain insects, particularly fleas and bedbugs." This is a much more likely cause than food allergy.—I am, etc.,

Norwich.

E. LISTER.

Pregnancy Sickness

SIR,—I have been greatly interested in the correspondence on pregnancy sickness and would like to add my own personal experiences. I have four children. At no time did I have any sickness, but during the first three months of each pregnancy I had a type of nausea that would be more accurately described as acute hunger. It was relieved by small frequent quantities of easily assimilated carbohydrate. I concluded the immediate cause was a low blood sugar, probably due to a metabolic failure to adjust to supporting the foetus. My further experience supported this. I fed all four babies. The last two were difficult to wean and at six months were having little else than breast milk in very large quantities. At this time I experienced nausea exactly the same as that of the first few months of pregnancy and

Obituary

E. B. BROOKE, M.B., F.R.C.P., D.P.H.

Dr. E. B. Brooke, consultant physician to the geriatric unit of the Southampton group of hospitals, and formerly physician-superintendent at St. Helier Hospital, died at his home at Southampton on January 13. He was 60 years of age.

Eric Barrington Brooke was born on May 11, 1896, and was educated at Gonville and Caius College, Cambridge, receiving his clinical training at St. Bartholomew's Hospital, and qualifying by taking the London Conjoint diploma in 1922. In the following year he obtained the degree of B.Chir. and in 1924 the M.B. He took the D.P.H. of the English Royal Colleges in 1925 and the M.R.C.P. in 1927. Four years ago he was elected F.R.C.P. After qualification he held the appointments of house-surgeon to the skin and venereal diseases department and house-physician at St. Bartholomew's Hospital and assistant medical officer at St. Giles's Hospital, Camberwell. Then followed a short period of work in South Africa before he took an appointment at the former Redhill Hospital, Edgware (now Edgware General Hospital), under the Middlesex County Council. From there he moved to the service of the Surrey County Council and became medical superintendent at its hospital of the same name at Redhill, Surrey. A few years later the Surrey County Council began to plan a new large hospital on the most modern lines to serve the rapidly increasing population in the north-east of the county. From the beginning Brooke was designated as the future medical superintendent of this hospital, which took its name from the near-by L.C.C. St. Helier housing estate. His first years in his new appointment were made difficult by the outbreak of war and the resultant shortages of men and materials. To make matters worse the building suffered a number of times from enemy action, and in 1944 the medical superintendent's house was destroyed by a flying bomb. Brooke was severely injured in this incident, losing an eye, but before long he was back to duty again. In the years after the war he became a leading authority on the medical care of the aged, and was a member of the B.M.A.'s Committee on the Care of the Elderly and Infirm. He moved to Southampton about four years ago.

Dr. C. P. PETCH writes: Eric Brooke was accustomed to observe that the heyday of medical superintendents passed with the appointment of consultants with full clinical responsibility to hospital staffs. He compensated for any loss of clinical interest by devoting his enthusiasm to the ever-increasing problem of the care of the elderly. It is for his work in this field, now known as geriatrics, that he is best known, and his reputation in it was not only national but international. He was much in demand as an adviser on the care of the elderly, and was frequently asked to lecture on this subject. He laid great insistence on the importance of keeping old people in their own homes for as long as possible, and to that end organized a variety of services to help them. In the early part of 1953 he was invited to assist in the organization of a geriatric service in the western half of the South-west Metropolitan Region, and in April of that year became consultant physician to the Southampton group of hospitals, with special duties in reference to geriatrics. Throughout his life he had battled with the handicap of severe asthma, and it was the hope of those who knew him that a move away from the London fogs

would be advantageous to his health. That hope has not been fulfilled, and it is sad that he will not see the development of his work in the Southampton area.

Mr. HENRY A. KIDD writes: The announcement of Eric Brooke's sudden death came as a shock to his many friends, and especially so to those who had been his colleagues at the Redhill, St. Helier, and Southampton Hospitals. Of the multitude of patients who have passed through the hospitals under his care, none will regret his passing more than those elderly and sick folk for whom he worked so indefatigably and successfully to make their lives a little brighter and happier and make them feel that they still had a useful part to play. He was one of the founders of modern geriatrics, and used his great skill and experience as an administrator and physician to further the interests of those who had no champion and who were only too often regarded in hospitals as unwelcome guests. His work as medical superintendent at Redhill Hospital was so well appreciated that in the early days of the war he was appointed as the first medical superintendent of the new 800-bed St. Helier Hospital. A new hospital has not only to gain a reputation for the quality of its work but to build a tradition and to find its soul. To that task Eric Brooke directed his great talents, and, in spite of the difficulties and dangers of opening a large hospital near London in the middle of a world war, he achieved for himself and his hospital a renown that spread beyond its immediate environment. He bore the loss of an eye with the courage and cheerfulness that those who knew him well would have expected. Although he was only 60 when he died, he had for many years been known affectionately at St. Helier Hospital as "Daddy" Brooke, a nickname which reflected his status as father of the hospital and the esteem in which he was held by his colleagues. Always sympathetic to other people's troubles, he had a puckish sense of humour and a sense of justice which endeared him to all who came in contact with him. In recent years his health had not been good, but at all times he strove to do his best to overcome his physical handicap, and in this he was immensely helped by the devotion and loving care of his wife. To her and to their two children we extend our heartfelt sympathy.

JOHN McGRATH, M.D., M.Sc.

Professor John McGrath, who before becoming professor of pathology and bacteriology at University College, Dublin, a few years ago was State Pathologist in Eire for about a quarter of a century, died suddenly on January 11, the day before his 56th birthday.

John McGrath was born at Cappoquin, Co. Waterford, on January 12, 1901, and from Clongowes Wood College entered University College, Dublin, graduating B.Sc. in 1921 and proceeding to the M.Sc. in the following year. Having decided upon medicine as a career, he went on to take the M.B., B.Ch. degrees in 1925, proceeding to the M.D. in 1940. After graduation he continued his medical studies at Vienna and Heidelberg, and for a time was an assistant at the Krankenanstalten, Mannheim.

Soon after his return to Dublin McGrath was appointed lecturer in medical jurisprudence at University College, and in the same year (1929) became State Pathologist. In this latter post his legal training—he was called to the Irish Bar in 1933—held him in good stead, and he proved to be a very able witness, giving his evidence in clear-cut, unambiguous terms. He examined in medical jurisprudence for the Dublin and Glasgow Universities and for the Queen's University of Belfast. When Professor Thomas T. O'Farrell retired from the chair of pathology and bacteriology at University College in 1952 McGrath was appointed to succeed him, relinquishing his appointment as State Pathologist to do so. During most of his career he was pathologist to

St. Vincent's Hospital and to the National Maternity Hospital, Dublin.

McGrath was elected a member of the Senate of the National University of Ireland in 1949, and for some years he had been a member and treasurer of the Medical Research Council of Ireland and a member of the Medical Registration Council. He was also chairman of the National Blood Transfusion Association of Ireland and a former assistant editor of the *Irish Journal of Medical Science*.

A colleague writes: The sudden passing of John McGrath—affectionately known as "Jock" to his familiars in every one of the counties of Ireland—came to us all with incredible swiftness. Less than 72 hours before, he had been of our company at the annual dinner of the hospital in which he had worked as student and as member of the staff for forty years; we knew that lately he had been gravely ill, yet that evening he bore little sign of it, and we rejoiced to hope from his obvious enjoyment of the gathering and the sustained vivacity of his conversation that he was on the road to recovery again. Next day, and the day after, he sat examining at the College; on the following afternoon, as he was setting out for his laboratory, he died, quietly, at the wheel within a few moments of entering his car. "Jock" died as he would have wished—in harness.

Through all those years we had recognized in him one of the most gifted men of his generation. The very concourse at his funeral obsequies bore witness to the gap his going has left, not merely in our Dublin medical corps but in almost every phase of Irish life—university, legal, medical, administrative, as well as in the wide and overlapping circles of Dublin's social life, in which he had an enormous acquaintance. While he was a tremendous worker, he was also a keen sportsman and a welcome lover of good company. Looking back more than a score of years, one can recall many a happy tussle at Portmarnock or Fitzwilliam, and the enthusiastic accounts with which he would entertain us envious stay-at-homes at this season of the year on his return from his annual trip to Switzerland to take part in the winter sports in which he excelled. A keen fisherman, too, he was no less expert with camera, and found deep pleasure in co-operating in his wife's accomplishment in their beautiful garden at the foot of the Dublin hills.

To the general public he was best known as the State Pathologist. As a scientific witness he had gained universal respect and repeated tribute in court for his objectivity and fairness, as well as for the accuracy and the clarity of his testimony. In the "lab" at hospital he enjoyed the same regard: ever helpful to a colleague seeking information, his exposition of a difficult slide or biochemical problem was invariably given in the simplest and clearest manner.

On his appointment to the chair of pathology at University College, he resigned his appointments as State Pathologist and as an active member of the Vincent's staff so that he might devote himself the more fully to the work of a university department. Last year he had been appointed dean of the Medical Faculty. Had providence seen fit to grant him another ten or even five years in which to expend his zeal and his wide intellectual gifts on the further development of the medical school, a coming generation would have reaped the benefit of his proved capacity for organization. His place will be difficult indeed to fill.

K. S. writes: For nearly 30 years John McGrath had, by his perception and skill in applying the fundamental principles of pathology, built up an international reputation as a medico-legal expert: he had travelled the length and breadth of his country to give his sage and practical advice on countless unexplained or more frankly suspicious deaths, and had become the unchallenged master of his field, State Pathologist to Eire, professor of forensic medicine and later of pathology also in his university school. He bore his authority with such evident humility and good sense that

no one—in court or in the field of criminal investigation—ever doubted his sound reasoning and absolute fairness. Everyone liked and admired him, quickly succumbing to his infectious warmheartedness and most generous personality. Here was the complete antithesis of Spilsbury's cold aloofness in a man of equal authority and standing among his fellows, much travelled and as much devoted to absolute justice, but warm, generous in company or opposition, capable of relaxation and pleasure in the company of his colleagues, a good club-fellow, knowledgeable in art and travel, music, wine, and book-lore, a conversationalist and raconteur—excellent company indeed. To see him relax in the garden of his country home under the Wicklow mountains, secure in the affections of his charming wife and his friends, or to sample his generous hospitality at his club in Dublin was to see an Irishman of learning and wit enjoy leisure as only the Irish can. Dublin University life has lost one of its wisest counsellors and teachers, the State its most experienced medico-legal opinion, and his many friends a most lovable companion.

DOROTHY WOODMAN, M.D., M.Sc.

Dr. Dorothy Woodman, lecturer in clinical pathology in the University of Bristol and consultant pathologist to the Frenchay Hospital, died in Bristol on December 21, 1956, aged 61.

Dorothy Woodman first trained as a physiologist, graduating B.Sc. in 1917 and proceeding to the M.Sc. in 1924. She then went on to study medicine at the London School of Medicine for Women, where she had previously been working in the department of physiology, and took the degrees of M.B., B.S. in 1931, proceeding to the M.D. three years later. After working as resident pathologist in the Royal Free Hospital and as an assistant in the pathological department of the Cancer Hospital, she won the A. M. Bird postgraduate scholarship in pathology at the London School of Medicine for Women, where she worked for a further year. She went to Bristol as lecturer in pathology in 1935, but three years later transferred to the department of preventive medicine, which, by arrangement with the city, was responsible for the laboratory services to the municipal hospitals. Although she continued to teach in the university, her main work was to organize the pathological services to Southmead, Ham Green, and, later, Frenchay Hospitals. She had continued responsibility for this throughout the war years, and only with the changes brought about by the introduction of the National Health Service did she confine her attention to Frenchay Hospital and the university.

K. E. C. writes: With the death of Dr. Woodman the University of Bristol and the regional board hospitals have lost a greatly valued pathologist, and her colleagues will deeply miss a warm friend. She enjoyed teaching, and in the years that followed her appointment as lecturer in pathology at Bristol many medical and lately veterinary students were privileged to have the benefit of her instruction. Her gift for simple exposition was valued also by the nurses and technicians to whom she gave great service as examiner, teacher, and adviser. Those who learnt from her also received understanding, encouragement, and friendship.

Her great administrative ability and capacity to organize complex pathological services became particularly evident during the war years. Before the coming of the Army Blood Transfusion Service to Bristol she organized the blood grouping. Later she carried out surveys by arrangement with the M.R.C. on haemoglobin levels, on vitamin-C levels, and on the resistance of pneumonias to sulphonamides. She arranged for the distribution of the very valuable and limited supplies of penicillin and tetanus antitoxin

then available to the local authority. Yet, when the bacteriology section of the preventive medicine laboratories was faced with epidemics of paratyphoid in 1940 and 1941, she and her staff took an important share in the work that this entailed.

With the introduction of the National Health Service, she accomplished smoothly all the necessary transfers of personnel to different hospitals, so that each person concerned felt that his or her wishes had been carefully considered, and that each was being placed where his or her gifts could be used to maximum advantage. Her great sense of duty, her patient and warm understanding, her cheerful resolution and determination, and her deep religious convictions all contributed to the love and affection in which she was held by all who really knew her.

T. A. B. HARRIS, M.D., F.F.A.R.C.S.

Mr. A. W. BADENOCH writes: May I add a few lines to what has already been written (*Journal*, January 12, p. 110) about the late Dr. T. A. B. Harris? He had been anaesthetist to St. Peter's Hospital for 25 years, and since the war was responsible for all my cases. Like all who have worked at St. Peter's, he became very attached to it and was always out to further its interests. He was delighted to welcome visitors and to make them feel at home. His knowledge of the theory of anaesthesia and the pharmacology of anaesthetics was profound, but no one could surpass him in speed of induction and delivery of patients into the theatre in quick succession. One of the best attributes a surgeon can recognize in an anaesthetist is efficient unobtrusiveness, and this could always be applied to "Tommy" in the theatre. One had never any doubt that he was complete master of the state of his patient. Outside the theatre he was full of verve, interested in all aspects of medicine, of life, and especially in his family. He used to delight in talking about his boys, and we hope they will continue to be the same unending source of comfort to his widow that they always were to him.

Dr. KATHLEEN O. VAUGHAN died in Alderney, Channel Islands, on November 26, 1956. She was well known as an advocate of pre-natal exercises for women. Kathleen Olga Vaughan received her medical education at the London School of Medicine for Women, and graduated M.B. from London University in 1900. After graduation she held the appointment of house-surgeon at the Royal Aberdeen Hospital for Sick Children and then obtained the post of medical officer in the Quarantine Office at Port Tewfik, Suez. In 1903 she moved further east to become superintendent of the Victoria Dufferin Hospital at Calcutta, and later she was appointed superintendent of the Diamond Jubilee Zenana State Hospital at Srinagar. She left India in the early nineteen-twenties and thenceforward lived in many different places in England and on the Continent. During the second world war she worked for a time in the Emergency Medical Service. She was the author of *Safe Childbirth: The Three Essentials*, published in 1937, and *Exercises Before Childbirth*, which appeared in 1951, and contributed an article entitled "The Expanding Pelvis" to this *Journal* in 1942.

Dr. DAGMAR WILSON writes: Dr. Kathleen Vaughan was associated with a time in Indian history which has already become legendary. She was a pioneer in bringing medical relief to Indian women and children, especially in the Princely States. During a long period of service in the State of Kashmir she not only built up the work of the hospital for women and children at Srinagar but found energy to undertake research on osteomalacia, a disease prevalent among poorer women living in seclusion in that city. Her convictions of the need for training Indian women as doctors caused her to take an active part in the founda-

tion of the Women's Medical Service in India. Dr. Vaughan lived to enjoy a long period of retirement in England, but during the second world war she helped organize maternity wards set up at Ruskin College, Oxford. Her chief interest remained the problems of childbirth, and she carried out extensive research on exercises during pregnancy. Dr. Kathleen Vaughan was a woman of keen wit and ready humour. Until prevented by ill-health, she was a regular attendee at the meetings of the overseas branch of the Medical Women's Federation, where she enlivened many discussions to the delight of her friends.

Dr. R. S. RENTON, who was in practice at Clevedon, Somerset, for 30 years, died on December 27, 1956, at the age of 79. Ralph Stuart Renton was born on September 7, 1877, and was a medical student in Newcastle upon Tyne, graduating M.B., B.S. from Durham University in 1902 and proceeding to the M.D. in 1914. Soon after graduation he settled in practice at Blackhill, Co. Durham, thus following in the footsteps of his father, Dr. George Renton, and his grandfather, Dr. John Renton, both of whom practised for many years in the same area. Dr. R. S. Renton became honorary surgeon to the Consett Hospital, and remained in practice at Blackhill until he entered the R.A.M.C. for service in Egypt and France in the first world war, service which was recognized by the award of the Military Cross in 1918. After the war he was in practice at Coltishall, Norfolk, for a year or two until 1921, when he finally settled at Clevedon, where he became honorary surgeon to the cottage hospital and medical officer to the Clevedon Convalescent Homes. He took a prominent part in the revival of the local branch of the St. John Ambulance Brigade, becoming divisional surgeon, and in 1946, for his long service to the movement, he was appointed a serving brother of the Venerable Order of St. John of Jerusalem. During the second world war he was a medical officer in charge of a first-aid post, and he also served on the Bristol medical board throughout the war. Failing health enforced his retirement from practice some six years ago. Dr. Renton had many outside interests, being a keen gardener, with a preference for the cultivation of roses, a breeder of deerhounds, a lover of cricket, a keen supporter of the local dramatic society, and a past president of the Clevedon Rugby football club, which he helped to form. In addition, he acquired such a deep knowledge of church architecture that his services as a lecturer on the subject were in frequent demand. He leaves a widow and one son.

Dr. TATIANA GOURLANDE died at her home in London on January 6 after an illness of some months. Born in Russia in 1887, in her youth she was a dramatic actress in Moscow. Later she studied medicine at the Women's Medical Institute in Moscow, but, owing to the revolution, had to leave Russia before her graduation. After living for a few years in London she became a medical student at St. Mary's Hospital Medical School and qualified M.R.C.S., L.R.C.P. in 1928. Dr. Gourlande specialized in gynaecology, and for a time was clinical assistant at the Hospital for Women, Soho Square, the Chelsea Hospital for Women, and the Samaritan Hospital. A kind and clever woman of the world, she was esteemed by her colleagues and patients. Her many friends will share a great sense of loss with her husband. —S.W.

Dr. D. H. BERRY died in the Peace Memorial Hospital, Watford, on December 31, 1956, at the age of 60. Douglas Haycraft Berry was born on April 25, 1896, in Watford, where his father, Dr. F. H. Berry, was a member of the oldest-established practice in that town. He was educated at Malvern College, and, soon after leaving, served as an infantry officer in the Bedfordshire and Hertfordshire Regiment during the first world war, being severely wounded during the fighting on the Somme. At the end of the war he entered Guy's Hospital, qualifying in 1922, the year that his father died, and, after holding resident appointments at Guy's, he joined the practice in 1923. Although often handicapped by ill-health, he worked very hard and conscientiously, building up an extensive practice. His quiet, unassuming manner and his kindly understanding, as well as his undoubted professional ability, resulted in his being deeply respected and loved by his many patients. For many years he was a member of the medical staff at the Peace Memorial Hospital, Watford. Owing to ill-health he retired at the end of last June, three months after a very sad bereavement, the death of his wife. For thirty-three years he never spared himself in the exacting life of a general practitioner, and he will be greatly missed by his many friends; his colleagues, and his numerous patients. The sympathy of them all is extended to his married son in Kenya and to his married daughter in Watford, with whom he lived after his wife's death.—L. K. W.

Medico-Legal

FATAL ATTEMPT TO SLIM

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

On December 5 last a married woman aged 47 died in hospital in Sheffield. She had been admitted at the instance of her family doctor, whose patient she had been for three years. Until July, 1956, he had attended her for minor ailments only, including cystitis. He had always found her sensible about her health and not given to patent medicines or homely remedies. Though inclined to be influenced by what people told her, he would not have expected her to take anything without consulting him.

On July 2, 1956, she consulted him complaining of a peculiar loss of vision in the left eye which came on during the night, with lights before her eyes, and she still complained of a black spot in the eye when he saw her. He found she had a haemorrhage of the eye and high blood pressure, for which he treated her, referring her to a specialist for the eye trouble. On test her urine was normal, and phenobarbitone and theobromine brought the hypertension down to about normal.

In August the eye haemorrhage returned. On October 26 she consulted her doctor again, complaining of distension of the abdomen. He saw her again on November 23, after learning that she had been put on the list for admission to hospital. The swollen abdomen was so much worse that he phoned the hospital and got her admitted within 48 hours.

On necropsy it was found that her liver was necrotic. It was slightly smaller than normal, with the right lobe particularly small, blotchy yellow in external appearance, and on cut section very fatty and yellow with a nutmeg pattern at the periphery. Death was certified as being caused by acute liver failure due to subacute hepatitis.

At the inquest held by the Sheffield City Coroner on December 13, 1956, the deceased's brother gave evidence that she had first become ill about Whitsun, 1956, when one night she had a temporary attack of blindness. Her local chemist gave evidence that in about May or June, 1956, she had come to his shop and asked for turpentine substitute, telling him that she had been told it was good for slimming. He refused to sell her any without asking a doctor if it would do her any harm. One of his doctor customers, when asked, said that if anyone was taking that they would not need his services much longer. When he passed this on she said, "My God," and made it clear to him that she had been taking it for some time but would take it no more.

The consulting pathologist to the hospital said that turpentine substitute, which was a distillate from coal and some form of hydrocarbon, taken internally up to the time of the conversation with the chemist could have caused the necrosis of the liver which he had found. Once the damage was done there was no cure, and although she stopped taking it the necrosis would get steadily worse until it caused death. Assuming that she had taken the turpentine substitute, he had no doubt that it was this which had caused the necrosis.

A verdict of death by misadventure was recorded.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending January 5 (No. 1) and corresponding week 1956.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.

† Includes primary and influenzal pneumonia.

§ Includes puerperal pyrexia

Vital Statistics

England and Wales in 1956

The infant mortality rate again reached a low record in England and Wales in 1956—namely, 23.8 per 1,000 related live births. It was 24.9 in 1955 and 52.8 in 1938. The number of infant deaths was 16,471. Live births numbered 699,059, which was the highest number since 1949. The birth rate was 15.7 per 1,000 population. The deaths registered in the year numbered 521,402, giving a rate of 11.7 per 1,000 population, the same as for 1955. The stillbirth rate was 23.0 per 1,000 live and stillbirths; this rate has not changed much in the last 5 years.

Fourth Quarter, 1956.—The live birth rate was 14.6 per 1,000 population and the infant mortality rate 23.9 per 1,000 live births—a record low figure for the fourth quarter. The general death rate was 11.3 per 1,000 population, as compared with 11.1 in 1955 and 11.4 in 1954.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases (deaths for influenza) of certain diseases notified weekly in England and Wales (great towns for influenza). Highest and lowest figures reported in each week during the years 1947-55 (influenza, 1952-5) are shown thus ----, the figures for 1956-7 thus —. Except for the curves showing notifications in 1956-7, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

Infectious diseases were more prevalent during the week ending January 5 in England and Wales, and the rises in notifications included 4,092 for measles, from 6,878 to 10,970, 844 for whooping-cough, from 1,265 to 2,109, 244 for acute pneumonia, from 400 to 644, 187 for dysentery, from 348 to 535, and 48 for scarlet fever, from 524 to 572.

The largest increases in the incidence of measles were 715 in Lancashire, from 1,877 to 2,592, 503 in Yorkshire West Riding, from 416 to 919, 433 in Essex, from 704 to 1,137, 360 in London, from 438 to 798, 307 in Surrey, from 129 to 436, 234 in Yorkshire East Riding, from 285 to 519. The largest rises in the notifications of whooping-cough were 90 in Glamorganshire, from 24 to 114, 73 in London, from 53 to 126, 64 in Yorkshire West Riding, from 74 to 138, 63 in Kent, from 103 to 166, and 57 in Lancashire, from 158 to 215. Only small fluctuations were recorded in the local returns of scarlet fever. 2 cases of diphtheria were notified, 1 fewer than in the preceding week.

63 cases of acute poliomyelitis were notified during the week, and these were 5 more for paralytic and 9 more for non-paralytic cases than in the preceding week. The largest returns were Lancashire 11 (Clitheroe M.B. 3, Bolton C.B. 2), London 6 (Woolwich 2), Middlesex 6 (Wembley M.B. 2), and Yorkshire West Riding 5 (Saddleworth U.D. 2, Bowland R.D. 2).

The largest returns of dysentery were Warwickshire 105 (Coventry C.B. 90, Birmingham C.B. 9), Yorkshire West Riding 105 (Bradford C.B. 24, Leeds C.B. 19, Sheffield C.B. 19), Lancashire 95 (Liverpool C.B. 23, Blackburn R.D. 18, St. Helens C.B. 10), London 43 (Woolwich 11), and Surrey 26 (Mitcham M.B. 17).

Week Ending January 12

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 528, whooping-cough 2,486, diphtheria 9, measles 9,281, acute pneumonia 648, acute poliomyelitis 72, dysentery 530, paratyphoid 4, and typhoid fever 1.

Medical News

R.C.P. and Medical Education.—A steering committee is meeting shortly to consider plans for a permanent organization for the discussion of problems connected with medical education and for the promotion of research in this field. The initiative for this move comes from the Royal College of Physicians of London. On November 23 the President, Sir RUSSELL BRAIN, invited some 70 persons, broadly representative of medical teaching and the licensing bodies, with others, to a preliminary conference at the College at which the proposal was discussed and the steering committee appointed. There will be a second meeting of the conference when the steering committee's recommendations are ready.

New General Hospital for Huddersfield.—The Leeds Regional Hospital Board has released some details of a new 600-bed general hospital which is to replace the Green Lea Hospital at Huddersfield. Clearing of the site is expected to begin on March 1, and building early next year. The total cost is rather more than £2.75 million. The work will be done in two phases. The first, costing £1.5 million and included in the Ministry's schedule of capital schemes for starting in 1957-8, will provide half the beds, four operating theatres, radiological, out-patient, and pathological departments, and various other buildings. It will take about 3½ years to complete. Besides the remaining 300 beds, the second phase includes plans, among other things, for a nurses' training school. The site being restricted, the new hospital will take the form of a "vertical" building: with its eight or nine stories, it will be high in relation to the ground area covered. While it is being built the functions and staff of the Green Lea Hospital will be transferred to St. Luke's Hospital.

Three New Journals.—Three new medical journals made their appearance during the last quarter of 1956. The first is a British edition of the American monthly *Antibiotic Medicine and Clinical Therapy*; the British edition will also appear monthly. It is published by MD Publications Inc., whose London address is Effingham House, Arundel Street, London, W.C.2. The annual subscription is £2 (single issues 3s. 8d.). On the cover it is stated that the circulation is 20,000. The editors, who all are American, are Dr. HENRY WELCH (chief), Dr. FELIX MARTI-IBÁÑEZ (associate), and Dr. A. H. HOLLAND, jun. (consulting). The British members of the editorial board of 26 are Professor George Brownlee, Professor Robert Cruickshank, Sir Howard Florey, Professor F. R. G. Heaf, Professor Alan Kekwick, Sir Cecil Wakeley, Dr. R. R. Willcox, Professor John Yudkin, and Dr. K. Zinnemann. From India comes a new quarterly—the *Indian Journal of Public Health*. This is the journal of the Indian Public Health Association. It is edited by Dr. B. C. DAS GUPTA, formerly director of health services in West Bengal. This journal, which is in English, is obtainable from the offices of the Indian Public Health Association, 110, Chittaranjan Avenue, Calcutta, 12. The cost to inland subscribers is Rs. 8 for a year; Rs. 2.8 for a single copy. The first issue runs to 106 pages. Besides a message of good will from the Minister of Health of West Bengal, Dr. A. D. MUKHERJI, there are six original contributions, leading articles, abstracts from current literature on public health, notes and news, reviews, and other features. The last journal, *Living Conditions and Health*, also a quarterly, is described as an "international" medical journal. It appears in identical form in English, Chinese, French, German, Russian, and Spanish, and is published in London, Peking, Paris, Vienna, Moscow, and Santiago. It owes its origin to a conference called the "World Congress of Doctors for the Study of Present-day Living Conditions," which was held in Vienna in May, 1953. The editor-in-chief is Dr. F. SCHOLL (29/3, Wollzeile, Vienna, 1, Austria), and included on the 33-strong editorial committee are Dr. P. D'Arcy Hart, Professor L. Penrose, and Dr. Alice Stewart

from Great Britain. The annual subscription is £1 6s. (single copies 7s. 6d.). Orders for the English edition may be placed with Dr. A. RYLE, the Caversham Centre, 25, Caversham Road, London, N.W.5.

Active Membership of W.H.O.—Albania and Bulgaria, who withdrew from active membership of the World Health Organization in 1950 and 1949 respectively, have now decided to resume their participation. These are the first two countries to respond to the resolution, passed at last year's World Health Assembly, which by waiving certain dues was designed to encourage resumption of active membership. There now remain seven inactive member nations—Czechoslovakia, Hungary, Poland, Rumania, the U.S.S.R., the Ukrainian S.S.R., and the Byelorussian S.S.R.

Standing Committee on Detergents.—The Minister of Housing and Local Government, in consultation with the Secretary of State for Scotland, has now appointed the standing technical committee on synthetic detergents, whose formation he announced to Parliament on December 18. Its tasks are to keep under review possible difficulties in sewage works, rivers, and water supplies occasioned by the use of detergents, and to encourage research on this problem and assist in its co-ordination. The committee is to report progress at least once a year. The chairman is Mr. H. W. CREMER, a partner in a firm of consulting chemical engineers. The committee includes two medical men, Dr. E. WINDLE TAYLOR, director of water examination of the Metropolitan Water Board, and Dr. N. R. BEATTIE, of the Ministry of Health. Also on the committee are scientific representatives of the major firms concerned in the manufacture of detergents, Government scientists and inspectors, and others. The secretary is Mr. D. H. A. PRICE, of the Ministry of Housing and Local Government.

Royal Society Research Appointments.—Dr. J. T. EAYRS, of the department of anatomy at Birmingham University, has been appointed Head research fellow from October 1, 1957. He will study mechanism in neural integration. Dr. D. W. KENNARD, of Cambridge University, has been appointed Stohert research fellow from January 1 last. He will investigate reflex activity of the spinal cord, working in the physiology laboratory at Cambridge.

Commonwealth Bursaries.—Two awards under the Royal Society and Nuffield Foundation Bursaries Scheme particularly concern medicine. Dr. H. J. HEINZ, head of the department of parasitology of the South African Institute for Medical Research, Johannesburg, receives an award to allow him to study ankylostomiasis in Nigeria. Dr. E. A. BOULTER, of the Government's Microbiological Research Establishment at Porton, goes for four months to the Australian National University, Canberra, to study the pox viruses and the virus of myxomatosis.

Bequests to Royal Free.—Among the bequests of the late Professor WINIFRED CULLIS, who died last November, were £1,000 to the Royal Free School of Medicine, and £200 to the Royal Free Hospital for the benefit of the nurses. Professor Cullis's association with the Royal Free spanned more than half a century. It began when she was appointed demonstrator of physiology there in 1901, and ended only with her death.

French Prize for Medical Films.—The last date for the receipt of films entered for *Presse Médicale's* annual 100,000-francs prize for hitherto unpublished medical films by amateurs is February 28. Films may be in colour or not, with or without sound, but they must be 16 mm. Films made by firms or commercially subsidized will not be eligible. The teaching value as well as technical excellence will be taken into account in judging the entries. Further details may be obtained from the editorial office of *Presse Médicale*, 120, Boulevard Saint-Germain, Paris, 6.

Prize for Registrar Anaesthetists.—The Section of Anaesthetics of the Royal Society of Medicine offers a prize of £30 for the best paper on a subject connected with anaesthesia by a registrar anaesthetist. Fellowship of the society

is not a condition of entry. Further details can be obtained from the hon. secretary of the Section, 1, Wimpole Street, London, W.1.

Welsh National School of Medicine.—Dr. J. G. LAWSON, lecturer in obstetrics and gynaecology at Aberdeen, has been appointed senior lecturer at the Welsh National School of Medicine. Dr. Lawson graduated (with distinction) at St. Andrews in 1943.

Honorary Degree for Lord Malvern.—Rhodes University, Cape Province, is to confer the honorary degree of Doctor of Laws on Lord MALVERN, formerly Prime Minister of the Federation of Rhodesia and Nyasaland. It is hoped to confer the degree at the graduation ceremony on March 29.

COMING EVENTS

Liverpool University Medical Students' Society.—Annual dinner for past and present members will be held at the Adelphi Hotel, Liverpool, on February 7. Tickets (25s.) from Medical Dinner Secretary, Medical School, Liverpool 3.

Contraceptive Technique.—Lecture-demonstration by MARIE STOPES, D.Sc., at the Mothers' Clinic, 108, Whitfield Street, London, W.1, on February 7 at 2.30 p.m. No fee is charged, but tickets must be obtained in advance.

Hunterian Oration.—Sir ERNEST FINCH will deliver the Hunterian Oration at the Royal College of Surgeons, Lincoln's Inn Fields, London, W.C.2, on February 14 at 4 p.m. His subject will be "The Influence of the Hunters on Medical Education."

Industrial Welfare Society.—One-day conference on industrial health at the Rembrandt Hotel, Thurloe Place, London, S.W.7, on February 21. Intended for executives, industrial medical officers, and senior nurses. Details from the society, 48, Bryanston Square, London, W.1.

Laboratory Animals Bureau.—Tenth congress will be held at the Royal (Dick) School of Veterinary Studies, Edinburgh, April 4 and 5. Details from the Laboratory Animals Bureau, M.R.C. Laboratories, Holly Hill, London, N.W.3.

NEW ISSUES

British Journal of Preventive and Social Medicine.—The new issue (Vol. 10, No. 4) is now available. The contents include: OCCURRENCE AND AETIOLOGY OF LUNG CANCER IN NORWAY IN THE LIGHT OF PATHOLOGICAL ANATOMY. Leiv Kreyberg. COHORT ANALYSIS OF MORTALITY RATES AS AN HISTORICAL OR NARRATIVE TECHNIQUE. R. A. M. Carr. COHORT ANALYSIS OF CANCER MORTALITY IN ENGLAND AND WALES, 1911-1954, BY SITE AND SEX. R. A. M. Carr. GENERAL PRACTICE ON A NEW HOUSING ESTATE. J. H. F. Brotherton and S. P. W. Chave. INDEX TO VOLUME 10, 1956.

Issued quarterly; annual subscription £2 2s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, January 28

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., films: (1) Bronchial Anatomy and Bronchoscopy; (2) Mechanical Artificial Ventilation of the Lungs.

Tuesday, January 29

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Professor C. A. Keele: Causes of Pain.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Mr. A. K. Munro: Gravitational Ulcers.

LIVERPOOL UNIVERSITY.—At Arts Theatre, Victoria Building, 5.15 p.m., Sherrington Lecture by Professor Wilder Penfield, O.M., F.R.S. (Montreal): Cerebral Cortex of Man: An Interpretation of Responses to Electrical Stimulation.

ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Sir Geoffrey Todd: Operative Treatment of Pulmonary Tuberculosis and its Prognosis (with lantern slides).

ROYAL STATISTICAL SOCIETY: MEDICAL SECTION.—At Keene Lecture Theatre, Westminster Medical School, 5.30 p.m., Mr. F. D. K. Liddell: Statistical Problems of the National Coal Board Medical Service.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Institute Theatre, 5 p.m., Mr. T. L. T. Lewis: Use of Drugs in Modern Obstetrics.

Wednesday, January 30

BRITISH PSYCHO-ANALYTICAL SOCIETY.—At Royal Society of Medicine, 8.30 p.m., Ernest Jones Lecture by Dr. Margaret Mead: Changing Patterns of Parent-Child Relations in an Urban World.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. H. Haber: Nodular Lesions of the Legs.

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. J. L. Livingstone: Asthma.

INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Mr. J. D. Fergusson: Prostatic Cancer.

LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.—At National Hospital, Queen Square, W.C.1, 8.30 p.m., Dr. Macdonald Critchley: Crimes of Dr. Marcel Petit.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Dr. N. H. Ashton: Pathology and Aetiology of Retrolental Fibroplasia.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—5 p.m., Burns Lecture by Dr. D. V. Hubble: Some Principles of Homoeostasis.

ROYAL MEDICAL SOCIETY, EDINBURGH.—2.30 p.m., Industrial Visit to Edinburgh Slaughterhouse.

Thursday, January 31

GLASGOW UNIVERSITY MEDICO-CHIRURGICAL SOCIETY.—7.30 p.m., Dr. Ian D. Grant: Medical Services in Other Lands.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Mr. A. K. Munro: Skin Tumours.

LONDON JEWISH HOSPITAL MEDICAL SOCIETY.—At Medical Society of London, 8.30 p.m., Dr. A. H. Douthwaite: Development of Sadium.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.30 p.m., Otolaryngology Lecture by Professor E. W. Walls: A Critical Anatomical Assessment of Certain Signs and Symptoms in the Field of Otorhinolaryngology.

ROYAL NORTHERN HOSPITAL.—2.45 p.m., Dr. A. Coady: The Medical Out-patient Service and the Family Doctor's Problems (discussion invited).

ROYAL SOCIETY.—11 a.m., discussion to be opened by Dr. A. S. Parkes, Sc.D., F.R.S.: Viability of Mammalian Cells and Tissues After Freezing.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Sir Paul Mallinson: psychiatric demonstration.

UNIVERSITY COLLEGE LONDON.—At Anatomy Theatre, Gower Street, W.C.1, 1.15 p.m., Professor L. S. Penrose, F.R.S.: Uncommon Case of the Porcupine Man.

UNIVERSITY COLLEGE LONDON: DEPARTMENT OF PHARMACOLOGY.—At Physiology Theatre, Gower Street, W.C.1, 5.15 p.m., Professor F. Bergel, D.Phil.Nat., Ph.D., D.Sc., F.R.I.C.: Recent Advances in Cancer Research.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Sir Paul Mallinson: psychiatric demonstration.

UNIVERSITY COLLEGE LONDON.—At Anatomy Theatre, Gower Street, W.C.1, 1.15 p.m., Professor L. S. Penrose, F.R.S.: Uncommon Case of the Porcupine Man.

UNIVERSITY COLLEGE LONDON: DEPARTMENT OF PHARMACOLOGY.—At Physiology Theatre, Gower Street, W.C.1, 5.15 p.m., Professor F. Bergel, D.Phil.Nat., Ph.D., D.Sc., F.R.I.C.: Recent Advances in Cancer Research.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Sir Paul Mallinson: psychiatric demonstration.

UNIVERSITY COLLEGE LONDON.—At Anatomy Theatre, Gower Street, W.C.1, 1.15 p.m., Professor L. S. Penrose, F.R.S.: Uncommon Case of the Porcupine Man.

UNIVERSITY COLLEGE LONDON: DEPARTMENT OF PHARMACOLOGY.—At Physiology Theatre, Gower Street, W.C.1, 5.15 p.m., Professor F. Bergel, D.Phil.Nat., Ph.D., D.Sc., F.R.I.C.: Recent Advances in Cancer Research.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Sir Paul Mallinson: psychiatric demonstration.

UNIVERSITY COLLEGE LONDON.—At Anatomy Theatre, Gower Street, W.C.1, 1.15 p.m., Professor L. S. Penrose, F.R.S.: Uncommon Case of the Porcupine Man.

UNIVERSITY COLLEGE LONDON: DEPARTMENT OF PHARMACOLOGY.—At Physiology Theatre, Gower Street, W.C.1, 5.15 p.m., Professor F. Bergel, D.Phil.Nat., Ph.D., D.Sc., F.R.I.C.: Recent Advances in Cancer Research.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Sir Paul Mallinson: psychiatric demonstration.

UNIVERSITY COLLEGE LONDON.—At Anatomy Theatre, Gower Street, W.C.1, 1.15 p.m., Professor L. S. Penrose, F.R.S.: Uncommon Case of the Porcupine Man.

UNIVERSITY COLLEGE LONDON: DEPARTMENT OF PHARMACOLOGY.—At Physiology Theatre, Gower Street, W.C.1, 5.15 p.m., Professor F. Bergel, D.Phil.Nat., Ph.D., D.Sc., F.R.I.C.: Recent Advances in Cancer Research.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Sir Paul Mallinson: psychiatric demonstration.

UNIVERSITY COLLEGE LONDON.—At Anatomy Theatre, Gower Street, W.C.1, 1.15 p.m., Professor L. S. Penrose, F.R.S.: Uncommon Case of the Porcupine Man.

UNIVERSITY COLLEGE LONDON: DEPARTMENT OF PHARMACOLOGY.—At Physiology Theatre, Gower Street, W.C.1, 5.15 p.m., Professor F. Bergel, D.Phil.Nat., Ph.D., D.Sc., F.R.I.C.: Recent Advances in Cancer Research.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Sir Paul Mallinson: psychiatric demonstration.

UNIVERSITY COLLEGE LONDON.—At Anatomy Theatre, Gower Street, W.C.1, 1.15 p.m., Professor L. S. Penrose, F.R.S.: Uncommon Case of the Porcupine Man.

UNIVERSITY COLLEGE LONDON: DEPARTMENT OF PHARMACOLOGY.—At Physiology Theatre, Gower Street, W.C.1, 5.15 p.m., Professor F. Bergel, D.Phil.Nat., Ph.D., D.Sc., F.R.I.C.: Recent Advances in Cancer Research.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Sir Paul Mallinson: psychiatric demonstration.

UNIVERSITY COLLEGE LONDON.—At Anatomy Theatre, Gower Street, W.C.1, 1.15 p.m., Professor L. S. Penrose, F.R.S.: Uncommon Case of the Porcupine Man.

UNIVERSITY COLLEGE LONDON: DEPARTMENT OF PHARMACOLOGY.—At Physiology Theatre, Gower Street, W.C.1, 5.15 p.m., Professor F. Bergel, D.Phil.Nat., Ph.D., D.Sc., F.R.I.C.: Recent Advances in Cancer Research.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Sir Paul Mallinson: psychiatric demonstration.

UNIVERSITY COLLEGE LONDON.—At Anatomy Theatre, Gower Street, W.C.1, 1.15 p.m., Professor L. S. Penrose, F.R.S.: Uncommon Case of the Porcupine Man.

UNIVERSITY COLLEGE LONDON: DEPARTMENT OF PHARMACOLOGY.—At Physiology Theatre, Gower Street, W.C.1, 5.15 p.m., Professor F. Bergel, D.Phil.Nat., Ph.D., D.Sc., F.R.I.C.: Recent Advances in Cancer Research.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Sir Paul Mallinson: psychiatric demonstration.

UNIVERSITY COLLEGE LONDON.—At Anatomy Theatre, Gower Street, W.C.1, 1.15 p.m., Professor L. S. Penrose, F.R.S.: Uncommon Case of the Porcupine Man.

UNIVERSITY COLLEGE LONDON: DEPARTMENT OF PHARMACOLOGY.—At Physiology Theatre, Gower Street, W.C.1, 5.15 p.m., Professor F. Bergel, D.Phil.Nat., Ph.D., D.Sc., F.R.I.C.: Recent Advances in Cancer Research.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Sir Paul Mallinson: psychiatric demonstration.

Germicidal Sprays

Q.—What value have germicidal sprays in reducing the incidence of infections in schools, offices, cinemas, etc.? One such contains D.D.T. in addition to chloroxyleneol and formalin. Is the D.D.T. likely to constitute any hazard if inhaled?

A.—"Germicidal sprays" can be of two sorts, designed either to kill microbes floating in the air or to kill microbes in floor dust, on furniture, etc. There is no good scientific evidence that any of the chemical air-disinfectants can control the spread of infection in places such as schools, offices, or cinemas. Nor is there good evidence that any substantial effect on the spread of illness can be obtained by disinfection of dust and fomites, though it is certain that large numbers of, for example, haemolytic streptococci may be present in the floor dust if nasal carriers are about.

There is ordinarily no hazard from sprays containing D.D.T., provided they are handled in accordance with the maker's instructions.

Vomiting of Pregnancy

Q.—Have there been any recent advances in the treatment of vomiting of pregnancy? What is the most effective drug to use?

A.—The basic principles of management of vomiting in early pregnancy have changed little in recent years. They are reassurance, mild sedation, a diet rich in carbohydrates and low in fats, and the taking of frequent small dry meals with fluids taken separately. The urine is tested, firstly to exclude any urinary infection and secondly for acetone. Acetonuria signifies that the patient's nutrition is being adversely affected and she should be transferred to hospital.

With the exact pathogenesis of the condition still unknown a variety of drugs are being employed, and they fall largely into three groups: sedatives, antihistamines, and B vitamins. Several proprietary preparations contain a combination of drugs from the three groups. Different hormones have enjoyed popularity at different times, and most recently corticotrophin and cortisone have been tried, but the more innocuous drugs mentioned earlier provide quite satisfactory results. Chlorpromazine has also been employed, especially in severe cases (hyperemesis), but the possibility of consequent jaundice has militated against its general adoption.

Infantile Gratification Habits

Q.—My daughter from about 4 months of age began to suck her night-dress or sheet when falling off to sleep, and the next morning we would find the night-dress or sheet sodden with her saliva. In an attempt to prevent this, we eventually gave her a soft napkin to suck instead. She is now nearly 20 months old and still cannot go off to sleep without it. Is there any way of breaking her of this habit, and is it harmful? Incidentally, when she awakes she is extremely thirsty. I presume this is due to her having lost so much saliva on the napkin.

A.—The questioner here rightly implies, in the way the question is asked, a doubt about whether this habit really is harmful. The same doubt could be expressed about any of the gratification habits. In young children they appear to be started off by some basic physical need, and their importance naturally depends on what that was.

In the case described the child began to suck excessively at the age of 4 months. It would be interesting to know what her feeding history and what her weaning history was. I am sure some children are seen nowadays who benefit nutritionally from starting mixed feeding at 4 months but who do not seem ready at this age to relinquish the comfort of sucking from breast or from bottle. If the onset of the sucking habit began at the time of a difficult weaning, then one might have a clue to what it represents—probably a relatively unsatisfied child—although such habits are not unknown in children who appear to

enjoy their time of sucking in an unimpeded and natural way for as long as they want. The child being thirsty is explained by the questioner by reason of the loss of saliva, but again one would wonder whether she had perhaps been very rigidly trained to accept breast or bottle at fixed times, or whether she was able to ask for it a little early or in between-times and be met with some kind of solace and response. Clearly at 20 months no one would suggest putting her back on a bottle, but there might be other ways of replacing the simple body-satisfaction that accompanies successful infant feeding.

This kind of sucking can deform the teeth, but there is no mention of this. The important thing, however, is to try to understand why this little girl wants to do it. I suspect that if her difficulty is understood, and something more done to give her simple physical gratification, as well as everything possible to encourage her to enjoy growing up, the napkin could be gently moved once the child is soundly asleep. She probably will need to go on using it for a time, but with most of these habits the less of an issue that is made of them the more easily the child seems to be able to drop them when he or she feels old enough to do without these essentially infantile types of gratification.

In short, it is probably best to regard this habit as indicating a need which the child feels to experience more comfort at the level of biological gratification, and that until she is ready to grow beyond that, or until she is helped to grow beyond it, it should be understood and used in helping her rather than arbitrarily stopped.

Painful Sequelae of Epididymo-orchitis

Q.—What investigations are indicated in the case of a man with a past history of epididymo-orchitis who complains of severe pain in the perineum and scrotum after sex-play? What treatment is advised?

A.—The most likely cause for the perineal and scrotal pain after sex-play is a residual prostatitis or vesiculitis, or both, following the attack of epididymo-orchitis. Chronic inflammation of one or both of Cowper's glands could also be responsible. A rectal examination, made before micturition and bathing in the morning, together with a laboratory report on any secretion expressed from the urethra, will show whether there is involvement of the prostate, seminal vesicles, or Cowper's glands. (It should be noted that a normal Cowper's gland is not palpable on bi-digital rectal examination.) Anterior and posterior urethroscopy may reveal a stricture of the anterior urethra or involvement of the ejaculatory ducts. Sensitivity tests on any organisms isolated will indicate what drug, whether sulphonamide or antibiotic, should be used. Massage of the affected gland may also be helpful.

Books of "Any Questions?" and Refresher Course Articles.—The following books are available through booksellers or from the Publishing Manager, B.M.A. House. Prices include postage. *Any Questions?* Volumes 2 and 3 (8s. each); *Refresher Course for General Practitioners*, Volumes 2 and 3 (26s. 6d. each inland, 26s. overseas); *Clinical Pathology in General Practice* (22s. 3d. inland, 21s. 9d. overseas).

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 4499. TELEGRAMS: *Atiology*, *Westcent*, *London*. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* and no unless the contrary be stated. Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1. on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad. ADVERTISEMENTS should be addressed to the Advertisement Director, B.M.A. House, Tavistock Square, London, W.C.1. (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 4499. TELEGRAMS: *Britmedad*, *Westcent*, *London*. MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association, TELEPHONE: EUSTON 4499. TELEGRAMS: *Medisecra*, *Westcent*, *London*. CLINICAL PICTURE OF PERNICIOUS ANAEMIA PRIOR TO INTRODUCTION OF LIVER THERAPY IN 1926 AND IN EDINBURGH SUBSEQUENT TO 1944

BY

Sir STANLEY DAVIDSON, M.D., P.R.C.P.Ed., F.R.C.P.

Professor of Medicine, University of Edinburgh; Honorary Physician to H.M. The Queen in Scotland

Thirty years have elapsed since Minot and Murphy (1926) published their historic report on the value of liver in the treatment of pernicious anaemia. With each passing year fewer and fewer physicians remain on the staffs of the teaching hospitals who have had personal experience of the clinical features and course of pernicious anaemia in the era prior to the introduction of liver therapy. During the period 1920-7, first as assistant and then as a lecturer in the Department of Medicine, University of Edinburgh, I had ample opportunity of observing the tragic and inevitably fatal termination of the disease in large numbers of patients admitted to the wards of the Royal Infirmary under the charge of my chief, Professor G. L. Gulland, a famous haematologist.

I believe that the number of persons suffering from pernicious anaemia at the present time is much greater than it was when I first became interested in the disease 36 years ago. Hence the importance of early and correct diagnosis. There are two main reasons for this increased incidence. Firstly, the introduction of liver extract and later of vitamin B₁₂ has enabled patients suffering from Addisonian pernicious anaemia to have a normal expectation of life. Secondly, at the present time there are many more people in the world within the age group 60-80 than there were at the beginning of the twentieth century, and therefore the number of persons who are liable to develop Addisonian pernicious anaemia is correspondingly greater. It has also seemed to me that certain clinical features present in the late stages of pernicious anaemia in the pre-liver era occurred so frequently and were so striking in character that they have continued to be reported as being of considerable diagnostic value, when in reality they are now of very limited importance in this respect.

Before this view could be accepted it would be necessary to demonstrate that the clinical picture of pernicious anaemia at the present time is in fact different from that seen prior to the discovery of liver therapy. Accordingly, I examined the records of 250 cases of pernicious anaemia which had been under my charge in Edinburgh during the period 1944-56 and compared them with the clinical features recorded in patients investigated prior to 1926: (1) by Davidson and Gulland (1930) in Edinburgh; (2) by Richard C. Cabot (1908) (1930) in Edinburgh; Cabot stated that he had studied the case records of (a) 337 patients under his charge in

private and hospital practice, (b) 320 case records collected from his medical friends in different parts of America, and (c) 543 cases selected by him after critical study of the literature, making a total of 1,200 cases; and (3) by Panton, Maitland Jones, and Riddoch (1923), who analysed 117 cases of pernicious anaemia admitted to the London Hospital between 1911 and 1920.

Age of Onset and Duration of Symptoms

Fig. 1 clearly shows that the age of onset of the disease is much later at the present time than it was 50 years ago. Thus more than 50% of the patients in the Edinburgh

FIG. 1.—Age of onset.

series (1950-6) developed the disease when over 60 years of age, as compared with only 10% in Cabot's series (1908). There can, however, be little doubt that this figure of 10% underestimates the true incidence. Cabot states that he included in his series 35 cases of the megaloblastic anaemia associated with pregnancy, a condition which develops in young women. In addition, some cases of the megaloblastic anaemia due to malabsorption must have been mistaken for Addisonian pernicious anaemia. Lastly, since diagnosis was much less accurate 50 years ago than it is at the present time, it would seem probable that the inclusion of cases of macrocytic anaemia due to aplastic, haemolytic, or leukaemic disease was partly responsible for the high incidence of "pernicious anaemia" stated by Cabot to occur under the age of 40 years.

TABLE I.—Duration of Symptoms

	Pre-Liver Series		Edinburgh Series 1944-56 Davidson 250 Cases
	1908 Cabot, Boston 1,200 Cases	1923 Panton, London 117 Cases	
Duration of symptoms before medical advice was sought	"Disability extending back for years"	Average 17 months	26% < 3 mths. 56% < 6 mths. 75% < 12 mths.

Table I indicates that the duration of symptoms prior to diagnosis is much shorter to-day than it was in the pre-liver era. Cabot states that many of his cases had symptoms

"extending back for years," and Panton states that the "average duration of the illness was 17 months prior to admission to hospital." Symptoms had been present for less than six months in 50% of the Edinburgh series (1944-56) and under one year in 75% of the cases.

Sex Incidence

Fig. 2 shows that in Cabot's series (1908) the disease affected males twice as often as females, whereas in an Edinburgh series of 600 cases seen during the period 1938-56

FIG. 2.—Sex incidence.

females were affected twice as often as males. A recent analysis of 223 cases examined in Glasgow showed an incidence of three females to one male (personal communication from Professor L. J. Davis). Wintrobe (1951) states that in the United States of America and in England males have been more frequently the victims of this disease than females, but in Germany and the Scandinavian countries the opposite has been recorded.

Symptoms

All authorities agree that the onset of the illness in the great majority of cases of pernicious anaemia is extremely insidious. This is as true to-day as it was 50 years ago. Patients continue to work for a surprisingly long time after the development of the disease before consulting their doctors. In addition, the anaemia is often much more severe than would be expected by the appearance of the patient or from a study of his symptoms. Table II shows

TABLE II.—Symptoms

	Pre-Liver Series		Edinburgh Series 1944-56 Davidson
	1908 Cabot, Boston	1923 Panton, London	
No. of cases	1,200	117	250
Weakness and tiredness	96%	91%	90%
Dyspnoea	88%	—	70%
Sore tongue	43%	24%	25%
	(of 372 cases)	(of 34 cases)	
Diarrhoea	51%	26%	9%
Constipation	35%	—	16%
Parosomias	100%	—	38%

that the two symptoms most commonly encountered in pernicious anaemia, both in the pre-liver era and at the present time, are *general weakness and tiredness*, and *dyspnoea on effort*. The third most frequent symptom is the feeling of numbness and tingling in the hands and feet (*paraesthesiae*). This symptom, however, occurs much less frequently now (38% of cases) than it did 50 years ago (approximately 100% of cases), as indicated in Table II. This is also true of *soreness of the mouth and tongue*, which was present in 25% of the Edinburgh series as compared with 43% of Cabot's series. Davidson and Gulland (1930) stated that this feature was present in approximately half of their cases.

While indefinite symptoms referable to the digestive tract, such as poor appetite and vague abdominal discomfort, are frequently encountered in patients with pernicious anaemia, *diarrhoea* occurred in only 9% of the Edinburgh

series. This is in marked contrast to Cabot's series, in which it was a notable feature in 51% of cases. Davidson and Gulland (1930) also state that *diarrhoea* occurred in approximately half of their cases at some stage of the illness. At the present time the complaint of constipation is twice as frequent as that of *diarrhoea*.

Signs

Apart from *pallor* of the mucous membrane and the skin, the most common finding in the Edinburgh series was a *pale smooth tongue* which was also moist and very clean. This was noted in no less than 64% of cases (see Table III).

TABLE III.—Signs

	Pre-Liver Series		Edinburgh Series 1944-56 Davidson
	1908 Cabot, Boston	1923 Panton, London	
No. of cases	1,200	117	250
Fever	79%	71%	22%
"Icterus"	Most cases	—	Uncommon
Acute glossitis (red and ulcerated)	42%	—	5%
	(of 372 cases)		
Chronic atrophic glossitis (pale and smooth)	—	—	64%
Splenomegaly	27%	18%	8%
Spinal cord damage	11%	—	7%
Ataxic type	7%	—	6%
Spastic type	4%	—	1%
Peripheral blood:			
< 2 million R.B.C./c.mm.	86%	Average	58%
< 1 million R.B.C./c.mm.	21%	1.39 million	1%

No percentage figure for this sign is available in Cabot's or Panton's series, nor in Davidson and Gulland's monograph (1930). An extraordinary cleanness of the tongue in pernicious anaemia has, however, been mentioned by many authorities as being a common feature, and this sign is undoubtedly the result of atrophy of the papillae and mucous membrane of the tongue (*chronic atrophic glossitis*). *Acute glossitis*, indicated by a beefy-red, painful, and often ulcerated tongue, was reported as being present in patients in the pre-liver era in up to 50% of cases, in contrast to only 5% of the Edinburgh series. The second most common sign in the Edinburgh series was *fever*, which was present in 22% of the cases, in contrast to 79% in Cabot's series. The frequency and degree of fever is related to the severity of the anaemia, and the pyrexia disappears when the blood supply to the heat-regulating mechanism of the brain is improved by blood transfusion or as a result of treatment.

Icterus was another sign to which much attention was paid in the pre-liver era. Cabot rightly says that it is doubtful if the waxy yellow colour of the skin, which is such a notable feature of pernicious anaemia in severe relapse, is actually due to jaundice. Be that as it may, I am certain that this appearance of the skin is much more rarely seen at the present time than it was in the era before the discovery of liver therapy.

Minor degrees of *splenomegaly* that is, the tip of the spleen being just palpable below the costal margin—were common in the pre-liver era. According to Cabot the spleen was palpable in no less than 27% of cases, but in the Edinburgh series it could be felt in only 8%. Gross enlargement of the spleen is so uncommon in pernicious anaemia that its presence should give rise to suspicion that the diagnosis is incorrect.

The *neurological features* of pernicious anaemia have always excited much interest. The name subacute combined degeneration of the cord was adopted to describe the lesions of the posterior and lateral columns of the cord which were so commonly present in patients dying of pernicious anaemia in the pre-liver era. The name is unsatisfactory in that the disease usually starts insidiously and not subacutely, combined lesions are often absent, and no cognizance is taken of the fact that lesions of the peripheral nerves occur much more frequently and much earlier than lesions of the central nervous system. If the name subacute

combined degeneration of the cord is to be retained it would appear logical to limit its use to lesions of the central nervous system. Unfortunately, even neurologists find it difficult to decide on the clinical features which clearly distinguish lesions of the posterior columns of the cord from lesions of the peripheral nerves. It is generally agreed that tendon reflexes, vibration sense, and positional sense may be reduced or absent and also that ataxia may be present in both conditions. There appear to be no infallible criteria which will distinguish the two lesions except histological examination of the affected structures.

Accordingly, the differential diagnosis during life has to be made on the basis of certain suggestive findings. Thus, hyperaesthesia of calf muscles strongly supports the diagnosis of peripheral neuritis, while loss of vibration sense extending up to the pelvis favours a lesion of the posterior columns. Lastly, a markedly disproportionate increase in the degree of impairment of muscle and joint sensibility and vibration sense on the one hand, as compared with the degree of loss of superficial sensations of touch and pinprick on the other, supports the view that the posterior columns are affected. The presence of an extensor plantar response (positive Babinski sign), clearly indicates that a lesion of the central nervous system is present, but it must be remembered that in pernicious anaemia the lateral columns of the cord are affected much more rarely and usually much later than are the posterior columns. It should also be noted that peripheral neuritis may be due to a specific deficiency of vitamin B₁₂ or it may result from anoxaemia of the peripheral nerves as a consequence of anaemia and cardiac weakness. In the former case it may be present when anaemia is minimal in degree and it will respond dramatically to vitamin B₁₂ therapy. In the latter case it may occur in association with any form of anaemia, but only if the degree of anaemia is sufficiently severe, and it will not respond to vitamin B₁₂ therapy, but will disappear when the haemoglobin level is raised by any method, including blood transfusion.

In assessing the incidence of subacute combined degeneration of the cord in the Edinburgh series of 250 patients, cases have not been included in which the only neurological features were of paraesthesiae and the subjective sensation of unsteadiness, since both these symptoms can be due to causes other than disease of the nervous system. Patients were classified as having involvement of the posterior columns if ataxia was a prominent feature, if tendon reflexes and positional sense were reduced or absent, and if vibration sense was lost as high up as the pelvis. They were classified as having lesions of the pyramidal tract if a spastic gait was present with increased tendon reflexes, extensor plantar response, and a greater or lesser degree of paralysis. These groups are therefore comparable to the two groups described by Cabot (1908) as the "ataxic type" and the "spastic type." Table III shows that involvement of the central nervous system was present in only 11% of Cabot's series and in 7% of the Edinburgh series. This is in contrast to the frequency of occurrence of paraesthesiae as indicated in Table II.

One of the most striking features of Table III is the difference in the degree of anaemia present in the three series when medical advice was first sought. Whereas 21% of Cabot's series had a blood count of less than one million red cells per c.mm., only 1% of the Edinburgh series showed a similar degree of anaemia. Panton's series also showed a very high incidence of severely anaemic cases, the average red cell count being 1.39 million per c.mm.

Summary and Conclusions

Evidence is presented to show that the clinical picture of pernicious anaemia is very different to-day from that seen prior to the introduction of liver therapy. This difference is due to the fact that as a consequence of the improved facilities for early diagnosis and treatment which are now available the degree of anaemia in

patients seeking medical advice at the present time is much less than was the case fifty years ago. Hence it is not surprising that certain clinical features which were held to be of particular diagnostic importance in the pre-liver era—namely, jaundice, splenomegaly, acute glossitis, *diarrhoea*, and subacute combined degeneration of the cord—were present in less than 10% of the patients with pernicious anaemia investigated in the Blood Clinic in Edinburgh during the past ten years. Accordingly, undue emphasis on such features in textbooks of medicine and in lectures is to be deprecated, since it will hinder rather than help early diagnosis.

It is essential to tell undergraduate and postgraduate students that there are no pathognomonic symptoms or signs which will establish the diagnosis of pernicious anaemia; that tiredness, breathlessness, paraesthesiae, and chronic atrophic glossitis are presenting features which occur frequently in other types of anaemia and in particular in cases of iron-deficiency anaemia; and that diagnosis must be based on accurate blood examination, supplemented sometimes by special methods of investigation.

I am grateful to Dr. J. Richmond, Lecturer in the University of Edinburgh, for his help in collecting and tabulating the data given in the Tables and Figures.

CLINICAL SIGNIFICANCE OF WEIGHT TRENDS DURING PREGNANCY

BY

A. M. THOMSON, M.B., D.P.H.

AND

W. Z. BILLEWICZ, M.Sc.

Obstetric Medicine Research Unit (Medical Research Council), Department of Midwifery and Gynaecology, University of Aberdeen

Regular measurement of body weight during pregnancy is clinically valuable. For example, progressive loss of weight helps to confirm the seriousness of vomiting, while a sudden increase of weight may precede the appearance of oedema. It is usually easier to explain a sudden alteration in the rate at which an individual patient gains weight than to explain why overall gains in different patients vary so widely. A few patients gain very little weight, while others gain 50 lb. (22.7 kg.) or more. The impression that many patients who develop pre-eclampsia have high average rates of gain is well substantiated, but there is comparatively little exact numerical information.

The statistical evaluation of weight changes in pregnancy is difficult. A true and complete picture could be obtained only by weighing all pregnant women in a representative community at frequent intervals from conception until delivery, which is practically impossible. It is usual to circumvent the technical difficulties by reporting only on patients fulfilling certain arbitrary criteria. For example, Humphreys (1954) studied 1,000

"normal" mothers, the criteria of normality including such items as first antenatal visit before the 13th week of gestation and last antenatal visit within seven days of delivery; while Scott and Benjamin (1948) selected 360 women weighed regularly at four-weekly intervals from the 16th week. It is difficult to know whether selection on such lines introduces much distortion of results. Some of the difficulties can be avoided by restricting analyses to weight changes during a limited period of pregnancy. Hamlin (1952) has suggested that the 10-week period, 20-30 weeks,* is especially significant in relation to the prevention of eclampsia and pre-eclampsia by weight regulation. Data for this period can be obtained for the majority of cases, since most women come under antenatal care before mid-pregnancy, and few are delivered before the 30th week.

In centres where weight gain is controlled as part of antenatal care it is impossible to obtain a "natural" picture. During the years under review no attempt was made to restrict the amount of weight gained by patients.

Primigravidae are more liable to develop pre-eclampsia and many other complications than multigravidae; therefore studies in which various parities are taken together are not easily interpreted. The analysis which follows relates the "natural" rate of weight gain in primigravidae, especially during the period 20-30 weeks, to the clinical outcome. The findings are discussed in relation to proposals by Hamlin (1952), Dieckmann (1952), and others that severe restriction of the rate of gain helps to prevent eclampsia and pre-eclampsia.

Methods

Patients were weighed at the first antenatal visit and again, as a rule, four to six weeks later. Most were then weighed monthly until 28-30 weeks of pregnancy, and more often during the final weeks. Accurate lever balances were used, and patients wore underclothes only. The week of pregnancy within which each weight was taken was accurately calculated in cases where reliable menstrual data were available. Since many patients did not attend during the first trimester, data for the first 13 weeks of pregnancy are too sparse to have any representative value. Trends in late pregnancy are necessarily derived from patients whose pregnancies continued until term or near it.

Records Used and Methods of Analysis

The analysis was restricted to records of legitimate first pregnancies of women resident in the city of Aberdeen and delivered in the Aberdeen Maternity Hospital as booked patients during the six years 1949-54. Multiple pregnancies were excluded. Out of 5,297 records, 1,083 were rejected because either the period of gestation was uncertain or the number of weighings was not large enough to provide the required data with sufficient accuracy. Patients whose records were thus excluded had a slightly lower average age and belonged more often to a lower social class than the remainder. The 4,214 cases analysed have pre-eclampsia, prematurity, and perinatal death rates very similar to those of all hospital-booked primiparae, and it is therefore thought that selection does not invalidate the conclusions drawn from the analyses which follow.

Since the average rate of weight gain is well known to be related to the occurrence of pre-eclampsia, the records were first divided into three clinical groups as follows: (a) Cases of pre-eclampsia with albuminuria (6.5% of all cases). (b) Cases with other hypertensive complications,

mostly mild pre-eclampsia without albuminuria (25.4%). This group includes a few cases diagnosed as essential hypertension. (c) Cases without hypertensive complications ("normotensive") (68.1%). The first group corresponds to "severe pre-eclampsia" as defined by Nelson (1955), who has discussed the problems of definition for epidemiological purposes. For the sake of brevity these relatively severe cases will in future be referred to as "pre-eclampsia," without qualification. "Hypertension" connotes a diastolic blood pressure recorded as 90 mm. Hg or above on two or more occasions separated by at least a day, or showing a definite or progressive pattern if the rise occurs in labour.

The problem was to determine whether the weight trends in each clinical group differed according to the stage of pregnancy at which weighing began. This was done by drawing average curves for 11 groups of normotensive patients, in which antenatal care began at different stages. The scatter was so small that it was thought justifiable to pool the results.

The scatter in groups of patients with pre-eclampsia and other hypertensive complications was also small.

The Chart shows the average weight curves from the 13th to the 38th week for all cases in each of the three clinical groups. The normotensive patients had the lowest average starting weight (118 lb.; 53.5 kg.), and "other hypertensive" the highest (124 lb.; 56.2 kg.). The average rate of gain, especially in the final trimester, was greatest in pre-eclamptic and least in normotensive cases. These findings justified the separation, *ab initio*, of the three clinical groups.

For each patient, weights in the 13th, 20th, 30th, and 36th weeks were determined, by interpolation if necessary, and the average weekly rates of gain in the three intervening periods calculated. These average weekly rates of gain were the data used for most purposes. The number of cases in each period is different, because some patients had not reported early enough, or were delivered too early or were weighed too irregularly, for inclusion in all three periods.

Results

Average Weight Gains and Variations of Gain

Table I shows the average gain per week in each of the three periods and three clinical groups, together with their standard errors. In normotensive patients the average rate

TABLE I.—Average Rates of Gains in Three Periods of Pregnancy

Clinical Group		13-20 Weeks	20-30 Weeks	30-36 Weeks
Pre-eclampsia with albuminuria	No. of cases	166	274	267
	Av. gain/week (lb.) (g.)	1.00 (.036) 454 (16)	1.23 (.027) 558 (12)	1.50 (.068) 680 (31)
"Other hypertensive complications"	No. of cases	533	1,072	1,067
	Av. gain/week (lb.) (g.)	0.95 (.019) 431 (9)	1.14 (.013) 517 (6)	1.08 (.017) 490 (8)
Normotensive	No. of cases	1,362	2,868	2,833
	Av. gain/week (lb.) (g.)	0.92 (.011) 417 (5)	1.03 (.007) 467 (3)	0.87 (.009) 393 (4)

Standard errors are shown in parentheses. In each period the differences between means for clinical groups are statistically significant.

Average weight-gain curves in three clinical categories of primigravidae.

of gain was greater in the period 20-30 weeks than either before or after, whereas in pre-eclampsia the rate of gain tended to increase as pregnancy progressed and was greater at all stages than in the average normotensive case. Further analysis shows that in the period 20-30 weeks the proportion of patients gaining more than 1.6 lb. (726 g.) per week is nearly three times as high in those who eventually develop pre-eclampsia as in those who remain normotensive. This ratio becomes 6 to 1 in the period 30-36 weeks, owing no doubt to oedema adding to the rate of gain in pre-eclampsia. There is, nevertheless, so much overlap that the predictive value of rates of gain is relatively small. The rates of gain are significantly less variable in the period 20-30 weeks than either earlier or later. This is to be expected, since complicating factors such as vomiting and oedema which affect rates of gain are least common in the period 20-30 weeks.

The 20-30 weeks series includes 11 patients who had eclamptic fits. The distribution of weight gains in these is very similar to that for cases of pre-eclampsia.

The total weight gains for the period 13-36 weeks are estimated to be 21.9, 24.6, and 28.3 lb. (9.9, 11.2, and 12.8 kg.) for normotensive, "other hypertensive," and pre-eclampsia cases respectively; for all cases together 23.1 lb. (10.5 kg.). To these may be added 2.5 lb. (1.1 kg.) for the first trimester (Chesley, 1944); while the gain from the 36th to the 40th week in normotensive cases was 3.2 lb. (1.5 kg.) and in all cases 4 lb. (1.8 kg.). Thus the gain during the whole of pregnancy is estimated to be 27.6 lb. (12.5 kg.) for normotensive cases alone and 29.6 lb. (13.4 kg.) for all cases in which pregnancy continued until term. A comparable figure for pregnancies complicated by pre-eclampsia would have limited significance, since a relatively high proportion terminate before the 40th week.

Average rates of weight gain do not vary greatly according to the social class, height, or age of patients. Women in the upper social classes and tall women gain slightly more in each period than the others, but the differences are too small to have clinical importance. Older women tend to gain slightly less than those who are young.

The rates of weight gain cannot be related to the usual non-pregnant weight for height (fatness or leanness), since the weight before pregnancy is seldom known. It was therefore decided to study the weight for height at the 20th week in relation to the rate of gain during the period 21-30 weeks. An "obesity index" was calculated for each patient by relating the weight at the 20th week to the median weight at the 20th week for all patients of the same height. The average weight gains did not vary much in relation to the "obesity index." Underweight women tended to gain the "obesity index." Underweight women tended to gain at slightly lower rates than usual. Since "obesity" was assessed at the 20th week of pregnancy, a high index may, of course, mean simply that the women concerned had put on a relatively great amount of weight during the first half of pregnancy. This may be why women who were moderately overweight at the 20th week had a slightly higher than average rate of gain during the next 10 weeks. On the other hand, women who were unusually heavy at 20 weeks did not gain more than the average.

Clinical Outcome in Relation to Weight Gain

The differences of weight gain in the three main clinical groups are shown in Table I and the Chart. In the analyses which follow, the data for all cases are grouped according to weight gain and the incidence of certain complications in each weight gain category is shown. The complications in each weight gain category are shown. The data used are those for the periods 20-30 and 30-36 weeks; analyses of clinical phenomena in relation to rates of weight gain before the 20th week are of limited value, since the necessary weight data are not available for more than half the cases (Table I). The cases omitted are known to have relatively high rates of prematurity and of perinatal death; they were, for the most part, women who first attended the clinic after mid-pregnancy.

TABLE II.—Clinical Outcome in Relation to Amount of Weight Gained in the 16-Weeks Period, 20-36 Weeks

Weight Gained		Pre-eclampsia %	Pre-maturity %	Percentage of Prematures* with Pre-eclampsia	Perinatal Mortality per 1,000	No. of Cases
lb.	kg.					
< 8	< 3.6	2.6	12.1	9	36.0	273
8	3.6	3.3	8.3	9	11.9	671
12	5.4	3.1	5.5	16	27.8	1,090
16	7.3	5.7	4.4	25		1,009
20	9.1	9.2	4.9	35		651
24	10.9	13.5	5.7	47		296
28+	12.7+	26.0	8.5	66		177

* Birth weight 5½ lb. (2,500 g.) or under.

Table II shows the trends in relation to the amount of weight gained in the 16 weeks period 20-36 weeks. Amongst women who gained 8 lb. (3.6 kg.) or less—that is, at an average rate not exceeding 0.5 lb. (227 g.) a week—the incidence of pre-eclampsia was 2.6%. The incidence increased steadily with increasing rate of weight gain until, in women gaining 28 lb. (12.7 kg.) or more, equal to an average gain of at least 1.75 lb. (794 g.) a week, it was ten times as great (26%). The incidence of prematurity (birth weight 5½ lb. (2,500 g.) or less) shows an opposing trend, falling as the weight gain increases, except that it rises again when the gain becomes very large, owing to the fact that a high proportion of the prematures in the groups with the high weight gain were the result of pre-eclampsia. The high rate of prematurity (defined as low birth weight) associated with low weight gains appears, in the main, to arise from poor foetal growth resulting in the birth of relatively small babies and not from the effects of the well-recognized diseases of pregnancy. But as the rate of weight gain increases, the proportion of prematures associated with pre-eclampsia rises steeply, and in the groups with the highest weight gain the relatively high rate of prematurity is due primarily to premature termination of pregnancy either spontaneously or after induction of labour owing to pre-eclampsia.

The perinatal mortality rates shown in Table II are underestimates, since pregnancies ending much before the 36th week, which have a very high mortality rate, are not included in the data.

Table III shows the incidences of pre-eclampsia, "other hypertensive complications," prematurity, and perinatal death according to the rate of weight gain in the periods 20-30 weeks and 30-36 weeks separately. The grouping of rates of gain is arbitrary, being designed to give reasonably adequate numbers in all categories.

Pre-eclampsia and "other hypertensive complications" both show the same pattern, the highest rates being found when the rate of gain is high in the 30-36 weeks period, irrespective of the rates of gain between 20 and 30 weeks. In the period 20-30 weeks, women gaining more than 1.2 lb. (544 g.) a week had a relatively high expectation of pre-eclampsia, unless the rate of gain subsequently fell below 1 lb. (454 g.) a week in the period 30-36 weeks.

In the case of prematurity, the highest rates are found where the weight gain has been low in the period 20-30 weeks, and especially when the rate of gain has been unusually low or unusually high in the period 30-36 weeks. The rate was only 3%, less than half the average, when the gain was moderate in both periods—that is, 0.8-1.2 lb. (363-544 g.) a week from the 20th to the 30th week, and 0.6-1 lb. (272-454 g.) a week from the 30th to the 36th week.

The advantage of this moderate rate of gain is even more strikingly demonstrated in the perinatal mortality rate. The very low death rate found, 11 per 1,000 births, could be as low as it is by pure chance; however, the statistical probabilities indicate that a rate higher than 20 is unlikely. This low death rate probably reflects the fact that in this weight-gain group the foetus has the best chance of escaping the hazards of pre-eclampsia and of prematurity. In general, the trends of perinatal mortality follow those of prematurity rather than of pre-eclampsia.

TABLE III.—Incidence of Certain Complications by Rates of Weight Gain in the Periods 20–30 and 30–36 Weeks of Pregnancy

Gain per Week, 20–30 Weeks		Gains per Week, 30–36 Weeks

* Rates in brackets based on fewer than five deaths.
† Including cases for which adequate 30–36 weeks' weight data were not available, and cases delivered from the 31st to the 36th weeks.
‡ Numbers in brackets are percentages in each "cell."

When analyses of the type shown in Table III are repeated, grouping the weight-gain categories in different ways, the same kind of pattern emerges. The same is true when patients are first subdivided according to weight for height or by "physical grade"—that is, the judgment of the obstetrician at the patient's first antenatal attendance as to her general physique and well-being. Women who were over average weight at 20 weeks had, however, higher rates of pre-eclampsia and lower rates of prematurity than underweight women in nearly all categories.

The last part of Table III shows the numbers involved and their percentage distribution. Forty per cent. of primigravidae were in the moderate weight-gain group for the period 20–30 weeks—that is, gained between 8 and 12 lb. (3.6 and 5.4 kg.). Nearly one-quarter gained less than 8 lb. (3.6 kg.). Only 15% of all cases were in the most favourable group, that which gained 8–12 lb. (3.6–5.4 kg.) from the 20th to the 30th week, and 6–10 lb. (2.7–4.5 kg.) from the 30th to the 36th week.

Discussion

The methods of analysis described were devised primarily to elucidate the clinical significance of various weight-gain patterns, the physiological basis of which will not be discussed. We have shown elsewhere (Thomson and Billewicz, 1955) that the rate of weight gain during pregnancy is positively correlated with the calorie value of the maternal diet.

The weight gains found are consistent with those previously reported. Our estimated average total gain in normal pregnancy, 27.6 lb. (12.5 kg.), and average rate of gain in the period 30–36 weeks, 0.87 lb. (395 g.) a week, are reasonably close to estimates for the total gain and for rate of gain during the last trimester made by Chesley (1944) and by Humphreys (1954).

The relationship between weight gain and incidence of pre-eclampsia follows expectation. As Chesley and others have already noted, the incidence of pre-eclampsia rises as the rate of weight gain increases, but measurement of the

rate of gain over a period of time such as 20–30 weeks has little predictive value in the individual case. It has often been suggested that the occurrence of a sudden acceleration in the rate of gain is of more clinical significance than a high average rate of gain. Our records show that this "sign" of incipient oedema or hypertension, while not without value, is not very reliable as a means of prediction.

Primigravidae who develop mild pre-eclampsia have a higher average "starting weight" (observed at the end of the first trimester) than those who develop severe pre-eclampsia or those who remained normotensive. This cannot be wholly explained in terms of age and height differences, and its significance is not clear.

The primigravida aged 30 or over is slightly taller and heavier and has a very slightly lower average rate of weight gain than the younger primigravida. As Nelson (1955) has shown, she also has an increased tendency to develop mild pre-eclampsia, but little or no special liability to severe pre-eclampsia; though when severe pre-eclampsia does supervene the foetal mortality is relatively high. But our more extensive data do not confirm Nelson's suggestion that the tendency to high rates of weight gain with severe pre-eclampsia in primigravidae occurs only under the age of 30. We have no evidence to support the claim of Tompkins, Wiehl, and Mitchell (1955) that women with abnormally low weight gains also have a raised incidence of pre-eclampsia.

It is reasonable to expect some correlation between rates of weight gain and birth weights, since the weight of the foetus accounts for part of the increase of maternal weight. This has been observed, for example, by Kerr (1943) and Beilly and Kurland (1945), and the present data confirm it. In our data, median birth weights rise steadily from 6.7 to 7.5 lb. (3 to 3.4 kg.) as the 20–30 week rates of gain increase from under 0.6 lb. (272 g.) to over 1.8 lb. (816 g.) a week. The high incidence of prematurity (birth weight 5½ lb. (2,500 g.) or less) associated with low maternal weight gains seems to be due more to depression of the foetal growth rate than to curtailment of the length of gestation. In cases of severe pre-eclampsia, usually associated with high rates of weight gain, depression of foetal growth as well as curtailment of pregnancy is usual (Baird, Thomson and Billewicz, 1957); both facts account for the excess of very small prematures in pregnancies where the 20–30 week weight gain was very large.

Where there is no policy of weight restriction during pregnancy, moderate rates of gain are clearly associated with the most favourable clinical experience. Thus, patients who gained 8–12 lb. (3.6–5.4 kg.) from the 20th to the 30th week, and at a slightly lower rate after the 30th week, had pre-eclampsia, prematurity, and perinatal mortality rates only about half the average. Higher rates of gain were associated especially with pre-eclampsia and lower rates especially with prematurity.

It does not follow logically that, if excessively high or low gains are avoided by dietary regulation and other measures, the clinical outcome will be as favourable as in those women who gain the "correct" amounts of weight when left to their own devices. But there is some evidence that restriction of excessive gains is helpful in preventing eclampsia; the evidence that such restriction prevents pre-eclampsia is less satisfactory, perhaps because pre-eclampsia is less easy to define.

Of recent reports along these lines, those by Hamlin (1952, 1953) are the most spectacular. He claimed the abolition of eclampsia (no cases in 6,600 booked patients) and a considerable reduction of severe pre-eclampsia in a large Australian hospital, thanks to an intensive programme of antenatal care, including measures aimed at limiting the amount of weight gained and the admission to hospital of cases of mild pre-eclampsia. Hamlin says that most primiparae who are allowed to gain more than 8 lb. (3.6 kg.) in the 20–30-weeks period will progress inexorably towards pre-eclampsia and eclampsia, but gives no evidence. Hughes (1951), reporting on the same Australian campaign,

merely observes that a gain exceeding 1 lb. (454 g.) a week after the fifth month of pregnancy points to the need for close observation of the patient. Of Aberdeen primiparae who remained normotensive throughout, 73% gained more than 8 lb. (3.6 kg.) in the period 20–30 weeks, compared with 85% of those who developed fairly severe pre-eclampsia. Hamlin's statement is therefore certainly not valid in Aberdeen.

Hamlin (1953) and also Nixon (1955) have republished a "normal" curve of weight during pregnancy derived from Dieckmann, Smutter, and Rynkiewicz (1952); this shows a gain of only 7.7 lb. (3.5 kg.) during the period 20–30 weeks. It is not clear how the patients from whom the curve was derived were selected, nor whether they were required to restrict their weight gains as part of antenatal care. In his monograph on the toxæmia of pregnancy Dieckmann (1952) recommends limiting the weight gain to 200 g. a week during the last 28 weeks of pregnancy, which implies a 20–30 weeks' gain of less than 5 lb. (2.3 kg.). He acknowledges that such targets may be difficult to attain even under ideal conditions: "The fact that we were only able to restrict one-third of the patients to what we consider the maximum gain during an intense nutrition study indicates how difficult it is to restrain calorie intake in these patients."

There is no doubt that, even without a policy of weight regulation, good out-patient antenatal care, backed by adequate hospital facilities, can do much to prevent eclampsia and the more serious consequences of pre-eclampsia. Between 1938–42 and 1954–5 the incidence of eclampsia in primigravidae booked in Aberdeen Maternity Hospital fell from 8 to 2 per 1,000,* and the stillbirth rate in cases of eclampsia and pre-eclampsia from 151 to 25 per 1,000 births. Nelson (1955) has discussed the reasons. We do not know whether progress would have been accelerated if weight regulation had been practised as part of routine antenatal care. The problem now is whether results can be further improved, and especially whether the need for antenatal beds required for the treatment of pre-eclampsia can be reduced by weight regulation.† These questions can be answered only by means of an *ad hoc* trial under controlled conditions.

Preliminary trials have shown that full scientific control is practically impossible to achieve because the measures needed for regulating weight changes inevitably mean that antenatal care is intensified in other respects; again, within one centre, the ideas promulgated at an experimental antenatal clinic soon begin to "infect" staff at the routine clinics from which control cases are drawn. These facts make the value of a policy of weight regulation difficult to assess scientifically. It will be some time before the data of our current trial can be quoted. It seems more easy, by careful dietary supervision, to restrict a rate of gain which has been excessive than to augment a rate of gain which seems unduly low.

The clinical hazards associated with very low "natural" rates of weight gain do not seem to have been systematically studied in the past, though the increased risk of prematurity (especially when the mother is underweight at the beginning of pregnancy) has been noted by Tompkins *et al.* (1955). Women who fail to gain an adequate amount of weight present a problem at least as important as those who gain excessively.

The rule of moderation is probably as sound when applied to weight gains during pregnancy as to many other aspects of existence. As a realistic target, we would suggest gains within the range of ½ to 1½ lb. (340 to 567 g.) a

*The current average incidence of eclampsia in booked cases of all parities, 0.8 per 1,000, is comparable with rates reported from a number of major American hospitals in 1947–9 (Dieckmann, 1952). In the latter, presumably, weight regulation has been practised for many years.

†About 16% of all Aberdeen booked primigravidae are admitted to the antenatal wards for treatment of pre-eclampsia and related conditions, which account for over 40% of the total antenatal bed-days due to primigravid admissions of all kinds, and absorb an average of about 4 antenatal beds per 1,000 booked primigravidae per annum. The equivalent figures for booked patients of all parities are 12% admitted, 26% of all bed-days, and 3 beds per 1,000 patients per annum.

week as being consistent with excellent clinical results. Roughly half of all primigravidae will "naturally" gain weight within this range from the 20th to the 30th week of pregnancy, and it may be that the proportion could be increased by measures practicable at out-patient clinics. The mean rate of gain, 1 lb. (454 g.) a week, is easily remembered, and the patients' progress easily assessed from one clinic visit to the next. There is no real justification for the lower rates that have been widely advocated. Weight restriction is not easy, and the mother who fails to comply with a rigorous schedule may become unnecessarily burdened with guilt; while the one who succeeds, possibly with considerable stress, may be running an increased risk of prematurity.

Summary

An analysis of the weight gains of primigravidae, not subjected to weight regulation, confirmed that the average rate of gain is higher in pre-eclampsia than in normal pregnancy, and that the incidence of pre-eclampsia rises as the rate of weight gain increases. These facts are of little value for predicting pre-eclampsia in the individual case.

The incidence of prematurity (birth weight 5½ lb. (2,500 g.) or less) is highest when weight gains are consistently low, falls as the rate of gain increases, and then rises again with high rates of gain. Pre-eclampsia is an important cause of prematurity in the high but not in the low weight-gain groups.

The most favourable outcome of pregnancy—in terms of pre-eclampsia, prematurity, and perinatal death—is associated with a moderate rate of weight gain, at least throughout the second half of pregnancy. A gain of about 1 lb. (454 g.) a week is suggested as a sound and realistic average to aim at. The more rigorous restriction of weight gain which has been advocated is not justified on present evidence and may be harmful.

We are grateful to Professor Dugald Baird and many of our colleagues for encouragement and criticism, and to the ladies of the records office for hard and accurate work.

"Infections in Laboratory Animals" is the subject of the fourth volume (1956) of *Collected Papers* published by the Laboratory Animals Bureau. It records the proceedings of a symposium held at the Royal Veterinary College, London, last April, and consists of seven papers on the following subjects: "Epidemiology and Laboratory Mice" (Mr. A. A. Tuffery); "Control of Ectromelia in Mouse Colonies" (Dr. M. H. Salaman); "Control of Infection in Laboratory Cats and Dogs" (Professor W. L. Weipers); "Infections in Laboratory Monkeys" (Dr. A. P. Goffe); "Control of Disease in Rabbits" (Dr. J. Stuart Paterson); "Control of Disease in Laboratory Poultry" (Dr. R. F. Gordon); and "Salmonella in Laboratory Animals" (Dr. Joan Taylor and Mr. J. D. Atkinson). In addition there are the opening remarks and summary of the meeting by the chairman, Professor J. W. Howie. The volume (pp. 68) is obtainable from the Laboratory Animals Bureau, M.R.C. Laboratories, Holly Hill, Hampstead, London, N.W.3, price 7s. 6d.

CALCIUM METABOLISM AND BONE CHANGES IN SARCOIDOSIS

BY

GORDON MATHER, M.D., M.R.C.P.

Physician, Southmead Hospital, Bristol; late Senior Medical Registrar, King's College Hospital, London

Although hypercalcaemia is uncommon in sarcoidosis it is important for two reasons. It may cause difficulties in reaching a correct diagnosis, and when persistent leads to complications such as renal failure or nephrocalcinosis. Unless this renal damage is recognized and treated it may be fatal. There is, moreover, evidence that the use of calciferol for the treatment of sarcoidosis in the last decade has increased the risk of hypercalcaemia and of its attendant dangers. The purpose of this paper is to record the frequency of disturbed calcium metabolism in a series of patients with sarcoidosis and to relate it to other features. As this involves a study of the bone lesions in the disease an account of their incidence and forms is also included, from which it is possible to estimate the value of bone radiographs as a diagnostic aid in sarcoidosis.

Clinical Material and Methods

The patients studied belonged to a group of over 160 seen personally during the last few years. The age range was 12 to 65 years, and females preponderated in a ratio of 3:2. About two-thirds of them had widespread pulmonary disease and most of the others had bilateral hilar lymph-node enlargement. Many were referred for investigation after a mass miniature radiograph had shown these abnormalities, and were free from symptoms at the time. About one-quarter of them had a uveitis, one-fifth superficial lymph-node or splenic enlargement, and one-tenth skin lesions. The diagnosis of sarcoidosis was based on a typical chest radiograph and clinical features, supported by negative cultures of sputum and urine for *Mycobacterium tuberculosis*. Confirmation by biopsy was obtained from liver, lymph nodes, skin, or conjunctiva in more than two-thirds of the series.

Radiographs of the hands and feet of 120 of these patients were examined and reported upon by a radiologist. In addition they were reviewed personally at the time of this survey and any doubtful abnormalities were scrutinized together. A control series of radiographs of 101 hands and 14 feet were taken from patients of the same age groups as those with sarcoidosis who attended the casualty department.

Estimations of serum calcium by the method of Trevan and Bainbridge (1926) were made in 86 patients with sarcoidosis (normal range 8.5–11 mg./100 ml.). The serum proteins were estimated by the micro-Kjeldahl method, albumin and globulin being separated by precipitation with sodium sulphate. All patients were examined by the slit-lamp for signs of corneal or conjunctival calcification. Radiographs of the renal tract and function tests were done when there was any reason for thinking that the kidneys were affected.

Bone Radiographs

Bone changes were seen in only 9 of the 120 patients with sarcoidosis (Table I). They were revealed by a coarse reticular pattern in two, typical cystic appearance in two, and intermediate states of medullary and cortical bone replacement in five (Figs. 1 and 2). Confirmation of the diagnosis by liver, skin, or lymph-node biopsy was possible in eight of the nine patients. Estimations of serum calcium in six gave normal results. Local bone pain occurred in

three and soft-tissue swelling in two. Five of the nine patients with bone lesions had cutaneous sarcoids, but only eight of the other 111 patients—confirming the relationship between these two forms of sarcoidosis which has long been suspected. The skin lesions did not occur over the areas of bone disease, nor were they of any particular type: all were confirmed by biopsy. Bone disease was not associated with any particular type of pulmonary disease or with other features such as uveitis.

Lesions resembling those of sarcoidosis were not seen in any of the control group of radiographs.

FIG. 1.—Radiograph of right foot of Case A, Table I. Destruction of cortical and medullary bone is seen most obviously in the middle phalanx of the second toe. (By courtesy of Drs. R. J. Cairns and J. D. Craig.)

FIG. 2.—Longitudinal section of the second toe of Case A, removed because of pain. Lines point to extensive replacement of bone and surrounding structures by sarcoid tissue. (Haematoxylin and eosin stain. X2.)

Serum Calcium in Untreated Sarcoidosis

A serum calcium over 11 mg./100 ml. was found in four of 86 patients tested and below 8.5 mg./100 ml. in four others (Table II). No patient had been treated with vitamin D. None of these eight patients had digital bone lesions. There was no relationship between the serum calcium and the serum albumin, but two patients were found to have a parallel change in the level of total globulins. In Case 4 hypercalcaemia was found together with serum globulin of 3.4 g./100 ml. and in Case 5 hypocalcaemia with serum globulin of 0.29 g./100 ml.

One patient only in the series had any symptoms or signs referable to a disturbed calcium metabolism. His case history is given in detail because of the many interesting features.

Case 1

A fit Service man aged 20, with no previous serious illness, was found by a mass radiograph in August, 1952, to have bilateral hilar-node enlargement and basal infiltration. Examination revealed a transient pleural friction rub and crepitations in the base of the left lung. The Mantoux reaction was positive to 100 T.U. *M. tuberculosis* was not isolated from repeated sputum cultures. A liver biopsy confirmed the diagnosis of sarcoidosis.

Two months later he developed enlarged superficial lymph nodes, iritis, and retinal periphlebitis. This responded to a two-months course of systemic cortisone, 100 mg. daily. His general condition remained good and he gained weight while resting in hospital. In August, 1953, proteinuria was noticed and a chest radiograph showed increased pulmonary infiltration. On account of this he was admitted to King's College Hospital in November. Examination then revealed vascularization of the right cornea and circumscribed retinal scars in the left eye. There was generalized lymph-node enlargement, and fine crepitations were heard at the base of the lungs.

Investigations.—Chest x-ray examination: bilateral hilar-node enlargement with infiltration at both bases. X-ray films of hands and feet: normal. Intravenous pyelography: horseshoe kidney with two stones in right renal pelvis, also calcified mesenteric node in right iliac fossa. Blood count: normal. E.S.R., 44 mm./hour (Westergren). *M. tuberculosis* not found on repeated sputum and urine culture. Lymph-node biopsy: typical sarcoid follicles. Urine: albumin +, hyaline casts +, white cells +, red cells +, sterile on culture. Urine concentration and dilution test: range of S.G., 1014–1010. Blood urea, 37 mg./100 ml.; standard

urea clearance, 40% of normal; serum calcium, 11.6 mg./100 ml.; alkaline phosphatase, 8 K.A. units/100 ml.; plasma phosphorus, 3.3 mg./100 ml.; serum proteins, 7.2 g./100 ml. (albumin 4.2 g., globulin 3 g.).

FIG. 3.—Calcium balance in Case 1 on a low and normal calcium intake from December 9–20, 1953, and January 2–21, 1954, respectively. Daily intake is measured downwards from and output upwards towards the zero line. The effect of potassium citrate is seen.

Calcium Balance (Fig. 3).—On an intake of 100 mg. of calcium and 90 I.U. of vitamin D per 24 hours there was a very low calcium excretion in the faeces, but an excretion in the urine which exceeded the intake by about 150 mg. per 24 hours; this was reduced by taking 9 g. potassium

TABLE I.—Bone Changes in Sarcoidosis (120 Patients)

Case	Age Sex	Clinical Features	Biopsy Positive	X-ray Examination		Serum Calcium (mg./100 ml.)

* One month later.

citrate daily. The citrate was given in order to see the effect of alkalinizing the urine, as the low calcium diet has an acid ash. On an intake of 983 mg. of calcium and 1,200 I.U. of vitamin D an average of 300 mg. of calcium was retained per 24 hours, with a normal proportion of urinary and faecal excretion; the urinary component was greatly reduced when potassium citrate was given. During this period the serum calcium rose from 11.6 to 14.7 mg./100 ml. The effect of calciferol (10,000 units daily) and cortisone on the calcium balance when on a calcium intake of 718 mg. is shown in Fig. 4. The serum calcium rose from

FIG. 4.—Calcium balance in Case 1 during treatment with cortisone from February 20 to March 28, 1954.

10.5 to 14.3 mg. during the 12 days with calciferol alone and there was a fall in the faecal excretion and a steady rise in the urinary excretion. The addition of cortisone, 150 mg. daily, coincided with a still greater urinary loss of calcium due to the calciferol, but this then diminished and there was a steady fall in the level of serum calcium to 10.4 mg. A short balance experiment after treatment with cortisone for six months, calciferol having been discontinued, showed a normal calcium balance and a normal level of serum calcium (10 mg.).

Progress.—During observation in hospital and investigation of the calcium metabolism the patient developed marked photophobia with aching in the eyes. On the exposed area of the bulbar conjunctiva follicles were found containing minute chalky granules, together with an early band-shaped opacity in each cornea. This appearance was thought to be associated with the hypercalcaemia, as the serum calcium at this time was 14.7 mg./100 ml. The follicles and band-shaped opacities resolved rapidly when the calcium intake was reduced, and had disappeared within six weeks, leaving only small amorphous deposits in the position of the follicles.

Treatment.—He was given a course of streptomycin sulphate, 1 g. intramuscularly daily, together with isoniazid, 100 mg. b.d., for three months. There was little response in either the clinical or the radiographic features. Cortisone, 150 mg. daily by mouth, was then added and produced a rapid reduction in the size of the superficial lymph nodes, a clearing of the pulmonary infiltration, and a shrinkage of the hilar nodes. The effect on calcium metabolism is shown in Fig. 4. This treatment was continued for three months, during which he returned to work. The dose of cortisone was then reduced to 100 mg. daily, and the streptomycin to 1 g. twice weekly. The chest radiograph and superficial lymph nodes remained normal, there were no signs of active uveitis, and the serum calcium was within normal limits. All treatment was stopped after one year. The patient remained well, and one year later there had been no relapse. The serum calcium was still normal,

and kidney function had improved; there was no albuminuria, and the standard urea clearance was 76% of normal.

Disturbed Calcium Metabolism Due to Treatment with Calciferol

No patients were treated with calciferol, but four were seen who showed signs of poisoning after having this drug elsewhere. They are not included in Table II. The case histories of three of them are given.

Case 9

A 51-year-old woman had complained of tiredness and lack of energy for three years. For two years she had noticed a skin lesion on the side of the neck and enlarged cervical lymph nodes which had increased in size six months previously. For 18 months she had had slight dyspnoea on exertion, with a cough productive of a few blobs of white sputum daily. In November, 1954, biopsy of a cervical lymph node had revealed sarcoid follicles. A chest radiograph showed extensive disease, thought to be tuberculous, although the sputum was negative for *M. tuberculosis*. She was treated by rest at home and given 2 pints (1,140 ml.) of milk a day, but there was no real change. Between February 7 and March 8, 1955, she was given 5 ampoules by mouth, each containing 600,000 units of calciferol. On March 11 headache and vomiting began, and the possibility of cerebral tumour was entertained until the serum calcium was found to be 15.4 mg./100 ml. and the blood urea 128 mg./100 ml. There was no frequency of micturition, and no pain or haematuria. The headaches and vomiting were temporarily relieved by chlorpromazine and compound codeine tablets.

When examined at King's College Hospital she displayed a slow mentality, perhaps due to the chlorpromazine. She was anaemic, but the skin was bronzed. In the eyes a few chalky fragments were visible on the exposed area of bulbar conjunctiva. The retinal vessels showed early hypertensive change. There were discretely enlarged cervical, right axillary, and epitrochlear lymph nodes and the spleen was just palpable. Bronchial breathing was heard over the right dorsal lobe, but there were no adventitious sounds. The cardiovascular system was normal apart from a blood pressure of 170/110.

Investigations.—Chest x-ray examination: bilateral coarse nodulation, becoming confluent in the upper lobes with upward retraction of the hila by fibrosis. Hands and feet: mild arthritic changes only. Kidneys: no calcification seen. Blood count: haemoglobin, 66%; white cells, 4,300, with normal differential count. E.S.R. (Westergren): 60 mm. hour. Sputum (×6) and E.M.U.: no *M. tuberculosis* on culture. Urine: sterile, albumin 1+, pus cells ++, occasional hyaline and granular casts. Blood urea 55 mg./100 ml.; standard urea clearance, 32%, normal. Range of specific gravity, 1006–1012. Serum proteins, 7.27 g./100 ml. (albumin 3.69 g., globulin 3.58 g.). Serum calcium, 12.7 mg./100 ml. Phosphorus 4 mg./100 ml. Alkaline phosphatase, 8 K.A. units/100 ml. E.C.G.: normal. Mantoux: positive to 100 T.U.

A calcium balance was undertaken three months after the last dose of calciferol. On a fixed intake of 615 mg. of calcium per 24 hours there was an excessive excretion of calcium in the urine: an average of 597 mg. in the urine and 336 mg./24 hours in the faeces during six days. The effect of 100 mg. of cortisone daily was to lower the blood calcium to normal, with little change in the proportion of calcium excreted in the urine and faeces during the 12 days in which these were measured.

Progress.—She improved steadily while taking cortisone. The nausea and headache ceased; she became more alert and energetic and resumed an active life. By November, 1955, she looked and felt very fit except for some dyspnoea on exertion due to her old pulmonary lesions, which were unaltered. Her serum calcium has remained within normal limits since June, 1955.

Case 10

A 53-year-old woman in 1940 noticed blurred vision due to uveitis. She developed parotitis and pulmonary sarcoidosis and later multiple skin lesions, and enlarged spleen and lymph nodes. During the next 10 years she became breathless from increasing pulmonary fibrosis. In 1950 she was treated with calciferol, 50,000 units, by mouth daily for nine days, without benefit, but this had to be discontinued on account of vomiting and weakness due to hypercalcaemia. The serum calcium rose to 12 mg./100 ml. In 1954 she had renal colic due to stones, which were later removed. Her blood pressure was 150/95 before treatment with calciferol, but steadily rose afterwards, and reached 235/135, with persistent albumin in the urine. It seems probable that all these complications were caused by the temporary hypercalcaemia. She took her own life in 1955; necropsy confirmed fibrosing sarcoidosis. There was extensive scarring of the kidneys from arteriolar disease, scattered calcification of the renal tubules and interstitial tissue but no sarcoid follicles, and a calculus in the right renal pelvis.

Case 11

A 45-year-old woman noticed enlarged lymph nodes in the neck and axilla in 1946 which were subsequently shown at biopsy to be due to sarcoidosis. Since 1949, during the summer months, she had developed lassitude, vomiting, and constipation of such severity as to make her cease work. In June, 1950, there was an episode of misty vision associated with a painful right eye. In November, 1955, she was given 50,000 units of calciferol daily by mouth for four weeks; but this caused severe lassitude, vomiting, and constipation. She was then referred to King's College Hospital for further investigation. Enlarged cervical, epitrochlear, axillary, and inguinal nodes were found, and an early corneal band-shaped opacity. The blood pressure was 180/90, but there were no abnormalities in the chest, heart, or abdomen.

Investigations.—Radiographs of the chest, skeleton, and kidneys were normal. A barium meal showed only delayed gastric emptying. The Mantoux test was positive to 100 T.U. E.S.R. (Westergren) 45 mm./hour. Cultures of gastric washings and urines were sterile. Serum calcium, 15.2 mg./100 ml. (repeated); phosphorus, 3.2 mg.; urea 65 mg. Total serum proteins, 8 g./100 ml. with increase of globulin on electrophoresis.

Progress.—She was treated with a low-calcium diet and cortisone, 150 mg. daily. Within a month the serum calcium had returned to normal limits (10.8 mg.) and her symptoms had disappeared. Her treatment was interrupted by an attack of acute appendicitis, which, however, gave the opportunity to confirm the diagnosis of sarcoidosis by biopsy of a mesenteric node. Treatment with cortisone has continued on a maintenance dose of 150 mg. daily; her lymph nodes have returned to normal size and gastrointestinal symptoms have disappeared.

Corneal Band-shaped Opacities

Although examination for these opacities was undertaken as a routine, they were found in only three patients. Case 1 was the most obvious. In another patient with uveitis and hilar-node enlargement, corneal calcification was seen, but unfortunately there was no histological proof of sarcoidosis and the serum calcium was not estimated. In the third patient (Case 12) there was circumstantial evidence of transient hypercalcaemia, but the serum calcium was not estimated at the time.

Case 12.—A 65-year-old diabetic woman developed uveitis in 1949 followed by parotitis and skin lesions, which on biopsy were shown to be sarcoids. One year later she developed neuritis, nausea, and vomiting; there was a trace of albumin in the urine, and the blood urea was 140 mg./100 ml. Band-shaped opacities developed, but the serum calcium was not estimated until two years later, when the nausea and vomiting had stopped and

the blood urea had returned to 65 mg./100 ml. There was persistent albuminuria. It is probable that both the kidney damage and the corneal opacities were caused by a transient hypercalcaemia.

Discussion

Bone Lesions

The earliest descriptions of the radiographic appearance of bone sarcoid were by Kienböck (1902) and Kreibich (1904), although Jüngling (1919) first described the histological changes. The frequency of bone involvement was found to be 9 in 55 cases by Holt and Owens (1949) and 19 in 100 cases by Longcope and Freiman (1952). Bone disease was found less often in the present series—only nine times in 120 patients. The true frequency of bone involvement may be much higher than any of these reports suggest, as the epithelioid cell follicles of sarcoidosis have been seen at biopsy or necropsy even when the radiograph has been normal (Schaumann, 1926). Also the earliest radiographic changes—a stippled medullary pattern from diffuse lacunar absorption—may be so indefinite that a firm diagnosis cannot be made, especially when the process affects many phalanges.

The explanation for the lower frequency in this series compared with others may be that most of the patients had predominantly intrathoracic sarcoidosis, and that there were only 13 examples of skin sarcoids, of which five showed digital bone disease. The relation between skin and bone sarcoidosis is well known (Holt and Owens, 1949), and it is because so many of the early reports of sarcoidosis were of skin lesions that bone changes were thought to be so frequent. In the last two decades pulmonary forms of the disease have been recognized to be the most common, so that bone sarcoid is seen relatively less frequently.

In the nine patients of this series the diagnosis of sarcoidosis had already been made from the clinical and radiographic features, supported by biopsy in eight. The finding of bone lesions in Cases F and H (Table I) was valuable support for the diagnosis, but their absence would not have changed this. Hence it is thought that radiographs of the hands and feet give little help in the diagnosis of sarcoidosis, and are wasteful as a routine procedure.

The most common type of radiographic change is a coarse reticulation of the shaft of the bone due to follicle formation along the cortical blood vessels, as seen in six of the nine cases. This and a stippled medullary pattern from diffuse lacunar absorption are the earliest changes. The classical punched-out areas in the medulla occurred in two cases, with less definite areas of bone replacement in four others. Thinning and expansion of the cortex, sometimes even with pathological fractures, have been reported due to the enlarging granuloma, but no examples were seen in this series. When the disease remits spontaneously there is seldom complete resolution of the bone lesions; a "cyst" of fibrous tissue may remain indefinitely. Bone sarcoid has been described in practically every bone in the body, but it has an overwhelming predilection for the middle and distal phalanges of the hands and feet. The reason is unknown.

In the differential diagnosis of bone sarcoid many diseases have to be considered. Both rheumatoid arthritis and gout have quite distinct clinical features. Here pain and swelling of the joints predominate, and the radiographic changes of osteoporosis or bony erosions are usually most pronounced at the articular ends of the bones, although in the arthropathy of psoriasis these may spread to involve the shaft as well. Enchondromata usually expand the cortex and are homogeneously translucent. Resembling these are the small degenerative cysts which occasionally occur as an incidental finding in the carpal and digits. Tuberculous dactylitis, a very rare condition in adults, causes the bone to appear distended and provokes a periosteal reaction; later destructive changes may occur accompanied by sinuses. Hyperparathyroidism should seldom be mistaken for sarcoidosis, as here there is decalcification affecting the whole skeleton,

with fibrous cysts in a few bones. Sometimes it may not be possible to separate xanthofibroma and tuberous sclerosis of the digits except by features of these diseases elsewhere. The most common error is to diagnose digital sarcoidosis too frequently through failure to appreciate the range of normal bone architecture. Areas of radiolucency in the metacarpal heads are especially apt to be interpreted falsely, as are the coarsening of the bone structure with increasing age and with osteoarthritis. Features which help in the diagnosis of sarcoidosis are the lack of joint involvement and periosteal reaction, and the usual absence of pain.

No relationship has been found between demonstrable bone disease and hypercalcaemia either in the past (Holt and Owens, 1949) or in the present series (Table I). This is not surprising, as other localized diseases of bone, such as osteomyelitis or tumours, likewise do not upset calcium metabolism. Bone sarcoid must be regarded as an oddity which seldom causes symptoms or demands treatment.

Hypercalcaemia

The first recognition of hypercalcaemia in sarcoidosis was by Harrell and Fisher (1939). Isolated reports of nephrocalcinosis and renal calculi had appeared (Salvesen, 1935), but their relationship to hypercalcaemia was not appreciated until 1941 (van Creveld). Estimates of the frequency of hypercalcaemia have varied from 11 in 44 patients (Longcope and Freiman, 1952) to 4 in 86 of the present series. Harrell and Fisher (1939) reported hypercalcaemia in 6 of their 11 patients, but in one patient the serum calcium was only 10.6 mg./100 ml., and, in another, hypercalcaemia developed only after intensive treatment with cod-liver oil. The explanation for the lower frequency in the present series compared with those of previous workers may be that many of the patients had disease affecting the hilar nodes or lungs alone and none was given vitamin D. Many of the reported cases had widespread disease, and no mention was made of whether vitamin D had been given as treatment. Hypercalcaemia in patients not receiving vitamin D occurs so infrequently in sarcoidosis that estimation of the serum calcium routinely is unnecessary. It should be done if there are symptoms of hypercalcaemia such as thirst, polyuria, tiredness, muscular weakness, and vomiting, if ectopic calcification is found, or if renal colic or albuminuria occurs, pointing to nephrolithiasis or calcinosis.

The explanation for the hypocalcaemia in four patients (Table II) is obscure, but merits further investigation. Case 5 was of particular interest in that there was an associated hypoglobulinaemia despite extensive sarcoidosis.

The cause of hypercalcaemia remains obscure. It bears no relation to a high serum protein (Harrell and Fisher, 1939; and Table II); in any case, protein disturbances affect only the serum globulin, which has little calcium-binding power (Schmidt and Greenberg, 1935; Gutman and Gutman, 1937). Also the hypercalcaemia is evidence that increased calcium in the blood is largely of the ionizable fraction. Hypercalcaemia is not due to parathyroid stimulation, as there is no hypophosphataemia or generalized osteoporosis. In several cases normal parathyroid glands have been removed (Albright and Reifenstein, 1948; Klatzkin and Gordon, 1953; Davidson *et al.*, 1954; Anderson *et al.*, 1954). One case has been recorded where hyperparathyroidism simulated sarcoidosis by showing diffuse pulmonary reticulation (Salmon and Meynell, 1951).

Hypercalcaemia is not due to widespread bone sarcoid, as there is seldom radiographic evidence of this, and in the nine cases (Table I) with known bone lesions there was no upset of calcium metabolism. Furthermore, balance studies do not support this hypothesis. It is not due to renal sarcoidosis, as there are many examples of hypercalcaemia where biopsy or necropsy has failed to show epithelioid cell follicles (Dent *et al.*, 1953; Davidson *et al.*, 1954; Correa, 1954; Case 10), and in those cases where renal sarcoidosis has occurred it is not extensive enough to cause impaired function (Longcope and Freiman, 1952). It may be due to a primary metabolic disorder, such as excessive sensitivity

to vitamin D as suggested by Anderson *et al.* (1954). Case 1 showed on the calcium balance an excessive absorption of calcium similar to that seen in their cases. This patient's metabolism also reverted to normal during cortisone treatment, a feature observed by Shulman *et al.* (1952), Lovelock and Stone (1953), Phillips (1953), Dent *et al.* (1953), Lane (1954), Citron (1954, 1955), and Anderson *et al.* (1954).

Further support for the hypothesis of vitamin-D sensitivity comes from the observations on Case 1 and of others that treatment with this drug even in small doses or with ultra-violet light may cause hypercalcaemia (Scadding, 1950; Cantwell, 1954; Letman, 1954; Anderson *et al.*, 1954). The recurrent symptoms of hypercalcaemia in Case 11 before calciferol was given all occurred during the summer months and were especially severe during the sunny summer of 1955. This suggests that the hypercalcaemia was provoked by ultra-violet light. Moreover, the clinical as well as the biochemical features of hypercalcaemia in sarcoidosis are in every way typical of hypervitaminosis D. Sensitivity to vitamin D is also thought to be the cause of infantile hypercalcaemia (Bonham Carter *et al.*, 1955; Schlesinger *et al.*, 1956), and there is some evidence that cortisone helps to reverse this abnormality (Creery and Neill, 1954).

The dangerous effects of hypercalcaemia, whether spontaneous or provoked by vitamin D, are primarily on the kidney, where irreversible damage may be done by nephrocalcinosis and renal stones (Cases 9 and 10). Impairment of function may be so severe that a fatal uraemia ensues (Cantwell, 1954; Correa, 1954; Davidson *et al.*, 1954). Hypercalcaemia may also cause band-shaped corneal opacities (Walsh and Howard, 1947; Cogan *et al.*, 1948; Cases 1, 9, and 11), and calcification in tissues, such as the blood vessels, lungs, subcutaneous tissue, and joint capsules. In addition to these potential dangers, there is considerable doubt about the efficiency of calciferol in the treatment of sarcoidosis. In the only recorded controlled trial of calciferol (Nelson, 1949) the frequency of remissions was the same in the treated and untreated groups. For these reasons the use of calciferol for the treatment of sarcoidosis should be discontinued.

When hypercalcaemia is encountered, a diet low in calcium and vitamin D may be effective. Cortisone has been shown to have some antagonistic action to vitamin D and is effective in reducing hypercalcaemia in sarcoidosis. It should be used when there is evidence of renal damage and when dietary measures prove ineffective.

Summary

Radiographs of the hands and feet have been examined from 120 patients with sarcoidosis: bone lesions were found in only nine. Such radiographs are thus of little value in diagnosis. The common association of cutaneous sarcoids with bone disease was confirmed (five out of the nine patients). No examples of disturbed calcium metabolism were seen in those with bone disease.

Estimations of serum calcium in 86 untreated patients showed hypercalcaemia in only four. Hypocalcaemia occurred in four. The effects of hypercalcaemia are described, with special reference to kidney damage. Examples of hypercalcaemia following the treatment of sarcoidosis with calciferol are given and its dangers emphasized.

Clinical and biochemical studies support the hypothesis that hypercalcaemia in sarcoidosis is due to excessive sensitivity to vitamin D. Control of this complication may be achieved by a diet low in calcium and vitamin D, although cortisone is sometimes necessary.

I thank Dr. A. M. Rackow, Dr. C. E. Dent, and Professor C. H. Gray for their help, and Mr. A. H. Dawson, senior

laboratory technician, for the biochemical estimations. I am also grateful to Dr. Clifford Hoyle for his constant encouragement and advice.

ANAESTHESIA FOR AORTIC RECONSTRUCTION*

BY

HARRY L. THORNTON, F.F.A.R.C.S., D.A.

Consultant Anaesthetist, St. Mary's Hospital, London, W.2

Reconstruction of the thoracic and abdominal aorta calls for an anaesthetic technique appropriate to other operations in the region of these structures. There are, however, certain features peculiar to this branch of surgery which demand some special thought from the anaesthetist. Apart from the technical problems involved in maintaining (often for many hours) an even state of anaesthesia, combined with the profound degree of muscular relaxation necessitated by the surgical approach, there are other, and vital, matters concerning blood and respiratory chemistry, fluid and blood replacement, and the control of the haemodynamic disturbances of the surgical procedure. The nature of the operation may necessitate interruption of the circulation to vital organs for long periods, and in such cases the operation can be conducted safely only with the aid of induced hypothermia; this technique will itself impose some problems of anaesthetic management.

The anaesthetic techniques described below have been followed in 71 of the cases of aortic occlusion or aneurysm undergoing operation by members of the surgical unit of St. Mary's Hospital, London, under the direction of Professor Charles Rob. The anaesthetic procedure was conducted by three members of the hospital consultant staff, and their assistants. The 71 cases concerned are briefly summarized in Table I.

*Abstracted from a paper read before the Section of Anaesthetics at the Annual Meeting of the British Medical Association, Brighton, 1956.

TABLE I

	Requiring Hypothermia	Not Requiring Hypothermia
Aneurysm	5	37
Thrombosis	6	22
Coarctation	1	0
Total	12	59

TABLE II.—Fatal Cases

Requiring Hypothermia	Not Requiring Hypothermia
Aneurysm:	Aneurysm:
Haemorrhage	Haemorrhage
Thrombosis	Myocardial infarction
Suprarenal failure	Paralytic ileus and pulmonary
Myocardial infarction	sepsis
	Undecided
Thrombosis	Haemorrhage
Coarctation	Coronary thrombosis
Total	3
	9

The operative mortality (deaths occurring in the first 24 hours of the operative period) was 12 out of 71 (16.9%) (Table II).

Anaesthesia as a contributory cause of death could be implicated for certain in one case (pulmonary sepsis following aspiration of vomitus during induction of anaesthesia for reopening abdomen 12 hours after operation for aortic aneurysm. Ileus not diagnosed pre-operatively). One other case (listed as "undecided") was a possible "anaesthetic death." In the light of later experience it was thought that respiratory acidosis might have been a contributory factor (see last two cases in second column).

Type of Patient

Although, in the main, the patients likely to be encountered in surgery of the aorta may be described as being "in the prime of life," they are by no means in the prime of physical condition. With some few exceptions (such as the rare traumatic case, and some cases of aortic coarctation) they have reached middle or late middle age, and are suffering from severe arterial disease. Atherosclerosis is not likely to be confined to the portion of the aorta requiring surgery; coronary, cerebral, and renal vessels are likely to share in the general disease. Often there is hypertension, which may be of severe degree. There may have been past episodes of cardiac infarction or cerebral thrombosis. Such patients tend to be "old beyond their years," physically flabby, and often obese.

This is our somewhat unpromising material, and to subject such patients to major surgery, with the attendant hazards of blood loss and traumatic shock, under general anaesthesia (possibly maintained for as long as 12 hours), without the most careful pre-operative assessment and preparation, would be to court almost certain disaster. Only in the case of true emergency (such as leading aneurysm or haemorrhage from other causes) is it justifiable to omit the full pre-operative routine which is described below. The period of assessment and preparation may precede the operation by 7 to 10 days.

Pre-operative Investigations

Aortography.—In all cases the site of the lesion is determined by an aortogram, usually performed under local analgesia, assisted by intravenous pethidine. Only in exceptionally difficult cases, or with unusually apprehensive patients, will a general anaesthetic be necessary; since complete apnoea at the time of the exposure and the prone position are demanded, this will require tracheal intubation

and controlled respiration. The choice of the subsequent anaesthetic technique will depend on the site of the lesion as revealed by the aortogram. Should the lesion be estimated to lie 2 cm. or less below the level of the renal arteries, clamping of the aorta above this level and interruption of the renal circulation must be envisaged. In lesions of the thoracic aorta the proximal clamp will occlude some part of the blood supply to the spinal cord via the spinal branches of the posterior intercostal arteries. Such cases will call for induced hypothermia.

In addition to a complete physical examination the following routine investigations are carried out on all cases: complete blood count; estimation of haemoglobin, serum proteins, blood sugar, and blood urea; and a complete picture of the plasma electrolytes. Renal and respiratory function tests are made. Wherever electrolyte imbalance is found, every endeavour is made to restore normality, and not until stability seems assured is surgery contemplated. Certain cases require additional investigation and preparation. Of particular importance are those showing respiratory insufficiency; an important example of this group is that of chronic emphysema, which most anaesthetists will recognize as a troublesome problem in major surgery. In all such cases the blood oxygen content, pH, and plasma carbon dioxide content are determined, and operation is deferred until physiotherapy, together with antibiotic treatment of residual infection, has resulted in maximal improvement in the patient's vital capacity. The problem of respiratory acidosis is of great importance in the management of anaesthesia for aortic surgery—and, indeed, for most other types of thoracic and abdominal surgery—and is referred to below.

On the night before operation water diuresis is induced by the slow intravenous infusion of 1-2 litres of 5% glucose in water. This is believed to give some measure of protection from subsequent renal failure, particularly when surgical interruption of the renal circulation is anticipated (Wynn, unpublished observation).

It will be seen that cases for aortic reconstruction (or disobliteration) fall into two main groups: (1) those with lesions situated more than 2 cm. below the renal arteries, and (2) those with lesions at, above, or close to the renal arteries or involving the thoracic aorta—that is, cases not requiring induced hypothermia (group 1), and those in which induced hypothermia is obligatory (group 2). For convenience these two groups are considered separately with regard to management, the simpler (non-hypothermic) group being taken first.

Anaesthetic Management of Group 1 Cases

In contrast with those of the second group, group 1 cases will suffer little disturbance of normal physiology, except that at certain stages in the operation severe variations in blood pressure are to be expected and considerable loss of blood may be inevitable. As in all abdominal surgery, muscular relaxation of a high degree is demanded, and, since the operation is likely to be lengthy, the anaesthetic agents must be of minimal toxicity. Our choice at St. Mary's Hospital is nitrous oxide and oxygen, preceded by thiopentone, and supplemented by pethidine. Curare is used to provide the necessary relaxation. Endotracheal intubation is invariably employed, and respiration is controlled manually throughout the operation, with carbon-dioxide absorption on the "to-and-fro" principle. We are careful to avoid small gas-flows, with their potential danger of underventilation.

The administration of parenteral fluids, both in replacement therapy and as vehicles for drugs required in the course of operation, has received some special attention from the team in our metabolic unit. This matter is discussed below. For group 1 cases we prefer to use an isotonic dextrose-saline solution (dextrose 4.3%, saline 0.18%), which is usually administered through a "polythene" intravenous cannula. The solution can be exchanged for whole blood when necessary. An intra-arterial blood transfusion can be set up at very short notice. Since the lower limbs

are not available for this purpose (on account of surgical occlusion of the aorta), a transfusion set, kept externally sterile, is retained for the use of the surgeon as need arises. We do not favour the use of the radial or other proximal limb arteries for transfusion purposes, because of the risk of spasm and ischaemia. In most cases the aorta, proximal to the clamps, is the vessel of choice. The necessary transfusion pressure is obtained by suspending the blood-bottle from the theatre gallery at a height of about 10 ft. (3 metres), an extension of the transfusion tube allowing for this distance. Blood pressure and pulse rate are recorded at 10-minute intervals, and electrocardiographic tracings are made when required.

Recently we have come to appreciate the great importance of maintaining a normal blood pH, and, in order to detect and check developing respiratory acidosis, estimations of arterial blood pH and total carbon dioxide are made at frequent intervals, or whenever there is clinical suspicion of rising blood pCO₂ (rising systolic and diastolic blood pressure, sweating, tachycardia). Further estimations are made at the conclusion of operation, when spontaneous respiration is re-established.

Blood Replacement.—So far as is possible, blood replacement is adjusted to blood loss. The suction-bottle is calibrated in millilitres, and all swabs and packs are weighed before and after use on a sterile balance, blood loss being calculated on a weight-volume coefficient. Since no wet packs are used, an estimate accurate to $\pm 10\%$ is possible. The most critical period of the operation is when the distal aortic clamp is released. Close co-operation between surgeon and anaesthetist ensures that the latter has ample warning and can take the necessary action to avert a dangerous fall in blood pressure. Provided that the intravenous blood

FIG. 1.—Pneumatic tourniquets control flow of blood to legs on release of clamps.

transfusion is capable of a rapid increase in rate of flow (500 ml. in five minutes) at least five minutes before release of the clamp, it is seldom necessary to transfuse intra-arterially. To prevent too rapid a loss of blood into the lower limbs we use pneumatic tourniquets, which can be gradually deflated, and, if necessary, reinflated to check dangerous falls in blood pressure (Fig. 1). Unless unusually severe leakage at the anastomosis occurs on removal of the clamps, blood pressure should be controlled and stabilized within 5-10 minutes.

Anaesthetic Management of Group 2 Cases

In the surgical unit of St. Mary's Hospital we have found the method of surface-cooling both simple and effective. We aim at reducing the body temperature to between 26 and 27° C. (78.8 and 80.6° F.), and require about one and a half hours to achieve this degree of hypothermia. The procedure is as follows.

One hour prior to cooling—that is, two and a half hours before the planned time of operation—the patient is pre-medicated with pethidine, 100 mg., scopolamine, 1/150 gr.

(0.43 mg.), and chlorpromazine, 25-50 mg. intramuscularly. My own practice is to give chlorpromazine, 25 mg., some days before operation, and to observe the effect. Should tachycardia or marked hypotension result I omit the chlorpromazine from the premedication entirely. If, on the

by removing some of the ice-bags, stopping the fans, and recovering exposed parts of the body with blankets. Operation is started as soon as the required basic temperature has been reached. At this stage it is usually necessary to give a further small dose of curare and/or pethidine.

Provided that the cooling process has proceeded smoothly, the patient, although presenting a somewhat alarmingly lifeless appearance, should by this time have suffered little or no fall in blood pressure. The pulse rate will have fallen considerably (50-60 a minute).

Cases of this group require especially careful handling at the time when the distal aortic clamp is released, for, although vasoconstriction is active as a result of the hypothermia, reflex hyperaemia will still occur in the lower limbs, in response to the restored circulation (Fig. 3). Unless this is adequately controlled by the tourniquets a hypotensive crisis will be precipitated, and this is likely to prove more difficult to treat than in the non-hypothermic cases. Infusion of noradrenaline (1/500,000) will be of great help in such cases, provided that there is not the additional complication of uncompensated blood loss.

A danger associated with massive blood transfusion is inherent in the quantity of sodium citrate which may be infused. Like glucose, the citrate ions of sodium citrate are not metabolized in the hypothermic state, and may reach a concentration high enough to be toxic to the myocardium (Bunker *et al.*, 1955). Furthermore, stored blood has a high potassium-ion concentration which can cause cardiac arrest. In all cases it is advisable that only freshly donated blood

FIG. 2.—Set-up of anaesthetic and other apparatus during induction of hypothermia. Note ice-bags. Left foreground: Control for cutting in thermocouple leads for direct temperature readings. Left background: Electrocardiogram. (The apparatus attached to right lower leg is for measuring calf blood flow.) Right foreground: Anaesthetic apparatus and sphygmomanometer.

be used and that an adequate supply be available at the time of operation. (Aneurysm cases may require as much as 3-4 litres; thrombosis cases, somewhat less.) If the quantity of citrated blood is necessarily heavy (above 4 litres) we advise the addition of calcium gluconate, 0.5 g. to each half-litre.

Post-operative Points

At the conclusion of the operation the anaesthetist must be satisfied upon the following points: (1) blood loss has been restored (verified gravimetrically and volumetrically); (2) blood pressure is stable at a safe level (not less than 100 mm. Hg systolic, with or without noradrenaline); (3) the neuromuscular block has been fully reversed by neostigmine; (4) central respiratory depression has been abolished (this may require nalorphine); (5) the blood pH and pCO₂ are normal and stable; and (6) rewarming of the hypothermic patient is proceeding at the rate of 1-1.5° C. an hour, but no faster.

FIG. 3.—Reflex hyperaemia of lower limbs following release of aortic clamp.

Maintenance of anaesthesia is by nitrous oxide and oxygen with manually controlled respiration. Increments of pethidine are added intravenously as required. Before cooling is started, tubocurarine chloride, 20-30 mg., is administered. This not only facilitates the control of respiration in a light plane of anaesthesia, but is essential in preventing shivering, with the attendant risk of ventricular fibrillation.

Cooling (conducted on the operating table) is begun by placing ice-bags in close contact with the patient's exposed neck, thorax, abdomen, flanks, thighs, and legs, covered overall by a wet cotton sheet, from which evaporation is assisted by electric fans. The theatre temperature is kept as low as possible (40-60° F.; 3.3-15.5° C.). Body temperature is constantly recorded by thermocouples placed in the upper and lower oesophagus and rectum. Pulse, blood pressure, and electrocardiographic tracings are taken at short intervals, the latter being particularly valuable in giving warning of ventricular arrhythmias (Fig. 2).

Since Wynn (1954) has shown that glucose ceases to be metabolized at a body temperature below 31° C. (87.8° F.), the only parenteral infusion used, apart from blood, is half normal saline, to which is added such drugs as are required in the course of operation. All active cooling is stopped when the body temperature has reached about 28° C. (82.4° F.), after which, in a cool theatre, it will continue to fall until it stabilizes at between 26 and 27.5° C. (78.8 and 81.5° F.). Too rapid a fall in temperature can be checked

These last two points deserve some further amplification, and the fifth point—that is, the matter of blood pH—will be taken first, since this applies to both hypothermic and non-hypothermic cases, and is closely related to the problems

of persistent neuromuscular block and central respiratory depression. In a proportion of cases, Wynn (1956, personal communication) and the metabolic team of the surgical unit at St. Mary's Hospital have found that there is a tendency to recurrence of a neuromuscular block which has been previously reversed by neostigmine at some time during the recovery period. It is possible that in the hypothermic patient curare may persist in some depot inaccessible to the action of neostigmine; or, in those cases where the renal circulation has been interrupted, there could be delayed excretion of curare. Undoubtedly there are other factors as yet not fully understood. Scurr (1954) has already drawn attention to the apparent synergism between carbon dioxide and the neuromuscular blocking agents, and it would seem that in certain circumstances a vicious circle could become established (Fig. 4).

To break this circle the full respiratory efficiency needs to be restored, and treatment must be at the appropriate level. Thus, if reversal of central respiratory depression plus reversal of neuromuscular block (nalorphine plus neostigmine) fails to restore the *status quo*, artificial ventilation aimed at elimination of carbon dioxide must be instituted without delay, and must be continued until the pH and pCO₂ return to normal and show no tendency to further change. Reintubation of the patient and connexion to a respiratory pump for an hour or more has sometimes proved necessary. Respiratory acidosis must never be allowed to develop. The longer treatment is delayed the more difficult will it be to reverse the process.

Illustrative Case

A somewhat obese plethoric man aged 44 had a recent history of claudication of buttocks and legs. Aortogram (under general anaesthesia) showed occlusion of abdominal aorta immediately below renal arteries, with well-marked collateral circulation. Operation was begun at 9 a.m. under induced hypothermic and thiopentone-nitrous-oxide-oxygen-pethidine-curare anaesthesia with manually controlled respiration. Duration of anaesthesia was about eight hours. Surgical procedure (disobliteration and graft) required clamping of aorta above renal vessels for about two hours. Operation was completed at 6 p.m.

Post-operative Course.—Patient regained consciousness and spoke rationally about 30 minutes after return to the ward. Although respiration was spontaneous on removal of endotracheal tube, there was marked "tracheal tug," which was not abolished by neostigmine, 2.5 mg., repeated after 20 minutes. Oxygen was administered by means of a plastic facepiece at the rate of approximately 8 litres a minute, a good colour being maintained. Rewarming proceeded normally; no shivering. Three hours later (9 p.m.) respiration became shallow and soon ceased, although the colour up to this time (with oxygen) had seemed satisfactory. Patient appeared deeply unconscious. Artificial respiration with oxygen by means of a bag and facepiece (later replaced by cuffed tube) was immediately begun. Blood samples were obtained for pH, HCO₃, and pCO₂, which revealed very gross respiratory acidosis (see Fig. 5).

Four hours later (1 a.m.) the patient still appeared deeply comatose; pH was now rising, and HCO₃ and pCO₂ falling slightly. At this stage a Waters CO₂ absorber was placed in circuit. Much heat was generated, requiring change of canister after 20 minutes. Artificial respiration continued until 6 a.m. (a further five hours), when consciousness and spontaneous respiration returned. Blood samples now showed an almost complete return to normal, except the pH, which remained a little low (7.35) for about a further hour. Thereafter the patient made an uninterrupted recovery.

Comment.—An interesting feature of this case was revealed some time later. The patient, who was himself a

medical man, was able to recall in detail many of the events which took place when he appeared to be deeply comatose. This would seem to be a case of respiratory acidosis simulating complete neuromuscular block (Scurr, 1954).

Rewarming of the hypothermic patient requires the most careful vigilance on the part of medical and nursing staff. If

FIG. 5.—Case of severe carbon dioxide retention.

rewarming proceeds too rapidly, vasodilatation will result in a severe fall in blood pressure; if too slowly, shivering and shock may be produced. We believe that a safe average rate of rewarming lies between 1 and 1.5° C. an hour. Heat-loss is prevented by blanketing in preference to the application of outside sources of heat, such as electric cradles. Should the body temperature rise too rapidly, and result in a fall in blood pressure, it may be necessary to reapply tourniquets to the limb from time to time, whilst removing some or all of the blankets.

Conclusion

It should be observed that although the operative death rate in cases of aortic reconstruction might appear to be high in comparison with that encountered in the general run of major abdominal and thoraco-abdominal surgery, due appreciation must be given to the extreme severity of the operations performed on patients almost invariably in the "poor-risk" group. As in all comparatively new branches of surgery, improvement in this respect may be expected to follow future improvements in technique, both surgical and anaesthetic. A decrease in the incidence of operative shock and blood loss is already beginning to reflect a steady diminution in total operating-time, whilst experience has taught us to avoid many of the earlier hazards of anaesthesia.

The paramount importance of team-work in the management of these cases must be stressed. Without the close co-operation of the many special departments (electrocardiographic, metabolic, biochemical, to mention only a few of those whose services we are fortunate in having at our disposal) the anaesthetic and operative risk in major aortic surgery would be formidable indeed.

Summary

The pre-anaesthetic preparation, anaesthetic technique, and post-anaesthetic management of cases of aortic reconstruction are described.

Blood loss, blood and fluid replacement, and the control of blood pressure are discussed.

The technique of induced hypothermia by the method of surface cooling is described, and some relevant problems are considered.

The importance of maintaining a normal blood chemistry, with particular reference to the blood pH and pCO₂, is stressed.

I thank Professor Charles Rob for giving me access to case notes and statistics of the St. Mary's Hospital Surgical Unit; Dr. Victor Wynn for much valuable assistance and for supplying the graph (Fig. 5) from his personal notes; and Dr. P. N. Cardew, of the St. Mary's Hospital photographic department, for the illustrations and diagrams.

CANICOLA FEVER IN MAN THROUGH CONTACT WITH INFECTED PIGS

BY

JOYCE D. COGLAN, Ph.D., B.Sc.

Lecturer in Bacteriology, University of Edinburgh

JOHN NORVAL, M.R.C.V.S.

Chief Veterinary Inspector to the City of Edinburgh

AND

H. E. SEILER, M.D., F.R.C.P.Ed., D.P.H.

Medical Officer of Health to the City of Edinburgh

Leptospiral infections in man resulting from contact with infected pigs have been reported from different parts of the world but have not previously been recorded in Great Britain. Thus the benign human leptospiroses known as "swineherd's disease" and "seven-day fever of Queensland" have followed contact with pigs infected with *Leptospira pomona* (syn. *L. suis*) and *L. mitis* (syn. *L. hyos*) respectively, while van Thiel (1948) quotes two published cases of Weil's disease where it seemed likely that the patient had contracted the disease through slaughtering pigs infected with *L. icterohaemorrhagiae*.

Neither *L. pomona* nor *L. mitis* has so far been isolated from man or pig in this country, but occurrences of *L. icterohaemorrhagiae* infection in swine in two rat-infested piggeries in the south-east of Scotland have been reported by Nisbet (1951).

One other type of leptospira—namely, *L. canicola*—has been isolated from swine. Williams *et al.* (1953) found during the investigation of an extensive outbreak of human canicola fever in a rural community in South Georgia that dogs, cows, and swine showed evidence of infection with *L. canicola*. All the human cases had bathed in the water of a creek to which animals had access, and, although the original source of infection remained obscure, it was the first record of *L. canicola* infection in animals other than dogs.

Previously it had been generally accepted that dogs were the only natural carriers of *L. canicola* (van Thiel, 1948) and that infection in man resulted directly or indirectly from contact with these animals. The disease in the dog varies in severity, but, whatever the degree of illness, the infection usually leads to leptospiuria, which

may persist for many months if recovery occurs, thereby providing a source of contamination for other dogs and for man. While the number of known cases of human canicola fever has been steadily increasing, its true incidence is difficult to assess, since it is a disease which must very often escape diagnosis. In some instances of human disease the history would seem to leave little doubt that infection was transmitted from a dog, but others have been recorded where no apparent connexion between patient and dog could be established (Broom, 1951) and where an alternative source of infection seemed probable. It may be that pigs are more frequently infected with *L. canicola* than is commonly supposed, and, if so, the question arises whether they may not act as reservoirs of infection to persons who feed and handle them. Investigations into a number of obscure cases of human canicola fever which occurred between 1950 and 1955 among piggery workers in and around the City of Edinburgh gave rise to a series of interesting results which point to the probable role of pigs in the transmission of canicola infection to man. These form the basis of the present communication.

Laboratory Methods

Agglutination-lysis tests were used for serological diagnoses. The methods of setting up the tests and interpreting the results were those developed by the staff of the Institute of Tropical Hygiene in Amsterdam, and are described in detail by Wolff (1954). Live cultures of leptospires were used, and the sera were diluted from 1 in 10 to 1 in 30,000. Titres of 1 in 100 and over are regarded as indicating past or present leptospiral infections. A few titres as low as 1 in 10 to 1 in 30 have been recorded, but they are to be treated with reserve since their significance is doubtful.

The isolation of leptospires from the organs of infected animals at necropsy was attempted by grinding small pieces of tissue in Korthof's medium in a Waring blender and inoculating tubes of medium with three or four drops of the emulsion so produced. Latterly, however, we were more successful in obtaining positive cultures by inoculating duplicate tubes of Korthof's or Stuart's medium with small pieces of kidney tissue punched out with a Pasteur pipette, after the surface had been seared with a red-hot scalpel blade (cf. Wolff, 1954). The tubes were incubated at 28° C. and examined at weekly intervals up to six weeks before being discarded as negative.

In addition to culture, hamsters approximately 3 weeks old were inoculated intraperitoneally with 0.5 ml. of tissue emulsions or with 0.5 ml. of centrifuged urine deposit suspended in 1 ml. of Korthof's medium.

Microscopical examinations of cultures, urine, and heart blood from experimental animals were made with dark-ground illumination using a 2-mm. objective.

Clinical Observations

The first case to be investigated occurred in November, 1954, when a man employed on a piggery (Farm A) was admitted to hospital with a feverish illness of eight days' duration characterized by severe frontal headache. Blood taken from the patient agglutinated *L. canicola* to a significantly high titre. Although, on inquiry, no history of recent illness was forthcoming, blood from four out of five other persons living and working on the farm gave positive agglutination findings. The results of these tests and other relevant features are shown in Table I.

There were three dogs on the farm, and, to determine whether they might have been responsible for the infection, specimens of blood and urine were obtained. Dark-ground examination of the urine failed to reveal leptospires. Two of the sera agglutinated *L. canicola* to titres of 1 in 30 and 1 in

TABLE I.—Details of Personnel Living and Working at Farm A

	Age	No. of Years Working with Pigs	Remarks	Serum Titre of Agglutination Against	
				<i>L. canicola</i>	<i>L. icterohaemorrhagiae</i>
Mr. A. . .	23	4 months	Case of canicola fever	(1) 1/30,000 (2) 1/30,000	1/1,000 1/3,000
Mr. W. D. .	60	45 years	Owner of piggery (no significant previous history)	1/1,000	1/300
Mrs. W. D. .	50	Intermittently over a number of years	Wife of owner (no significant previous history)	1/10,000	1/300
Mr. J. D. . .	30	15 years	Son (no significant previous history)	1/3,000	1/300
Mrs. J. D. .	30	No association with pigs 20 years	Daughter-in-law	Negative	Negative
Mr. B. . .	40		Piggery worker (no significant previous history)	1/3,000	"

100, while none of them agglutinated *L. icterohaemorrhagiae*. These low agglutination titres and the absence of leptospirae in the urine did not point to the dogs as the direct source of infection, and, as the only person in the piggery whose blood failed to agglutinate leptospirae was also the only one of the six persons concerned who had no contact with pigs, it occurred to one of us (J. N.) that the pigs might be harbouring the organisms and serving as a reservoir of infection. Consequently, blood samples were taken at random from 75 of the animals and submitted for serological examination. The results are shown in Table II.

TABLE II.—Results of Leptospira Agglutination Tests with Pig Sera from Farm A

	Total Tested	Titres of Agglutination							
		Neg.	1/10	1/30	1/100	1/300	1/1,000	1/3,000	1/10,000
<i>L. canicola</i>	75	17	1	11	24	7	8	4	3

Thus evidence of infection with *L. canicola* based on positive serological findings was present in 46 of the 75 pigs tested (61%), while in 12 others a low degree of agglutination was obtained. Although, in the cases of the positive sera, cross-reactions occurred with *L. icterohaemorrhagiae* the titres never exceeded those with *L. canicola* and were usually much less. Twelve sera were also tested against *L. pomona* and *L. mitis* with negative results.

The interesting results obtained at Farm A were a stimulus to further study and, as a first step, inquiries were directed to another piggery (Farm B), in connexion with which a confirmed case of canicola fever had occurred two months previously. Specimens of blood were obtained from this man and his nine fellow workers, and also from 98 pigs taken at random on the farm. The results of leptospira agglutination tests, with other details, are given in Tables III and IV.

Table III shows that in four out of nine persons working at the piggery there was serological evidence of previous infection with *L. canicola*. Apart from the original patient, none of these workers, in spite of careful interrogation, gave a history of an illness suggestive of canicola fever.

It will be seen from Table IV that 40% of the pigs tested had antibodies to *L. canicola* present in their sera to a significant extent.

Inquiries were now extended to 10 other piggeries, and specimens of blood were obtained from 31 workers. Serological tests in 21 were negative, but the other 10 were positive and their agglutination titres with other relevant information are set out in Table V.

It should be mentioned that at three of the piggeries all eight workers examined were free from evidence of infection. No pigs were examined on these farms. The 10 cases with positive sera were among the 23 employees at the remaining seven farms. It is also of interest that at one of the latter farms 12 pigs out of 31 tested were found to have sera positive to *L. canicola*.

Summarizing the results shown in Tables I to V, it appears that of a total of 47 blood specimens taken from persons employed or living at 12 pig farms, 19 (40%) were found to contain antibodies to *L. canicola* in amounts sufficient to signify a past infection with that organism. Five of the persons concerned had had previous illnesses diagnosed at the time on clinical and serological grounds as canicola fever, while an additional five gave histories of undiagnosed illnesses, the symptoms of which, in retrospect, suggested canicola fever. As regards the pigs, 86 out of 173 (50%) at Farms A and B showed evidence of infection with

L. canicola to a significant degree. None of these animals revealed noticeable signs or symptoms of disease.

These findings strongly suggested the probability that infection had been transmitted from pig to man, but so far it had not been possible to isolate the leptospira from either pigs or man. Only one of the five human cases of confirmed canicola fever was ill during the course of the present investigation, and in his case blood cultures, dark-ground examination of the urine, and animal inoculation gave negative results, probably because he was not brought under notice at a sufficiently early stage of the disease. Specimens of urine from the bladders of a large number of pigs on Farm A showed no leptospirae on dark-ground microscopy, and we failed to isolate the organism by inoculating hamsters with kidney tissue from "non-thriving" pigs with high antibody titres for *L. canicola*. It should be noted, however, that there was in the piggery at the time a concurrent infection of *Pasteurella septica* which killed the hamsters rapidly and contaminated the culture media inoculated at necropsy.

Because of the failure to demonstrate leptospirae by these methods, it was decided to carry out experimental work to determine whether pigs could be artificially infected with *L. canicola* and whether leptospirae could then be isolated from the urine of these pigs.

Experimental Investigations

1. Artificial Infection of Pigs with *L. canicola*

Six pigs aged 2–3 months whose sera failed to agglutinate *L. canicola* and *L. icterohaemorrhagiae* were inoculated with a culture of *L. canicola* (strain Aldgate) kindly supplied by Dr. J. C. Broom, of the Wellcome Laboratories of Tropical Medicine. This strain is highly virulent (a hamster inoculated with 0.3 ml. of the culture died on the fifth day). The pigs were inoculated by the following routes: (1) Subcutaneously through the soft skin of the groin (0.5 ml.). (2) By scarification of the skin behind the ear, one drop of culture being placed on the scarified area, covered with cotton-wool, and held firmly in place with medicated elastic adhesive bandage. (3) Intranasally by rubbing the inside of each nostril with a swab saturated in the culture. (4) Routes 1, 2, and 3 combined. (5) By mouth: 1 ml. of the culture was introduced into the back of the throat by means of a syringe. (6) Control.

Evidence of Disease Resulting from Inoculations.—Rectal temperatures of the pigs recorded before the experiment and each day afterwards showed no significant rise. No apparent symptoms of disease developed and the pigs continued to gain in weight.

Serology.—Ten days after inoculation, and periodically thereafter until the pigs were killed, blood was withdrawn from the ear veins and agglutination tests were carried out with the sera against *L. canicola*. The results are shown in Table VI. These results show that a marked serological

TABLE VI

6	Control	"	"	Negative	Negative

* Pigs 1 and 4 were killed on the 18th and the 12th day respectively.

response followed inoculation of the culture by all routes except the intranasal one. Subcutaneous inoculation and inoculation through the scarified skin resulted in strongly positive agglutinating sera within 10 days. On the other hand, antibody production in the pig inoculated by mouth was delayed and titre had reached only 1 in 100 by the 28th day, continuing to increase to 1 in 3,000 by the 40th day. It is possible in this case that the actual infection may have

been acquired through contact with the pigs already infected by the other methods, although it is noteworthy that pigs 3 and 6 failed to show any evidence of infection 47 days after the beginning of the experiment. The result in the pig infected through scarified skin (No. 2) is particularly interesting, since it not only indicates that the serological response must have resulted from invasion of the tissues by the leptospirae but also that it is possible for natural infection to follow leptospiral contamination of wounds, so often inflicted when pigs fight with one another.

Attempts to recover infecting organisms were unsuccessful. Dark-ground examination of blood from the infected pigs taken 10 days after inoculation and urine specimens taken periodically thereafter failed to show leptospirae.

Pig 4 was killed on the 12th day, pig 1 on the 18th day, and pigs 2 and 5 on the 40th day after inoculation. At necropsy no lesions were seen in any of the organs, and we were unable to recover leptospirae from the kidney and liver of these four pigs either by cultural methods or by inoculation of hamsters.

2. Introduction of Non-infected Pigs into the Infected Piggery

In order to observe the effect of introducing non-infected pigs into an infected piggery the following investigation was carried out at Farm A.

Two pens of 20 pigs were chosen for this study. The pigs in the first pen—pen 1—had been introduced into it direct from the local market three weeks previously; those in the second pen—pen 2—one week previously. Both pens had housed pigs which on serological evidence were infected with leptospirae, but after these had been removed for slaughter the pens had been given their customary cleaning by hosing and left vacant for 24 hours prior to the introduction of the fresh pigs. Three pigs from each pen were chosen, and blood specimens from the ear veins of the six were found to contain no leptospiral antibodies. Subsequent specimens of blood were taken from the six at intervals and tested against *L. canicola* and *L. icterohaemorrhagiae*. The results are shown in Table VII.

TABLE VII

Pig No.	Length of Time in Piggery							
	1 Week		3 Weeks		5 Weeks		8 Weeks	
	<i>L. can.</i>	<i>L. ictero.</i>	<i>L. can.</i>	<i>L. ictero.</i>	<i>L. can.</i>	<i>L. ictero.</i>	<i>L. can.</i>	<i>L. ictero.</i>
Pen 1	1	—	—	Neg.	Neg.	Neg.	1/1,000	1/300
	2	—	—	"	"	"	1/10,000	1/1,000
	3	—	—	"	"	"	1/10,000	1/1,000
" 2	4	Neg.	Neg.	1/300	1/100	1/300	1/300	1/100
	5	"	"	Neg.	Neg.	Neg.	Neg.	Neg.
	6	"	"	"	"	"	"	"

From the serological results shown in this Table it appears that the three pigs in pen 1 became infected within six to eight weeks of their introduction into the piggery. In pen 2 the blood of one of the pigs agglutinated leptospirae weakly to a titre of 1 in 300 after three weeks, but the titre failed to rise during the subsequent weeks and its significance is therefore doubtful. The other two pigs continued to be serologically negative.

Isolation of *L. canicola* from Urine.—A specimen of urine taken from the floor of pen 1 during the eighth week was examined by dark-ground microscopy and found to contain numerous leptospirae (approximately one per field of uncentrifuged urine). The following day a pooled specimen of urine collected in a sterile long-handled pan from 12 pigs in this pen was examined, and again numerous active leptospirae were seen (up to four per field). Separate specimens were then obtained in sterile containers from individual pigs in the pen and five out of six were found to be positive. On the other hand, eight specimens of urine taken from individual pigs in pen 2 were examined by dark-ground microscopy but no leptospirae were seen. This accords with the negative serological findings for this pen.

A pooled specimen of urine from the pigs in pen 1 was inoculated into two hamsters: one of these died on the sixth and the other on the eighth day after inoculation. At necropsy, apart from some congestion of the blood vessels of the peritoneum, there were no obvious lesions. Dark-ground examination of heart blood failed to show leptospire, but six drops inoculated into Stuart's medium produced growth after 14 days' incubation. The culture was sent to Dr. Broom at the Wellcome Research Laboratories, and was identified as a strain of *L. canicola*.

3. Experimental Infection of Pigs with Infected Urine

Two of the six pigs used in experiment 1—namely, the one inoculated intranasally and the control animal—continued to show no serological evidence of infection. No leptospiral antibodies were present in either of these animals 47 days after the beginning of experiment 1. The following day they were inoculated with infected urine collected from 10 pigs in Farm A (pen 1). (The presence of leptospire was confirmed by dark-ground microscopy.) Pig 3 was inoculated subcutaneously with 3 ml. of untreated urine, while in the case of pig 6 a piece of cotton-wool soaked in urine was placed on an artificially scarified area behind the ear and held in place with medicated elastic adhesive bandage.

Symptoms of Disease Following Inoculation with Infected Urine.—Rectal temperatures were taken before the inoculations were made and daily thereafter. In both pigs a rise of several degrees was noted, from 102.5 to 106° F. (39.2 to 41.1° C.) on the sixth day in the case of pig 3, and from 102.8 to 104.6° F. (39.3 to 40.3° C.) in pig 6 on the 10th day. No other obvious symptoms developed. Blood cultures from a subcutaneous vein on the fifth day failed to produce a growth of leptospire. Blood-agar, plates inoculated with the blood and incubated aerobically and anaerobically remained sterile, showing absence of concurrent septicaemia. Dark-ground examinations of urine taken on the 15th, 19th, and 20th days failed to reveal leptospire. Agglutination tests carried out with blood taken at intervals resulted in the titres with *L. canicola* and *L. icterohaemorrhagiae* shown in

TABLE VIII

Pig No.	Inoculated	Days After Inoculation					
		5		11		21	
		<i>L. can.</i>	<i>L. ictero.</i>	<i>L. can.</i>	<i>L. ictero.</i>	<i>L. can.</i>	<i>L. ictero.</i>
3	Subcutaneous	Neg.	Neg.	1/3,000	1/30	1/30,000	1/300
6	By scarification	"	"	1/10,000	1/1,000	1/30,000	1/1,000

Table VIII. It will be seen that inoculation of the infected urine by both routes was followed by a high antibody level by the 11th day.

Necropsy.—The two pigs were killed 22 days after inoculation. The post-mortem examination revealed no abnormalities. Bottles of Stuart's medium were inoculated with kidney and liver tissue from both pigs. Leptospire grew in one of the bottles inoculated with kidney from pig 6. The growth was slight after 12 days, but by the 18th day numerous leptospire were present. One of two hamsters inoculated with emulsified kidney from pig 6 died 14 days later, showing epistaxis and a post-mortem picture characteristic of a leptospiral infection with pronounced haemorrhages in the lungs. A blood culture from this animal gave a fair growth of leptospire by the 7th day and cultures of the kidney were positive one week later. A few drops of the heart blood introduced intraperitoneally into the second hamster resulted in its death 10 days later. A blood culture from this second animal resulted in growth of leptospire within one week. We failed to isolate leptospire from pig 3 either by culture or by animal inoculation, although two out of four hamsters inoculated with emulsified kidney died in 11 days with haemorrhagic lesions characteristic of leptospiral infection.

Discussion

The evidence submitted above has indicated that 19 out of 47 (40%) piggery workers engaged in 12 different farms in the environs of Edinburgh had been infected at some time with *L. canicola*. It seems probable that the infection resulted through contact with infected pigs, since in one farm 77% of the pigs tested, and in another 44%, had serum antibodies to *L. canicola* and the organism was shown to be excreted at times in large numbers in the urine. This high incidence of infection in humans is particularly striking, since in view of the small number of cases which result from man's contact with infected dogs (the only source of infection previously known to exist for man) it was thought that *L. canicola* had a low infectivity to man. When one takes into consideration the large number of dog-owners in the country and the fact that 25–40% of dogs show serological evidence of infection (Stuart, 1946; Broom and Macintyre, 1948) it is surprising that cases of human canicola fever do not occur more often. Broom (1951) found that persons most liable to become infected were those who had nursed a sick dog and cleaned up its dejects. On the other hand, McIntyre and Seiler (1953), investigating in Edinburgh the incidence of canicola fever among owners of dogs known to be infected with *L. canicola*, found that of 99 persons who had been in contact with sick animals and including 45 who were responsible for removal of the dejects, none were serologically positive to *L. canicola*.

It may be that in the case of piggery workers the conditions under which these men work predispose them to infection. It is known that they frequently suffer from open cuts and wounds in their hands which are apt to become contaminated when cleaning out the pens. In Farm A, where the rate of infection both in humans and in pigs was most striking, conditions in the pens may have been conducive to maintaining the infection. This piggery usually houses a herd of 400 pigs, which are all swill fed. No breeding is done and replacements are made as required from the local markets at ages of 2–3 months. Little bedding is used and the pens are hosed daily, so that the floors, other than the sleeping quarters, are rarely dry and often very wet. The pigs are crowded together from 20–30 in a pen, a practice adopted to maintain a high temperature in the piggery. It seems possible that the leptospire may remain viable for a fairly long time on the moisture-laden floors. It is not known how the pigs were originally infected, but it seems likely that the farm dogs which have access to the piggery may have introduced it and, once established in the herd, the infection has passed from pig to pig through infected urine contaminating skin abrasions or the mucous membranes of the mouth and throat.

While canicola fever in man is not as a rule a killing disease, two fatal cases have been reported (Weetch *et al.*, 1949; Wolff *et al.*, 1951). Furthermore, clinical infection with *L. canicola* gives rise to a sharp illness with meningeal symptoms alarming to the patient and his relatives and incapacitating the victim for some weeks. It is clear, therefore, that all possible steps should be taken to prevent the disease.

Up to the present the main emphasis has been placed on the possibility of spread of infection from dogs, but the results described in this paper indicate that infected pigs are a more important source. This fact should be made widely known to pig owners and their employees so that they may be aware of the danger and the necessity for employing a high standard of hygiene in the piggery. After the animal pens have been thoroughly cleaned by hosing it is recommended that they be treated with a hypochlorite solution* and allowed to dry. So far as it is possible, dogs should not be allowed to come into contact with the swine; the workers should be encouraged to wash and dry their hands and equipment after cleaning out the pens, and to cover immediately any cuts and abrasions with adequate protective dressings.

*Davidson and Smith (1936) found that "chlorox" diluted 1 in 64 was effective in killing leptospire in premises contaminated with the urine of rats.

Summary

Five cases of canicola fever, diagnosed on clinical and serological evidence, occurred during a period of five years among piggery workers engaged in farms in the environs of Edinburgh.

A survey of 47 piggery workers in 12 Edinburgh farms showed from the results of serological examinations that 19 (40%) had at some time been infected with *L. canicola*. In addition to the five known cases this figure includes five others with histories of illness suggestive of canicola fever.

Specimens of blood from pigs from the two farms in which most of the cases occurred were found to contain antibodies to *L. canicola* in titres high enough to indicate a leptospiral infection. In one farm 46 out of 75 (61%) of the pigs were positive and in the other 40 out of 98 (40%).

Four out of six pigs newly introduced into one of the infected piggeries developed antibodies to *L. canicola* within three to eight weeks. On the 47th day after admission leptospire were being excreted in large numbers in their urine.

A hamster inoculated with the infected urine died after six days and leptospire were grown in culture from the heart blood. They were identified as *L. canicola*.

Six pigs were inoculated each by a different route with a virulent culture of *L. canicola*. Those which were inoculated subcutaneously and through a scarified area of skin developed antibodies to titres of at least 1 in 10,000 within 10 days. No obvious symptoms of disease followed the administration of the culture by any of the routes employed.

Pigs which were inoculated with urine from infected pigs subcutaneously and by scarification developed antibodies to *L. canicola* within 13 days. No symptoms other than a slight febrile reaction and a tendency to be less vigorous followed the inoculations.

The above evidence indicates that pigs may harbour *L. canicola* without showing any noticeable symptoms of disease. The organisms are excreted in the urine, and infection is passed from pig to pig. Human infection may result through contact with infected pigs.

The incidence of canicola fever in piggery workers is high, and this is in contrast to the recognized low infectivity rate among dog owners.

Our thanks are due to Mr. W. T. Forrest, assistant veterinary inspector of the City of Edinburgh, for valuable assistance with the animal experiments; to Dr. A. Wilson Taylor, senior lecturer in bacteriology at the Royal (Dick) School of Veterinary Studies; and to Dr. J. C. Ives, consultant bacteriologist, Royal Infirmary, Glasgow, for their help with the serological examinations of pigs' sera. We are also indebted to Dr. J. T. Stamp, Director, Animal Diseases Research Association, Moredun Institute, Edinburgh, for his kindness in providing accommodation for the experimental pigs and laboratory facilities at the Institute; and to Dr. J. C. Broom, of the Wellcome Laboratories of Tropical Medicine, for identifying the pig strain of leptospira.

NORADRENALINE IN SHOCK DUE TO VISCERAL PERFORATION

BY

D. D. DAVIES, M.R.C.S., L.R.C.P., D.A.

Department of Anaesthetics, Central Middlesex Hospital, London

In states of shock survival of the patient ultimately depends on removing the cause of the shock. Some temporary measure to tide the patient over the hypotensive crisis is, however, often necessary to prevent the vicious circle of progressive irreversible shock, and may be absolutely essential if the patient is to survive a major surgical procedure.

The following three cases of shock associated with visceral perforation all responded only temporarily to the infusion of moderate amounts of blood and dextran, and the early use of a continuous noradrenaline infusion over a period of days appeared to play a necessary part in maintaining an adequate blood pressure and in ensuring the recovery of the patients from the condition of circulatory failure. The cases described are three consecutive cases of this type that were admitted to the Central Middlesex Hospital.

Case 1

A woman aged 66 collapsed at noon on December 22, 1955, with very severe pain in the left iliac fossa, the pain soon radiating across the whole abdomen. When seen she was grey and very ill. Her blood pressure was 95/70 and her pulse volume was poor.

An intravenous infusion was set up and 1 pint (570 ml.) of dextran was given. Her general condition improved, and immediately prior to operation (six hours after the onset of symptoms) her systolic blood pressure was 125.

Anaesthetic induction and maintenance was with nitrous oxide, trichlorethylene, and oxygen. Orotracheal intubation with a cuffed tube was performed under suxamethonium relaxation. Gallamine, 40 mg., was given, and later a suxamethonium drip was set up. Operation revealed faecal fluid and also solid faeces in the peritoneal cavity, due to a rupture of the sigmoid colon. Distal to the rupture there was an annular thickening of the wall of the bowel, this almost certainly being neoplastic in nature. The peritoneum was cleaned of faeces so far as possible and the perforated gut was delivered as a loop colostomy. After operation intensive antibiotic therapy with penicillin, streptomycin, and oxytetracycline was instituted.

After induction the systolic blood pressure rose to 130, but thence gradually fell during the course of the operation even though a further $\frac{1}{2}$ pint (284 ml.) of dextran was infused. The pulse volume became very poor and eventually the systolic pressure was barely 80. The patient was cold and very pale. Intravenous injection of 14 mg. of methylamphetamine hydrochloride ("methedrine") in two divided doses produced only a slight and very transient improvement in the blood pressure. A blood infusion was then started, but no immediate improvement followed.

In order to raise the blood pressure intravenous noradrenaline was given at the conclusion of the operation. A strength of 4 mg. of the bitartrate in 1,000 ml. of dextrose-saline was used, and at 60 drops a minute the systolic blood pressure rose from 80 to 125 within a matter of minutes (Fig. 1).

Back in the ward the intravenous noradrenaline was temporarily discontinued, one hour after its commencement, to see if the blood pressure would be maintained. At this time the patient had had a total of $1\frac{1}{2}$ pints (850 ml.) of

dextran and nearly 1 pint (570 ml.) of blood. There was an immediate fall in blood pressure to 90 systolic and the pulse rate rose from 140 to 160. Consequently the intravenous noradrenaline was recommenced. The blood pressure immediately rose and the pulse rate fell again.

Two hours after its commencement, the infusion was doubled in strength to 8 mg. of noradrenaline per 1,000 ml., and was utilized at this strength for the next 13 hours at a rate that varied between 32 and 80 drops a minute. Notwithstanding this, the systolic blood pressure sometimes fell to 75 and remained there at one period for four hours. The pulse volume remained very weak and the condition of the patient was poor.

Fifteen hours after operation the strength of the infusion was again doubled (now 16 mg. of noradrenaline per 1,000 ml.). At varying rates up to 60 drops a minute the systolic pressure was maintained at about 85 for the next

FIG. 1.—Chart showing the response of the systolic blood pressure to noradrenaline infusion (Case 1).

five hours. At 20 hours from operation the pressure rose to 100 and was maintained between 100 and 120 at 40 to 60 drops a minute. The general condition of the patient now showed some definite improvement.

Still later the strength of the infusion was increased to 32 mg. of noradrenaline per 1,000 ml. At a drip rate varying between 30 and 60, the systolic pressure was maintained fairly constantly in the region of 100. The pulse rate was 110 and the condition of the patient was now much improved.

At 40 hours from operation the drip rate was slowed to 10 and finally stopped about 47 hours after operation. Subsequently the systolic pressure was well maintained at over 110, and later became stabilized in the region of 130. The pulse rate remained about 100. The patient continued to gain strength day by day.

No further blood or dextran was given to the patient other than that received before, during, and immediately after the operation—a total of 1½ pints (850 ml.) of dextran and 1 pint (570 ml.) of blood.

The urinary output during the first post-operative 24 hours was only 8 oz. (227 ml.). During this period the systolic blood pressure was for long periods between 75 and 90. Urinary output during the second 24 hours was 33 oz. (938 ml.). During this period the systolic pressure was maintained between 100 and 130 for most of the time. Urinary output during the third 24 hours was 84 oz. (2,387 ml.).

A further operation, at a later date, revealed that the carcinoma was inoperable, and the patient went home with a permanent colostomy. Her general condition, however, was remarkably good.

Case 2

A man aged 49 on January 6, 1956, gave a history of sudden onset of acute central abdominal pain. When

admitted he was in great pain and in a shocked condition. His blood pressure was 93/55 and pulse rate 140.

He was given morphine, ½ gr. (16 mg.), and an infusion of dextran was started. Immediately prior to operation (about nine hours after the onset of symptoms) he had had 1 pint (570 ml.) of dextran and his systolic blood pressure was 100.

Anaesthetic induction and maintenance was with nitrous oxide, trichlorethylene, and oxygen. Orotracheal intubation with a cuffed tube was performed under suxamethonium relaxation. Later gallamine, 80 mg., and further suxamethonium were given. Operation revealed a large quantity of faecal fluid and lumps of solid faeces in the peritoneal cavity. There was a rupture in the wall of the sigmoid colon. The peritoneum was cleansed, the distal colon emptied of faeces, and the rupture in the sigmoid colon sutured. A transverse colostomy was performed. Following operation antibiotic therapy with penicillin and streptomycin was instituted.

Six minutes after induction the systolic blood pressure rose from 100 to 120, but thereafter there was a steady fall in pressure even though another full pint (570 ml.) of dextran was infused fairly rapidly. Towards the end of the operation the systolic pressure was 90 and infusion of blood was started. Two-thirds of a pint (380 ml.) of blood was given in 35 minutes before the patient was returned to the ward; the systolic pressure was then 100. Back in the ward the remainder of the blood was given, and the blood pressure rose to 115/70. A total of 2 pints (1,140 ml.) of dextran and 1 pint (570 ml.) of blood had then been given. The patient received no further intravenous dextran or blood.

Subsequently, however, the blood pressure progressively fell and in 75 minutes had dropped to 70/50. Intravenous noradrenaline was then begun one and a half hours after the end of the operation, and the blood pressure was raised to 100/60 in 30 minutes using a strength of 8 mg. of noradrenaline to 1,000 ml. of dextrose-saline running at 25 drops a minute. Later the drip rate had to be increased to 60 to keep the systolic pressure between 90 and 110, and at nine hours after operation the rate had to be increased to 80.

Eleven hours after operation the infusion strength was increased—to 24 mg. of noradrenaline per 1,000 ml. At 20 drops a minute the pressure fell to 70/50, but at 36 drops it was maintained fairly constantly at 100/70. The general condition of the patient was now improved.

Twenty-six hours after operation the infusion strength was again increased—to 32 mg. of noradrenaline per 1,000 ml., and a drip rate of about 40 maintained the blood pressure at approximately 115/70. Forty hours after operation the drip rate was cut down to 25 and later reduced still further. The blood pressure was maintained about 125/70 and the general condition of the patient was now fairly good.

Sixty hours after operation the noradrenaline infusion was discontinued. Although the patient had been weaned off

FIG. 2.—Chart showing the relationships of the blood pressure and the urinary output to the noradrenaline infusion (Case 2). Following the cessation of noradrenaline infusion there was a 24-hour period of hypertension.

this fairly gradually there was a fall in blood pressure to 90/60 and later to 80/50, the period of hypotension persisting for about 24 hours. As the condition of the patient was then good and he showed no other signs of shock it was decided not to restart the noradrenaline infusion. The blood pressure eventually rose above 100 systolic and became stabilized about 110/65.

The urinary output during the first 24 hours following operation was 13½ oz. (383 ml.) and during the second 24 hours was 33 oz. (938 ml.). Twenty-four hours before the cessation of the noradrenaline infusion the output was 43 oz. (1,221 ml.) but fell to 16 oz. (454 ml.) for the 24 hours during the period of hypotension following its cessation (Fig. 2). The input during this latter period was greater than the input of the previous 24 hours.

The colostomy was later closed and the patient eventually left hospital fit and well. A pathological state that could have accounted for the rupturing of the colon was never found.

Case 3

A man aged 75 awakened in the early hours of the morning of January 18, 1956, with severe epigastric pain which rapidly spread to the rest of the abdomen. When seen about six hours later he was in great pain and was pale and shocked. His blood pressure was 86/50 and his pulse 102.

A dextran infusion was started and morphine, ½ gr. (11 mg.), was given. Immediately before operation (about eight hours after the onset of symptoms) he had had 1 pint (570 ml.) of dextran and his systolic blood pressure was 110.

Anaesthetic induction and maintenance was with nitrous oxide, trichlorethylene, and oxygen. Orotracheal intubation with a cuffed tube was carried out under suxamethonium relaxation; later gallamine, 60 mg., was given. Further relaxation was provided by using intermittent suxamethonium. Operation revealed a large pyloric ulcer which had perforated. Several pints of free fluid and much gas were found in the peritoneal cavity. A partial gastrectomy was performed with moderate difficulty.

Fifteen minutes after induction the systolic pressure had risen from 110 to 120. As operation began a slow blood infusion was set up. However, within the next 35 minutes the systolic pressure had fallen to 80 and consequently the rate of the blood infusion was accelerated very considerably. There was an immediate response and the systolic pressure eventually rose to 140. Following cessation of the blood infusion, however (after 1 pint (570 ml.) had been given), there was a fairly abrupt fall in pressure down to 75 systolic. Intravenous methylamphetamine hydrochloride (8 mg.) raised the systolic pressure immediately to 130, but this was very transient and a further intravenous dose of 8 mg. had to be

given 20 minutes later, together with 12 mg. intramuscularly (Fig. 3). Again a good but relatively transient response was obtained.

At the conclusion of the operation voluntary respirations were relatively shallow, and while still intubated the patient suddenly collapsed, his radial pulse becoming impalpable. Whilst apparatus for a noradrenaline infusion was being assembled the patient was inflated with oxygen and recovered in under a minute, his systolic pressure returning to 110. Atropine, 1/100 gr. (0.65 mg.), and neostigmine, 2 mg., were given intravenously, and voluntary respirations definitely improved and soon appeared to be quite adequate. As the systolic pressure was being maintained over the next 15 minutes the noradrenaline infusion was withheld.

On return to the ward the patient's systolic pressure fell, and one hour after leaving the theatre was only 75—it remained about this level for two and a half hours. During this period a further ½ pint (284 ml.) of blood was infused, but no significant rise in the blood pressure occurred. A total of 1 pint (570 ml.) of dextran and 1½ pints (850 ml.) of blood had then been given. As the general condition of the patient was very poor a noradrenaline infusion was begun, a strength of 8 mg. of noradrenaline to 1,000 ml. of dextrose-saline being used. The infusion was run very slowly at first; the systolic pressure was gradually raised to 100 and was maintained fairly constantly at this level, running at 40 drops a minute.

Six and a half hours after the commencement of the infusion the strength of the noradrenaline was doubled (to 16 mg. of noradrenaline per 1,000 ml.) and the rate cut down to between 20 and 25 drops a minute. The systolic pressure was maintained fairly constantly at 100 to 110 and later between 110 and 120. The general condition of the patient showed marked improvement over the next 16 hours. Further steady improvement continued day by day.

The noradrenaline infusion was continued for a total of 40 hours; for most of the time the rate was approximately 20 to 30 drops a minute, the strength of solution being 16 mg. of noradrenaline per 1,000 ml. The infusion was discontinued fairly suddenly and the systolic pressure fell from a constant 120 down to 105. Within a further three hours, however, it was being maintained constantly between 115 and 120.

Twenty-seven hours after the commencement of the noradrenaline infusion the patient's pulse was noticed to be irregular. This was probably due to auricular fibrillation, but it might have been caused by multiple extrasystoles. No fall in the blood pressure occurred and the patient's general condition remained steady. Intravenous digoxin was given in the infusion. The irregular pulse persisted for over 24 hours after the time the noradrenaline was discontinued.

Owing to incontinence the exact urinary output during this period could not be accurately ascertained, but, apart from the first 24 hours, it appeared to be adequate.

On the twelfth day after operation the patient was very well and was beginning to eat a light diet. Unfortunately, in the evening he suddenly collapsed and died. Post-mortem examination revealed a pulmonary embolus.

Discussion

Although a systolic blood pressure below 70 or 80 mm. Hg may be tolerated for some considerable time in an otherwise fit individual, there is little doubt that in an ill and toxic patient such a hypoten-

FIG. 3.—Chart showing the response of the systolic blood pressure to rapid blood infusion, intravenous methylamphetamine hydrochloride, anoxia, and noradrenaline infusion (Case 3).

sion persisting for more than an hour or so must seriously prejudice the chances of recovery. Therefore in ill toxic patients every endeavour must be made to raise the systolic pressure to about 90 mm. Hg or above.

In the treatment of shock due to visceral perforation simple infusions of blood or dextran alone are usually effective in permanently maintaining an adequate blood-pressure level provided that the factors causing the shock are effectively treated. Therefore, in the first instance, infusions of blood or dextran should be instituted. Should such simple measures fail, then the early use of continuous noradrenaline infusion probably holds out the best chance of recovery.

In the three cases of this series the responses to intravenous infusions of blood and dextran were initially good, but in none of them was the blood pressure maintained permanently at a reasonable level even after the infusion of moderate amounts—2½ to 3 pints (1,400 to 1,700 ml.)—of these fluids. However, intravenous noradrenaline quickly brought up the blood pressures, and, by a regulation of the rates of infusion, maintained them, by and large, at a constant satisfactory level. In the absence of some such measure to maintain a satisfactory blood-pressure level, it is possible that none of these patients would have survived. Perhaps further transfusions of blood and dextran might have achieved similar results, but they could, at the same time, have led to a dangerous overloading of the circulation. Certainly the use of very large amounts of blood would appear to be a more unphysiological line of therapy notwithstanding the limitations of noradrenaline as a pressor agent.

Objection to the use of noradrenaline in hypotensive states has been made because it is thought that, although the blood pressure is raised, the blood flow to vital organs is, owing to the completely unselective nature of the vasoconstriction produced by the pressor agent, actually reduced. This is undoubtedly true when considering the effect of noradrenaline on normotensive individuals, or on shocked subjects whose symptoms are due to reduced blood volume, but the haemodynamic response that occurs when noradrenaline is administered to a subject whose shocked state is not associated with any significant oligæmia may not be at all times comparable, and clinical experience tends to confirm this view. The heightened level of consciousness often seen in such shocked patients as the blood pressure rises under noradrenaline therapy is strongly indicative of an increased cerebral blood flow. The vastly increased urinary output is, similarly, a strong indication that the renal blood flow has increased, although some increase in urinary output is theoretically consistent with a reduced blood flow if the filtration fraction is sufficiently increased.

No obvious change in the level of consciousness was noted in these patients, mainly, no doubt, because the infusions were started in the immediate post-operative period. A significant effect on the urinary output was, however, apparent in Case 2, and its effect on the output in the other cases was probably no less significant. In Case 2 there was a 24-hour period of hypotension following the cessation of the noradrenaline infusion (60 hours after operation), and during this period the urinary output fell dramatically notwithstanding the fact that the input was slightly greater than the input of the previous 24 hours (Fig. 2). It is therefore reasonable to infer that noradrenaline played an important part in the maintenance of an adequate urinary output, and that its effect in maintaining such an output was so great that it is reasonable to assume that renal blood flow, during the period of noradrenaline therapy, was greater than the blood flow in the period immediately after its cessation. The effect of noradrenaline on the blood flow to other vital organs was probably comparable.

The early promotion of an increase in blood flow to vital organs, including centres in the medulla, together with the correction of any myocardial ischaemia following an increase in coronary blood flow, almost certainly helps to prevent the

development of an irreversible phase, refractory to treatment (including noradrenaline therapy), and progressing rapidly to complete circulatory standstill.

The need to increase progressively the dose of the drug as the duration of its administration increases may be evidence of deterioration in the condition of the patient, but it may, on the other hand, be due to the patient developing an acquired tolerance to the drug. It was met with in Cases 1 and 2, but not in Case 3. It was so marked in Case 1, where there had been such a dramatic initial response, that the systolic pressure was allowed to fall dangerously low: the strength of the noradrenaline solution should have been increased earlier than it actually was. Should this diminished response to the drug be due to acquired tolerance then it is possible that the administration of cortisone or corticotrophin might prevent it occurring.

Following induction of anaesthesia there was in all cases a slight rise in the systolic blood pressure and a marked diminution of the facial pallor. This may have been due to the removal of one of the possible factors causing the shock—namely, the severe pain. However, it is possible that more efficient oxygenation, following induction and intubation, was responsible for the temporary diminution of the signs of shock.

The paramount importance of adequate oxygenation in the shocked patient is clearly illustrated in Case 3. Here the patient collapsed after operation because voluntary respirations were too shallow for full oxygenation. Vigorous inflation with oxygen alone led to recovery in a very short time (Fig. 3). This episode underlines the need for ensuring that any respiratory depression due to relaxant drugs has been fully counteracted before extubation, and poses the question whether long-acting relaxants should be avoided in cases of shock or in very ill patients.

The noradrenaline infusions were maintained for 47, 60, and 40 hours respectively. Toxic effects attributable to the drug were not noticed.

Summary

Three cases are described in which noradrenaline had to be used in order to maintain an adequate blood pressure after traditional methods of resuscitation had failed. The cases are consecutive ones of their type. The two patients with perforation of the large bowel recovered completely; the patient with peptic ulcer perforation showed a good immediate recovery but died 12 days later owing to a pulmonary embolus.

It is suggested that in these cases of shock traditional methods of resuscitation should be tried first, but if these methods fail the use of a continuous noradrenaline infusion should not be delayed.

Noradrenaline therapy is very far from being the complete answer to the problem of the treatment of the shock due to visceral perforation, but its early use in the shocked state probably produces an increase in blood flow to vital organs. This and the correction of myocardial ischaemia (following the increase in coronary blood flow) may be important factors in helping to prevent the development of an irreversible phase which is refractory to treatment and where noradrenaline therapy is of no avail and may possibly do more harm than good.

The paramount importance of adequate oxygenation in the shocked patient is stressed.

My thanks are due to Mr. T. G. I. James for permission to publish Cases 1 and 3 and to Mr. J. D. Fergusson for permission to publish Case 2—under whose care these patients were respectively; to Dr. R. D. Levis for his interest and help; to others who have offered help and criticism; and to Mrs. I. M. Prentice, of the department of medical art, who produced the charts.

REPORT OF TWO SIBLINGS DIAGNOSED AS CASES OF ACUTE LYMPHATIC LEUKAEMIA

BY

MARY E. CARTER, M.B., B.S.

House-Physician, St. Mary's Hospital, London

The cases described below concern a brother and sister in both of whom acute lymphatic leukaemia was diagnosed during life. In the sister the disease followed a classical course to an early death, but in the brother, although he too died after a short illness, certain unusual features were noted during life and at necropsy. This report is presented because of the rarity of familial leukaemia and because of the interest of the case of the brother.

Case 1

The patient, a housewife aged 38, was admitted to West Middlesex Hospital early in March, 1950, because of pallor, generalized pains and weakness developing during the last three months, epistaxes, and the passage of blood clots per vaginam apart from normal menstruation. There was nothing relevant in the past history. Results of blood examination on March 3 were: haemoglobin 53% (Haldane); R.B.C. 2,390,000 per c.mm. Total white cell count not available, but differential count showed polymorphs 12%, lymphocytes 71%, prolymphocytes 9%, and nucleated R.B.C. 8%.

Clinical examination revealed a pale woman with bilateral subconjunctival haemorrhages and suborbital bruising, petechiae, and bleeding gums. There was no lymphadenopathy, but spleen and liver were each enlarged to two fingerbreadths and were tender; two small haemorrhages were noted in the left optic fundus. Blood pressure was normal, the urine clear, and the temperature 99.6° F. (37.55° C.). Blood examination on March 10 showed: haemoglobin 34%; R.B.C. 1,200,000 per c.mm.; W.B.C. 50,700 per c.mm. (polymorphs 2.5%, lymphocytes 77%, lymphoblasts 20%).

The patient's condition rapidly deteriorated, with epistaxes, haematemesis, and melaena, and she died in cardiac failure on March 17, 1950.

Case 2

This patient, a brother of Case 1, aged 31, was admitted to King Edward Memorial Hospital, Ealing, on July 5, 1955. He had first complained of lumbar pain, with swollen inguinal and axillary lymph nodes, eight weeks previously, and at that time was thought to be suffering from glandular fever. There was no history of past illness. On June 8 a fever. There was no history of past illness. On June 8 a blood count revealed: haemoglobin 94%; W.B.C. 6,000 per c.mm. (polymorphs 10%, lymphocytes 89%, monocytes 1%), some large and atypical lymphocytes being similar to those seen in glandular fever.

Two weeks later severe gingivitis and some petechiae on the left arm developed. Cervical and submandibular

lymph nodes swelled and he became pyrexial. On June 24 the blood count was: haemoglobin 78%; W.B.C. 7,000 per c.mm. (polymorphs 56%, lymphocytes 36%, monocytes 4%, eosinophils 3%). No atypical "glandular fever" cells noted.

On his admission to hospital on July 5 the patient was pale and had visibly enlarged cervical and submandibular lymph nodes. There were no abnormalities in the cardiovascular or respiratory system. The tip of the spleen was just palpable, but the liver was not enlarged. There was

Fig. 1.—Case 2: Sternal marrow smear on admission to hospital. (×180.)

generalized lymphadenopathy, also generalized petechiae becoming confluent over chest and abdomen. Temperature was 101° F. (38.3° C.). Blood picture on admission: haemoglobin 57%; R.B.C. 4,400,000 per c.mm.; W.B.C. 3,400 per c.mm. (atypical non-granular immature cells 27%, neutrophils 6%, lymphocytes 67%); platelets 166,000 per c.mm. On sternal marrow puncture large numbers of primitive leucocytes (blast cells) and a very few normal elements were found (Fig. 1). Blood was transfused repeatedly, but no remission occurred. In view of the low total leucocyte count the patient was not given radiotherapy, or any drugs, apart from sedatives. He steadily became weaker, and on July 26 a severe throat infection with monilia occurred which did not respond to treatment.

By August 1 the lymph nodes had rapidly decreased in size and then remained so. Clinically the spleen did not appear to enlarge further. A swinging temperature—98°–101° F. (36.7°–38.3° C.)—was maintained throughout the illness. A blood count on July 27 showed: haemoglobin 70%; W.B.C. 2,400 per c.mm. (lymphoblasts 20%, polymorphs 14%, lymphocytes 64%, monocytes 2%); and on July 30: haemoglobin 57%; W.B.C. 1,400 per c.mm. (differential count as before). The blood picture continued to deteriorate, and on August 10 the figures were: haemoglobin 25%; W.B.C. 800 per c.mm. (lymphoblasts 8%, polymorphs 6%, lymphocytes 84%, monocytes 2%). The patient died two days later.

Comment

There is no other family history of leukaemia, but the father and a brother and sister, who are alive and well, state that the patients' maternal grandfather died of a "rare disease." Their mother was said to have died "at the menopause," and she lost three infants before the birth of the two patients and the surviving brother and sister, the cause of their death being unknown.

Unfortunately no post-mortem examination was held on the woman. The following is taken from the necropsy report (Dr. W. S. Killpack) on her brother: "Emaciated

young adult male, slightly jaundiced. **Cardiovascular System:** Heart as a whole, dilated; pericardium healthy, no haemorrhages; myocardium very pale but fairly firm; endocardium healthy; vessels healthy. **Respiratory System:** Lungs very bulky due to oedema; numerous emphysematous bullae in right upper lobe; extensive congestion of lower lobes, ? also interstitial haemorrhage; no pneumonia found. Air passages: Some frothy mucus present; thrush membrane on epiglottis and vocal cords. Pleurae dry; fibrin over left lower lobe. **Alimentary System:** Tongue clear; extensive thrush membrane on pharynx. Oesophagus dilated with almost cylindrical, firm thrush membrane. Stomach dilated, healthy. Small gut: a few ulcers up to 1 cm. diameter in terminal ileum. Large gut: similar ulcers with membrane in caecum and descending colon. Liver (2,200 g.): normal pattern; cut surface rather brown. Gall-bladder distended with watery bile. Pancreas healthy. **Urogenital System:** Kidneys (320 g.) generally pale, marked cloudy swelling, number of pin-point haemorrhages. Bladder healthy. Genital organs healthy. Spleen (170 g.): cut surface congested, normal pattern. Lymph nodes: all groups enlarged to about twice normal size except those on lesser curvature of stomach, which were firm and greatly enlarged. Bone marrow uniformly pink and creamy. Adrenals oedematous; complete lipid depletion. Thyroid healthy."

The histological report is as follows. Sternal marrow practically acellular; oedematous young connective tissue with small collections of lymphocytes and plasma cells and histiocytes; occasional groups of undifferentiated cells (Fig. 2). Spleen: Extramedullary haematopoiesis and siderosis without fibrosis; widespread infiltration by histiocytes (? reticulum cells), many multinucleate; undifferentiated cells here also scattered in small groups. Kidney: small focus of proliferating histiocytes or reticulum cells,

FIG. 2.—Case 2: Appearance of sternal marrow smear post mortem. ($\times 180$.)

with some new connective-tissue formation. Lung: oedema and "monocytic pneumonia." Oesophagus: monilial oesophagitis. Liver: some fatty change; no obvious infiltration.

Discussion

The interesting features of the brother's case were the rapid regression of the enlarged lymph nodes, and the change in the sternal marrow from being full of proliferating primitive cells to being virtually empty of everything but connective tissue. The enlarged submandibular and cervical nodes were very prominent at the time of his admission and subsequently. Their size diminished rapidly, literally overnight, so that by the morning of August 1,

1955, his face had resumed its normal contours. What had happened during the course of a few hours to the cellular or other tissues responsible for these swellings? And what had happened to the cells crowding the marrow cavity? Two possible diagnoses might be considered: (1) atypical reticulum-cell sarcoma with bone-marrow depression; and (2) acute lymphatic leukaemia with atypical termination. But both seem rather unlikely, for in effect there was little sign of either condition at necropsy, especially in the histological sections. No record of a similar case has been found, and it is considered that no recognized diagnosis can be applied to the present case. The case perhaps illustrates the point made by Marshall (1956), that "owing to the effects of specialisation in peripheral blood and bone marrow studies there is still a tendency to regard leukaemia as a separate disease entity instead of as a symptom in a number of neoplastic reticular tissue proliferations."

The rarity of familial leukaemia is shown by a comparison between the number of cases reported in the literature and the total number of deaths from leukaemia, which in England and Wales alone averages over 2,000 a year, the figures for 1952, 1953, and 1954, as given by the Registrar-General in his quarterly returns, being respectively 2,043, 2,121, and 2,160. By contrast there have been only about 110 cases of familial leukaemia reported in the world literature since the first descriptions of leukaemia in 1845 (Virchow; Bennett; Craigie). The first authenticated case of familial leukaemia which Videbæk (1947) allows was described by McGavran in 1922 and included in Petri's 1933 review.

Videbæk's appears to be the last review of the literature on familial leukaemia to have been published; this author found 82 leukaemic subjects in all age groups belonging to 37 different families, in none of which was there consanguinity. Since its publication, so far as I can ascertain, another 28 unquestionable cases in 12 families (excluding cases without supporting laboratory evidence) have been reported (Frech, 1948; Riel, 1948; Barbier *et al.*, 1949; Smith and Horne, 1950; Anderson, 1951; Bieber, 1951; Debré *et al.*, 1951; Portmann and Robinson, 1951; Reilly *et al.*, 1952; Stobbe and Taeschner, 1952; Ward *et al.*, 1952).

Summary

The cases of a brother and sister diagnosed in life as suffering from acute lymphatic leukaemia are reported, with a discussion of certain unusual aspects of one of the cases. Both patients died.

Brief reference is made to cases of familial leukaemia reported in the world literature.

I wish to thank Dr. J. W. Litchfield, under whose care Case 2 was admitted, for permission to publish. Case 1 was under the care of the late Dr. J. A. Torrens. I would also thank Dr. W. S. Killpack (who performed the necropsy in Case 2) and Dr. R. R. Wilson for their opinions on the bone-marrow smears and necropsy sections, and am greatly indebted to Dr. R. R. Wilson for help in preparing the article.

TWO CASES OF RUPTURE OF THE EXTRAHEPATIC BILE DUCTS

BY

JOHN A. MCCREDIE, F.R.C.S., F.R.C.S.Ed.
Principal Tutor, Department of Surgery, the Queen's University of Belfast

Closed abdominal injuries that are not rapidly fatal rarely cause damage to the extrahepatic bile ducts. The cases of two children are described in whom, as a result of a traffic accident, there was leakage of bile into the peritoneal cavity, which ceased spontaneously without any local repair at operation.

Case 1

A deaf boy of 5 years was run into by a car in March, 1952. He was struck on the left side and thrown to the side of the road. On admission to the Royal Belfast Hospital for Sick Children he was pale, with a pulse rate of 160 and a blood pressure of 60/30 mm. Hg. There was no superficial bruising. His abdomen was tender and diffusely rigid. X-ray examination of his chest and abdomen revealed nothing abnormal. After a blood transfusion his general condition greatly improved.

At laparotomy five hours after the injury about 15 oz. (430 ml.) of blood was evacuated from the abdominal cavity. The only other abnormality discovered was a large haematoma distending the right half of the lesser omentum in its free margin; neither the spleen nor the liver had been torn. As bleeding had already ceased nothing further was done and the abdomen was closed without drainage.

His condition was satisfactory until the eighth post-operative day, when a faint tinge of jaundice appeared; it progressed steadily and was accompanied by increased bile pigment in the urine and absence of stercobilin from the faeces. At the same time the abdomen became so distended with fluid that between the fourth and eighth post-operative weeks it was aspirated four times, in all about 7 pints (4 litres) of heavily bile-stained but uninfected fluid being removed. By the end of the eighth post-operative week the abdominal swelling had subsided, the jaundice had gone, the excessive bile pigment had disappeared from the urine, and normal pigmentation had returned to the faeces. Throughout these eight weeks he made no complaint of abdominal discomfort, had a moderate appetite, and never had any abdominal tenderness or rigidity other than in the operation wound. When last seen (January, 1956) he was in excellent health.

Various investigations were undertaken. The liver-function tests showed no abnormality: bromsulphthalein test, 1% retention after 45 minutes; total serum proteins, 7.2 g. per 100 ml. (albumin 5.3 g., globulin 1.9 g.); serum alkaline phosphatase, 6.9 King-Armstrong units; serum bilirubin, 0.2 mg. per 100 ml. The blood picture was normal: Hb, 11.9 g. per 100 ml.; white cells, 9,520 per c.mm.; platelets, 253,000 per c.mm. "Biligradin" visualization of the biliary tract showed no abnormality.

Comment.—The injury damaged some part of the extrahepatic biliary system which, for a while, allowed all or almost all the bile it transmitted to leak into the peritoneal cavity, from which it was aspirated or absorbed. The absence of stercobilin from the faeces suggests that for probably about six weeks the bile was all either diverted or obstructed. With no operative treatment the biliary passages re-established their continuity.

Case 2

A boy aged 6 years was admitted to hospital on December 10, 1953, after being hit by a car. On admission he was severely shocked, showing signs of internal haemorrhage from a closed abdominal injury. A radiograph of the chest

and abdomen showed no abnormality. After blood transfusion his general condition greatly improved.

At laparotomy through an upper midline incision six hours after the injury a considerable amount of blood was found in the abdominal cavity. As the spleen was found to be torn, splenectomy was performed. A tear of the liver 2 in. (5 cm.) long and $\frac{1}{4}$ in. (6 mm.) deep was found in the groove for the falciform ligament. A large haematoma, as in the previous case, distended the right half of the lesser omentum and there was a tear in the centre portion of the lesser omentum (see Fig.). A retro-peritoneal haematoma was present, extending over the pancreas and the left kidney. Haemostasis was secured and the abdomen was closed with drainage.

Diagram showing haematoma in the right half of the lesser omentum and a tear in its central portion (Case 2).

The general condition remained good, but within two days a biliary fistula formed at the drainage site.

After draining profusely for about three weeks it dried up spontaneously. The faeces remained normal, no excess bile pigment appeared in the urine, and there was no sign of jaundice. The abdomen did not distend.

The patient has remained a healthy schoolboy with no abnormality detectable on physical examination. Biligradin x-ray films show no abnormality of the biliary tract.

Discussion

Injury to the extrahepatic ducts is a rare surgical problem, probably because the associated injury to neighbouring structures causes early death. Fewer than 100 cases were recorded in the last century (Mason, Sidbury, and Guigan, 1954). The present two cases are the only ones in the records of the Royal Belfast Hospital for Sick Children for the last 25 years.

The extrahepatic ducts can be injured by direct violence from crushing against the vertebral column, but our first case and that described by Benson and Prust (1953) both received blows on the left side. Possibly the injury was caused by indirect violence as a result of sudden stretching of the structures in the right (free) border of the lesser omentum following flexion of the trunk to the left.

Both cases presented with signs of intraperitoneal haemorrhage, which before operation was thought to be due to rupture of the spleen or liver. In each a large haematoma completely obscured the anatomy in the region of the free border of the lesser omentum, and in neither was it thought advisable to disturb it. It may be that in each case the presence of the haematoma prevented the escape of bile at the time of laparotomy and that only as the haematoma was absorbed was bile able to leak out. Another possibility is that the wall of the duct sloughed later.

The escape of sterile hepatic-duct bile into the peritoneal cavity does little harm (Harkins, Harmon, and Hudson, 1936), causing an exudation of some fluid and a slight rise in pulse and temperature. Both of our cases had post-operative escape of bile into the peritoneal cavity without any general systemic upset. The drain in Case 2 allowed the bile to escape, preventing abdominal distension. In this case also a small tear was present in the liver which could have allowed the escape of bile; but since the discharge was so copious and prolonged, and since the haematoma in the

lesser omentum was exactly similar to that in our previous case, we feel that an extrahepatic duct must have been torn.

A partial or complete tear may occur in the extrahepatic ducts which may or may not be obvious at the time of operation. Many forms of surgical treatment have been advocated. Waugh (1916) had a case, very similar to our first, in which two laparotomies were carried out for upper abdominal distension and signs of obstructive jaundice and in which the condition suddenly cleared up spontaneously. Benson and Prust (1953) treated a case successfully by marsupialization and drainage of a false cyst of biliary ascitic fluid which had formed. Gross (1953) had two cases; one was treated successfully by simple drainage from the site of the injury, while in the other an attempt was made at primary repair. Stenosis of the common bile duct, however, developed, necessitating cholecysto-duodenostomy, which led to cholangitis, cirrhosis, bleeding oesophageal varices, and death. Mason *et al.* (1954) had a case which developed stenosis requiring cholecysto-duodenostomy even though no attempt at repair had been made at the primary operation. Hicken and Stevenson (1948) advocated a cholecystostomy to decompress the biliary system, and suggested that cholangiograms could be taken later to demonstrate healing of the tear and also to make sure that any associated traumatic pancreatitis which might obstruct the lower end of the common bile duct had settled before removing the tube.

It is quite clear that injuries to the extrahepatic ducts often heal spontaneously without the development of stenosis, and it is possible that an attempt to repair a recently traumatized duct may increase the likelihood of stenosis. Simple abdominal drainage, and possibly cholecystostomy, should be performed initially; if stenosis develops it can be treated later.

Summary

Two cases of rupture of the extrahepatic bile ducts are described in which the lesion was not recognized at operation. Biliary ascites with minimal systemic upset developed in one, necessitating frequent aspiration. In the other a drainage tube allowed the bile to escape externally. Spontaneous healing of the fistula occurred in both.

The General Register Office's analysis of the occupations of persons in England and Wales included in the 1951 Census has been published as *Census 1951, England and Wales, Occupational Tables* (H.M.S.O., price seven guineas). It is based on the full figures, thus replacing the results of the 1% sample published in 1952. The findings are compared with those of the 1931 Census. Owing to the difference in school-leaving age at the times of the Censuses, the 1931 occupational figures include some 285,000 children under 15, while the 1951 figures relate to those over that age. In 1951 14 million of the 16 million males were gainfully occupied, and 6½ million of the 18 million females. Of the occupied men, 29% were under 30 and only 4% over 65; of the occupied women, 44% were under 30 and 5% over 60. In 1951 there were 11 million married women, of whom 22% were gainfully occupied compared with 10% in 1931. The two commonest occupations for the married women were as charwomen and clerks—149,000 of each.

THE ANTIBACTERIAL ACTIVITY OF CHLOROPHYLL

BY

SHEILA MOWBRAY, B.A.

From the Wright-Fleming Institute of Microbiology,
St. Mary's Hospital Medical School, London, W.2

Numerous reports have been published describing the successful treatment of chronic infected wounds with water-soluble chlorophyll preparations. In many cases healing has been induced where there had been no response to conventional treatment. Bowers (1947) treated 400 various surgical cases with water-soluble chlorophyll and noticed that infected wounds became free from suppuration and odour within two or three days. Combes, Zuckerman, and Kern (1952) produced a similar reduction in suppuration in secondarily infected ulcers, contact dermatitis, and pemphigus. Carpenter (1949) observed an early eradication of infection and early healing in 127 cases of suppurative osteomyelitis and chronic ulcers: the healthy appearance of granulation tissue under chlorophyll therapy was stressed.

Whereas chlorophyll derivatives in wound healing are generally regarded as promoters of healthy granulation, some clinical reports suggested that they have antibacterial properties. Smith (1944) observed *in vitro* bacteriostasis of staphylococci, streptococci, and the anaerobic spore-bearers, while Nevin and Bibby (1954) showed that chlorophyll inhibited the growth of staphylococci, streptococci, and lactobacilli.

The present experiments were designed to investigate further, by *in vitro* methods, the antibacterial activity of a chlorophyll preparation.

Material and Methods

The water-soluble chlorophyll preparation used throughout these experiments was sodium potassium copper chlorophyllin (which is the base of "chloresium" preparations) kindly supplied by Rystan Company, New York. A fresh 10% solution was prepared daily in sterile distilled water, and dilutions of this used in all experiments.

The sensitivity of various organisms to chlorophyll was determined, using a plate method modified from that described by May and Morley (1952). Levinthal agar was used throughout. All organisms were grown in nutrient broth for five hours and the standard inoculum was one loopful, approximately 10^8 organisms. Plates were incubated aerobically for 16 hours at 37° C. The highest concentration of chlorophyll incorporated in solid media was 1/100. This was governed by the solubility of the preparation; a 10% solution was the maximum concentration possible.

Chlorophyll sensitivity was also determined by making bacterial counts of organisms growing in fluid media. Growth curves were plotted by the method of Miles, Misra, and Irwin (1938), with organisms grown in nutrient broth containing dilutions of chlorophyll.

Results

Sensitivity of Various Organisms to Sodium Potassium Copper Chlorophyllin.—The results of the plate method are shown in Table I. Chlorophyll was found to inhibit the growth of some Gram-positive bacteria, but had no effect on the Gram-negative organisms tested. No change in antibacterial properties was produced by heating the chlorophyll at 100° C. for one hour. The presence of 10% horse serum in the medium did not affect the inhibitory level. Since *Staph. aureus* is a common wound contaminant it was chosen as the test organism for all further experiments.

TABLE I.—Sensitivity of Various Bacteria to Chlorophyll

Organism	Inhibitory Level of Chlorophyll	Organism	Inhibitory Level of Chlorophyll
<i>Staph. aureus</i> ..	1/800	<i>Cl. welchii</i> ..	1/200
<i>Staph. albus</i> ..	1/800	<i>Cl. oedematiens</i> ..	1/100
<i>Str. pyogenes</i> ..	1/1,600	<i>Cl. sporogenes</i> ..	1/100
<i>Str. viridans</i> ..	not at 1/100	<i>Cl. tetani</i> ..	1/100
<i>Str. faecalis</i> ..	not at 1/100	<i>Ps. pyocyanea</i> ..	not at 1/100
<i>Pneumococcus</i> ..	1/1,600	<i>Pr. vulgaris</i> ..	not at 1/100
<i>B. pumilis</i> ..	1/800	<i>E. coli</i> ..	not at 1/100

Sensitivity of Different Strains of *Staph. aureus*.—Thirteen strains of *Staph. aureus* were streaked over chlorophyll-Levinthal agar: five were inhibited at a chlorophyll concentration of 1/800, seven at 1/400, and one at 1/100.

Effects of Age of Culture, Time of Inoculation, and Size of Inoculum.—Cultures of one strain of *Staph. aureus* incubated for 2, 4, 6, 8, and 24 hours were plated out on chlorophyll-Levinthal agar. A dilution of 1/800 chlorophyll inhibited growth after 16 hours' incubation in every case. After 24 hours' further incubation *Staph. aureus* grew in the presence of all concentrations of chlorophyll. It appears, therefore, that either chlorophyll is inactivated at 37° C. or it does not completely inhibit growth. Chlorophyll-Levinthal agar maintained at 37° C. for 24 hours before use still inhibited growth for 16 hours at a concentration of 1/800. Hence growth of the test organism after long incubation periods is not due to inactivation of the chlorophyll. The organisms are temporarily inhibited, but after 24 hours bacterial multiplication proceeds. The size of inoculum, ranging from 10^4 to 10^8 organisms, did not affect the inhibitory level.

Growth of *Staph. aureus* in the Presence of Chlorophyll.—The growth curves shown in Fig. 1 confirmed the conclusion drawn from the results of the plate method that chlorophyll

FIG. 1.—Growth curves of *Staph. aureus* in nutrient broth containing various concentrations of chlorophyll. n_t = Number of organisms per ml. at time t . n_0 = Number of organisms per ml. at start of experiment.

temporarily inhibits the growth of *Staph. aureus*. Some organisms were killed, the number increasing with chlorophyll concentration, but even when this was 1/20 bacterial multiplication began after 24 hours. Thus it seems that *Staph. aureus* became resistant to chlorophyll. The emergence of chlorophyll resistance could not be demonstrated by the usual methods because the solubility of the preparation is such that a concentration completely inhibiting the organism for indefinite periods could not be used. However, *Staph. aureus* was grown on Levinthal agar containing 1/100 chlorophyll by incubating at 37° C. for 48 hours. After eight subcultures of successively reduced incubation periods the organism grew well in the presence of 1/100 chlorophyll after 16 hours at 37° C. It therefore seems that some form of resistance to chlorophyll is acquired.

Copper Content of Sodium Potassium Copper Chlorophyllin.—The copper content of the chlorophyll preparation

used was 4.16%, and it was thought that its bacteriostatic properties might be due to the copper present. Three different organisms were cultured on two batches of Levinthal agar, one containing dilutions of chlorophyll and one containing copper sulphate in concentrations such that the two batches of medium contained identical amounts of copper. The results are shown in Table II. It may be concluded that the antibacterial properties of chlorophyll are not due to its copper content.

TABLE II.—Comparison of Sensitivity of Three Organisms to Chlorophyll and Copper Sulphate

Organism	Inhibitory Level of Chlorophyll	Inhibitory Level of CuSO_4 *
<i>Staph. aureus</i> ..	1/800	> 1/100
<i>Staph. albus</i> ..	1/800	> 1/100
<i>Str. pyogenes</i> ..	1/1,600	1/200

* Expressed as concentration of chlorophyll containing same amount of copper.

Effect of Chlorophyll on Bacteriostasis Produced by Antibiotics

The bacteriostatic effect of chlorophyll is slight, and it was thought that it might be better demonstrated by the use of synergism, as in the method described by Dye, Lynch, Cullen, and Sprague (1952). They increased the sensitivity of the agar diffusion assay of viomycin by incorporating sulphadiazine in the medium. The possible potentiating effect of antibiotics on the antibacterial activity of chlorophyll was investigated, using a routine plate assay method. Two-layer plates were poured. Both layers contained a subinhibitory level of penicillin, and the surface layer was seeded with an inoculum of an overnight *Staph. aureus* culture sufficient to produce confluent growth. Six porcelain cylinders were placed on the surface of each plate and were filled with equal volumes of different dilutions of chlorophyll. The plates were incubated for 16 hours and the diameters of the zones of inhibition around each cylinder were measured. The square of the diameter of the zone of inhibition was plotted against the log. of the concentration of chlorophyll.

Subinhibitory concentrations of penicillin incorporated in the medium were found to increase only slightly the zones of inhibition of growth of *Staph. aureus* produced around porcelain cylinders containing chlorophyll. The small size of zone of inhibition around a chlorophyll solution is probably due in part to the low diffusibility of the preparation; the green colour does not extend far beyond the porcelain cups. Hence the two substances were reversed; a subinhibitory concentration of chlorophyll was incorporated in the medium, and penicillin dilutions were put in the porcelain cylinders. A marked difference was observed in zone diameter between those produced on assay media containing chlorophyll and those on straight assay media. The same effect was demonstrated with oxytetracycline ("terramycin") and streptomycin, using *B. pumilis* as the test organism for oxytetracycline and *Staph. aureus* for streptomycin.

These findings are demonstrated graphically in Figs. 2, 3, and 4. It is obvious that subinhibitory concentrations of chlorophyll in the medium cause a vertical shift in the dose-response curves for penicillin, streptomycin, and oxytetracycline.

Growth curves were plotted of *Staph. aureus* growing in nutrient broth in the presence of penicillin alone, chlorophyll alone, and combinations of the two. No synergistic effect could be demonstrated as in the agar diffusion method. Therefore it appears that the increase in sensitivity of the agar diffusion assay of antibiotics produced by subinhibitory concentrations of chlorophyll is due to some physical property of the preparation and is not true synergism. Chlorophyllin is a surface-active agent, and may, by virtue of this property, increase the sensitivity of organisms to antibiotics under the conditions of an agar diffusion assay. Smith and Livingston (1945) found that experimental wounds

treated with chlorophyll and antibiotics healed more quickly than when treated with either agent alone. This effect may partly be due to an enhancement of the antibiotic's activity by the surface active properties of the chlorophyll.

FIG. 2.—Inhibition of *Staph. aureus* by penicillin in the presence of three concentrations of chlorophyll.

FIG. 3.—Inhibition of *Staph. aureus* by streptomycin in the presence of three concentrations of chlorophyll.

FIG. 4.—Inhibition of *B. pumilis* by oxytetracycline in the presence of three concentrations of chlorophyll.

Summary

Soluble sodium potassium copper chlorophyllin (which is the base of "chloresium" preparations) shows some bacteriostatic action against certain Gram-positive organisms, including *Staph. aureus*, *Str. pyogenes*, the pneumococcus, and the pathogenic clostridia. After a period of bacteriostasis, bacterial multiplication proceeds in the presence of all concentrations of chlorophyll tested.

After repeated culture in the presence of chlorophyll *Staph. aureus* becomes resistant to the temporary bacteriostatic effect of this substance.

The activity of some antibiotics is potentiated by the presence of subinhibitory concentrations of chlorophyll.

This work was carried out during the tenure of a research grant from Rystan Company, New York.

Medical Memoranda

Rupture of the Uterus Involving the Bladder

Ruptured uterus involving the bladder is a very rare condition. It is more likely to be met with after a previous caesarean section in which the bladder is firmly adherent to the uterine scar. The following case is of unusual interest in that the patient had had no previous operation and gave no history to indicate that the bladder might be adherent to the lower uterine segment. Nevertheless she sustained an extensive tear of the uterus and the bladder during labour, which resulted in the baby's shoulder being lodged in the bladder cavity.

CASE REPORT

The patient, a Yoruba of Western Nigeria aged about 36, was admitted into Massey Street Maternity Hospital, Lagos, Nigeria, on November 16, 1954, with a history of nine months' amenorrhoea and labour pains which had started 18 hours previously. She was a gravida 4, para 3, one alive; the last confinement being three years before admission. Previous pregnancies and deliveries had been uneventful. Her general condition on admission was fair, although she appeared dehydrated. Her temperature was 99° F. (37.2° C.), pulse 120, respirations 24, and B.P. 130/70.

The bladder appeared to be full and was palpable up to the level of the umbilicus. The fundus uteri was level with the ensiform cartilage. The abdomen was very tense and the foetal parts were difficult to palpate. The foetal heart was not heard. Vaginal examination revealed slight bleeding, an almost fully dilated os, with a thick rim of cervix felt posteriorly, and the presentation was a face jammed in mid-cavity. The suspicion of ruptured uterus was confirmed when blood escaped during an attempt to pass a catheter by displacing the head upwards.

At operation blood-stained fluid was found in the abdominal cavity. The bladder peritoneal reflection was raised, dark purplish, and oedematous. When this was opened blood clots were exposed and a longitudinal tear in the lower uterine segment was seen. On reflecting the bladder from the uterus the baby's shoulder came into view and the glistening mucous lining of the bladder was observed. It then became apparent that the bladder was involved in the rupture.

Examination of the damage revealed a longitudinal tear in the lower uterine segment and a T-shaped tear in the bladder, the longitudinal arm of which extended downwards, splitting the trigone of the bladder symmetrically in two and involving the upper third of the urethra.

A subtotal hysterectomy was performed and the bladder repaired with a No. 0 chromic catgut suture. The patient's condition was satisfactory throughout and she appeared very little shocked in spite of the extensive damage. An indwelling catheter was inserted and the abdomen drained. The patient made an uninterrupted recovery but developed

a urethro-vaginal fistula, which was successfully repaired two months after the operation for ruptured uterus.

I am indebted to the Chief Medical Adviser to the Federal Government of Nigeria for permission to publish this case.

Obstetrician in Charge, Massey Street Maternity Hospital, Lagos.

Perforated Duodenal Ulcer Complicating Prednisolone Therapy

Many instances of serious gastro-intestinal complications occurring during treatment with prednisone and prednisolone have been recorded. Bollet *et al.* (1955) and Boland (1956) found a high incidence of peptic ulceration in rheumatoid arthritis patients treated with these drugs. Kofman *et al.* (1956) reported peptic ulceration as a complication of prednisolone treatment for metastatic breast cancer. Muller (1955) and Bickel (1955) described two cases of intestinal haemorrhage on prednisone. Gluck *et al.* (1955) treated a case of rheumatic carditis with a combination of cortisone, prednisone, and prednisolone; at necropsy a large gastric ulcer was found which had been symptomless. They also briefly described a case of perforated duodenal ulcer after seven days on prednisone. Fentress *et al.* (1956) reported the case of a rheumatoid patient on prednisone who had a perforated duodenal ulcer, and Pickert (1956) a fatal case during treatment for scleroderma.

Of 11 patients with rheumatoid arthritis treated by us with these steroids, four had severe gastric irritation necessitating treatment and reduction in dose, and one treated with prednisolone had a perforated duodenal ulcer. The latter is the subject of this report.

CASE REPORT

A 50-year-old married woman, first seen in January, 1950, had rheumatoid arthritis, established by clinical, laboratory, and x-ray findings. During the next three years she was twice admitted to hospital, but in spite of the usual treatments, including rest, analgesics, blood transfusions, gold, and phenylbutazone, her condition did not improve. During her second stay in hospital (June, 1951) intramuscular corticotrophin was given for 21 days with definite benefit. As the drug was scarce at that time it had to be discontinued.

Cortisone therapy, 75 mg. daily, was begun in January, 1953, and she improved greatly over the next six months. Then increasingly larger doses—up to 125 mg. daily—were needed and the drug was finally discontinued in December, 1953, because of her lack of response and a troublesome gain in weight. Her condition waxed and waned until August, 1955, when she had so deteriorated that cortisone—a replica of the first course—was recommenced. In November, 1955, she was admitted to hospital for the fourth time. Examination then showed a moon-faced, severely crippled woman, with advanced rheumatoid changes in the hands, wrists, elbows, shoulders, knees, ankles, and feet. Cardiovascular, respiratory, central nervous, and gastro-intestinal systems were normal. A blood examination showed: Hb, 70%; W.B.C., 10,000 (normal differential count); E.S.R., 83 mm. in one hour (Westergren); serum sodium, 144.7 mEq/l.; serum potassium, 4.98 mEq/l. X-ray examination: chest normal; joints showed advanced rheumatoid changes.

Prednisolone, 20 mg. daily, was begun on November 21. For the first three weeks the pain was lessened and there was a slight increase in mobility. She then received this treatment as an out-patient. On January 17, 1956, she had epigastric pain lasting only a few days. On January 31 joint pain and stiffness had increased, and, as there had been no recurrence of epigastric pain, the dose was stepped up to 25 mg. daily.

On February 3 she was admitted to hospital because of the sudden onset of severe pain in the right hip 12 hours

previously. There was no history of trauma. The right leg was held in a position of external rotation, with limitation of all movements. X-ray examination showed a fracture through the neck of the right femur, with some absorption of the neck and considerable upward displacement of the shaft. It was decided to apply skin traction as a first measure, and full sedation was given. That evening she became pyrexial (102° F.; 38.9° C.), with a pulse rate of 122 and respirations 28, and during the night she vomited 30 oz. (850 ml.) of bile-stained fluid. Nausea and vomiting continued throughout the next day.

An intravenous infusion of N/5 saline was begun, a Ryle tube passed, and systemic penicillin given. Her condition improved, and still no localizing signs could be elicited in the abdomen. Straight x-ray examination of the abdomen showed no abnormality. Investigations on this day gave Hb, 74%; W.B.C. 14,500 (82% polymorphs, 16% lymphocytes); serum sodium 135 mEq/l.; potassium 4.7 mEq/l.; chlorides, 93 mEq/l.; blood urea, 39 mg./100 ml.

On the morning of February 7 the patient's condition was regarded as satisfactory. Her temperature, pulse rate, and respirations were normal, and electrolyte balance was maintained.

At 2 p.m. she complained—for the first time since admission—of abdominal pain, which gradually became more severe and was localized to the right hypochondrium. Examination revealed a rigid abdomen, and preparations were made for immediate laparotomy. At operation an acute perforation was found in the anterior wall of the first part of the duodenum. There was no evidence of peritonitis, and the perforation was closed without difficulty.

Intramuscular cortisone and corticotrophin replaced prednisolone as soon as the abdominal symptoms began, and were continued during and after operation. The dosage was then gradually reduced and steroid therapy was stopped 21 days post-operatively, when an uneventful recovery had been completed. An ulcer regime was maintained for the next two months, and, as the patient remained symptomless, a return to full diet was then allowed. At the time of writing she was still in hospital awaiting an operation for excision of the femoral head, and unfortunately there had been a reactivation of the rheumatoid disease.

COMMENT

It is interesting to note that in this case and in the one reported by Fentress *et al.* (1956) the suppression of clinical signs and symptoms, usually anticipated with the use of steroid therapy, did not occur.

Herzog *et al.* (1955) have shown by biological experiments on animals, and Bunim *et al.* (1955) by clinical assessment, that these new steroids have three to four times the potency of the older corticosteroids. It would appear from recent reports that the incidence of digestive complications is in the same proportion. It is for this reason that many authorities—for example, Boland (1956)—now advise pre-treatment investigation of the gastro-intestinal tract and routine antacids and semi-bland diets.

We thank Dr. E. T. D. Fletcher for permission to publish, and Mrs. D. Barclay for surgical advice.

Reviews

HUGH OWEN THOMAS

The Life of Hugh Owen Thomas. By David Le Vay, M.S., F.R.C.S. (Pp. 135+vii; illustrated, 25s.) Edinburgh and London: E. and S. Livingstone Ltd. 1956.

It is interesting to find Hugh Owen Thomas among the first few biographies, which include those of Lister and Hunter, so ably published by E. and S. Livingstone, especially as it is not unlikely that only a few have knowledge of Thomas. He was born some years after Lister and before Victoria ascended the throne; he started practice before the establishment of the *Medical Register*. The author has studied the writings of Thomas and much that has been written of him, and presented a "Life" which is built up around his work. His graphic description portrays the figure of the man and a personality agreeing well with what has been told and written by Robert Jones and T. P. McMurray.

The author invites the reader to consider who influenced this able and unusual man in his work. Was it his father, who had the reputation of a successful bonesetter, or Syme or Brodie or Hilton? The reader will realize that Thomas had no hospital appointment, but it is made clear that his services to patients undoubtedly overshadow any ability he may have had of imparting knowledge to colleagues and students. However, we are told that his influence on Ridlon (and so on American orthopaedic surgery) and on Robert Jones has been of the greatest importance, so it would be interesting to read more of the association between uncle and nephew. Too little is told us in this "Life" of what has been given to us by Thomas. Tests and splints associated with his name are not all he has left to us. The author does not indicate whether he expects the reader to consider Thomas a genius and a great man, or whether circumstances or lack of these influenced his life. We are not told if there is evidence that he helped mankind by special skill and original methods. There seems little doubt that his work has been of benefit alike to surgeon and patient since his time; partly through the teaching of Robert Jones, who also was responsible for the provision of the Thomas thigh splint to the Services in the war of 1914-18, after the monstrous loss of life and limb resulting from wounds of the thigh.

The study of the life of Hugh Owen Thomas is a lesson to all surgeons, and will interest the lay reader. This book would be enjoyed by those visiting Liverpool.

ST. J. D. BUXTON.

PARASITOLOGY

Parasites and Parasitism. By Thomas W. M. Cameron. (Pp. 322+xix; illustrated, 35s.) London: Methuen and Co. Ltd. New York: John Wiley and Sons Inc. 1956.

This is one of the most original books on parasitology to appear in recent years. Unlike the majority, it is less concerned with morphology than with life-cycles, while it hardly touches treatment or prevention, but devotes nearly a third of the text to the relation of the parasite to its host, either in the present or speculatively in the remote past. The biochemistry of many organisms is discussed freely, and this indicates one of the important trends the subject is assuming to-day, not only in the metabolic processes of the parasite but in relation to the immunity reactions in the host. The book is more likely to be useful to the biologist or advanced student than to the medical man or veterinarian seeking information about the diagnosis or treatment of a parasitic infection. In fact, the author makes it clear in the preface that he has tried to avoid the anthropocentric or economic point of view. The subject is considered in three main divisions—the Protista, the lower Metazoa (chiefly the helminths), and the higher Metazoa (including vertebrates such as lampreys and vampires). This part is finely illustrated with line drawings which vividly present life-cycles or the natural history and evolution of

the organisms. The author is well known for his work on helminthology, and the sections relating to this subject are masterly. In describing the Protista there are a number of errors and omissions which rather spoil this part of the book—for instance, there is no mention of the occult trypanosomes whose life histories would provide useful confirmation of some of the author's views. Later sections in the book describe briefly the epidemiology of parasites; the index is novel in its inclusion of the definition and origin of the more important terms.

P. C. C. GARNHAM.

ANGIOCARDIOGRAPHY IN CONGENITAL HEART DISEASE

Angiocardiographic Interpretation in Congenital Heart Disease. By Herbert L. Abrams, M.D., and Henry S. Kaplan, M.D. (Pp. 233+viii; illustrated, 95s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1956.

This excellent monograph should prove of great value to radiologists, to whom it can serve as a reference book, and also to cardiologists. It is arranged in two parts. The first part describes the historical background of angiocardiography, the technique, the equipment and media employed, and also the general principles of interpretation. Aortography is also presented. The second part deals in individual sections with each of the congenital abnormalities. In addition to presenting the angiocardiographic features, each section opens with a clear, simple presentation of the chief clinical and pathological features of the relevant condition; there is intelligent and useful reference to the literature, although it is a pity that the tiresome numeral system is used and not the Harvard system. It is this inclusion of a simple clinical introduction to each condition which should prove of great help to those who are not fully experienced in congenital heart cases. The illustrations are abundant (161 figures) and well produced. The only criticism is that rather too much is read into some of the postero-anterior views. Perhaps these less satisfactory illustrations will be replaced by better ones in a later edition.

The monograph can be thoroughly recommended.

RUSSELL BROCK.

The Handbook of Medical Library Practice (2nd ed., Chicago, American Library Association, 1956) is a comprehensive guide through the intricacies of medical literature which is invaluable to medical librarians and others responsible for its collection, care, and accessibility. It provides information on library methods and services, on bibliographical tools, and on the historical aspects of medicine. It contains chapters on organization and administration, professional training and qualifications of medical librarians, classification, cataloguing, photoduplication methods, reference and bibliographical services, and rare books, and concludes with a valuable annotated bibliography of 1,965 reference works and histories in medical and related fields. The *Handbook* is the work of a team of American medical librarians under the editorship of Miss Janet Doe and Miss Mary Louise Marshall, and is obtainable in this country from the Woolston Book Co., Gamble Street, Nottingham, price 80s.

The *Medical Annual* for 1956 (John Wright and Sons Ltd., 38s. 6d.) is the 74th consecutive issue of this compact and informative yearbook. Its popularity is fully deserved, for the editors, Sir Henry Tidy and Professor R. Milnes Walker, obtain from their distinguished team of contributors a well-balanced review of progress in nearly every field of medicine, including even "Legal Decisions and Legislation." None of the important medical topics of the day are neglected, and there are authoritative contributions on such subjects as the treatment of advanced cancer, the hormone treatment of cancer, the status of cortisone, the surgery of the heart and great vessels, and the chronic rheumatic diseases. A survey of the work on otosclerosis during the last 20 years is particularly useful. When it comes to new drugs, even a yearbook cannot keep up with the output of the pharmaceutical industry, and the fact that the *Medical Annual* for 1956 does not mention the latest "tranquillizing" drugs (though there are useful paragraphs on chlorpromazine and reserpine) shows how little time there is for judicious appraisal of new remedies before they come into general use.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY FEBRUARY 2 1957

PATHOGENESIS OF RHEUMATIC ENDOCARDITIS

It is gratifying to see a pathological problem simplified by the discovery of new information, and this seems to have happened with rheumatic endocarditis. Hitherto it has been assumed that two different processes play a part in this condition, one in the early acute stage and the other in the chronic. Now it seems that the same process may account for both. This is indeed a simplification, for, while it is easy to see how the vegetations of acute rheumatism are produced by the deposition of blood platelets and fibrin on the valves, it is not so easy to accept the orthodox view that chronic thickening and stenosis are produced by inflammation, especially as the signs of inflammation are so hard to find. F. R. Magarey¹ has provided, on the lines of the thrombosis hypothesis, what seems a more likely explanation by showing how valvular thickenings can be produced by the organization of fibrin deposits, and his observations have now been confirmed by P. S. Tweedy.²

The thrombosis hypothesis dates from a time when the microscope had hardly begun to influence pathology. C. von Rokitsansky, the great Viennese morbid anatomist of the last century, described atheroma of the aorta as a deposition of fibrin on the internal surface of the vessel, with subsequent change of the fibrin into fibrous tissue. The microscopists rejected this hypothesis on the grounds that the fibrous thickenings in atheroma were under the endothelium and therefore in the vessel wall rather than on the surface. Virchow described them as reactive overgrowths of the intimal fibrous tissue, and this was the accepted teaching for the next hundred years until the thrombosis hypothesis was revived by J. B. Duguid.³⁻⁵ He showed that when a mural thrombus

forms in a blood vessel it becomes covered with endothelium and is thus incorporated in the vessel wall, so that when subsequently organized it forms a fibrous thickening of the intima. The endothelium, according to him, is an adjustable membrane and cannot therefore be taken as a fixed landmark by which developmental relationships can be determined.

Duguid's findings have been confirmed by other workers,⁶⁻⁹ and now the same principle has been applied by both Magarey and Tweedy to interpreting chronic endocarditis. Magarey showed that when fibrin is deposited on the heart valves it undergoes organization and is converted into fibrous tissue, which becomes incorporated in the valve substance and so adds to its thickness. He also showed how deposits at the junctions of the cusps form adhesions between them and thus narrow the valve orifices. He has thus not only brought the theory of chronic endocarditis into line with that of acute, but has also given a convincing explanation of valvular stenosis.

It may seem hard to believe that so simple a process could have remained so long unrecognized, but histologists have had as a rule to take appearances at their face value. When fibrin is fully organized it is no longer identifiable as such but looks like any mass of fibrous tissue, and when it is incorporated in a heart valve it merges with the original fibrous structure so as to be practically indistinguishable. Thus, unless the histologist is prepared to use imagination—an exercise not always encouraged in his line of work—he must assume that it is part of the original structure; and should that structure seem to be increased in size he is forced, if he subscribes to the doctrine of cellular pathology, to conclude that there has been an overgrowth of it.

There is, moreover, a further difficulty, in that the transformation of fibrin into fibrous tissue requires intermediate changes that have not yet been assigned their final place in the scheme of histopathology. Most observers, while recognizing the presence of fresh fibrin on the surface of the valves in chronic endocarditis, have directed their attention more to the peculiar hyaline substance which so often appears under the surface, hoping perhaps to find in it the underlying cause of the disease. Sometimes this material clearly shows the staining reactions of fibrin; nevertheless, because it appears to be embedded in the valve, it has been taken to be a kind of degeneration of the collagenous connective tissue of the valve itself. Thus the idea of a "fibrinoid degeneration" of collagen has arisen, and, since the same substance is seen in atheroma and kindred lesions of the arteries, the elaborate concept of the "collagen vascular diseases" with all its manifold implications has been

built up. Both Magarey and Tweedy, however, with one accord identify the substance in question as incompletely organized fibrin deposit, and now Tweedy seeks to shake the whole edifice by suggesting that the so-called fibrinoid degeneration is a superfluous concept.

These revolutionary ideas are not founded merely on the imagination of one or two histologists. The principle of the incorporation of fibrin deposits in the vascular system is well established on experimental evidence. C. V. Harrison,¹⁰ B. E. Heard,¹¹ and N. G. B. McLetchie⁸ have shown that particles of fibrin introduced into the veins of rabbits lodge in the pulmonary arteries and are converted into fibrous thickenings of the intima bearing no resemblance to fibrin. Moreover, G. Williams,¹² in a study of experimentally produced arterial thrombi, has shown that before organization occurs there is a stage in which the fibrin becomes condensed and assumes that hyaline appearance we have been taught to look on as a collagen degeneration. It is possible, therefore, that the concept of collagen diseases is based on a wrong interpretation.

How unsafe it is to take histological appearances at their face value has been brought out most strikingly by some recent electron-microscopic studies. C. I. Levene¹³ has found that fibres from the surface layers of atheromatous plaques, despite their collagenous appearance, have the electron-microscopic pattern of fibrin, and W. J. S. Still and E. H. Boulton¹⁴ have found that the same applies to the surface layers of endocardial fibro-elastosis. Thus even when organization appears to be complete the histology may still be deceptive, and substances which by staining methods are identifiable as one form of tissue may be quite another. If these findings are confirmed, we shall have to admit the existence of an additional form of connective tissue—a fibrous tissue composed not of collagen but of fibrin, and derived not from fibroblasts or any other connective tissue cells but from fibrinogen of the circulating blood.

LIVING WITH A COLOSTOMY

During the past few years a large general hospital serving a medium-sized city and its surrounding villages has been carrying out approximately 50 colostomies annually. As the population at risk is about 250,000 people it might reasonably be inferred that the number of colostomy operations carried out each year in Great Britain is of the order of 10,000. Most of them are permanent, being commonly done as part of the surgical treatment of carcinoma of the rectum and lower colon. The prognosis for most of

these patients is good, but since they are often middle-aged or elderly their natural expectation of life is not long. The figure of 10,000 colostomies carried out annually therefore agrees fairly well with the statement¹ that there are more than 100,000 patients with a permanent colostomy in Great Britain—enough to populate a good-sized town. How do these people fare for the rest of their lives?

The possession of a colostomy used to be regarded as a very serious handicap. It was usual for the surgeon to advise that the colon be regularly washed out each day with warm water, and the patient was commonly hung about with more or less complicated pieces of apparatus requiring cleaning and manipulation. In 1945 W. B. Gabriel² opposed the regime of daily wash-outs on the grounds that they were unnecessary, harmful, and dangerous: they were unnecessary because colostomies would usually function regularly once or twice a day with proper training and attention to diet; harmful because the irrigation of liquids into the colon irritated the mucosa and set up a condition like mucous colitis; and dangerous to life because of the risk of perforation of the colon. He had collected nine cases of perforated colon due to colostomy wash-outs, and of these eight had proved fatal. A little later C. E. Dukes³ gave his views on the management of a permanent colostomy after visiting 100 patients in their own homes. He found that about one-third of the patients continued to give themselves a daily wash-out because they had been told to do so, and about two-thirds had either never washed out the colostomy or had given up the practice some years before. Both groups were in good general health. He concluded that daily colostomy wash-outs were unnecessary for most patients and that less inconvenience was caused if the patient could train his colostomy to act naturally.

E. Clayton-Jones¹ likewise advocates training the bowel to act at regular times, pointing out that colonic irrigation is impracticable without adequate facilities—"What may be a simple operation in Mayfair could be impossible in the Gorbals." He gives some practical hints on the care of permanent colostomies. Different diets have to be tried until a formed stool is produced, which usually means avoiding fruit with pips and other coarse roughage and being moderate in the consumption of green vegetables and fruit generally. Another useful measure is to take by

mouth regularly an agent which retains water and thus renders the stool soft but formed. Various preparations of vegetable origin, such as karaya gum, agar, and psyllium seeds, have been used, but Clayton-Jones prefers the use of methylcellulose in the form of granules. Methylcellulose is a synthetic product, unabsorbed by the intestine, and it forms a smooth gel with water. According to Clayton-Jones it has the additional valuable property in relation to a colostomy of being a deodorant, and if the recommended routine is followed he suggests that the number of motions passed can be limited to one before breakfast and perhaps another in the evening. An alternative to methylcellulose is a mixture of kaolin and activated charcoal in the form of granules. Some patients find that taking generous quantities of this by mouth will render the stool well formed and odourless. There is clearly scope for individual trial and error in these methods of gaining control of the colostomy and eliminating faeculent gases, so that there need be no limitation of ordinary social activities.

Provided full control of the colostomy has been achieved, the dressings required are simple. It is enough to cover the colostomy with a piece of gauze or linen smeared with petroleum jelly and to place over this a good-sized square of absorbent cellulose wadding or cotton-wool, which is held in place by a colostomy belt or by a "roll-on" or ordinary corset. If necessary a disk of cardboard or of plastic may be worn under the belt to give added support. At night a wide elastic bandage to hold the dressing in place is sufficient. Whenever the dressings are changed the skin round the colostomy should be cleaned with warm soapy water and then dried thoroughly.

Diarrhoea from a colostomy is a troublesome complication. In a patient who is normally regular a bout of diarrhoea may be checked by giving such drugs as aspirin, amphetamine sulphate, or kaolin combined with an opiate. Opiates should not be given for more than a few days on end for fear of addiction. If diarrhoea persists a full investigation must be made, for, as B. N. Brooke⁴ has pointed out, there may be some underlying disease such as regional ileitis which is causing the symptom. Some patients almost inevitably suffer from "wet colostomies" if it has been necessary to make the artificial anus in the proximal part of the colon, but fortunately they are in the minority: for them the introduction of disposable plastic bags has been a great convenience.

There are still many surgeons who prefer to train their patients to wash out their colostomy daily, believing that if the colon is well emptied in the morning the passing of a motion is less likely during the rest of the day. D. Benjamin⁵ includes complete and

regular cleansing of the large bowel as one essential feature in a "triad of colostomy care," and A. Hurwitz and D. B. Alderman⁶ also assume irrigation of the colostomy to be usual; they describe a special apparatus for this purpose which is inexpensive, easy to clean, and leak-proof. How much time can be spent over the process of a daily irrigation can be gauged from their own words: "Most patients employ two 1-litre irrigations and require about 45 minutes for the entire process." While irrigation of the colon continues to be practised there will be the occasional fatality from perforation of the bowel, although this risk can be minimized by inserting into the colon only tubes made of some soft and pliable material and by not irrigating at a high pressure. P. A. Kaufman and H. Swerdlow⁷ have reported two cases of colonic rupture after an enema through a colostomy, one of which was fatal, and they review other cases previously reported. E. Hoffman and A. Macht⁸ have reported two further cases: both patients recovered with prompt surgical treatment.

It is not merely the correct mechanical functioning of the colostomy which should engage the surgeon or physician who is caring for these patients. The idea of an artificial anus provokes instinctive disgust, and frank explanation and discussion are necessary before the operation, unless this is being done as an emergency. "Even those patients for whom an artificial anus is expected to be only temporary will be shocked by its revelation on the abdominal wall post-operatively unless they have received a previous warning."⁴ Thereafter they need instruction in diet and in the care of the colostomy—instruction which is usually well given in hospitals. It is when the patients go home that they often run into difficulties. A recent article by Ruth B. Dyk and A. M. Sutherland⁹ on the adaptation of other members of the family to the patient with a colostomy makes it plain that a patient who goes home to a sympathetic and understanding atmosphere is indeed fortunate: details given in this paper provide support to the view that whenever possible daily irrigation should be avoided and "natural" regulation of the colostomy achieved, but the authors do not discuss this aspect of their data, for in common with most other American workers they appear to accept as inevitable the tyranny of the douche-can. For example, A. S. Lyons¹⁰ states: "An occasional patient can be found who has a spontaneous evacuation once or twice daily without irrigation, but I do not believe it to be wise to expect this set of circumstances except in relatively rare instances."

The ideal specification for a permanent colostomy can be summarized shortly: it acts "naturally"

morning and evening at well-regulated times; it requires the minimum of attention in the form of dressings and toilet; and the patient is able to carry out his normal job, live happily in his family, and enjoy his usual recreation. Fortunately, with the help of their medical advisers many patients are able to attain this ideal.

FATAL REACTIONS TO LOCAL ANAESTHETICS

Idiosyncrasy to local anaesthetic drugs resulting in a severe anaphylactic type of response and death is extremely rare.¹ That such a reaction is due to idiosyncrasy can be accepted only when it follows an exceedingly small amount of the drug. Sudden death within a few seconds of the topical application of a small dose of cocaine may be due to a direct action on the heart, causing ventricular fibrillation, but the unique pharmacological properties of cocaine—sympathomimetic and adrenaline-potentiating—imply that such a reaction would be peculiar to this agent. Such dramatic and unpredictable fatalities are fortunately rare, and with the justifiably diminishing use of cocaine should soon not occur at all. Most fatal reactions to local anaesthesia, as to general anaesthesia,^{2,3} are the result of faulty technique.

The usual type takes the form of convulsions followed by respiratory and finally circulatory failure. Premonitory signs include pallor, apprehension, and restlessness. Treatment to control the convulsions (for example, by a small dose of intravenous barbiturate or relaxant), artificial respiration with oxygen to prevent anoxia, and thereafter support of the circulation should prevent a fatal outcome if instituted in time. The heart may stop owing to anoxia or to the direct toxic effect of the drug. In this event cardiac massage must be undertaken without delay.

The occurrence of such reactions depends on the toxic threshold of the drug and on the factors which lead to a blood concentration above this level in the patient. The reaction threshold may vary in a given patient from time to time, according to nutritional state, the effect of premedication, and other factors. It is low in drugs with a high inherent toxicity; cocaine and many of the more potent compounds fall into this class, and it is perhaps wise to avoid using them whenever a safer drug will give an equally satisfactory clinical result. The blood concentration attained in the patient depends on the rapidity of entry into the blood stream and on the rate of concurrent elimination or destruction of the drug. Cocaine is detoxified more slowly than many synthetic local anaesthetics, another factor reducing its safety.

Inadvertent intravenous injection, overdosage, and giving unnecessarily high concentrations of local

anaesthetics all lead to high blood levels, with the danger of toxic effects. Drugs such as procaine and lignocaine are commonly dispensed in 2% concentration and often given in that strength for infiltration (more than 30 ml. of this strength would constitute an overdose in most patients); with either agent $\frac{1}{2}$ –1% concentration would be adequate for most purposes and is preferable for safety. Adrenaline is often included in solutions of local anaesthetics, since it retards absorption into the blood stream and prolongs the anaesthetic effect; but dangerous and even fatal results have followed excessive amounts of adrenaline given in this way, and the dosage needs to be carefully checked.

Many of the reported fatal reactions follow the topical application of local anaesthetic agents. In part this is because the more toxic agents are the more effectual for this purpose and because relatively high concentrations are used. For example, only 1 ml. of 10% cocaine contains 100 mg., which amount is regarded as the maximum permissible for topical application. Again, topical application of a local anaesthetic solution to the mucous membrane of the respiratory tract can result in rapid absorption of the drug, leading to a high blood level. The exceedingly rapid absorption of fluids injected into the respiratory tree was reported a century ago⁴; the rate of entry to the blood stream may approximate to that of direct intravenous injection. J. E. Steinhaus⁵ has confirmed this experimentally by spraying local anaesthetics down the tracheas of rabbits. Doses thus have to be small, and drugs with the least possible toxicity are best given. 1 ml. of 2% amethocaine contains 20 mg., and the drug is about ten times more toxic than procaine after intravenous injection. A number of fatalities, one recently reported,⁶ have followed the topical application of 2% amethocaine to the respiratory tree. D. C. Moore and J. Green¹ suggest that the dosage should be restricted to 40 mg. and that it should be used as a 0.5% aqueous solution; a total dose of 8 ml. is regarded as the maximum permissible for topical anaesthesia of the larynx and tracheobronchial tree. They state that this strength is adequate for satisfactory anaesthesia. Lignocaine in 2–4% concentration is a highly efficient surface anaesthetic, and its toxicity is only slightly greater than that of procaine (for instance, 0.5% lignocaine can be administered intravenously for various therapeutic purposes in a similar fashion to procaine solutions). If this or similarly safe agents⁷ supplanted the more toxic drugs for topical anaesthesia many fatal reactions would probably be averted.

MUMPS ORCHITIS

The importance of mumps lies mainly in its complications, of which epididymo-orchitis is the most frequent and the most severe. It affects young adult males, being very rare before the age of puberty.¹ It causes severe pain, is always accompanied by pyrexia, and often by prostration or even delirium. It may lead to partial atrophy of the testicle and sub-fertility, though the evidence for this is not very convincing, and most

clinicians will know of patients who have proved fertile after unilateral and even bilateral orchitis due to mumps. It is nevertheless a very disabling complication while it lasts and hitherto has not responded readily to treatment. Several reports now suggest that the use of corticotrophin or cortisone may be worth further study.

L. Martoni² reports excellent results in three cases. Hydrocortisone was given orally in doses of 125 mg. the first day, followed by 100 mg., 75 mg., and 50 mg. on the next three days. Pain was relieved and the temperature fell in 24 hours, and the swelling and tenderness subsided in two days. Examination 20 to 25 days later revealed no sign of atrophy. J. H. Solem³ treated two severe cases with 100 I.U. of long-acting corticotrophin. Both had had orchitis for several days before treatment and in both cases tenderness and swelling subsided within 24 hours. One of these patients had a recrudescence of the orchitis, which a second injection promptly controlled. A. G. Bower⁴ gives no figures or case histories but claims that cortisone by mouth in an initial dose of 300 mg. followed by 100-mg. doses every six to eight hours for two to four days caused diminution of pain in six to twelve hours and subsidence of swelling in two to four days. He claims that the initial dose should be at least 300 mg. by mouth. G. C. Risan⁵ is less enthusiastic. He gave cortisone to five patients in doses of 75 mg. every six hours for one day, followed by 50 mg. every six hours for three days, and then smaller doses for three to six days more. In all of five patients pain was relieved within 24 hours, but the fever and the swelling were not affected. In three patients swelling of the other testicle developed during treatment, but the swelling and duration of symptoms were milder. In one patient, who had both testes affected at the same time, one increased in size during treatment but responded rapidly to increased dosage. It is evident that the claims of different authors vary considerably, though all claim some improvement. Details of dosage and time of administration need further study, and the treatment cannot be accurately assessed until many more cases have received it.

TORULOSIS AND HODGKIN'S DISEASE

Torulosis is a systemic fungal disease caused by a yeast-like organism now known as *Cryptococcus neoformans*. The first description of the disease was that of O. Busse and A. Buschke in 1895,⁶ and cases have been reported in small numbers since then. B. R. Gendel, M. Ende, and S. L. Norman⁷ referred in 1950 to a total of 165 cases, and in 1951 V. P. Collins, A. Gellhorn, and J. R. Trimble⁸ mentioned 241 cases. The causal organism has been isolated from soil, as have the organisms of certain other systemic mycoses, and it appears to have a saprophytic role in nature. The commonest site of human lesions is the central nervous

system, which is involved in about 80% of patients with the disease. In these cases the subarachnoid space is seen at necropsy to be characteristically distended by gelatinous material, and often small cysts containing the cryptococci are present in the cerebral substance. Clinically the condition is manifested by a meningo-encephalitis, and cryptococci can often be recovered from the cerebrospinal fluid. The next most common site of disease is the lung, which is believed to be the usual portal of entry of the infection. Again, gelatinous lesions may be found there, or sometimes the lesions are granulomatous. Dissemination may take place, and then lesions will be found in many organs, including lymph nodes. The skin may ulcerate, and cryptococci can sometimes be isolated from the fluid which exudes from the lesions.

In 1923 W. Freeman and F. D. Weidman⁹ reported a case in which torulosis and Hodgkin's disease were believed to coexist in the same patient, and since then the apparent association of the two diseases has received some attention. Gendel and colleagues⁷ referred to 14 cases in which the two diseases were believed to be present in the same patient, though the number may be no more than 11 if cases are excluded in which the evidence for both torulosis and Hodgkin's disease is perhaps open to question.⁸ More recently further cases in which cryptococci were found and the histological findings supported a diagnosis of Hodgkin's disease have been described.^{10–12} The association between cryptococcal infection and a form of lymphadenopathy closely resembling, or even identical with, Hodgkin's disease seems to be proved, for it occurs too often to be a matter of chance. But that cryptococcal infection is the specific cause of Hodgkin's disease is out of the question: many cases of cryptococcal infection are known in which there is no evidence of Hodgkin's disease, and in the great majority of cases of Hodgkin's disease there is no evidence of cryptococcal infection. In animal experiments, too, no lesions resembling those of Hodgkin's disease have been produced by infection with cryptococci. Two possible explanations of this association have been considered—first, that cryptococcal infection can produce a granulomatous type of tissue reaction which is similar to that of Hodgkin's disease, and secondly that infection with cryptococci is a late event and occurs as a complication of Hodgkin's disease. It is at present not possible to decide between these two views with certainty. In support of the first is the fact that infection with cryptococci has been found in association not only with Hodgkin's disease but also with other types of

lymphadenopathy.⁸ In some cases the diagnosis of a specific lymph-node lesion was considered to be established, and this group includes Hodgkin's disease, lymphosarcoma, and leukaemia. In others the histology of the lymph nodes varied. A further point in support of this view is that cryptococci have sometimes been recovered from the glands of patients with Hodgkin's disease in whom there was no clinical evidence of torulosis¹³ and from stomach washings in such a patient.⁸ One difficulty in accepting this view is that in most cases in which the diseases are believed to coexist either the cryptococci are not recovered at all from sites where the tissue changes are those of Hodgkin's disease or, if present, they are so only in small numbers.^{10 12 14} In support of the other view, that cryptococcal infection is a late event in cases of Hodgkin's disease, there is a certain amount of indirect evidence. I. N. Dubin¹⁵ has found that patients with Hodgkin's disease have a generally poor immunological response to infection, and M. Levene and L. Michaels¹² point out that many organisms such as diphtheroid bacilli, avian tubercle bacilli, and *Brucella* can be secondary invaders in Hodgkin's disease. R. W. Benham¹⁶ reported that cryptococci can be recovered from the skin of normal subjects, and these might well become established in the body if the immunological response of a patient was poor. That there is an association between torulosis and a lymphadenopathy closely resembling Hodgkin's disease, an association occurring too frequently to be explicable by chance, seems proved. But at present it does not seem possible to decide whether the cryptococci known to cause torulosis can cause this and other reactions of lymphoid tissue or whether they appear late on the scene as secondary invaders in patients whose immunological response to infection is impaired.

NOMENCLATURE OF BLOOD-CLOTTING FACTORS

The object of nomenclature is presumably to facilitate the interchange of knowledge, and yet there can be few fields of research where it is causing more confusion and misunderstanding than that of blood coagulation: clotting factors are known by different names not only from country to country but within single countries and from laboratory to laboratory. It is not surprising that many clinicians find the whole subject baffling. The classical theory of blood coagulation postulated certain factors, and there is widespread agreement on the meaning of the terms prothrombin, thrombin, fibrinogen, fibrin, and calcium, though thromboplastin is less clearly understood than the others. But there are at least four additional factors which appear to be important in the phenomenon of clotting, and each of these four has received a variety of names. To give an example of the confusion which exists, one of these substances has been described as Factor VII, proconvertin, serum-prothrombin-conversion accelerator, stable factor, auto-prothrombin I, serozyme, kappa factor, prothrombino-gen, co-thromboplastin, serum accelerator, prothrombin

conversion factor, and the prothrombin converting factor. As a result, communication between English-speaking workers has been definitely retarded, and for those who do not read English the possibility of misunderstanding is even more serious. In addition, substances of platelet origin and blood-clotting inhibitors are now being studied in detail and new names are being proposed for these.

Realizing the harmfulness of this confusion, a number of the leading workers in this field decided at the First International Congress on Thrombosis and Embolism in Basle that it was their responsibility to try to reach some agreement on nomenclature, and they therefore set up a committee to determine whether it would be possible to introduce a standardized nomenclature for those factors which are generally agreed to play a part in the physiological clotting of blood. The committee had a further meeting during the Sixth International Congress on Haematology at Boston last August, when the membership was further increased and a number of working parties were given the task of collecting the evidence in favour of the different blood-coagulation factors and of suggesting some neutral nomenclature which might be intelligible to medical practitioners whatever the country they lived in. The task confronting the committee presents very real difficulties, because with few notable exceptions the factors thought to be concerned in normal blood coagulation have not been isolated and identified. The committee wisely determined that any nomenclature selected as an international one should not be tied to any theory of coagulation, since the constant changing of theories has in the past led to repeated changes of terminology. It was also agreed that the existing terms prothrombin, thrombin, fibrinogen, fibrin, and calcium, being already used in most countries, should not be changed; that, for the reasons given above, any provisional terminology should not imply any supposed function or constitution of the factor to which it refers; and that international terms should be short, simple, and readily understood by people of different nationalities. Probably a common symbol, either a name or a number, will be selected for each factor, and each author will be encouraged to use this together with such a synonym as he may wish to use, the international symbol to be in brackets.

The work of the committee cannot reach fruition without the collaboration of different scientific societies in Europe and America, and it is hoped that the European and American societies of physiology, haematology, clinical pathology and so on will be willing to assist the committee in its endeavours, and, if they or their individual members have views they wish to put forward on the question of nomenclature of blood-clotting factors, that they will communicate with the secretary of the international committee, who is Dr. M. Verstraete, Cliniques Universitaires Maladies Internes B, Laboratoire de Physiopathologie, 57, Kapucijnenvoer, Louvain, Belgium. Thus by international collaboration it is hoped to achieve a nomenclature which will be workable and to get rid of much of the confusion which exists at the present time.

Nova et Vetera

ISAAC BUXTON (1773-1825)

"ON THE USE OF A REGULATED TEMPERATURE IN WINTER COUGH": A CONTRIBUTION TO THE HISTORY OF CHRONIC BRONCHITIS

BY

V. C. MEDVEI, M.D., M.R.C.P.

The combined meeting of the Sections of Pathology and Epidemiology of the Royal Society of Medicine on February 21, 1956, dealt in an admirable manner with problems of the epidemiology, bacteriology, and morbid anatomy of chronic bronchitis. It was pointed out that North-Western Europe seems to show a greater prevalence than the rest of the Continent, with England and Wales in the lead. A number of factors responsible for the origin were mentioned, such as respiratory infection, air pollution, type of bacteria (allergic), sensitivity of the mucous membranes, cigarette smoking, and several others.

In the discussion which followed, somebody asked if temperature studies had been made, taking into account the rapid change of climatic conditions even within a restricted area, such as a district of London, which may occur within a few hours, or even an hour: the transition from severe frost in the early morning and a snowstorm between 8 and 8.30 a.m. to sunshine and thawing conditions an hour later is a quite common experience. Such studies have apparently been carried out abroad ("microclimatology"), and seem also to have taken into account conditions of internal heating, windows, ventilation, and allied problems; from the reply given it seems that there is no similar study in existence in this country.

The problem is not new. The question of regulated temperature in relation to winter cough and consumption was described in detail by Isaac Buxton, M.D., Physician to the London Hospital and Surrey Dispensary in 1810.

Norah Schuster, in her paper on Buxton (*Proc. roy. Soc. Med.*, 1955, 48, 326), mentions this essay, but refers mainly to his enthusiasm concerning the heating and ventilation of sick-rooms.

Isaac Buxton was born on May 6, 1773, in Grange Walk, Bermondsey. At 9 years of age he went to St. Paul's School as a Foundation Scholar. About his later youth up to 1800 little is known. In that year he went to Göttingen to study medicine. In 1802 he wrote his thesis and obtained his doctorate. He then returned to London and became a pupil dresser to Astley Cooper at Guy's, and in 1805 obtained the Licence of the Royal College of Physicians. A year later we find him on the staff of the Surrey Dispensary, and after some fight he was elected to the staff of the London Hospital in 1807. During the following period of increasing practice he married Janet Travers, a cousin of the surgeon Benjamin Travers. Whether he ever used a stethoscope is not known, but he might have known it when he retired in 1822. He understood French and had read Laennec, so it was possible that the use of the stethoscope was quite familiar to him. He was elected to the Council of the Hunterian Society, but his health began to fail. In 1822 he resigned from the London Hospital on grounds of ill-health. Three years later he died in Camberwell and was buried in Bunhill Fields, and, as Norah Schuster says, "has rested in obscurity ever since."

Apart from the above-mentioned essay, he seems to have been fascinated by the possibilities of vital statistics, as he studied and wrote up the statistics of London Hospital admissions for 70 years until 1820, offering a most valuable analysis on the nature and spread of outbreaks of fever in the East End in 1817 and 1818.

He was a founder of the infirmary which later became known as the Royal Chest Hospital (in 1814), and where, for the first time, wards were kept at a constant warm

temperature, to the great benefit of the poor sufferers from chest disorders. He aimed at a temperature of 60 to 65° F. (15.5 to 18.3° C.) day and night during the winter months. Although the idea was not entirely original, Buxton was one of the first to put it into practice.

The complete title of Buxton's article is: *An Essay on the Use of a Regulated Temperature in Winter-cough and Consumption; including a Comparison of the Different Methods of Producing such a Temperature in the Chambers of Invalids*. It deserves, however, a much more detailed appreciation. The description of winter cough is perfect.

"It is absolutely necessary that I should be more minute in my description of what I mean by 'Winter cough'; because this disease, although perhaps more frequent than consumption, has not been described so often and so minutely; . . . Those who are affected with winter cough, generally feel themselves very well during the warm weather of summer. But, when the winter comes, they are afflicted with severe coughing. This cough is often so extremely troublesome during the night, as almost entirely to deprive them of rest. It is generally brought on with a considerable degree of violence whenever they go out into the cold air; and is easiest during the time of their continuance in a warm room. . . . Their breath is generally extremely short, so short that they frequently walk about with a considerable degree of difficulty; and an exertion rather greater than usual is very severely felt. If they draw in the breath deeply, pain is often occasioned in the chest, together with sudden catching and cough. Tightness across the same part is another symptom which they experience. Patients with this complaint in general expectorate considerably. The expectoration varies much; but, for the most part, it is thick, and large in quantity. . . . Sometimes they spit blood; but the quantity is usually not very large. Their complaints vary in the winter season, according to the state of the weather; so that when the wind is southerly they feel relieved, and when it changes to the north or north-east, every symptom is materially aggravated. . . . towards the latter end of winter or beginning of spring they are extremely thin and debilitated. Patients of this description are very liable to take cold; . . . and, when they have caught cold, the cough, the pain, the expectoration, the shortness of breath, and other symptoms, are considerably aggravated."

"As the spring advances, and mild weather comes on, the cough and other affections of the chest gradually abate; till, on the arrival of warm, settled summer weather, it . . . entirely quits them; and probably they enjoy, for a time, the pleasing hope that they are now thoroughly recovered. . . . But the succeeding winter destroys the pleasing delusion. They are again affected with the winter cough; and, if the weather is at all severe, most probably in a greater degree than during the preceding winter. In general the cough and other symptoms of the complaint become worse and worse every succeeding winter; and the remission between the attacks, during the summer, shorter, till at last patients frequently have the cough both winter and summer, although most severely during the winter. . . . The same train of symptoms has had various denominations applied to it. . . . I do not adopt the term chronic catarrh (perhaps the most proper denomination) because, although understood by medical men, it would not be so readily apprehended by others; nor do I employ the word asthma, because I think it better to follow Cullen's* example, and to confine the use of that expression to one particular kind of complaint. Winter cough is not the term I would fix on, were I writing a system of nosology, as I am well aware that it is liable to some objections. But since it is generally adopted in common life, not liable to ambiguity, being intelligible to persons medical and non-medical, and sufficiently designating the disease in question, I thought proper to employ it."

In the next paragraph he discusses the "frequency of winter cough and consumption," based on returns from "authentic documents," such as Dr. Willan's "Reports on the Diseases of London," rather than on "random modes of judging" from his own private practice: another feature which sounds more like present-day methods of studying the problem. In paragraph 4 he talks "of the Fatality of these disorders," and the introductory sentences are again worthy of detailed quotation:

"What renders consumption and winter cough still more worthy of our attention is, the amazing number of persons who fall victims to these complaints. No one will be surprised that

*Dr. Wm. Cullen (1710-90), also quoted by Badham (pp. 20-21 in the 2nd ed.), was Professor of Medicine in Glasgow and Edinburgh.

this is said, relative to consumption. But that an assertion of this kind should be made relative to winter cough, may, at first sight, appear extraordinary. Yet it is a certain fact, that a very considerable proportion of those who are affected with winter cough, ultimately die either of that complaint or of its consequences. . . . Consumption is a disease that kills of itself, i.e., without inducing another disease, which, although a consequence of the first complaint, puts on a particular character. Winter cough superinduces other complaints, which kill the patient; the death is then set down to the latter disorder and not to the winter cough."

In the following paragraph the usual terminations of winter cough are discussed—namely (1) consumption; (2) pneumonia (inflammation of the lungs); (3) dropsy, obviously as an expression of the failing heart; and (4) water in the chest (pleurisy), often in connexion with acute pneumonia.

In paragraph 6 important observations are made on the causation of these complaints:

"It is always of great importance to discover the causes of a complaint, as such discovery may probably lead either to its prevention or cure. . . . We have not to go far to discover the principal causes of consumption and winter cough. I am persuaded they will on examination be found to lie chiefly in the variableness and frequent severity of the climate. . . . When do these diseases make their commencement? Certainly in the severest and most variable weather of winter and spring. . . . If we go into the warm, settled climates, such as Spain, Italy, and the South of France . . . we shall scarcely ever meet with tedious cough and shortness of breath, such as we have described by the name of winter cough. Yet the inhabitants of some of these climates, when removed to England, are still more liable to these diseases than even the natives themselves. . . .

"Exposure to alternations of heat and cold is the common origin of protracted cough and shortness of breath, as well as of consumption. . . . We have before observed, that this winter cough vanishes on the approach of summer, and, could summer be always continued, would never again appear. All this, I think, is abundantly sufficient to prove, that variable and severe weather is materially concerned in producing and supporting by far the greater number of consumptions and protracted coughs."

In this country, Charles Badham (1780-1845) is regarded as the father of bronchitis, because he used the term first. Badham was a scholar and poet, as well as a doctor. He was an M.D. Edinburgh, which degree he obtained in the same year as Buxton did his in Göttingen. He added to it the M.D. Oxford fifteen years later, and was elected F.R.S. and F.R.C.P. in 1818; eventually he became a Censor of the College of Physicians (1821), and professor of physic in Glasgow in 1827. At the time of the first publication of his description of bronchitis, he was physician to the Westminster General Dispensary. He also was a Royal Physician to the Household of the Duke of Sussex. His treatise—which was, incidentally, dedicated to the Duke—was first published in 1808, two years before Buxton's essay. He set to work more methodically than Buxton, in so far as he gave a good historical introduction, and a systematic classification of various types of bronchitis based on punctilious clinical and morbid anatomical observations. He also gave a detailed account of the treatment, and devoted a full chapter to the "History and Treatment of Chronic Coughs, etc." which covers more or less the subject of Buxton's essay. In two respects, however, it seems inferior to Buxton's study. There is no mention of vital statistics to prove the prevalence and mortality of the disease. On the other point, Buxton, who was familiar with Badham's tract, wrote: "Dr. Badham gives his sentiments relative to this treatment of chronic bronchitis—that is, winter cough—in the following terms (Observations on the Inflammatory Affections of the Mucus Membrane of the Bronchiae, p. 122†). 'An uniform moderate temperature, to be secured only by confinement to the house during the unfriendly winters of this climate, is a measure about the propriety of which (where it can be adopted) no person can doubt.' Thus, therefore, both these writers perfectly agree with

me as to the propriety of the measure. But neither of them has brought forward any instance where it was used" (pp. 99-100).

Buxton's essay can be regarded as a minor classic. His description of the clinical picture can hardly be bettered; the choice of the name of the disease appears sound; the follow-up, the modes of termination, and the fatality of the illness are better assessed than by Badham. The attempted use of vital statistics shows Buxton at least half a century ahead of his contemporaries.

His real point is that the temperature changes are so rapid and by no means merely seasonal: cold summers, two or three very warm winter months followed by two or three weeks of sharp frost and icy snow blizzards are by no means uncommon; but the main problems are the great daily variations of temperature in any given spot—for example, in the heart of London.

The task, therefore, to cope with only one single aspect although it is an important factor—of the problem of prevention and mitigation of winter cough is a very great one: no wonder it has taken 140 years to appreciate and heed Isaac Buxton's opinion and suggestions. It may take another 50 years before they are fully carried into practice. Isaac Buxton deserves to be remembered when the history of bronchitis is written.

Reports of Societies

TOXOPLASMOSIS: A WIDESPREAD INFECTION

RECOGNITION AND TRANSMISSION

The Royal Society of Tropical Medicine and Hygiene discussed toxoplasmosis at a meeting on January 17 at Manson House, London. Owing to the increasing number of recorded human infections, especially severe and fatal forms of the congenital disease, much attention has been devoted to *Toxoplasma* in recent years. Infection in man (and animals) has been found in many parts of the world.

Professor P. C. C. GARNHAM (London School of Hygiene and Tropical Medicine) introduced the speakers with the observation that it might be asked why a tropical society should discuss a subject with no special tropical significance. He regretted so little work on the disease had been done in the tropics, and suggested that workers there should look out for more cases, ascertain the incidence in the general population, and define the local animal reservoirs.

Clinical Picture and Incidence

The variety of presentation in human infections was outlined by Professor C. P. BEATTIE (Sheffield). The syndrome in infants might be characterized by internal hydrocephalus or microcephaly, choroidoretinitis, signs of central nervous system involvement, or cerebral calcification. The mortality rate in severe congenital cases was high, and children surviving were usually mentally retarded. At necropsy, distension of the ventricles with yellowish fluid, miliary granulomata, necrosis, and caseation were frequent features, while *Toxoplasma* might be found in the tissues. The disease might be noticed at birth, but could become obvious only days, weeks, or even months later by many signs indicating damage to the nervous and ocular systems. There could be jaundice with a purpuric or maculo-papular rash, enlargement of the liver and spleen, and lymphadenopathy. The frequency of congenital infection was incompletely known. In Britain Professor Beattie put the figure at about 1 in 35,000 live births: from 1950 to the end of 1956 110 cases were diagnosed in children under 5 years in England.

Even with congenital infections, however, severe disease was the exception, said Professor Beattie; and, although in adults acquired disease could be severe, afebrile lymphadenopathy seemed the common mode of presentation.

Surveys indicated that from one- to three-quarters of the populations in different countries possessed antibodies against *Toxoplasma*. Turning to transmission, Professor Beattie suggested that attention should be paid to direct transfer from man to man and to the possible importance of entry via the respiratory tract. He presented figures indicating infection to be commoner in rural areas than in urban localities, and that animal-handlers have a higher infection rate than other occupational groups, as suggested by serological tests. Variation in the virulence of the organism was difficult to explain, but concomitant illness might be important in deciding the severity of the attack.

Serological Tests in Diagnosis

Dr. I. A. B. CATHIE (Hospital for Sick Children, Great Ormond Street) gave the results of investigations on the specificity of the various serological tests for *Toxoplasma*. Several authors had found an unexpectedly high proportion of sera to be positive for the dye test among animals infected with such organisms as *Sarcocystis*, *Trichomonas*, and *Trypanosoma cruzi*. He had been able to substantiate these findings for *Sarcocystis*, but had found that the "toxoplasm-hostile factor" involved could be inactivated by heating at 56° C. He had also shown that properdin did not interfere with the dye test; similarly the results of testing sera from patients with *T. cruzi*, *T. gambiense*, and *Trichomonas* gave no evidence that antibodies affecting the dye test were produced by these organisms. Nor did infection with *Salmonella typhi* or malaria give rise to a positive complement-fixation reaction for toxoplasmosis as reported by some other authors. Dr. Cathie concluded therefore that, so far as the human subject was concerned, the reliability of both the dye test and the complement-fixation test for *Toxoplasma* was upheld. In diagnosis, however, both tests should be used: for example, a dye test of 1:64 with a negative C.F.T. would be of little significance, but an additional C.F.T. titre of 1:16 would be corroborative. From his evidence, Dr. Cathie considered that much experimental work on animals was not applicable to man, at least so far as trichomonad and trypanosome infections and the dye test are concerned.

Animal Reservoirs of Infection

Toxoplasma infection in animals was discussed by Dr. R. LAINSON (London School of Hygiene and Tropical Medicine). Such infections appeared to be world-wide, he said. Whereas no warm-blooded animal species seemed to possess complete natural immunity, it had yet to be proved that cold-blooded animals were infected in nature. It was generally agreed that only a single species of *Toxoplasma* existed.

The study of host reservoirs for human infection was complicated by the extremely wide range of host species and our ignorance of modes of transmission. Among dogs, and only about a hundred cases had been reported where the parasite had been demonstrated, although serological evidence suggested that they might often suffer from chronic infections. Cats, too, often showed antibodies against *Toxoplasma*, but there had been few instances of actual isolation. The organism had also been isolated from cattle, pigs, sheep, rabbits, pigeons, and poultry. Infections had been found in wild rats, but the incidence was apparently not high; occasionally house-mice were infected.

Dr. Lainson stressed that the only absolute proof of infection was the isolation of the parasite, and he discussed how this might best be achieved. After intraperitoneal inoculation of brain tissue into mice he had succeeded in isolating *Toxoplasma* from 6 of 113 domestic rabbits, all of 5 members of the Mustelidae (stoat family), and 1 of 99 *Rattus norvegicus*. No infections were found in 122 wild rabbits, 399 house-mice, and 85 birds. He mentioned also the difficulties in detecting avirulent strains of the parasite. Interpreting these findings, Dr. Lainson concluded that *Toxoplasma* was not uncommon in wild and domestic animals, but normally there was a very well-balanced host-

parasite relationship. The highly virulent forms of *Toxoplasma* were probably aberrant or altered strains. He thought it possible that humans might become infected through handling raw, infected meat—either through cuts and abrasions on the hands or by direct conveyance of parasites to the mouth. Carnivorous animals seemed to be more commonly infected than omnivores or herbivores, and this suggested oral transmission. Cats and dogs were often fed on raw meat, and might, if they became infected, act as sources of the human disease. In an investigation of London dogs he had found that 42% had antibodies against *Toxoplasma*.

Discussion

Opening the discussion, Dr. J. K. A. BEVERLEY (Sheffield) gave case reports in support of Professor Beattie's suggestion that the visceral stage of congenital infection could be eliminated by passively acquired antibodies. He agreed with Dr. Cathie's views on the specificity of the serological tests for toxoplasmosis, and gave illustrations to support this. As to the significance of antibody titres, he considered a dye-test titre of 1:800 and a C.F.T. titre of 1:16 indicated active or very recent infection, but more significant was a rise in titre between the early stages of infection and convalescence. Low dye-test titres might indicate very recent infections or past subclinical ones; the parasites had been isolated in cases showing such low titres.

With regard to the treatment of toxoplasmosis, Dr. Beverley discussed the action of the following drugs: in mice, sulphonamides, diamino-diphenyl sulphones, and diaminopyridines (all effective); in rabbits, pyrimidine-substituted sulphonamides and diamino-pyrimidines (ineffective) and thiazole-substituted sulphonamides and diphenyl sulphones (both good). In acute human infections there was evidence that sulphadimidine and pyrimethamine were effective. In chronic cases chemotherapy might help by preventing future relapses due to rupture of cysts, but could not help in cases with tissue breakdown due to hypersensitivity. Cortisone was often useful in acute exacerbations.

Professor R. J. V. PULVERTAFT (Westminster Hospital) showed an interesting film of the motility and mode of entry of *Toxoplasma* into the host cells, while Dr. J. D. FULTON (National Institute for Medical Research) described useful methods whereby the parasite might be obtained in pure suspension for biochemical assay. Several other speakers described their experience of cases of congenital toxoplasmosis.

Recently a W.H.O. team visited Austria to advise on the health problems raised by the influx of Hungarian refugees. The team was particularly concerned with the risk of epidemics and the mental health of the refugees. Apart from the immediate effects of their journey—cold and hunger—the team reports that the refugees were, generally speaking, in good physical health. Vaccination programmes in Hungary appeared to have been thorough, particularly against smallpox and diphtheria, and precautions were being taken against outbreaks of typhus. The team emphasizes the importance of understanding the psychological difficulties of the refugee in planning help. In spite of individual differences and variations in the causes of flight, refugees the world over had a number of features in common: they were afraid of what they were fleeing from; their attitude towards rules and regulations had changed because they had had to break rules in order to save their lives; they suffered from some form of home-sickness; and they expected a great deal from the country and the people that received them. Unless the many willing helpers appreciated these things, states the team, disappointment on both sides was inevitable, and disturbances would occur. A typical refugee reaction after the triumph of at last reaching safety was to become completely exhausted, to make no effort at all after the tremendous effort of flight. This should be regarded as a normal reaction. What was needed was human contact: anything that bound the refugee to a society should be encouraged.

Two New Human Genes

SIR.—Your annotation (*Journal*, January 19, p. 154), "Two New Human Genes," on the interesting findings of Allison and McWhirter,¹ conveys the inaccurate impression that the two hypothetical inherited factors "As" and "bt" are well established, like blood antigens or haemoglobin variants. No report about these new factors, based on a large series of families, seems to be available. Moreover, it is not yet known how far the phenomena of beetroot pigment and methane-thiol (methyl mercaptan) excretion are independent of incidental influences, such as rate of absorption from the gut or peculiarities of intestinal flora. Until these matters have been settled it seems premature to discuss the evolutionary significance of the observations.—I am, etc.,

Translumbar Aortography

SIR.—Mr. H. Gaylis and Dr. J. W. Laws, in their account of dissection of the aorta as a complication of translumbar aortography (*Journal*, November 17, 1956, p. 1141), have shown how easily the middle coat of the aorta can be split when the injecting medium goes astray. This easy splitting is, of course, the explanation of the dissection of the aorta in dissecting aneurysm. In 1951 I called attention to the ease with which this can be done by plucking at the inner wall of the aorta with catch forceps.¹ The cleavage is a natural one, as the separation can be readily produced in the aorta of the newly born. What still requires explanation in dissecting aneurysm is the rupture, usually transverse, into the lumen of the vessel which enables the blood to enter and cause the dissection. From the usual situation and size of these tears it seems probable that the rupture is due to physical stress. My colleague, Mr. R. Culver, a senior lecturer in civil engineering now in England on study leave, is interesting himself in the solution of this problem and I am sure would welcome any help or suggestions from our profession.—I am, etc.,

Toxic Psychosis Caused by "Preludin"

SIR.—Dr. M. F. Bethell (*Journal*, January 5, p. 30) describes a patient who became irritable and suspicious and developed paranoid delusions after taking large amounts of "preludin" for some weeks prior to admission to hospital. The following notes relate to a patient who also showed marked addiction to this substance.

A married woman, aged 31 years, was brought to St. Francis Hospital mental observation ward on October 31, 1956, on an order of a duly authorized officer from a hostel where she had been staying. She had become increasingly restless, agitated, and depressed, and kept craving preludin tablets, to which she had become addicted. She stated that she had started taking them in January, 1956, for slimming, but found that besides decreasing her appetite they gave her increased self-confidence. She had increased the dosage steadily, and for the month prior to admission had been taking 60 tablets a day. However, for about six weeks prior to admission her confidence had waned; she had been sleeping poorly and become increasingly agitated and restless.

Physical examination revealed a generalized erythematous rash (which the patient stated had been present for about three months) and cutaneous hyperaesthesia of the skin of her lower limbs. Mentally she was agitated and restless, apprehensive and

depressed, but had no defects in memory and no evidence of delusions or hallucinations. She became rather aggressive in manner when told that she could not have any more preludin, but after 24 hours in hospital she ceased her demands for it. Her personal history revealed abundant evidence of a "psychopathic personality." She had come from a very disturbed home background, and she had formed no close relationships with either her parents or siblings. She had never worked but drifted around forming transient relationships, and her marriage had broken up and her children been taken from her care. She had been treated at several hospitals for alcoholism and generally had proved a failure in everything she attempted (she described rather interesting parties in Soho and Chelsea, where the guests regaled themselves from bowls of "benzedrine" and "dexedrine" tablets). During the week she was in hospital she gradually settled down and became calmer, possibly aided by chlorpromazine 100 mg. three times a day. She refused to accept a mental hospital vacancy we had arranged for her as a voluntary patient and left hospital on November 8. However, after leaving hospital she recommenced preludin and was admitted to another hospital. Haematological examination revealed no abnormalities (this was done for fear of a blood dyscrasia resulting from prolonged abuse of a new drug).

There seems little doubt that in patients with a "psychopathic personality" any drug, no matter how innocuous its makers claim it to be in the normal dosage, is likely to be taken in dosages never imagined by its sponsors. Whether this justifies the placing of all such preparations in Schedule I is a matter for discussion. For example, aspirin with its known toxic and lethal effects is still freely available, despite the numerous suicides from over-dosage with it.—I am, etc.,

London, S.E.5.

LEWIS CLEIN.

Glycyrrhetic Acid

SIR.—Forgive my intrusion into a correspondence in which originally I had no intention of taking part. Since the "halloo" was sounded by Drs. R. P. Warin and C. D. Evans (*Journal*, August 25, 1956, p. 480), Dr. F. R. Bettley (*Journal*, October 13, p. 882), and Dr. B. Russell (*Journal*, November 10, p. 1113) there has been an almost unseemly rush to be in at the death of a new drug. There must be some explanation why such widely varying results with glycyrrhetic acid have been reported.

At this stage I think it is wise to consider a few general observations which may occasionally be overlooked in the evaluation of any particular form of local treatment. Take, for example, the use of ichthyol calamine liniment in the treatment of dermatitis: (1) It may give continued relief. (2) It may relieve to begin with, but later irritate. (3) It may fail at first, but help later. (4) It may be helpful in some areas—e.g., face, neck, and arms—but only partially help or fail to help on the legs. Variations in response, provided the same batch of liniment has been used, must be due to fluctuation in the primary cause, the degree of reaction at times being greater than the degree of response. This explains the necessity at times for internal measures as well as local treatment.

Some adverse comment has been made with regard to the so-called hydrocortisone-like action of glycyrrhetic acid. I am sure that it will be agreed that among the important effects of hydrocortisone are to be found the following: (1) an anti-pruritic effect—seen in its most dramatic form in some cases of ano-genital pruritus; (2) inflammation-masking effect—best illustrated in some cases of dermatitis of various types; (3) immunity-lowering action—seen in onset of acute impetigo after infantile eczema and a folliculitis after an irritant dermatitis. Each of these happenings has been noted, not possibly so dramatic, with the use of glycyrrhetic acid in the following series of cases.

Treatment was carried out by members of my staff at the Western Infirmary, the Royal Hospital for Sick Children, and the Southern General Hospital in Glasgow, and to these are added a few cases seen in private practice. In some, no control was exercised other than various, and at times numerous, preceding older forms of local therapy. Others were more fully controlled. In suitable cases glycyrrhetic acid ointment, its base, hydrocortisone ointment, and some other older applications were

applied by the ward sister, the clinical observers being unaware of the disposition of the remedies. Response noted did not necessarily mean cure.

In all, 33 patients have been treated: 8 of these were scarcely expected to improve—5 being chronic psoriasis rubra, 1 reticulosis, and 1 tinea pedis, in both of which the ointment was used to see if itch might be relieved, and finally a case of folliculitis—to see frankly whether the condition might be aggravated, as indeed happened. The remaining 25 cases were made up of dermatitis in all its forms: infantile eczema, flexural eczema, seborrhoeic, infective, sensitization, contact, exfoliative and herpetiformis (in the last-named, itch was relieved when other local measures failed), and finally 2 cases of drug eruption. Of the 25, 16 showed improvement, a specific response, 2 a non-specific response (did as well with base), 4 showed no response, and 3 were actually irritated. Of the 18 improved, 7 later relapsed, including the 2 which had shown non-specific improvement.

These results do not suggest that glycyrrhetic acid is a panacea for all ills or even God's gift to dermatology, but they do suggest that any inference or statement that glycyrrhetic acid is an inactive substance is both misleading and wrong. More research is necessary. It may be that a new "isomer" or a salt may be found to be more stable or active and that additional bases or an increase in percentage strength may be required.—I am, etc.,

Glasgow, C.2.

JAMES SOMMERVILLE.

Herpes Zoster and Chicken-pox

SIR.—The article by Dr. R. M. McGregor on herpes zoster, chicken-pox, and cancer in general practice (*Journal*, January 12, p. 84) prompts me to record two case histories of "chicken-pox" developing after exposure to herpes zoster infection.

In the first, I myself developed, some three weeks after examining a typical case of herpes zoster, a generalized eruption resembling chicken-pox. Two weeks later my daughter, then aged 2, produced a similar eruption. Neither of us had had any relevant exposure to chicken-pox, and I had contracted it as a child. In the second, a child of 3 developed "chicken-pox" three weeks after exposure to herpes zoster. In this instance the mother, assisting a neighbour with herpes, was accustomed to take her two children with her and they would play on his bed. I have to-day examined the second child, aged 16 months, with an exactly similar rash appearing 15 days after the first. Once again there are no local chicken-pox contacts.

In my experience the rash in these cases is much less dense than in chicken-pox and the constitutional disturbance negligible. I therefore prefer to believe that it is an instance of the leopard changing his spots and that what we are observing is a form of generalized herpes zoster, analogous to generalized vaccinia, and should be properly so termed.—I am, etc.,

Drug Sensitivity Presenting as Penile Herpes

SIR.—I was interested to read Dr. John E. Underwood's letter (*Journal*, January 19, p. 162) regarding drug sensitivity presenting as a penile herpes. Phenolphthalein and sulphonamides are known to be common aetiological factors in the production of fixed drug eruptions, and the following history illustrates such a case caused by sulphadimidine.

In December, 1952, a miner, aged 26 years, developed circular erythematous patches on the dorsum of the tongue, the left side of the glans penis, the under surface of the penis, and the dorsum of the left hand, the latter showing a vesiculo-bullous eruption. The lesions were accompanied by a burning sensation and were very irritable. At first it was thought that this was a herpes, until he developed identical eruptions following the ingestion of sulphadimidine tablets in October, 1953. It transpired that the patient had a supply of the tablets which remained from the treatment of a relative's illness and which he was in the habit of taking each time he developed an upper respiratory infection. In December, 1953, when free from the latter, he was given a

tablet of sulphadimidine with the subsequent production of lesions in the previously mentioned sites. Within five minutes of taking a tablet the irritation started as a burning and throbbing sensation. On the first day of the attack the lesions were red and erythematous, followed, on the second day, by multiple small vesicles which rapidly became confluent to form a bullous type of lesion. The lesions lasted for five days in all and caused the patient considerable discomfort. After the first attack there was no residual staining of the skin. The second attack, however, was followed by a very faint brownish discoloration of the skin which has remained since.

I am indebted to Dr. Peter Inman, dermatologist at the Royal Infirmary, Sunderland, for his advice on this case of fixed drug eruption.—I am, etc.,

Peterlee, Co. Durham.

W. A. BROWN.

SIR.—The condition mentioned by Dr. John E. Underwood (*Journal*, January 19, p. 162) is well known to venereologists and dermatologists. It is sometimes associated with a urethritis. The syndrome has been fully described in a monograph by my friend and former colleague, Mr. A. H. Harkness.¹—I am, etc.,

London, N.W.8.

REFERENCE

¹ Harkness, A. H., *Non-gonococcal Urethritis*, 1950, p. 301. E. S. Livingstone, Edinburgh.

Neostigmine-resistant Curarization

SIR.—So-called "neostigmine-resistant curarization" cases described by Dr. A. R. Hunter (*Journal*, October 20, 1956, p. 919) have provoked many letters, but no one has been humble enough to suggest that even in these days of modern anaesthesia patients must die. As patients gradually become moribund and die all the signs seen in the neostigmine-resistant cases occur. Surely, when these elderly cases receive such an insult as an intestinal obstruction or perforation some must reach a point of no return, when they must die. I venture to suggest that this "moribund syndrome" would explain why succinylcholine, gallamine, curare, serum potassium, and other biochemical estimations are collectively or severally castigated. If Dr. Albert Christie (*Journal*, December 1, p. 1303) happened to tackle a "moribund syndrome" case with his "less spectacular method" he would view the post-operative peripheral failure, gradual intercostal and diaphragmatic paralysis, and death in proper perspective.—I am, etc.,

Adelaide, Aust. alla.

J. A. SCANLON.

Psychiatry in Africa

SIR.—In his article on neuropsychiatric problems in Nigeria (*Journal*, December 15, 1956, p. 1388) Dr. Adeoye Lambo, within a few paragraphs, makes the following statements: "Some of the native treatment centres which I have seen may well play a useful part in solving our immediate problems. Their psychotherapeutic measures are as effective and as scientifically sound as any I have seen practised in Europe." "It is known that institutionalized confessions, trances, dances, and primitive religious rites and ceremonies, all of which are found to form the basis of the treatment armamentarium of these centres, are powerful psychotherapeutic measures."

Dr. Lambo goes on to quote approvingly another authority who has emphasized "the tremendous psychotherapeutic power which magic has, not only for those for whom it is performed, but above all for the performer himself." He further states that "these native treatment centres claim greater success in the sphere of neuroses [greater than what we are not told]. Some of the medicine-men think that incipient or latent psychosis responds in the same way." I have no wish to minimize the enormous difficulties under which Dr. Lambo and his colleagues have to work in a grossly under-doctored area, but it would be derogatory to his dignity as an African trained in our medical schools to pass some of these remarkable statements without criticism.

(1) Is the claim that psychology and psychiatry are scientific disciplines valid in Western Europe, when their results are reproducible and even bettered by primitive magic in Africa? (2) Dr. Lambo endorses Tooth's statement: "So that, until African psychiatrists can be trained, it would seem better to allow the care of the majority of the insane to remain in lay hands." What conceivable reason is there for training Africans in the principles of Western psychiatry if their own psychotherapeutic measures practised at the natives centres "are as effective and as scientifically sound" as any seen in Europe?

The *B.M.J.* is the official organ of the B.M.A., one of whose primary objects is the promotion of the medical and allied sciences (*B.M.A. Year Book*, 1956-7). You, Sir, have an annotation (p. 1420) on Dr. Lambo's article without once commenting on the use of magic in medical treatment, so patently commended by the author. I should be glad to know how you reconcile this omission with the declared objects of the Association.—I am, etc.,

Glasgow, W.2.

Common Infectious Diseases in General Practice

SIR,—Dr. G. I. Watson's excellent article on common infectious diseases in general practice (*Journal*, January 5, p. 39) is indeed thought-provoking. I would take issue with him on one point particularly, and that is his "German measles tea parties" for schoolgirls. It is believed that permanent immunity almost always results from a single attack of rubella. But how effective is this "tea-party" immunity and what degree of protection will still exist after perhaps 10 or 20 years? Secondly, there is an obvious risk that some of the "tea-party" girls might have mothers in the early stages of pregnancy. Also, what about the girls that would contract a mild infection or show no symptoms or signs at all? Could it be assumed that this was due to inherent immunity, or should they be exposed to a further attack and, if so, when? Lastly, German measles is usually a minor ailment, but the possibility of severe infection and even neurological complications cannot be ruled out. Much more experience is required before such an unusual procedure can be recommended.—I am, etc.,

Taunton.

Tonsils and Adenoids

SIR,—I read with interest Dr. John Fry's article, "Are All 'T's and A's' Really Necessary?" (*Journal*, January 19, p. 124). That he is not the first to ask this question enhances rather than reduces the value of his observations. While I am in substantial agreement with these, may I be allowed to make a few comments?

(1) He does not distinguish clearly between the indications for tonsillectomy and adenoidectomy. Although, for practical reasons, the two operations are often performed at the same time, it is important to realize that the indications are distinct and that it may be correct to perform one only. I have in mind particularly adenoidectomy without tonsillectomy. (2) In adults tonsillectomy is rarely criticized because, when done for good reasons, the result is only beneficial. It is probable that the pathology of "chronic tonsillitis" in adults and children is not quite the same, but perhaps sauce for the goose is sometimes sauce for the gosling. (3) There seems little doubt that the tonsils have a definite function in early childhood, as the late A. J. Wright suggested in his Semon Lecture in 1949.¹ The removal of tonsils which are still functioning may result in compensatory hyperplasia of the other lymphoid structures of the pharynx. As this may cause a chronic sore throat which is almost untreatable, we must certainly be

chary of operating on young children unless the reasons are very good. In my experience this does not apply to adenoidectomy.

We should ask ourselves, "Is it really necessary?" before advising any operation, and this is particularly so with tonsillectomy.—I am, etc.,

Taunton

PETER HUGGILL.

REFERENCE

¹ Wright, A. J., *J. Laryng.*, 1950, 64, 1.

SIR, Unfortunately, provocative articles in medical journals are eagerly seized on by the popular press, as in the case of Dr. John Fry's paper (*Journal*, January 19, p. 124). As a result, an operation which Dr. Fry admits to be useful and valuable in its place tends to be discredited in the public mind. Surely the fact that the number of tonsillectomies per 100 children has fallen by half in the past twenty years is evidence that the more critical approach sought by Dr. Fry already exists.

A list has been given of "the most usual reasons" for operation, which ought not to be confused with the indications, although Dr. Fry has combined them. Among the proper indications are several not mentioned—after peritonitis, which does occur in childhood (tonsillectomy), chronic otitis media maintained by nasopharyngeal infection, persisting conductive deafness, and chronic suppurative sinusitis (adenoidectomy). Borderline cases are decided between the G.P. and the E.N.T. surgeon: the latter is no more "in a quandary" than is any surgeon when asked to see any patient referred from a practitioner for consideration of an operation. Lastly, many adult tonsillectomies are still required in spite of the high rate of incidence of operation in children in the past.—I am, etc.,

Maidstone.

J. D. TRETOWAN.

SIR,—Dr. John Fry's interesting and stimulating paper on tonsillectomy (*Journal*, January 19, p. 124) would have been of greater scientific value if it had been possible to include two control series from other practices. Dr. Fry's statistics suggest that the harmful effect sometimes produced by enlarged tonsils and adenoids often disappears, but takes some years to do so. It would be of interest to know whether this period is significantly cut short (1) where tonsillectomy is done as a routine, and (2) where cases are selected but the net is spread much wider than in Dr. Fry's practice. Three points would be worth considering in particular: the amount of medical attention required for, say, three years after operation; the rate of growth; and absenteeism from school. If these are significantly affected, surely most doctors and parents would agree that operation was worth while at a time of life when satisfactory development is so important.

My first eight years in practice were in an industrial area, where definite indications for removal of tonsils and adenoids seemed very frequent. It was usual for the children to grow more rapidly, and not to need attention for ailments of any kind, for two or three years after operation. With rare exceptions the operation was done at home, in any kind of home. Possibly that is why psychological trauma did not occur. One boy, seeing the benefit to his elder brother, asked to have his own tonsils removed. Complications were very rare. There were no sulphonamides then, but also no cross-infections in the patient's own home.—I am, etc.,

Bracknell, Berks

L. G. JACOB.

SIR,—Dr. John Fry's stimulating and provoking article (*Journal*, January 19, p. 124) shows a capacity for statistical research. He neglects, however, the most important factors. "A prophylactic ritual carried out for no particular reason with no particular result." This misstatement by the M.R.C.¹ offers the answer. There is a reason. There is a result. The sacrifice of lymphoid tissue pacifies the parents and relieves the general practitioner of anxiety and frustration.

What is the family doctor expected to treat? A natural hypertrophy? A sore throat without pathogens? A running nose in a child that neither sniffs nor blows? Mechanical

irritative and obstructive features of the upper respiratory tract? Not surprisingly, the results are bad. Why does the family doctor treat the child? Mother's complaint that the child is always ill is belied by its appearance. Her continuous anxiety, despair, guilt, and agitation are transferred to the practitioner, and "Something must be done" leads to the mutilation. It must not be assumed that all cases of recurrent catarrh and sore throats are brought to the doctor. Witness the children running to school coughing, spluttering, and noses dripping, but still laughing and happy. Surprisingly, no comment has been offered on the child's own reaction to his illness: the warmth and comfort of bed, the attempt at spoiling, the singling out from the siblings for extra favours, and the holding up to ransom of the parents. Even where the inner need for retributive punishment is causative, where the child hates the enforced rest, these factors may easily be elucidated.

The mother's overt anxiety is accepted as a direct result of the child's condition. Her related deeper anxieties, unconscious like her guilt, remain unrecognized and indeed neglected. Irrespective of her aggression to the child or her over-indulgence of it, these are the factors at play. The mother desires cure of her own illness and offers a sacrifice. The result of operation relieves mother's anxiety temporarily, and the assessment of improvement is of her own condition. The child's growing-up problems, his jealousies, fears, and difficulties of adjustment—in these spheres lies the answer to the catarrhal child. The problem is one of utilization of illness by the parents and, less commonly, the child, sickness that is rarely infective or allergic but is almost always psychogenic.

Dr. Fry describes anxiety in the child's parents, relatives, and teacher, but offers them a policy of *laissez faire* and sympathy. He prefers to wait for the child to grow out of his catarrhal stage to save enormous operation costs, but this will not affect the mental health of the mother, nor make her a less frequent visitor to his surgery. A direct psychotherapeutic approach and the elucidation of the meaning of the illness to the mother is required. He finds anxiety and agitation in everyone but the child, and offers sympathy instead of psychotherapy. Over the past two years I have seen no child deserving tonsillectomy but many mothers requiring psychotherapy. Correlation of the pre-Oedipal and Oedipus phases with the normally accepted illnesses of childhood has yet to be finally assessed. In the hands of the general practitioner lies the opportunity for increasing efficient psychotherapy and less referral to otorhinology.—I am, etc.,

Sidcup.

Sudden Infant Deaths

SIR,—The paper on sudden unexpected death in infants by Dr. J. L. Emery and Miss E. M. Crowley (*Journal*, December 29, 1956, p. 1518) does not in our view help to elucidate this difficult problem, and may in fact give false impressions. While we agree that the case history taken by the coroner's officer may be at variance with that taken by the parents in a different manner, it is subsequently by one trained in a different manner, it is doubtful if either version can contribute materially to producing a more accurate diagnosis in obscure cases. Many of some interest had the authors interviewed 50 control mothers whose babies did not die. Following the tragedy of an unexplained death it is the natural tendency of both parents to remember and magnify a minor ailment, which may or may not be of importance. The group showing no significant symptoms remains.

Do the authors really believe that, had some attention been paid to the symptoms, many of the cases could have been diagnosed and treated? We have carried out been diagnosed and treated? We have carried out been necropsies when the symptoms prior to death were absent or minimal, and no satisfactory cause could be discovered

either histologically or bacteriologically. They represent about a third of the cases of sudden death in infants, and we think that such a view would be unfair to both the parents and the family doctor. The authors' statement that their policy is "to give some definite cause of death at inquests" puzzles us. What causes do they give in such cases? Do the authors feel that it is safe to put a baby in a cot with a pillow, especially when it is ailing? We fear that it will be necessary to suspend judgment in this important matter until new methods of examination for virus infections become available to the routine pathologist.—We are, etc.,

E. S. DUTHIE.

Southampton.

Bolus Obstruction

SIR,—I feel that brief mention of the following two cases may be of interest, particularly at this time of year. During the course of one afternoon two men were admitted to the Merthyr General Hospital from widely separated areas. Both gave a history of severe upper abdominal pain and vomiting for six hours. The possibility of an acute pancreatitis or perforated peptic ulcer was considered and a laparotomy was performed in each case. Both were found to have a brussels sprout impacted in the ileum, in one case 1 ft. (30 cm.) and in the other case 2 ft. (61 cm.) from the ileocaecal valve. The obstruction was relieved by removing the bolus, and recovery ensued. I do not recollect seeing mention of brussels sprouts among the numerous food materials cited as causes of bolus obstruction, and these cases illustrate their potential danger if not properly masticated. Once again, it may be said that food which enters as a friend may become an enemy in our midst.—I am, etc.,

Merthyr Tydfil.

R. J. WILLIAMS.

Advertisements for Cigarettes

SIR,—The leading article on mortality and smoking (*Journal*, November 10, 1956, p. 1104) ended with these impressive words: "The new evidence now published makes it more than ever imperative for all concerned to see that the public is repeatedly informed of the possible dangers to health and life from smoking cigarettes." But the same issue of the *Journal* carried a full-page advertisement for one brand of cigarettes. My inquiry about this striking inconsistency was referred to the Journal Committee, which has since resolved that no action should be taken. Its policy remains "to take advertisements for cigarettes, provided the 'copy' is acceptable."

To continue advertising cigarettes in the face of the overwhelming medical evidence of the dangers of tobacco addiction can only be considered extremely reprehensible, more especially when we recall that the most damning indictment is based upon the high death rates among heavy-smoking doctors (Dr. R. Doll and Professor A. Bradford Hill, p. 1071). The *Journal of the American Medical Association* refuses to carry tobacco advertisements. This enlightened attitude was urgently adopted in 1954—when the mortality rate from bronchogenic carcinoma in the United States was only half that in England. What possible excuse can the *British Medical Journal* offer for not following this example? In protest against the *Journal's* refusal to practise what it preaches, I am tendering my resignation from the B.M.A.—I am, etc.,

Leicester.

J. P. ANDERSON.

Carcinoma of Cervix and Corpus Uteri

SIR,—It is commonly held that carcinoma of the cervix uteri is much more common than carcinoma of the corpus—e.g., Anderson,¹ "Carcinoma of the cervix composes about 90% of all uterine cancer"; Novak,² "In round figures it may be said that about 1 out of every 8 uterine cancers will be found to be of the body type"; and Willis,³ "Broadly it may be said that cervical carcinoma is three or four times

as common as endometrial." Probably the proportion given by Willis is that found in the large industrial centres of Great Britain, but this may be untrue in rural areas. In this rural area carcinoma of the cervix has formed only about one-third of the total cases of uterine carcinoma during the past few years, and Dr. E. M. Martland tells me that for many years before this it has formed only a small proportion. This low proportion is not due to patients with cervical carcinoma by-passing the hospital here by being sent direct to a radiotherapy centre, and biopsies are taken here irrespective of whether further treatment is to be surgical or by irradiation.

The table shows the figures from (1) a large industrial centre, (2) two mainly rural areas, and (3) from three rural areas.

Centre	Period (Months)	Carc. Cervix	Carc. Body	C/B
Jessop Hosp., Sheffield	24	127	44	2.91
Carlisle	39	102	78	1.31
Winchester	60	65	50	1.30
Portsmouth	36	111	89	1.20
Bournemouth	24	31	34	0.94
Salisbury	24	16	30	0.53

It would be unwise at the moment to speculate on possible reasons for a difference in incidence between industrial and rural populations. Far more figures than those given above are necessary to establish that there is in fact such a difference. I should be grateful to receive figures from pathologists throughout the country, and meanwhile I thank Drs. C. G. Paine, J. S. Faulds, H. G. H. Richards, J. D. Clay, and T. K. Owen for the figures quoted above.—I am, etc.,

General Infirmary,
Salisbury, Wilts.

Congenital Absence of Spleen

SIR,—Your annotation (*Journal*, January 19, p. 153) states that congenital absence of the spleen is a rare anomaly. In a series of 126 cases of congenital abnormalities of the heart and great vessels coming to necropsy, mostly in the first year of life, I have encountered three cases in which the spleen was absent; two showed dextrocardia associated with Fallot's tetralogy and ostium atrioventriculare commune respectively, while the third showed transposition of the great vessels; in none was situs inversus of any abdominal viscera present.

The assessment of the rarity of a condition rests largely upon the frequency with which it appears in the literature. Congenital anomalies of the heart of sufficient severity to cause death within the first few weeks of life are generally not considered of sufficient interest to warrant publication, but it is in this group that absence of the spleen is most common. Since the anomaly probably arises in the fifth to seventh week of intrauterine life it would be surprising if it were not a relatively frequent incidental finding in any series of infantile deaths due to severe cardiac anomalies.—I am, etc.,

London, E.2.

N. E. FRANCE.

Pregnancy Sickness

SIR,—Recent letters from Dr. Doreen S. Ball (*Journal*, December 22, 1956, p. 1487) and Dr. R. Bauer and Dr. Margaret MacFetridge (*Journal*, January 12, p. 105) provide further evidence of the complete failure of research into the aetiology of pregnancy sickness. Further evidence, if any is needed, is provided by the multiplicity of drugs, diets, and routines recommended by the different adherents, and, incidentally, all of them equally useless. Dr. Bauer suggests an allergic basis for some of the cases, and on that ground

explains the effectiveness of antihistamines in some. On the other hand, is it not possible that the success of antihistamines might be due to (1) suggestion, (2) sedative action, and/or (3) an action similar to that in travel sickness? Dr. MacFetridge feels that it is possible that the trouble may be due to hormonal imbalance, and describes the sickness and nausea caused by stilboestrol (taken to stop lactation) as identical to the nausea and vomiting of pregnancy. Here again there seems to be an anomaly, because large doses of stilboestrol seem to be very well tolerated when given to terminate lactation. Similarly, large doses are well tolerated indefinitely when given to men with carcinoma of the prostate.

Finally, there are a number of cases of pregnancy sickness which never reach either the antenatal clinics or the obstetricians. I refer to sickness in "expectant fathers." Reference to the literature reveals little mention of this type of sickness. F. J. Browne¹ mentions one case reported by Atlee in support of his psychological theory. I am sure, however, that this type of sickness is much more common than is generally appreciated. Over the past year I can call to mind four cases of men who suffered from typical pregnancy sickness. In each case the sickness of the wife was much less than with previous pregnancies. In one case pregnancy was not even suspected (so I am assured) and sickness was absent in the wife but typical in the husband. In another case sickness was controlled in both husband and wife by a widely advertised pregnancy sickness tablet. It would seem that here is a condition which could be the subject of large-scale research by general practitioners under the supervision of the College of General Practitioners. I am, etc.,

Nuneaton, Warwicks.

Incidence of Diphtheria

SIR,—The fall in the incidence of diphtheria in the past few years is much more striking than is shown in your table (*Journal*, January 19, p. 176), which is evidently based on uncorrected notifications. The figures for corrected notifications, as published by the Registrar-General, are approximately one-quarter of those in your table. During 1954 and 1955 the total corrected numbers of cases for the whole year were approximately one-fifth of the average weekly numbers in the pre-immunization period.—I am, etc.,

London, W.C.2.

H. I. WINNER.

Rupture of Hind-waters and Haemorrhage

SIR,—I have read the report by Dr. J. K. Russell, Mr. D. F. Smith, and Mr. R. Yule (*Journal*, December 15, 1956, p. 1414) with interest. In their discussion they mention their practice of sweeping the membranes off the lower uterine segment as far as it can be reached with the examining finger before puncturing the hind-waters with the Drew Smythe catheter, but point out that the placenta may not be reached.

With this instrument the amniotomy is performed through an area which cannot be assessed by palpation; bleeding is a frequent occurrence as a result of passing the catheter between the placenta and the uterine wall, and should be an indication for its withdrawal and passage in a direction at least 90° from the original. With low puncture of the membranes and drainage of the fore-waters the amniotomy is performed through a part of the membranes which has been palpated and may even have been visualized, hence disruption of the placenta from its site is obviated. Only once out of many hundreds of cases have I seen foetal bleeding occur, from an unsuspected vasa praevia, in a case of induction by low puncture of the membranes.

In the two cases reported the causes of death are given as being due to or contributed to by the exsanguination, yet the haemoglobin in the child delivered alive was estimated

at 10.3 g. per 100 ml. and the amount of blood lost 90 ml. In the other infant the loss was heavier. However, both these were the offspring of mothers suffering from toxæmia of pregnancy, and in one case (the stillbirth) labour occurred nine days after her expected date of delivery. The post-mortem findings in case 1 are consistent with the baby having died from toxæmia, possibly aggravated by the blood transfusion, but the abrupt cessation of the carefully recorded foetal heart in the early stages of labour at or about 10 days over term is common. It would thus seem that, though blood loss from the foetal circulation is to be avoided, neither of these deaths can truly be laid to this cause.

In these two case reports, and according to their "invariable" practice of sweeping the membranes off the lower uterine segment, it would appear that the os admitted the examining finger with ease, and I suggest that, given such conditions, low puncture of the membranes is a safer procedure for the foetus and a more certain method of inducing labour without the time-lag of 24-36 hours usual with draining the hind-waters. The examining finger in such cases is also able to exclude the presence of a cord presenting with danger of prolapse at the time of "bursting of the waters," whether spontaneous or artificial.

As a method of induction of labour the Drew Smythe catheter has another disadvantage, shown by Dr. Russell and his colleagues, to add to the uncertainty of the method, the slow response where successful, the danger of placental separation (especially in toxæmia where repeated small infarcts may have brought the placental sufficiency to a borderline level), and the danger of intra-amniotic infection by contamination.—I am, etc.,

Nova Scotia.

HENRY FITZGIBBON.

Vaginitis

SIR,—We were very interested in your annotation entitled "Vaginitis" (*Journal*, January 19, p. 155), for in this clinic we treat a considerable number of cases of vaginitis due to *Trichomonas vaginalis* and to *Candida albicans*. We are surprised, however, that you recommend the use of "an oral trichomonicide such as aminitrazole." Our own experience with trichomonicides, including aminitrazole, has been most discouraging. Administration of aminitrazole alone, unsupported by local treatment, has, as far as we have been able to observe, no therapeutic effect whatsoever. It therefore seems to us unlikely that this drug contributes in any way to the efficacy of the scheme of treatment described. We should be interested to know details of the experience of others with oral trichomonicides.—We are, etc.,

London, E.1.

R. D. CATTERALL.
E. M. C. DUNLOP.
EVA GALLAGHER.

Varicose Ulcers

SIR,—The logical and successful treatment of any disease depends upon the knowledge and application of certain fundamental principles. This applies no less to the healing and prevention of varicose ulcers. The number of diverse treatments for varicose ulcer is mainly due to lack of understanding or failure to apply these principles.

First, it is necessary to understand the process of repair. A surgical wound, even though strictly aseptic, is not bacteriologically sterile. Carrel¹ demonstrated that an aseptic wound will not heal if all debris and blood clots are removed and the wound is protected from outside irritation. An open wound heals from below by granulation, and the youngest tissue is at the surface; it is highly vascular and bleeds readily. Healing is delayed if these granulations are torn off or caused to bleed. The use of antibiotics in treating a varicose ulcer is unnecessary and may retard healing. It does not matter what sort of dressing is used on the ulcer, provided the patient is not sensitive to it and provided it does not stick to or in any way damage the granulations.

Secondly, it is necessary to understand and apply the teaching of Hilton.² A varicose ulcer can be completely at rest when the patient is walking about and is not necessarily at rest when the patient is in bed. To immobilize a varicose ulcer the leg should be bandaged from the toes to the tibial tubercle, and the heel must be included. It does not matter what sort of bandage or support is used, so long as there is a firm, even pressure to the skin. If the bandaging is efficient it will control the high-pressure venous leaks in the deep fascia in the same way that a truss controls a hernia. The so-called calf pump is repaired, and when the patient walks the blood supply to the ulcer is improved, and also the oedema rapidly disappears. Activity is therefore an essential part of the treatment.

By applying these principles I have been able to heal every varicose ulcer I have treated, except one which was owned by a lady who persistently removed her bandages. I include patients whose work involves standing all day and who continue to work during treatment, and one patient with an artificial limb. Zinc oxide spread on gauze is a convenient and cheap dressing which does not stick. Two 4-in. (10-cm.) crepe bandages are far more comfortable for the patient than "elastoplast" or elastic webbing and are much easier to apply. Patients with ulcers less than 2 in. (5 cm.) in diameter I treat in the normal course of the surgery and can dress and bandage them in less than five minutes. In conclusion, there is no more grateful patient than one whose varicose ulcer has been healed without time off from work, particularly if he has previously had operative treatment. In order that he shall remain grateful it is necessary to explain that his ulcer will recur unless he continues to wear support for most of the time and to advise him to raise the foot of his bed about 3 in. (7.5 cm.).—I am, etc.,

PETER DARBY.

Antibiotic Cover for Dental Extractions

SIR,—We have read the letters from Dr. R. Cutler and Mr. Adrian Cowan (*Journal*, January 19, p. 162). It was our sincere hope that our communication (*Journal*, December 29, 1956, p. 1501) would revive interest in the fundamental observations of Okell and Elliott¹ and later of Elliott,² that a *Str. viridans* bacteraemia follows not only the major trauma of dental extractions but also the rocking of teeth in infected gum sockets in the course of mastication and teeth grinding.

The mouth, gums, and dental sockets are the normal habitat of *Str. viridans*, and it is improbable that by any local or systemic medication the organism will be eliminated even for short periods of time. It is our belief that so long as teeth or dental remnants are present in the jaws the ideal mechanism is present to produce a *Str. viridans* bacteraemia. For any patient who has developed subacute bacterial endocarditis due to *Str. viridans* we believe that this dangerous mechanism should be completely eliminated. In the cases referred to in our communication the opinions upon the teeth of our patients were those expressed by the clinical dental staff of the hospital and the radiologists whose opinion was sought in specific relation to the possibility of any evident and treatable source of infection in the teeth or gums. "Good" indicated that no defect was detected by either dentist or radiologist; "bad" indicated that defects were present. Whatever steps are taken to promote the more rapid healing of a dental socket after the extraction of a tooth, these are unlikely to control the bacteraemia incidental to the extraction.—We are, etc.,

Obituary

C. L. GIMBLETT, M.D., F.R.C.S., M.R.C.P.

Mr. C. L. Gimblett, formerly senior surgeon at the Westminster Branch of Moorfields Eye Hospital, died in the Westminster Hospital on January 21, aged 66.

Charles Leonard Gimblett was born on June 19, 1890, the only son of Robert Wheddon Gimblett, of Somerset. From Clifton College he went on to Gonville and Caius College, Cambridge, where he took the Natural Sciences Tripos, continuing his clinical studies at St. Thomas's Hospital. Qualifying in 1914, he graduated M.B., B.Ch. the following year, proceeded to the M.D. in 1918, and took the M.R.C.P. in 1919 and the F.R.C.S. in 1922. At St. Thomas's he was casualty officer, house-surgeon, house-physician, resident anaesthetist, and senior ophthalmic house-surgeon, but before completing this impressive series of house appointments he served from 1915 to 1919 in the Royal Navy, like so many of his name. Early in his career he decided to devote himself to ophthalmology, and during part of his wartime service he was in charge of the eye departments at the Royal Naval hospitals at Portland and Chatham. In 1923 he was appointed assistant surgeon to the Royal Westminster Ophthalmic Hospital and ophthalmic surgeon to the Royal Northern Hospital, and he was also ophthalmic surgeon to the East Ham Education Committee, for which he prepared a report on the incidence of myopia in the schoolchildren in the borough during the years 1920 to 1926. In 1927 he became full surgeon at the Royal Westminster Ophthalmic Hospital, and twenty years later senior surgeon there, retiring from the active staff last August. During the second world war he worked at the Haymeads Hospital, Bishop's Stortford, and was appointed to the staff of the General Hospital in that town. For nearly twenty years he was a member of the staff of the Lord Mayor Treloar Orthopaedic Hospital at Alton, a hospital for which he always had a very great love. Last July he was appointed emeritus consultant there, and he remained chairman of the medical advisory committee up till the time of his death.

Orthoptics was Mr. Gimblett's special interest, but he wrote on a variety of subjects and contributed the chapter on eye diseases in Romanis and Mitchiner's *Science and Practice of Surgery*. In 1949 he was elected vice-president of the Ophthalmic Section at the Royal Society of Medicine.

Mr. Gimblett married Audreen Isobel McKenzie McNicol in 1935, and she survives him with two sons.

G. G. P. writes: Mr. Gimblett was keenly interested in orthoptics, carrying on the work of Claud Worth, whose practice he took over, and on the inception of the orthoptic department at the Royal Westminster Ophthalmic Hospital he was appointed medical officer in charge. He was also the first chairman of the Orthoptic Board. A clinical ophthalmologist of the best kind, he never spared himself and was always painstakingly thorough in his work. It was with the utmost difficulty that he could be persuaded to take a holiday. In spite of two severe illnesses he continued his hospital work, even going on after the normal retiring age when asked to do so. He continued with his private practice right to the end. He was beloved by his patients, with whom he was patient and tactful to a degree, and by his colleagues, to whom he was a loyal and faithful friend and who always enjoyed his charming sense of humour. His services were invaluable as chairman of the

medical committee and on other committees at the Westminster Branch of Moorfields. He had a fine collection of books on mediaeval art. His delight when he did take a holiday was to go to the Mull of Kintyre with his family and have a sailing holiday. All his many friends will extend their deepest sympathy to Mrs. Gimblett and her sons in their grievous loss.

J. D. BENJAFIELD, M.D., D.P.H.

Dr. J. D. Benjafield, formerly bacteriologist at St. George's Hospital, died in his sleep at his home in London on January 21. He was 69 years of age.

Joseph Dudley Benjafield was born in London on August 6, 1887, the son of Dr. W. B. Benjafield, and was educated at Marlborough College and at University College Hospital, London. He qualified by taking the London Conjoint diploma in 1909, and in the following year he obtained the London University degrees of M.B., B.S., with honours in medicine. He proceeded to the M.D. in 1912, and in 1924 took the D.P.H. of the English Royal Colleges. After qualification he held the appointments of house-surgeon at the Evelina Hospital for Sick Children and house-physician at University College Hospital. From 1913 to 1920 he was bacteriologist to the Western Skin Hospital, in the Hampstead Road, and the Kensington, Fulham, and Chelsea General Hospital, and, later, to the All Saints' Hospital for Genito-urinary Diseases. He served in the R.A.M.C. from 1915 to 1919 during the first world war and from 1940 to 1942 in the second world war. After demobilization in 1919 he was appointed assistant bacteriologist at St. George's Hospital and lecturer in bacteriology in the medical school, where subsequently he became lecturer in clinical pathology.

In his younger days Benjafield was a well-known racing driver of Bentleys at Brooklands and Le Mans, where, with Mr. S. C. H. Davis, he won the Grand Prix d'Endurance in 1927. Two years later he came in fourth. A founder member of the British Racing Drivers' Club, he was a vice-president and former treasurer. His enthusiasm was infectious and did much to encourage British drivers to enter for the Le Mans events and similar meetings on the Continent. He leaves a widow and a son.

J. A. B. writes: Benjafield was not a learned bacteriologist. He was, in fact, a clinical pathologist whose theory and practice were derived from the time early in this century when it was hoped that the lessons of bacteriology might be applied usefully not only to the diagnosis but to the treatment of the individual patient. The fashion waned (until revived by antibiotic treatment), but Dudley remained faithful to the meticulous examination of cultures from every orifice of the body and to treatment with vaccines from these sources. The theory may have been unsound and its application outmoded, but he remained a successful and much-loved consultant because each one of his patients, in hospital and in Harley Street, was to him an individual with whose troubles he sympathized and for whom he did his very best. When he went on holiday he used to leave me a catalogue of notes on expected patients, which were masterly summaries not only of their ailments but of their virtues and failings.

Although he put on weight quite early in life his energy was amazing. He performed his teaching and other duties at St. George's scrupulously. He held appointments at other hospitals, and his private practice was very large. He always arrived in a hurry (and in later years rather out of breath), but time was never too short for his cheerful courtesy to great and small. He played as hard as he worked. Others can tell of his motor racing; I found a journey in his car

unrestful. When he abandoned this sport for fishing he became a skilful if rather petulant angler, but there were no bounds to his enthusiasm. A few hours after salmon in the Teifi were to him well worth a drive to West Wales and back crammed into a short week-end. He appreciated personal and material elegance, and he liked the pleasures of the table. Above all, he liked the life he led, and retirement had no attraction for him. He had few illusions about his fellow men and none about himself. Many of us must be grateful for having enjoyed his friendship.

Dr. REX BINNING writes: I first met Dudley Benjafield when I was a student at St. George's Hospital. He was a popular figure among the students, for his prowess as a racing motorist was well known. He was a most patient lecturer and demonstrator of bacteriology and an excellent teacher of laboratory technique. In addition to being a first-class bacteriologist he was also a very wise and shrewd clinician. As students, we learned to respect his ready wit and biting tongue, but it never left a mark except upon the pompous or petty-minded. Dudley Benjafield was always young in mind, and had many friends among his juniors. His counsel was often sought, but never in vain. In 1941 I shared a cabin with Benjafield in a crowded troopship I then making the long and tedious voyage round the Cape. I then came to know him better and to admire his active mind and capacity for work. He decided to write his reminiscences of his motor-racing days, and on hot sweltering afternoons in the tropics, when most of us were lying in our bunks, he would be writing the 3,000 words that were his target for the day. At night, after perhaps an evening playing poker, he would read over to me what he had written. When I myself was confined to my bunk with a carbuncle he was kindness itself, directing the treatment, doing the dressings himself, and bringing me my meals. Dudley Benjafield will be mourned by a host of friends, who will remember him for his zest for life, for his wit, his charm, and for many acts of kindness that were known only to a few.

CHARLES NOON, O.B.E., F.R.C.S.

Mr. Charles Noon, formerly senior surgeon to the Norfolk and Norwich Hospital, died at his home at Norwich on January 19 at the age of 71.

Born in Leicester on November 22, 1885, Charles Noon was educated at Blairlodge School, Stirling, and at St. Bartholomew's Hospital Medical School. Qualifying in 1910, he held the appointments of house-surgeon and resident anaesthetist at St. Bartholomew's Hospital, and house-physician at the Royal Northern Hospital, and resident chief assistant to the department of gynaecology at St. Bartholomew's Hospital. Having taken the F.R.C.S. in 1914, he went to Norwich in the following year as a major in the R.A.M.C., taking charge of the surgical section of the Thorpe War Hospital, a post which he held until the end of the war. For his services there he was appointed O.B.E. in 1919. In that year also he was elected assistant surgeon to the Norfolk and Norwich Hospital, becoming full surgeon in 1932 and senior surgeon in 1946. He retired from the active staff in 1955. He was also consultant surgeon to many local hospitals, including St. Andrew's Hospital, Thorpe, the West Norwich Hospital, and the Jenny Lind Hospital for Children. Always keenly interested in the welfare of war pensioners, Mr. Noon was at one time surgeon-in-charge of the Ministry of Pensions out-patient clinics and limb-fitting centre at Norwich. Treatment of malignant disease by radium therapy was a method which he had studied closely, and over thirty years ago he had purchased his own supply of radium, which he used freely in the hospitals to which he was attached. During

the second world war he was once again in charge of the Thorpe Hospital, this time under the Emergency Medical Service. Since the inception of the National Health Service he had been a member of the surgical advisory committee of the East Anglian Regional Hospital Board.

He married Cicely, daughter of Mr. F. South, and she survives him, together with one son.

J. M. R. T. writes: Charles Noon was a shrewd and far-seeing man whose advice and guidance, willingly given, were always of the utmost value. To those who met him for the first time he could give the impression of being remote and even cynical, but to the few who were privileged to know him well real kindness was the mainspring of his personality. Surgery was the absorbing interest of his life. Gifted with a profound clinical instinct, he taught generations of registrars and housemen to use their five senses rather than to rely on the "investigations" judged indispensable in the surgery to-day. His out-patient clinics, ward rounds, and operating sessions were enlivened by his forthright personality, his great store of surgical aphorisms, and his wide knowledge of medical history. He was a man who never suffered fools gladly, and he always expected everyone to give of his best.

Charles Noon was an enthusiastic bibliophile and collector, but among his many treasures his books and papers relating to every facet of the medical work and history of Bart's took pride of place. His enthusiasm and admiration for his own teaching school never waned. It was an education in itself to hear him talk when surrounded by the *lares et penates* which he had acquired with the discerning patience of a connoisseur.

P. S. FLEISCHMAN, M.D.

Dr. Paul S. Fleischman, who might be regarded as the doyen of the group of German doctors who came to Britain in the days of the Third Reich, died in the Regent's Park Nursing Home on January 16 after a short but not unexpected illness at the age of 77.

He was born on July 23, 1879, of a well-known banking family at Fürth, in Bavaria, and on his mother's side he was related to the famous Romberg. His school days were spent in Berlin, but he returned to Bavaria for his medical studies at Munich, where one of his teachers was Röntgen, and he graduated in medicine in 1902. After qualification he travelled and studied in many centres, in Paris with Metchnikoff, in London with Sir Almroth Wright, in Berne with Sahli and Kronecker, and then he went to the famous Charité in Berlin, working under von Leyden and His, father and son. Rising through the various stages of this German medical faculty, he was eventually appointed after fifteen years of junior posts as "ausserordentlicher" professor at the Charité Hospital. The two "ordinarius" professors at this time were the famous and witty Friedrich Kraus and Wilhelm His of "bundle" fame. Wilhelm His was particularly fond of Fleischman, who was his chosen doctor in his last illness, being not only his medical adviser but his intimate friend.

Other appointments followed, numerous papers from his pen appeared in the German literature in these years, and he became one of the most sought-after physicians in Berlin. Then at the height of his career came tragedy, and humiliation after humiliation was heaped upon him until finally his *venia legendi* was taken from him and he could no longer talk to his students.

Beneath these bludgeonings of fate his head was "bloody but unbowed," and he came to London, 57 years old, with his wife and three young children. The one-

never lost heart for long, and her natural zest for living, her kindness and quick brain, made her a delightful friend and interesting companion. She had outbursts of indignation over various subjects, to which her friends would listen amazed at the wide range of knowledge of history and facts she displayed, though usually unable to accept the sweeping condemnations made. She had great clinical acumen and skill, and deservedly won the love and confidence of many patients. The constant inflow of lovely flowers during months of illness gave ample testimony of this love. Dr. Hanby was retiring and shy of meeting strangers, and was little known outside the small circle of her local practice near Bolton. Hers was a quiet, unobtrusive, and courageous life, like that of many who give themselves devotedly to the service of their patients and have themselves to struggle against great odds. She made no contributions to medical literature and did nothing spectacular, but will long live in the memory and affection of those who, by intimate contact with her, could recognize the flashes of that fine and undefeated spirit that was herself.

Medical Notes in Parliament

Treatment of the Elderly Sick

When Parliament reassembled on January 22 after the Christmas recess Lord AMULREE, with the support of Lord COTESLOE and Lord HADEN-GUEST, called attention in the House of Lords to the case of old people and administrative difficulties arising between the working of the National Health Service Act and the National Assistance Act.

He was concerned with the substantial minority of old people, mostly pensioners—and particularly those living alone—who were on the border between health and sickness, neither fit enough to look after themselves nor yet sick enough to need hospital treatment. The B.M.A. in 1947 set up a committee (of which he was a member) whose report advocated that old people who were not really ill, but frail and infirm, should come under the umbrella of the Health Service rather than being separated under the Assistance Act. Unfortunately that was not done, and the difficulties still remained. The Guillebaud Committee in 1956 reported that they were very worried about it. One suggestion, that there should be amending legislation to put the matter back under one authority, he dismissed as impracticable. Another that might be encouraged was that regional boards and local authorities should make a joint appointment when they appointed doctors to take care of the old people in their hospitals, so that they would have charge of the people under Part III of the Assistance Act. That had been done in one or two cases, and was working well. A third suggestion, which was included in the Guillebaud report, was that the welfare services might be transferred to the health committee of the local authority, which would mean that the medical officer of health would be in the chair and they would have a medical side to them. It was a medical matter, and the more that kind of balance could be kept the better.

Lord COTESLOE, who is chairman of the North-west Metropolitan Regional Hospital Board, said that administrative difficulties arose mainly from the dichotomy under the two Acts, by which regional hospital boards were responsible for the aged sick and the county councils for the welfare of the senile and infirm. It was not a practical possibility to make a single authority, either local or hospital, responsible for the care of all the old people in an area. What was needed was not such a tidy, theoretical solution but a real understanding and knowledge of the problems and needs of the individual old people on the part of hospital officers on the one hand and the welfare officers and wardens of old people's homes on the other, and the closest co-operation between them locally. That was the course that should be pursued in the search for a solution.

Lord HADEN-GUEST advocated a national survey by a committee and the formulation of a plan for the country as a whole.

The EARL OF HOME, speaking for the Government, said that progress must rest on greater efficiency in organization, greater co-ordination of the efforts of hospitals, doctors, and welfare authorities, and greater appreciation by local authorities of the needs of the old. In spite of all that had been done, there was room for much better co-ordination between hospital and welfare authorities. He was inclined to think that the root of the trouble was the lack of accommodation for those who need no longer be kept in hospital, and that part of the trouble was lack of personnel to look after those old people in their homes. But some things could be done with advantage. One of them was Lord Amulree's suggestion about the joint appointment of geriatric physicians. Further attention ought to be given to the powers of local authorities to a direct meals service, in addition to assisting voluntary associations. There had been a survey between 1954 and 1956 by Ministry of Health officers and the services affecting the elderly sick. The results had been assessed on a national basis, and the Minister proposed to issue memoranda, with suggestions arising from the survey, to all hospitals and local authorities. No Government or Act of Parliament could compel co-operation, but if common sense was applied great improvements could be made.

Mental Hospital Patients

Mr. NORMAN DODDS (Erith and Crayford, Lab.) asked the Minister of Health on January 23 if he was aware of the concern that had arisen from the knowledge that a person could be certified as insane under the Lunacy Act, 1890, by one doctor at one interview lasting no more than five minutes, with the reasons for certification denied to the person concerned or to relatives; and what action was proposed to minimize the risk of mistakes, which could have a grave effect on the liberty of the individual, and to bring this aspect of national life more into keeping with modern practice. Mr. DENNIS VOSPER stated that he did not accept the implication. A summary reception order might be made by a justice of the peace on a certificate by one medical practitioner. It was for the justice himself to examine the person, to make inquiries, and to satisfy himself that the person was of unsound mind and a proper person to be detained. The law on this subject was being reviewed by a royal commission at the present time.

He informed Mr. Dodds that the numbers of persons detained under the Lunacy Acts were, in 1945, 130,462; in 1950, 120,698; in 1952, 117,948; and in 1955, 110,788. The numbers detained under the Mental Deficiency Acts were, in 1945, 55,336; in 1950, 59,417; in 1952, 61,211; and in 1955, 63,255.

Mr. DODDS asked how many persons in mental institutions, up to the latest convenient date, were detained under the Mental Deficiency Acts for other reasons than being mentally defective. Mr. VOSPER: I am not aware of any such persons. Mr. DODDS asked the Minister, in view of the large number of young people who had in the past been certified under the Mental Deficiency Acts because of being in need of care and attention rather than being mentally defective, and because of the difficulties that such patients had in invoking the law to have the certification set aside, what action he was taking to have a thorough investigation made of each case with a view to enabling as many as possible to lead normal and useful lives. Mr. VOSPER: I am not aware of any such persons.

Immigrants' Health Certificates

Captain H. KERBY (Arundel and Shoreham, Con.) asked the Minister of Health on January 25 if he was aware that Great Britain was the only Commonwealth country that any immigrant could enter without producing a certificate of good health; and what steps he proposed to safeguard

Great Britain from imported communicable diseases. Mr. VOSPER informed him that the existing Public Health (Ships) and (Aircraft) Regulations, 1952, gave wide powers to port medical officers to deal with any case or suspected case of communicable disease arriving in this country. In addition, alien immigrants might be medically examined under the Aliens Order, 1953.

February Meeting with Minister

The new Minister of Health, with the Secretary of State for Scotland, has agreed to meet representatives of the medical profession towards the middle of February. Mr. DENNIS VOSPER stated this in answer to three questions on January 28 asking for a statement on the salary negotiations. He added, "For the present, I have no statement to make."

Mr. ARTHUR LEWIS (West Ham, North, Lab.) asked for an assurance that the Minister would deal with the matter on its merits, and not treat the doctors in the same shabby and dirty way that the Government had treated M.P.s' salaries. Mr. M. LIPTON (Brixton, Lab.) suggested that, as the Government's honour was at stake, they should agree to arbitration to settle a firm basis for any future adjustment of doctors' salaries. Viscount HINCHINGBROOKE (South Dorset, Con.) spoke about the enormous importance of the State honouring its obligations to important sections of the community, and of seeing that justice, as pledged in the past, was fully discharged. He suggested that the Minister could argue with the Chancellor of the Exchequer that the possible inflationary consequences in the present instance could be taken care of by other means.

Mr. J. RANKIN (Glasgow, Govan, Lab.) asked the Minister if he was prepared to accept the contractual obligation implied in the Spens report on the basis of all future salary negotiations with the medical profession. Mr. VOSPER: I am advised that no legal contractual obligation exists. Mr. RANKIN said this was one of the points that had caused every scalpel in Scotland to be drawn over the week-end. There would be no satisfactory issue unless this matter was dealt with. Doctors did not accept the explanation which had been given. Mr. VOSPER: I am going to meet the doctors, and I shall not meet them on the basis that a legal contractual basis exists.

Cigarette Smoking

Mr. LIPTON asked the Minister of Health whether he would move to appoint a select committee to consider what immediate and practical steps could be taken to reduce cigarette smoking. Mr. VOSPER replied "No." He did not consider that a select committee would be an appropriate body for this purpose. Mr. LIPTON questioned whether, as a definite connexion had been established between cigarette smoking and lung cancer, the hundreds of millions of pounds made by the Government out of cigarette smoking could be regarded as moral earnings. Were not the Government under a solemn obligation to warn the public of the risks? Should they not take more positive action, even if it meant upsetting the Chancellor and the tobacco magnates? Mr. VOSPER retorted that if Mr. Lipton had raised the matter in an adjournment debate, as he had said he would do, it would have been possible to deal with some of the rather unfair allegations he had made. Mr. SOMERVILLE HASTINGS (Barking, Lab.) asked whether the evidence was not sufficiently strong for something definite to be done by the Ministry. Ought not young people and children in schools to be warned of the dangers of cigarette smoking? Mr. VOSPER said that he intended to look further into this, and take the advice of those concerned.

Pharmaceutical Products.—Discussions with the pharmaceutical industry on prices of proprietary preparations have recently been concluded, and in the light of these the industry has revised its proposals, which the Minister of Health is considering.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending January 12 (No. 2) and corresponding week 1956.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

Vital Statistics

London in 1955

The population of the County of London in 1955¹ was 3,295,000, which was 27,000 fewer than in 1954. In comparison with England and Wales as a whole, there were relatively fewer people aged under 25 and over 44, with relatively more aged 25-44. Females exceed males by 6.5%, as compared with 3.7% in England and Wales. The live birth rate, at 15.1 per thousand population, was the lowest since the 1946 peak of nearly 21, but was well above the figures of the 1930's—about 13.5. It is much the same as the rate for England and Wales, though the proportion of women of child-bearing age is greater in London.

The general death rate was 11.5 per thousand population. It has not changed much since the end of the war, having fluctuated about one point above or below that figure. It is near the rate for England and Wales. The infant mortality rate, at 23.2 per thousand live births, showed a slight rise from the rate for 1954—namely, 20.6. The rate for London is normally lower than the rate for England and Wales, which in 1955 was 25.

Cases of diphtheria were more numerous in 1955, being 16 as compared with 4 in 1954, and 2 deaths were reported. The County Medical Officer has recently started a campaign to increase the numbers of immunized children in London; only about 54% of children aged under 5 were immunized at the end of 1955. Other deaths caused by infectious diseases were 7 from whooping-cough, 15 from measles, 27 from diarrhoea in children aged under 2, 164 from influenza, 22 from meningococcal infections, 1 from erysipelas, 26 from acute poliomyelitis, and 561 from tuberculosis (517 respiratory). The commonest source of tuberculous infection nowadays is a human case; such was the source even in a recent outbreak among monkeys at the Zoo. B.C.G. vaccination is offered to all tuberculin-negative 13-year-old children attending London schools whose parents give written consent. By the autumn of 1955, 19,301 children had been vaccinated.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases (deaths for influenza) of certain diseases notified weekly in England and Wales (great towns for influenza). Highest and lowest figures reported in each week during the years 1947-55 (influenza, 1952-5) are shown thus ———, the figures for 1956-7 thus ———. Except for the curves showing notifications in 1956-7, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

¹ Report of the County Medical Officer of Health for the Year 1955 (L.C.C., 2s. 6d.).

Infectious Diseases

The only large variations in the returns of infectious diseases during the week ending January 12 in England and Wales were falls of 1,689 in the number of notifications of measles, from 10,970 to 9,281, and 44 for scarlet fever, from 572 to 528, and a rise of 377 for whooping-cough, from 2,109 to 2,486.

The largest falls in the incidence of measles were 453 in Lancashire, from 2,592 to 2,139, 346 in Yorkshire West Riding, from 919 to 573, and 324 in Essex, from 1,137 to 813; the only large rise was 151 in Northumberland, from 318 to 469. Only small fluctuations were reported in the trends of scarlet fever. The largest increases in the number of notifications of whooping-cough were 83 in Lancashire, from 215 to 298, 48 in Durham, from 109 to 157, 46 in Staffordshire, from 98 to 144, and 46 in Warwickshire, from 71 to 117. 9 cases of diphtheria were notified, being 7 more than in the preceding week.

72 cases of acute poliomyelitis were notified, and these were 3 more for paralytic and 6 more for non-paralytic cases than in the preceding week. The largest returns were London 10 (Battersea 2, Islington 2, Stepney 2), Surrey 10 (Reigate M.B.

7, Kingston-upon-Thames U.D. 2), Essex 7 (Dagenham M.B. 2), Kent 6 (Crayford U.D. 2), Sussex 6 (Hove M.B. 3), and Lancashire 5 (Bootle C.B. 2).

The notifications of dysentery numbered 530, being 5 fewer than in the preceding week. The largest centres of infection were Lancashire 110 (Accrington M.B. 27, Liverpool C.B. 14, Manchester C.B. 11, Bolton C.B. 10), Yorkshire West Riding 91 (Leeds C.B. 21, Sheffield C.B. 16, York C.B. 12), Warwickshire 74 (Coventry C.B. 66), London 49 (Woolwich 10), Staffordshire 22 (Kidsgrove U.D. 16), and Yorkshire East Riding 22 (Kingston-upon-Hull C.B. 20).

Channel Islands Census

At the 1951 census the population of the Channel Islands was 102,806 persons, an increase since 1931 of about 9,600. 2,066 visitors were enumerated in Jersey in 1951 and 1,131 in Guernsey and adjacent islands.

Householders were asked to state whether they had exclusive use of, or shared with another household, or were without a piped water supply within the house, a cooking stove or range, a kitchen sink, a water-closet, and a fixed bath. In Jersey 40% of all private households and in Guernsey and adjacent islands 36% had exclusive use of all five of these household arrangements. A further 8% in Jersey and 9% in Guernsey and adjacent islands had all except a fixed bath. These figures compare with 52% for England and 19% for Wales.

The populations of the islands were on the average slightly older than that of England and Wales. 12.6% of the population of Jersey were aged 65 and over, and 12% in Guernsey and the adjacent islands. The figure for England and Wales was 11.0%. Since 1931 the proportion of married people has increased particularly among young people. At age 20-24, in Jersey, there were 245 married males per thousand as compared with 168 in 1931, and 461 married females per thousand compared with 291. In Guernsey and the adjacent islands the changes were similar. Fertility in Guernsey was higher than in Jersey. In Guernsey and the adjacent islands there were 186 live-born children per 100 married women under age 50, while in Jersey the figure was 167. In England and Wales it was 169.

Week Ending January 19

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 693, whooping-cough 2,664, diphtheria 4, measles 8,175, acute pneumonia 516, acute poliomyelitis 41, dysentery 477, paratyphoid fever 2, and typhoid fever 5.

Medical News

Benefactions by the Wellcome Trust.—This week the Wellcome Trustees announce grants totalling £173,500 to scientific institutions in Britain. In addition, the Trustees have agreed in principle to present a motor cruiser to the Medical Research Council to assist communication between the Council's laboratories at Fajara on the Gambia River and the branch laboratory near the village of Keneba, some 70 miles further up the river. This vessel would be adaptable as a mobile research laboratory for use in field studies in the interior of the Gambia territory. Appropriately enough, the Trustees point out, probably the first floating laboratory to be made was the one built in 1907 to the order of the late Sir Henry Wellcome. It was used on the Nile by the staff of the Gordon Memorial Hospital, Khartum. Details of the grants to scientific institutions are as follows:

Leeds University.—Up to £60,000, towards building research laboratories for medical physics and urology on the site of the General Infirmary.

Edinburgh University.—Up to £35,000, for rebuilding animal houses at the Institute of Animal Genetics.

Royal College of Surgeons of England.—Up to £35,000, for the completion of the Wellcome Museums at the College.

Manchester University.—Up to £13,000, for a mobile radiographic and laboratory unit for use primarily in field work on the rheumatic diseases.

St. Andrews University.—Up to £15,000, for adding Wellcome Laboratories of Pharmacology to the Gatty Marine Laboratory.

Rowett Research Institute, Aberdeen.—Up to £5,000, for a building to house special equipment for research in animal nutrition.

University College of South Wales and Monmouthshire, Cardiff.—Up to £3,000, for an ultracentrifuge for indefinite loan to the department of biochemistry.

Liverpool Medical Institution.—£5,000 spread over five years, for cataloguing the library and rebinding books published before 1850.

Royal Faculty of Physicians and Surgeons of Glasgow.—£2,500 spread over five years, for rebinding historical volumes in the library.

Caesium Unit at Royal Marsden Hospital.—The radiotherapy department of the Royal Marsden Hospital is carrying out a clinical trial of radioactive caesium as a source for beam therapy at its branch hospital, the Downs Hospital, Sutton. The unit, which was designed by Professor W. V. MAYNEORD, is the second of its kind in the world, the first being at Oak Ridge, Tennessee; another unit, at Southampton, with a rotating apparatus containing two caesium sources, is expected to start work in a few months' time. The caesium comes as a waste product from the Atomic Energy Authority's reactor at Windscale, where it is extracted by a complicated chemical process and sealed in platinum capsules. The active material is the 137-isotope which emits gamma rays. The caesium source has a number of advantages over the usual 250-kilovolt x-ray therapy machine: the quality of its beam, with the energy concentrated over a very narrow waveband of short wavelength, is about equivalent to that produced by the much more costly 660-kilovolt machine; as a consequence, absorption is much more even in the various tissues and there is little trouble from differential absorption in bone; the risk of damage to the skin is also less. On the other hand, the amount of protection needed is far less than with a cobalt-60 source, a factor of importance in the design of both the treatment room and the container for the caesium; the apparatus is thus more manoeuvrable and better adapted for treatment at short distances, such as for tumours in the head and neck. In spite of these advantages, the caesium unit is also attractive economically. Its capital cost is about the same as for a conventional x-ray therapy plant—there is even a considerably cheaper "utility" model available—and, apart from the hire of the caesium, running costs are negligible. The trial is under the direction of Professor D. W. SMITHERS.

Teaching Hospital in the West Indies.—In September, 1952, the Teaching Hospital of the University College of the West Indies was opened with 240 beds. The hospital is in Jamaica. The intention of the Jamaican Government, as stated in a law establishing it in 1948, was a 500-bed teaching hospital for the instruction each year "of not less than thirty medical students in such subjects as are usually provided in medical schools forming part of the University of London." January, 1955, was given as the deadline. Since the hospital was opened a further 81 beds have been added, "provisional recognition" has been accorded by London University, and plans have been prepared for further expansion. A report has been published (Colonial No. 327, H.M.S.O., price 2s. net) giving the views of a four-man committee, appointed by the Colonial Secretary, on the hospital's future development. The committee consisted of Dr. R. S. AITKEN, vice-chancellor of Birmingham University (chairman); Dr. E. R. BOLAND, dean of Guy's Hospital Medical School; Dr. J. W. P. HARKNESS, medical adviser to the Comptroller for Development and Welfare in the British West Indies; and Mr. G. A. PHALE, secretary to the United Birmingham Hospitals. Their principal recommendations are that the teaching hospital should be enlarged to provide for fifty students in each of three clinical years, a recommendation which would involve bringing the number of beds up to 454 at a capital cost of £1m.; and that the hospital's board of management should be increased so as to include members

from British Caribbean territories other than Jamaica and one member of the hospital medical staff besides the dean. Recommendations are also made about recurrent costs.

Report of an Accident.—The United States Atomic Energy Commission has published a report on the medical findings among the Marshall Islanders and members of the American task force who were accidentally contaminated by the hydrogen bomb exploded at Eniwetok in March, 1954. The report, edited by Dr. E. P. CRONKITE, Dr. V. P. BOND, and Dr. C. L. DUNHAM, is titled, *Some Effects of Ionizing Radiation on Human Beings*, and may be obtained from the U.S. Government Printing Office, Washington, 25, D.C., for \$1.25. The report runs to 106 pages, and includes as its final chapter a general discussion on radiation injury from atomic weapons. The accident was due to an unexpected change in the wind.

Scholarships Abroad.—The British Council announces about a hundred scholarships for British students (mostly university graduates or undergraduates) for study abroad. They provide for free tuition and maintenance, usually for a full academic year. The British Council helps with the recruitment of candidates, and further details may be obtained from the controller of the council's education division, 65, Davies Street, London, W.1.

Active Membership of W.H.O.—The Government of Poland has now informed the World Health Organization of its desire to resume active membership. Similar requests by Albania and Bulgaria were noted in this column last week (p. 237). Poland's active participation lapsed in August, 1950.

W.H.O. Regional Director for Europe.—Dr. P. J. VAN DE CALSEYDE, director-general of public health at the Belgian Ministry of Health, has been appointed director of the World Health Organization's regional office for Europe from February 1. He succeeds the late Dr. NORMAN BEGG.

Otser Club.—At a meeting on January 24 at the Royal College of Physicians, Sir RUSSELL BRAIN, P.R.C.P., gave an address on Dr. Thomas Lawrence (1711-83), a former president of the College and a friend of Dr. Samuel Johnson. Dr. W. S. C. COPEMAN, the Club's president, was in the chair. An exhibition of historical books, papers, and portraits was held subsequently in the library.

North of England Obstetrical and Gynaecological Society.—At the annual meeting on January 18 the following were elected officers for 1957: president, Mr. F. STABLER; vice-presidents, Dr. E. A. GERRARD (Manchester), Mr. P. MALPAS (Liverpool), Mr. H. AGAR (Leeds), Mr. G. R. MACDONALD (Sheffield), and Dr. W. HUNTER (Newcastle); hon. treasurer, Mr. C. H. WALSH; hon. general secretary, Mr. F. J. BURKE; and hon. reporting secretary, Miss U. M. LISTER.

Postgraduate Medical Studies at Oxford.—Surgeon Rear-Admiral J. HAMILTON is the director of Postgraduate Medical Studies at Oxford, not Dr. JANET VAUGHAN and Dr. G. E. F. CHILVER as we stated on January 19 (p. 179). They have been appointed to the board of electors for the directorship.

Professor W. C. W. Nixon, professor of obstetrics and gynaecology at University College Hospital, London, has been appointed to the World Health Organization's expert advisory panel on maternal and child health.

COMING EVENTS

Lecture in Belfast.—Sir CECIL WAKELEY will deliver the Sir Thomas and Lady Edith Dixon Lecture at the Royal Victoria Hospital, Belfast, on Friday, February 8, at 4.30 p.m. His subject will be "External Herniae."

Corneo-plastic Unit, East Grinstead.—Lecture-demonstrations to illustrate the relationship of ophthalmic and plastic surgery will be held on February 2, March 2, March 9, and April 6 at 2 p.m. Details from the secretary, Corneo-plastic Unit, Queen Victoria Hospital, East Grinstead.

Tenth International Hospital Congress.—Lisbon, June 3-7. Registration before March 15. Details from Captain J. E. STONE, 10, Old Jewry, London, E.C.2.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, February 4

MARLBOROUGH DAY HOSPITAL.—8.15 p.m., Dr. T. F. Main: The Past and the Present in Neurosis.
● UNITED HOSPITALS CATHOLIC SOCIETY.—At 13, Devonshire Place, W., 6.15 p.m., Mr. A. J. King: Marriage—Moral and Medical Concepts.

Tuesday, February 5

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. N. B. Myant: Biliary Excretion of Thyroid Hormone.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. T. Brain: Electrotherapeutic Techniques.

ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Dr. J. T. Scales: Metals and Plastics in the Treatment of Disease.
ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., Milroy Lecture by Dr. D. D. Reid: Environmental Factors in Respiratory Disease.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—3.45 p.m., E. Rawns Wilson: Demonstration by Dr. G. T. Allen: Histological Variations in Basal Cell Tumours.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Institute Theatre, 5 p.m., Mr. D. W. S. Gordon: Some Unusual Lesions of the Vulva.

Wednesday, February 6

ASSURANCE MEDICAL SOCIETY.—At Medical Society of London, 5 p.m., Presidential Address by Dr. K. Shirley Smith: Revision of Underwriting Standards in Life Assurance.

EDINBURGH ROYAL CLUB.—4 p.m., visit to Department of Cardiology, Edinburgh Royal Infirmary.

GLASGOW UNIVERSITY MEDICO-SURGICAL SOCIETY.—7.30 p.m., meeting with Queen Margaret Medical Society. Professor Ian Donald: The Dominant Sex.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. W. Riddell: Laboratory Procedures for Mycotic Infections.

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Mr. T. Holmes Sellers: Surgical Treatment of Pulmonary Stenosis.

INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Mr. H. G. Hanley: Disorders of Micturition in Females.

LIVERPOOL MEDICAL INSTITUTION.—8 p.m., Professor J. H. Dible: Pathology of Peripheral Ischaemia.

MIDLAND MEDICAL SOCIETY.—At 154, Great Charles Street, Birmingham, 8.15 p.m., Dr. H. W. Donovan, Dr. C. F. Hawkins, Professor E. Brodie Hughes, and Dr. L. Nagley: Symposium on the Relief of Pain.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Dr. Alick Isaacs: Influenza and Adenoviruses.

ROYAL MEDICAL SOCIETY EDINBURGH.—8 p.m., clinical meeting.

Thursday, February 7

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. H. M. Sinclair: Vitamins in Nutrition.

FACULTY OF HOMOEOPATHY.—5 p.m., Dr. L. R. Twentymen: Approach to the Pre-cancerous State; Dr. A. E. Stricker: Review of Treatment of Pneumonia and Acute Bronchitis in Children Admitted to the Royal London Homoeopathic Hospital Since 1948.

NORTHAMPTON MEDICAL SOCIETY.—At Northampton General Hospital, 3 p.m., clinical meeting.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., Milroy Lecture by Dr. D. D. Reid: Environmental Factors in Respiratory Disease.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Dr. J. H. Paterson: Neurology demonstration.

ST. JOHN'S HOSPITAL DERMATOLOGICAL SOCIETY.—4.30 p.m., demonstration and discussion of clinical cases.

UNIVERSITY COLLEGE LONDON.—At Eugenics Theatre, 5 p.m., Mr. D. J. Payne: Compensation for Industrial Injuries.

UNIVERSITY COLLEGE LONDON: DEPARTMENT OF PHARMACOLOGY.—At Physiology Theatre, Gower Street, W.C., 5.15 p.m., Professor F. Berger: Pharmacology.

D.Phil.Nat., Ph.D., D.Sc., F.R.I.C.: Chemical Aspects of Psychopharmacology.

Friday, February 8

● INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. D. I. Williams: clinical demonstration.

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. K. Robson: clinical demonstration.

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—3.30 p.m., Mr. C. Gill-Carey: Tinnitus.

MIDLAND CENTRE FOR NEUROSURGERY.—At Holly Lane, Smethwick, near Birmingham, 8 p.m., Sir Francis Walshe, F.R.S.: Aetiology and Nature of the So-called Traumatic Neuroses.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—10 a.m., Professor F. R. Winton: Renal Circulation.

ROYAL MEDICAL SOCIETY, EDINBURGH.—8 p.m., talk by Dr. R. M. Marquis: Impact of Surgery on Cardiology.

● UNITED KINGDOM COMMITTEE FOR THE WORLD FEDERATION FOR MENTAL HEALTH.—At County Hall S.E., 5.45 p.m., Dr. Margaret Mead: Mental Health in a Changing World.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Griffiths.—On January 14, 1957, at the Imperial Nursing Home, Cheltenham, Glos., to Elizabeth (formerly Poulton), wife of Dr. Eric Griffiths, a brother for Lynn-Anthony Eric.

Spalding.—On January 1, 1957, at Oxford, to Dr. Elizabeth (formerly Falle) and Dr. John Spalding, a daughter.

Way.—On January 19, 1957, at the C.S.T. Hospital, Karim-Nagar, India, to Dr. Hedi Way (formerly Papigay), wife of Dr. Gilbert Way, a sister for David—Erica Ruth.

DEATHS

Pittman.—On January 19, 1957, John Cecil Pittman, M.B., B.S. Thomas.—On January 11, 1957, at 80, Chatsworth Road, Croydon, Surrey.

Rufus Clifford Thomas F.R.C.S.Ed., F.R.C.O.G.
Wilson.—On January 5, 1957, William Mitchell Turner Wilson, M.B., Ch.B., of 951, Harrow Road, Wembley, Middlesex, aged 73.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

"Spanish 'Flu'"

Q.—What is the "Spanish 'flu'" mentioned recently in the newspapers, and why is it so named? Is it true that it carries a particularly high mortality, and, if so, what is the reason for this?

A.—The term "Spanish 'flu'" was at one time applied to the virulent form of influenza which afflicted the whole world in 1918-19. The term was a misnomer, as there is no reason to believe that the disease came from Spain. It did cause a high mortality, particularly in young adults. This was due to pneumonia in which various secondary infecting organisms were involved. There is no reason to believe that such a virulent strain of influenza has been current in recent years.

Cancer Hazard from Tar Lotions

Q.—There is no doubt that coal tar contains carcinogens, yet why is it that many dermatologists still persist in using tar preparations for chronic dermatitis and eczemas? These conditions themselves predispose to carcinomatous changes.

A.—Although it is true that coal tar contains carcinogens, in the concentrations usually used its carcinogenic effects are negligible. There are probably very few dermatologists who avoid the use of tar as an antipruritic because they fear the development of malignancy. We see very many patients who have used tar lotions and ointments over many years, yet the development of tar dermatoses and malignant changes is of the greatest rarity. A few cases have been recorded of carcinoma developing in the skin after long-continued application of tar, but this happens so seldom that one may indeed doubt whether the tar has had much to do with it.

Coal-tar applications are extremely valuable for the relief of irritation, and it seems entirely reasonable to suppose that their value more than offsets this very small risk. Incidentally, it is very doubtful whether chronic dermatitis or eczemas have the slightest tendency towards malignant change.

Two Attacks of Tetanus

Q.—A boy of 10 with chronic otorrhoea, living in India, has had two very severe attacks of typical tetanus separated by a year's interval. Both attacks were treated by large doses of antitoxin. (1) How long is the usual immunity after an attack of tetanus, and are second attacks common? (2) Could the aural infection have had any bearing on the attacks, and, if so, what treatment is advised for it? (3) Should active immunization with tetanus toxoid be undertaken after an attack of tetanus; if so, how soon, and what dosage scheme is recommended? At what intervals should boosting doses of toxoid be given?

A.—(1) The evidence suggests that the immunizing effect of a clinical attack of tetanus is very slight.^{1,2} Repeated attacks have been known to occur in the same person, but they are very uncommon.

(2) An infection of the middle ear is a well-known source of tetanus infection. Basic treatment should consist in eradication or drainage of the infected focus after active or passive immunization, but the actual procedure should be varied to suit the individual patient. A chronic middle-ear infection, secondarily infected with tetanus bacilli, might well give rise to two attacks of tetanus separated by a long interval. Such a case was described in a letter by Dr. Trevor Phillips recently.³ The mechanism is probably as

follows: A large dose of antitoxin would neutralize circulating toxin and allow natural recovery from tetanus to take place and symptoms to subside. However, spores remaining in the wound might germinate later and produce a further clinical attack of tetanus which would again subside with antitoxin treatment.

(3) Although second attacks of tetanus are rare, active immunization is the only certain way of preventing them. Payling Wright and his colleagues⁴ have pointed out that the previous injection of a soluble antigen leads to its much faster removal from the circulation on subsequent injection, an action that reduces the therapeutic effect of second doses of antitoxin. They therefore recommend that once a person has received an injection of a horse-serum antitoxin, irrespective of the disease for which it may have been given, that person should be promptly immunized against diphtheria and tetanus with the appropriate toxoid. However, it is wise to delay active immunization until after the injected antitoxin has had a chance to be eliminated—a process which should not take longer than six months. The method of initial active immunization recommended by the Army Pathology Advisory Committee¹ consists of two injections of tetanus toxoid, spaced by not less than 6 weeks but not more than 12 weeks, followed by a third injection 6 to 12 months later. A reinforcing dose is usually given every five years.

Granuloma Annulare

Q.—What is known of the aetiology of granuloma annulare, and how should the condition be treated?

A.—The cause of granuloma annulare is completely unknown, and recent views about its aetiology involve abandonment of former ideas rather than the acceptance of new ones. For example, the tuberculous aetiology has been entirely given up, and although the histopathology shows some resemblances to that of the rheumatic diseases there is no clear relationship between the two conditions.

For most dermatologists views on treatment have tended to undergo a somewhat similar change. The tendency now is to leave the lesions untreated; it is known that they clear up eventually without scarring and that there are no systemic complications of any sort. Most methods of treatment involve physical destruction, which leads to scarring and is hard to justify. Carbon dioxide snow is favoured by some.

Prognosis in Treated Pernicious Anaemia

Q.—What is the prognosis for patients with pernicious anaemia treated with adequate amounts of vitamin B₁₂? Are they ever cured in the sense that treatment is no longer necessary?

A.—The introduction of vitamin B₁₂ (cyanocobalamin) is too recent for there to be reliable statistics on survival and morbidity among patients with pernicious anaemia treated with the pure vitamin. Clinical observation, however, suggests that such patients have an expectation of life and a morbidity no worse than that of the general population: in fact, it has been suggested that they may be better off, because they come under review every month or two when they receive their injections.

In his presidential address to the Manchester Medical Society last October Dr. J. F. Wilkinson reviewed a personal series of 2,211 cases of pernicious anaemia seen over the past 28 years. Of course, only in the last few years would pure vitamin B₁₂ have been available for the treatment of these patients, but the mortality in this series was only 0.83% per year. Almost all died from conditions other than pernicious anaemia; but, of those who died of cancer, in about half the primary was in the stomach. In Dr.

Wilkinson's experience the expectation of life for the patients in this regularly supervised group of patients was rather better than for people without pernicious anaemia. Of the 1,550 patients still attending his clinic, no fewer than 758 were over 70 years of age, 283 over 80 years, 39 over 90, and one over 100.

Patients with pernicious anaemia are never cured in the strict sense of the word, though if adequately treated their lives are in every respect as if they had been. The chief pathological change is the atrophy of the gastro-intestinal mucosa, which so far has proved irreversible. Very occasionally a patient who discontinues treatment remains well for months or even years before relapsing, but these are exceptional cases and afford no general grounds for the discontinuance of treatment. Treatment must be for life.

Nasal Sprays for the Common Cold

Q.—Manufacturers continue to advertise nasal sprays of one sort or another, some of them containing sulphonamides, antibiotics, hydrocortisone, or vasoconstrictors, for the treatment of the common cold. Is it advisable to use any or all of these medicaments in this way?

A.—The use of nasal sprays containing sulphonamides or antibiotics is to be deplored, on account of the grave danger of sensitization which it incurs. A patient who has used a nasal spray of this sort for a relatively trivial condition may find that subsequent use of the antibiotic or sulphonamide for the treatment of a serious disease is made difficult or impossible by a sensitivity reaction. With regard to hydrocortisone, there may be a place for the use of this in the management of severe vasomotor rhinitis, seasonal or otherwise, but its use in infections of the common-cold type may, in theory, increase the risk of secondary bacterial infection. Vasoconstrictors may give temporary relief to nasal congestion and obstruction, but in the early acute stage of a cold this relief is transient and may be followed by aggravation of the symptoms. Later, when secondary bacterial infection has given rise to a purulent phase with involvement of the nasal sinuses, vasoconstrictors may be useful in permitting intermittent drainage of secretions from the affected sinuses.

Injury and Central Retinal Vein Thrombosis

Q.—Can an injury produce thrombosis of the central retinal vein or one of its branches?

A.—Central retinal vein thrombosis has been reported after a contusion as a rarity (von Wiser, 1901; Hillemans and Pfalz, 1905; Pincus, 1907; Cozzoli, 1916).¹

Sensitivity to Arsenic and Penicillin in Tertiary Syphilitic

Q.—A patient with tertiary syphilis is sensitive to arsenic and penicillin. How should he now be treated?

A.—Most of the antibiotics derived from lower-grade fungi are effective in the treatment of primary, secondary, and tertiary syphilis, and attempts to desensitize patients who have become intolerant of arsenic and penicillin, besides being often unsuccessful, are unnecessary.

A ten-day course of oxytetracycline or chlortetracycline (0.5 g. six-hourly) is recommended. The dosage suggested by some workers, including Taggart and his collaborators,¹ is 60 mg. per kg. of body weight daily for six to eight days. Antibiotic therapy should be followed by a ten-week course of intramuscular injections of bismuth (injectio bismuthi, B.P., 1.5 ml. once weekly), and, as iodides assist materially in the resolution of tertiary lesions, a mixture containing potassium iodide, 15 gr. (1 g.), should be taken three times a day at the same time.

NOTES AND COMMENTS

Retraction of the Prepuce.—Dr. A. E. SELIGMANN (Barking) writes: I was glad to read your expert's opinion ("Any Questions?" December 8, 1956, p. 1382) that it was doubtful if the practice of gentle retraction of the prepuce from 6 months onwards would affect the incidence of necessary circumcisions. Even during the first six months it is unusual for the prepuce to be left alone, and among hundreds of male babies seen at infant welfare clinics I have not yet met one whose mother has been taught to respect the waiting period of six months. On the other hand I was surprised to learn that "most prepuces will retract spontaneously by the age of 2 or 3 years." As a school medical officer I have seen an appreciable number of school-entrants with fully or half-adherent prepuces. In some cases mothers have even told me that the boy "had been done" as a baby, that she had been unable to persevere with it, and that the foreskin had become "stuck again" (if it was ever mobilized in the first place). I suspect that these late adherent cases do right themselves spontaneously after a few more years. Or do medical officers in the Forces still see many adherent cases?

OUR EXPERT replies: Dr. Seligmann is clearly correct in his observations about adherent prepuces in boys at school-entrance age. In my answer to the original question I said "most prepuces" will retract spontaneously by 2 or 3 years of age. This was certainly not meant to exclude the "appreciable number" encountered by Dr. Seligmann. There are inevitably a number which take longer—and a few which will require active intervention. The answer to the question whether medical officers in the Forces will see many cases depends on the definition of "many." They certainly see "a few."

Lignocaine in Pudendal Block for Low Forceps.—Dr. NORMAN MORRIS (London, W.12) writes: An answer discusses the use of 0.5% lignocaine for pudendal block anaesthesia ("Any Questions?" December 29, 1956, p. 1559). Whilst advising that "the maximum amount of this concentration that may be safely given is 200 ml." Dutton,¹ however, in another report recommends 50 ml. of 0.5% lignocaine as "effective and safe." The majority of obstetricians would, I think, agree with this statement. Hunter² has made a careful study of the toxicity of lignocaine, and he considers that 500 mg. is the maximum safe dose, even when adrenaline is added—that is, 100 ml. of an 0.5% solution. It would be a great pity if this extremely useful anaesthetic and method fell into disrepute because of complications resultant upon unnecessary overdosage.

SOME QUESTIONS ON CANCER OF THE LUNG, LARYNX, AND URINARY TRACT*

BY

Sir ERNEST KENNAWAY, D.M., D.Sc., F.R.S.

From the Department of Pathology, St. Bartholomew's Hospital, London

The study of cancer as it occurs in man must be carried on empirically while others attack the fundamental question, "How, and why, does a cell divide?" The distribution of cancer in man, and all factors which might affect this distribution, must be examined systematically.

Some Characters of Cancer in Man

These characters are: (1) *sex incidence*; (2) *prevalence*—increasing, decreasing, or stationary; (3) *social gradient*—rise or fall, or neither, in relation to the Registrar-General's Social Classes I to V; (4) *urban-rural rates*—urban +, rural +, or neither.

Sexes must always be considered separately. They may or may not be found to behave in the same way. Figures for the total incidence of any one form of cancer are of little if any value.

The reason for any difference in these characters can be the subject of inquiry. It may not be possible to

prove what the reason is, because: (1) one cannot experiment on man; (2) the time lag of such effects is very largely unknown; and (3) social conditions and atmospheric pollution are continually changing.

Thus about 150 years ago the Industrial Revolution began to change England from an agricultural to an industrial country, and about 1850, in the districts most affected by this change and in others to the east of them, about 50 species of *Lepidoptera* began to change their protective colour from lighter to darker shades as the lichens on the blackened bark of trees were killed by the sulphur dioxide and other constituents of town

*These notes are based upon data used in May, 1956, for the Richardson Lecture at the Massachusetts General Hospital and for talks given at the Sloan-Kettering Institute for Cancer Research, and in Professor W. U. Gardner's Department of Anatomy at Yale, with the addition of material obtained from Dr. E. Cuyler Hammond and Dr. Oscar Auerbach. It is a great pleasure to acknowledge my debt to all who did so much to make this visit enjoyable and valuable in every way.

smoke (Fig. A). Now atmospheric pollution is decreasing with more efficient combustion of coal and the increased use of gas and electricity for heating. (Kettlewell, 1955a, Fig. 1.)

Sexual Incidence of Cancer of Lung

Doll (1953) concluded that the incidence of cancer of the lung was about the same in non-smokers of either sex. But no inferences can be drawn from the incidence of cancer of the lung upon smokers of one

sex with regard to the other sex, as is very often done, because we simply do not know whether any intrinsic sexual factor is concerned. The kind of wholly impossible experiment which is required is to set up populations of, say, 10,000 persons of each sex, of the same age distribution, who will smoke 30 cigarettes daily for 30 years. Our present knowledge does not allow any forecast of the resulting sexual incidence of cancer of the lung.

The Registrar-General's figures (Table I) show that the immense increase in deaths from cancer of the lung in the 12 years 1943 to 1954 has not been accompanied by any change in the ratio of the death rates of the two sexes (1:5.8 in the first half and 1:5.9 in the second half of the period). This fact suggests that the agent causing this rise has changed uniformly. The data from Japan (Stocks, 1956) provide an interesting comparison (see Table VII).

Incidence of Cancer in Town and Country* and in Smokers and Non-Smokers

A comparative study of the incidence of all forms of cancer in town- and in country-dwellers, and in smokers and in non-smokers, in both sexes is needed urgently. The two problems are very much of the same nature and require

*Since this paper was written the Registrar-General's *Statistical Review of England and Wales* (1953, Text) has been issued, which contains a very large amount of data on this subject.

TABLE I.—Cancer of the Trachea, Bronchus, and Lung, England and Wales, 1943-54 (Registrar-General, Statistical Review, 1953-54, Tables, Part I, Medical)

	Males			Females		
	Deaths	Rate per Million Living	Increase in Mean Rate	Deaths	Rate per Million Living	Increase in Mean Rate
1943	4,943	303		1,166	54	
1944	5,331	329		1,237	57	
1945	5,805	354		1,356	62	
1946	6,607	355		1,437	65	
1947	7,581	387		1,623	73	
1948	8,403	413		1,759	79	
Mean of first 6 years	6,445	375.0		1,430	65.0	
1949	9,130	444		1,845	82	
1950	10,254	485		1,987	87	
1951	11,166	530		2,081	91	
1952	11,981	568		2,237	98	
1953	12,881	607		2,251	98	
1954	13,995	658		2,336	101	
Mean of second 6 years	11,568	548.7	46.3%	2,123	92.8	42.8%

Ratio of mean rates, female to male: first 6 years, 1: 5.8; second 6 years, 1: 5.9.

the same kind of investigation. Tobacco and coal are both plant products, one of which is about 300 million years older than the other.

Thus when one is exposed to the irritating atmosphere of a fog a good deal of mucus upon which particles have been arrested passes back from the nose into the pharynx, and comes up from the bronchial passages into the mouth, and this material, if not expectorated, is swallowed. Is it quite harmless to the alimentary canal? Similarly, the subject of "smoker's throat" may swallow a good deal of mucus when smoking.

Urban Factors

A number of investigations have shown, with varying degrees of distinctness, a higher incidence of various forms of cancer among town-dwellers. In seeking for a reason, the fact that better methods of diagnosis are more accessible in towns is always easy to invoke and difficult to assess. Any numerical estimate of the effect of improved diagnosis can only be arbitrary. Thus Kreyberg (1954) considers that in Norway a four-and-a-half-fold increase in lung cancer in females is due to better diagnosis, while a sevenfold increase in men is a real one.

Where the respiratory tract is concerned one must of course consider atmospheric pollution and exposure to soot containing at least two carcinogens—namely, 3:4-benzpyrene and arsenic—and doubtless others not yet identified. But do these factors penetrate to and affect any other parts of the body? Some data showing the very large range of atmospheric pollution in various towns and countries are given in Table II.

Thirty years ago my wife and I showed that cancer of the scrotum is rare in agricultural workers and is almost

TABLE II.—Some Examples of Atmospheric Pollution. (Published and Other Data from H.M. Fuel Research Station: J. M. Campbell, R. L. Cooper, F. Goulden, E. L. Kennaway, M. E. Urquhart, and R. E. Waller)

unknown in those social classes who wash most (Kennaway, 1925; Kennaway and Kennaway, 1946), and the suggestion was made that "it would seem possible that cancer of the scrotum is influenced by exposure to coal-smoke—in other words, possibly all town-dwellers are in some very slight degree liable to 'chimneysweep's cancer.'" Probably various carcinogens, with the exception of sunlight, are more abundant in towns, and their actions may summate, a process about which we know very little; one of the latest contributions on this question is that of Cloudman *et al.* (1955).

When comparing various batches of data about atmospheric pollution one must bear in mind that the materials concerned may not be the same in different countries or even in different towns in the same country. Thus the suspended matter of Liverpool might have a carcinogenic effect which summates with that of tobacco (Stocks and Campbell, 1955), while the corresponding material of Oslo might not do so (Kreyberg, 1954).

A very valuable source of data on this question is available in the official figures for mortality and morbidity from Norway, Denmark, and Finland, which are classified under urban and rural districts, and in the two last-named the figures for the capital† also are given separately. The populations of these three countries are of the order of one-eleventh of that of England and Wales, and present a more manageable problem.

The first evidence brought forward suggesting that urban conditions induced cancer of the lung and larynx was perhaps that showing the low incidence upon male outdoor workers. Calculations based on the Registrar-General's figures showed (Table III) that a group of open-air occu-

TABLE III.—Cancer of Lung and Larynx in Out-of-Door Occupations, England and Wales (Kennaway and Kennaway, 1936, 1947)

Occupation	Ratio of Registered to 100 Calculated Deaths			
	Cancer of Lung		Cancer of Larynx	
	1921-32	1933-8	1921-32	1933-8

Cancer	Standard Mortality Ratio. Males aged 20-64	
	Social Class IV Partly Skilled	
	Agricultural Workers	Others
Larynx	13*	115*
Lung, bronchus, trachea	62	97

* Based upon fewer than 10 deaths.

pations (gardeners, farmers, agricultural labourers, including shepherds, and farm bailiffs and foremen), which included about 954,000 men, had low ratios for cancer of the lung (22 to 61) and of the larynx (29 to 79). The highest figures in each case are given by gardeners, of whom many live in or near large towns.

[Some evidence that the same character of open-air occupations persists in recent years is given by the smaller numbers derived from the 1951 Census 1% Sample Tables (Table IV).]

These results led to further investigation comparing the whole population of England and Wales of both sexes (Curwen, Kennaway, and Kennaway, 1954). This showed that the standard mortality ratio for cancer of the lung in both sexes, and of the larynx in males, falls with decreasing urbanization, as is shown in Fig. 1 by the series—county boroughs (mostly towns with a population of 100,000 or more), urban districts (other towns), and rural districts (the

†An important instance of the value of such data is given below, in the section on Cancer of the Urinary Tract.

FIG. 1.—Urban and rural incidence of cancer of the lung and larynx, England and Wales (Curwen *et al.*, 1954). Reproduced, by permission, from the *British Journal of Cancer*.

rest of the country). The gradient is less steep for cancer of the lung in women, and cancer of the larynx in women shows exactly the reverse relationship. This peculiar behaviour of cancer of the female larynx has at present no explanation, although one might suspect a diet consisting too largely of white bread and tea.

When considering urban factors in relation to cancer one must of course seek for other conditions besides atmospheric pollution by smoke from various sources. There may be differences in the diet, both solid and liquid, of town and country dwellers, and radioactivity increases in any enclosed place owing to emanation from walls. Thus Dawson (1952) observed that: "In the laboratory there was usually twice the activity found at the open-air site on the roof. At Chiswick, ventilating the room lowered the activity by as much as one-half, whilst in the coal-cellar the activity was 14 times greater than at the site in the garden. In the Post Office air-raid shelter the ventilation was as restricted as any found in habitable buildings; the activity was 120 times as high as at the open-air site."

Smokers and Non-Smokers

The classification of persons affected by cancer of the lung into smokers and non-smokers is easy, but the matter is not so simple. A person who is going to develop cancer of the lung whether he smokes or not, may be a smoker, and a heavy smoker. Possibly with further knowledge we may be able to identify such cases by the histological type of the tumour. Some possible categories of persons affected by cancer of the lung are shown in Table V.

TABLE V.—Classification of Some Persons Developing Cancer of Lung

Carcinogen:		
Intrinsic	Tobacco	1. Non-smoker.
		2. Smoker who would have developed cancer of lung if non-smoker.
Extrinsic	Atmospheric pollution	3. Smoker not exposed to atmospheric pollution.
		4. Smoker exposed to atmospheric pollution.
		5. Non-smoker exposed to atmospheric pollution.

The relation of atmospheric pollution and tobacco, together, to the causation of cancer of the lung is the subject of considerable difference of opinion. The summation of carcinogenic action is a subject about which we have much to learn, even under the comparatively simple conditions of experiments upon animals. Data on a very wide range of atmospheric pollution are now available (Table II) thanks to the co-operation of Professor Niels Dungal, of Reykjavik, Professor Leiv Kreyberg, of Oslo, and Dr. Johannes Clemmesen, of Copenhagen. When such data can be correlated with those for smoking habits and for cancer of the lung it may be possible to decide this question. If such summation occurs, a smoker in, for instance, Reykjavik should be able to smoke more cigarettes with

impunity than if he were in Sheffield or Salford. Stocks and Campbell (1955) show the interesting inferences which can be drawn if this process of summation is accepted.

The simple adding together of amounts of materials—for example, arsenic or 3:4-benzpyrene inspired with town air, and with tobacco smoke, is misleading, because the greater part of the former is taken in through the nose, which arrests 80% of particles larger than 2.5 μ (Davies, 1949), while tobacco smoke evades this filter altogether.*

Scar-Cancers of the Lung: Possible Importance of Cholesterol

The cancers of the lung associated with scars (*Narbenkrebs*) and with deposits of cholesterol described by the German pathologists Rösle (1953) and Lüders and Themel (1954) have been investigated in this country by Raeburn (1956), who states: "Further cases of lung cancer associated with scarring have been studied in detail. The scars are of various aetiology—collapse pneumonia, tuberculosis, and even foreign body. The common factor is proliferation of bronchial epithelium within the fibrous framework of the scarred area. Twelve cases of cancer in association with tuberculosis are receiving separate attention. These scars are rich in cholesterol."

This proximity of cholesterol to malignant growth is of great interest in view of the discovery by Hiebert (1949) of the carcinogenic power of cholesterol, which is not diminished by drastic purification (Schwenk process). Of course, the juxtaposition of these crystals and a carcinoma is very far from proving that one is the cause of the other, but what more evidence can one expect from histological appearances?

The Process of Smoking a Cigarette

The physical and chemical changes which take place when a cigarette is smoked are complex, and the conditions under which they occur are unlike those present

FIG. 2.—Diagram of a cigarette.

in most other combustions. The changes include: (1) oxidation, (2) pyrolytic condensations producing polycyclic compounds, (3) volatilization repeatedly, and (4) condensation repeatedly.

Commins, Cooper, and Lindsey (1954) threaded a thermocouple through a cigarette and observed the readings as the burning zone approached. They found that the maximum temperature ranges from 650° to 700° in the centre, to 900° at the surface, where the oxidation is most rapid. The temperature drops very rapidly behind the burning area—for example, from 770° to 100° in 3.5 mm. (Harlow, 1956). Hence a continuous process of volatilization and condensation takes place in a "leap-frog" manner as the cigarette is smoked.

For the present purpose, nothing matters but what emerges at the stump, and in this respect there may well be a considerable difference between smoking, say, 66% and 80% of the cigarette (Fig. 2).

*The first smokers of tobacco seen by Europeans (two companions of Columbus in Cuba in 1492) inspired the smoke of cigars through the nostrils; but their example was not followed (Koskowsky, 1955).

†The work of Dr. Hiebert and Professor L. F. Fieser on the carcinogenic action of cholesterol was the subject of a talk which I gave at the Sloan-Kettering Institute for Cancer Research, and in Professor W. U. Gardner's Department of Anatomy at Yale in May, 1956, and is dealt with at length in Chapter 3, entitled "The Carcinogenic Effect of Cholesterol," of a book *Cancer* (in the press).

The investigation shown in Fig. 3 is very elementary, but we seem to have few data of this kind. Cigarettes of two well-known British brands were weighed, and smoked in the ordinary way by one or other of two habitual smokers who dropped the ash, and stump, into weighing-bottles. The mean figures show that the ash and stump together make up

FIG. 3.—Ash and Stump of cigarettes.
C=Cigarette. S=Stump. A=Ash.

A valuable piece of evidence on smoking habits in the U.S.A. is given by Harlow (1956) in his study of temperatures in a cigarette. He says: "In our experience, not one cigarette smoker in 1,000 smokes to a butt length less than 23 mm." A length of 23 mm. is 29% of 70 mm., which is the length of an English cigarette of a very popular brand; hence almost always less than 71% of the length of the cigarette is smoked, as compared with 80% which is commonly smoked in this country (Fig. 3), and was adopted by Commins *et al.* (1954) in their method of artificial smoking. Anyone from this country who observes ash-trays in the United States will note the difference in the length of the cigarette ends.

Work of Dr. E. L. Wynder on the Carcinogenic Action of Cigarette Smoke

The emphasis laid upon the collected negative results of painting experiments from various laboratories, and the more or less explicit suggestion that these discredit Wynder's results (see, for instance, *Nature*, 1956), suggest that, in this instance, where smoking is concerned, the comparison of evidence from man and from animals may not always be conducted with complete impartiality. We do not smoke chromium compounds and no one doubts that these are carcinogenic to the human lung on the ground that we have no confirmatory evidence from animals. Positive results, if obtained by legitimate methods, must take precedence of negative results.

Recently I had the opportunity of seeing, and handling, Dr. Wynder's mice, which showed no sign of undue injury to the skin; and, in any case, no process of simple ulceration of the skin of the mouse, or of any other tissue, will give carcinoma in 44% of cases (Wynder *et al.*, 1953). To anyone who has any experience of such work with mice it is clear that the material used is carcinogenic under these conditions. The suggestion has been made that Wynder's mice are "hypersensitive"; one might just as well assert that other mice are "hyposensitive."

Negative results of smoke-inhalation experiments on rodents seem to me to be of no significance, because the animals, presumably, unlike smokers, keep their mouths shut and pass the smoke over their turbinates, which, in the rabbit at any rate, are more complex than our own.

Comparison of Cigars and Cigarettes

A cigar consists of intact portions of tobacco leaf arranged more or less concentrically, while a cigarette is made up of more finely divided material packed together; the conditions for combustion, and therefore its products, are different, quite apart from any difference due to the quality of the tobacco. The smoke from a cigar gives an

alkaline condensate, and that from a cigarette an acid one. The very large difference between cigar smokers and cigarette smokers in regard to cancer of the lung which is shown by Dr. Hammond's figures (see below) suggests that if one could ascertain the cause of it one might attempt to construct something which would embody this quality of a cigar in something sufficiently like a cigarette to be adapted for smoking during short periods, which character is the chief advantage of the cigarette over the cigar. One could then offer smokers a precaution which would not involve "giving up smoking." A cigar is comparatively large and expensive, and hence the economical smoker wishes to smoke one as completely as possible.

Dr. Lindsey, at the Sir John Cass College, and Mr. J. M. Campbell, in Professor Blacklock's department at St. Bartholomew's Hospital, are examining cigar smoke, and will compare their results with the considerable experience which they have gained in the study of cigarette smoke.

I asked Dr. Hammond what kind of cigar would be smoked by persons who furnish the bulk of his statistical material. He writes: "I went to a cigar store located on a street which is near the dividing line between a rich residential district and a poor residential district. The customers appear to be largely middle class or lower middle class, but many are labourers and some are rich men. They sell a very large number of different brands, with prices ranging from \$0.04 to \$1.25 per cigar. I asked the owner to sell me one each of his best-selling cigars." Dr. Hammond has very kindly sent to us samples of 18 of these brands.

In this country at the present time a person who smokes a cigarette uses 1 g. of tobacco, costing perhaps about 2d., in 10 to 15 minutes. One of the smallest cigars on sale here, weighing 2 g., costs 8d.—that is, nearly twice as much per gramme; we have not as yet any figure for an average time taken to smoke such cigars. The cigarillos commonly smoked by women in Denmark weigh about 1.8 g.; some of the smallest cigars smoked in the U.S.A. weigh 3 to 3.4 g. and cost 4 to 5 cents.

Dr. Hammond has kindly obtained for me the figures of the U.S. Internal Revenue Service for the retail price range of cigars sold in the U.S. in 1955:

Retail Price Range	%
Not over 2½ cents	0.48
Over 2½ to 4 "	3.68
" 4 to 6 "	39.04
" 6 to 8 "	9.64
Subtotal: Up to 8 cents	52.84
Over 8 to 15 cents	40.79
" 15 to 20 "	3.28
Over 20 cents	3.09
Subtotal: Over 8 cents	47.16
Total—all classes	100.00

Thus 89% of the cigars sold cost from 4 to 15 cents (3½d. to 1s. 1d.).

Cigarette Smoking and Cancer of Lung

Statistical Inquiries.—No attempt is made here to summarize the very numerous papers of recent years on the relation of cigarette smoking and cancer of the lung. Such investigations may be either retrospective, dealing wholly with data from the past; or, prospective, in which current events are followed. Hammond, in a personal communication in 1956, referred to 17 studies of the first class from five among medical practitioners in Great Britain by Doll and Bradford Hill (1954, 1956), and by the geographical survey of Stocks and Campbell (1955), which is also retrospective. The prospective scheme of the American Cancer Society, designed by the statistician Dr. E. Cuyler Hammond, is chosen for brief mention here because it is an extremely interesting example of organization on a very large scale.

Inquiry by American Cancer Society planned by Dr. E. Cuyler Hammond

This investigation by means of a questionnaire is in progress in nine States of the Union in 394 counties, urban

and rural, selected chiefly because they have well-organized units of the American Cancer Society. Female volunteers, 22,000 in number, were asked (1) to give a copy of the questionnaire "to white men aged 50 to 69 years whom they knew well enough to be able to trace for the next several years"; and (2) to secure the filling up of a follow-up form yearly on November 1. The progress of the inquiry may be summarized as follows:

Questionnaires suitable for study collected between January and May 31, 1952	190,134
Of these persons, on October 31, 1954	
Alive	179,973
Dead	8,105
Not traced	2,056
Death certificates	8,019
Deaths attributed to cancer of the lung	288
Regular cigarette smokers at some time	107,978
Currently smoking a pack or more of cigarettes a day	25,561

Some early results are as follows:

Ratio of Mortality from Lung Cancer

Regular Cigarette Smokers	1/11/52 to 31/10/53	1/11/53 to 31/10/54
No*	1.0	1.0
Yes	7.3	7.3
Pack-a-day or more	14.1	15.6

* Includes pipe and cigar smokers and occasional cigarette smokers.

Number of Deaths and Annual Death Rate from Lung Cancer per 100,000

Smokers	All 245 Cases Reported		Well-established Diagnosis, Excluding Adenocarcinoma (161 Cases)	
	Deaths	Death Rate	Deaths	Death Rate
Never	9	14.0	2	3.1
Occasional	2	8.4	2	8.4
Cigar only	5	16.5	4	13.3
Pipe only	9	35.2	6	24.1
Cigarette only	151	141.6	97	87.2
Cigarette and other	69	81.9	50	57.7

Cigarette Smoking Habits in 1952	Annual Death Rate from Lung Cancer per 100,000	
	All Cases	Well-established Cases Excluding Adenocarcinoma
Never smoked regularly	12.6	4.5
Ex-regular smokers {None	39.1	31.6
Occasional	71.0	71.0
Packs {1	101.3	67.3
2	101.7	61.1
3	208.4	119.0
4+	340.7	278.7

In the well-established series the incidence of lung cancer upon heavy cigarette smokers is 62 times greater than that upon those who had never smoked regularly.

	Cities 50,000+	10,000-50,000	Suburb or Town	Rural
Cigarette smokers per 100 of male population	62.6	60.1	56.9	50.3
Lung cancer death rate {Standardized for age	82.5	67.8	74.6	50.5
and smoking habits	78.7	70.3	78.7	60.0

The urban-rural difference is distinct when all diagnosed cases of lung cancer are taken together, but is much less so among well-established cases in cigarette smokers after exclusion of adenocarcinoma.

The death rates in these tables of the American Cancer Society are standardized for the white male population of the U.S.A. in 1953.

Work of Dr. Oscar Auerbach

At the Veterans' Hospital, East Orange, New Jersey, Dr. Oscar Auerbach and seven other workers (1955, 1957) are investigating "the anatomical approach to the study of smoking and bronchiogenic carcinoma."

As soon as possible after death the trachea and lungs, fixed in formalin, are divided in the coronal plane so as to separate the cartilaginous from the muscular part of the trachea, and the posterior portion is rejected; the bronchial tree is separated by blunt dissection, carried sometimes to within 1 cm. of the pleura, and divided transversely into blocks, usually 208 in number (Fig. 4), and from one to five sections from each block are examined for (1) basal-cell hyperplasia, (2) stratification, (3) squamous metaplasia, and (4) carcinoma-in-situ.*

The results obtained in 28,638 slides from 117 out of the first 150 cases (all white males, of whom more than two-thirds were aged from 50 to 70 years) show (1) a remarkable parallelism between the smoking habits of the deceased and the four changes named above; and (2) carcinoma-in-situ in unexpected numbers, and over a wide area, including the trachea, a discovery which is of obvious surgical importance and complicates the already difficult problem of localization. Cases of "recurrence" after operation may actually be due to growth developing from another centre of carcinoma-in-situ. One now has to explain not only the development of cancer-in-situ at many different points but also the prevention of further growth at the great majority of these.

The histological examination of each slide was carried out by from two to five persons who were "ignorant of the smoking histories and the clinico-pathological data." Unfortunately the cases of carcinoma of the lung did not include a single non-smoker; all were "moderate to heavy smokers." Cigar smokers and pipe smokers and ex-cigarette smokers were excluded from the three classes of smokers.

The results of this investigation are presented in an unusual manner (Table VI). The percentage of slides from

TABLE VI.—Histological Changes in the Respiratory Tract in Relation to Cigarette Smoking (Auerbach *et al.*, 1955)

Histological Changes	Deaths from Causes other than Cancer of Lung		Deaths from Cancer of Lung	
	Per Cent. of Slides			
	Never Smoked Regularly	Less than 1 Pack Daily	1 Pack or More Daily	
Basal-cell hyperplasia { Three or more cell rows { Five or more cell rows	18.6	22.0	36.1	43.5
Stratification	2.9	5.6	10.8	15.0
Squamous metaplasia	4.2	7.1	10.4	13.4
Carcinoma-in-situ	1.9	6.3	9.5	11.7
	1.0	4.1	6.0	6.3
No. of cases	16	20	47	34
				Total 117

the respiratory tract which show each one of the four changes named above is recorded separately for each of three classes of smokers, and for cases of cancer of the lung. "In subjects who died of bronchiogenic carcinoma, basal-cell hyperplasia, stratification, squamous metaplasia, and carcinoma-in-situ were diffusely distributed throughout the epithelium of the bronchial tree in both lungs as well as the trachea." Details of the extent to which these changes occur in the trachea would be of great interest, as carcinoma of the trachea is very rare.

Future Course of Research on Cancer of Lung

The study of the aetiology of cancer of the lung is complicated by several factors; (1) Cancer of the lung has several different histological forms which may differ in aetiology, and these distinctions are lost in figures for total incidence. (2) We do not know which, if any, forms of atmospheric pollution can summate with tobacco smoke as carcinogens. A carcinoma of the lung in a smoker might perhaps be due to the combined action of radio-

*Could not some more appropriate name be found for "carcinoma-in-situ," which tissue lacks the essential invasive property of carcinoma? "In situ" contributes nothing of value to the term; everything at rest is *in situ*. One might suggest "pre-carcinoma."

activity and of several constituents of both atmospheric pollution and tobacco smoke. (3) The recent work of, for example, Salaman and Roe (1956) and Gellhorn *et al.* (1956) shows the complex state of our knowledge of initiators and promoters of malignant growth. (4) The significance of carcinoma-in-situ, which, according to Auerbach, occurs on a very large scale, is most difficult to assess, as it is in other forms of cancer (cervix, prostate). (5) Lungs of persons of known smoking history, for chemical and histological research, are difficult to obtain here either from operation or from necropsy.

Cancer of Larynx

The statistical study of cancer of the larynx is made difficult by several factors. (1) Cancer of the larynx in men and that in women are to a large extent different diseases, as the so-called "extrinsic cancer of the larynx" is much more common in women; it is not a cancer of the larynx at all, and would be much better described by some other name (see discussion by Lederman, 1954). (2) The evidence of death certificates does not allow a reliable separation of cases of intrinsic and extrinsic cancer of the larynx. (3) The improvements in surgical and radiological treatment of cancer of the larynx may have reached a stage when the number of deaths is not a reliable measure of the incidence of the disease. Hence cancer registration is required. This system is in operation in Denmark, Finland,

and Norway, and in such countries, with populations of not much more than four million, the establishment of registration is easier than it is in England and Wales, with a population of 44 millions. However, our General Register Office already registers about 70% of the cases of cancer in England and Wales, and the Anna Fuller Fund has given us a grant for a Fellowship to be devoted to the study of the new material obtained by registration.

FIG. 5.—Deaths from cancer of the lung and larynx. Males. England and Wales, 1921-51 (Curwen *et al.*, 1954). (Reproduced, by permission, from the *British Journal of Cancer*.)

FIG. 4.—Schematic diagram of the tracheobronchial tree showing the distribution of the 208 blocks. (Auerbach *et al.*, 1956.)

Cancer of the Larynx and Tobacco

We do not know if there is any association in this country between cancer of the larynx and smoking. Whatever factor is affecting the incidence of cancer of the lung in men does not appear to be affecting cancer of the larynx (Fig. 5), but, as we are not certain about the total of the latter, the question is not settled. Wynder (1955) finds that in the U.S.A. "pipe and cigar smoking are more closely associated with cancer of the larynx than with cancer of the lung" (Wynder, 1955, p. 111; Wynder *et al.*, 1956).

A dissociation of the incidence of cancer of the lung and of the larynx, similar to that shown in Fig. 5, appears in the very valuable study of cancer in Japan by Stocks (1956). In comparing Japan with England and Wales he says: "For the larynx the figures are similar in the two countries up to age 70, but for lung cancer registered mortality of men in Japan is less than one-tenth of the English rates at most ages, and amongst women the ratio is between one-half and one-third" (Table VII). Data about the smoking habits of the Japanese would be of great value.

TABLE VII.—Age-Specific Death Rates from Cancer Per Million in Japan (1952) and in England and Wales (1952-4) (Stocks, 1956)

Age Group	Males				Females			
	Larynx		Lung		Larynx		Lung	
	Japan	E. & W.	Japan	E. & W.	Japan	E. & W.	Japan	E. & W.
0-24	0.1	0.1	0.7	2.1	0.1	0.1	0.7	0.6
25-34	0.5	0.2	5	26	1.1	0.8	2.4	10
35-44	1.2	1.8	6	97	0.8	2.2	3.5	26
45-54	6	5	21	249	0.8	3.3	11	52
55-64	18	13	43	577	7	18	89	89
65-74	32	33	114	2,002	15	17	40	201
75-84	57	75	181	2,543	28	19	65	287
85-94	85	101	236	2,922	32	24	80	384
95-104	151	156	219	2,592	34	32	93	379
105-114	146	225	190	2,072	42	33	70	445
115-124	125	294	110	1,267	33	39	18	362

Prevalence.—The Registrar-General (*Statistical Review*, 1952, Text, p. 158) states that: "Above 75 there has been no change in the male rate, but both the equivalent average death rate (0-64), and the rates between ages 45 and 75 have fallen by about 40% since 1936, while the female rates have remained constant." (Fig. 6. These figures of course refer to death rates.)

Alcohol and Cancer of Larynx

Men concerned in the sale of alcoholic drinks are especially liable to cancer of the larynx (Kennaway and Kennaway, 1936, 1947), while cancer of the lung appears to be unaffected.

TABLE VIII.—Ratio of Registered to 100 Calculated Deaths From Cancer of Lung and Larynx in Occupations Concerned With the Sale of Alcoholic Drinks. England and Wales

	Lung		Larynx	
	1921-32	1933-8	1921-32	1933-8
Barmen	104	122	469	275
Cellarmen	92	87	319	502
Licensed victualliers	128	124	185	199

Social Incidence of Cancer of Larynx

In 1921-3 and 1930-2 cancer of the larynx in males showed a very distinct social gradient, the incidence being highest in the poorer classes (Table IX). In 1950 this gradient had disappeared, and in this respect cancer of the larynx provides a very distinct contrast to cancer of the stomach, in which the gradient has remained the same throughout the whole period. The decreased strength and increased cost of alcoholic drinks during the 16 years

since 1939 must be considered in relation to the change in the mortality from, and social distribution of, cancer of the larynx. Television might in time have a similar effect, owing to lessened consumption of alcohol, but the results could hardly be apparent as yet.* Cancer of the oesophagus, of which the incidence is certainly high upon occupations concerned with the consumption of alcohol, shows a similar diminution in social gradient.

Cancer of Bladder and Kidney

An increase in cancer of the bladder in recent years has occurred both in Denmark (Clemmesen and Nielsen, 1956) and in England and Wales (Registrar-General, 1954, 1955) (see annotation, this *Journal*, January 26, 1957, p. 218).

Clemmesen and Nielsen say: "... there has been a steady increase in the number of cases notified for papillomata and carcinomata of the urinary bladder among men in the capital. In provincial towns and rural areas a less pronounced increase occurred during the years 1951 to 1953, the significance of which is doubtful, so far. No increase in incidence was observed for tumours of the bladder among women nor for malignant neoplasms of the kidney."

The Registrar-General's figures, on the other hand, show an increase in both sexes in cancer of the bladder and of the kidney in the eleven years 1944-54 (Table X). The percentage increase in the death rates for cancer of the bladder is somewhat greater in women than in men, and for cancer of the kidney it is equal in the two sexes.

Possible Effects of Tobacco upon the Urinary Tract

The importance of a search for carcinogenic effects of tobacco other than those upon the mouth and respiratory tract has been emphasized in a recent paper (Kennaway, 1955) in which attention is drawn to the antidiuretic action (Walker, 1949) which must facilitate any such carcinogenic effect. The quantity of compounds absorbed from tobacco smoke is made plain by the very numerous investigations of their effects upon the circulatory system (see, for instance, Wynder, 1955, Chapters 2 and 3).

Steele, Koch, and Steiner (1951) obtained fibrosarcoma in about 19% of mice after subcutaneous injection of an extract (butyl alcohol, after extraction with benzene) of human urine, presumably from unselected persons. Dr. A. J. Lindsey allows me to say that he is examining, at the Sir John Cass College, the urine of smokers and of non-smokers for compounds which he and his fellow-workers (Commins *et al.*, 1954; Cooper and Lindsey, 1955) and J. A. Campbell in this laboratory have identified in cigarette smoke.

BENACTYZINE AS AN AID IN TREATMENT OF ANXIETY STATES

PRELIMINARY REPORT

BY

G. R. HARGREAVES, O.B.E., M.R.C.S.

Nuffield Professor of Psychiatry

M. HAMILTON, M.D., D.P.M.

Senior Lecturer

AND

J. M. ROBERTS, M.B., D.P.M.

Senior Registrar and Tutor

Leeds University Department of Psychiatry, the General
Infirmary at Leeds

Benactyzine hydrochloride has been found to reduce or modify stress-induced behaviour in animals (Jacobsen and Sonne, 1955; Jacobsen and Skaarup, 1955a, 1955b). It has also been found to diminish the autonomic responses of human beings to emotionally disturbing experiences (Jacobsen *et al.*, 1955). Favourable results have been reported in Denmark with clinical use of the drug for the treatment of psychiatric cases (Jensen, 1955; Ostenfeld, 1955), and it has recently been introduced into the United Kingdom. Beresford Davies (1956) reports its use in a group of 110 patients suffering from psychiatric conditions, with favourable results in 67 patients. Further trials have been reported by Raymond and Lucas (1956) and Seager and Leitch (1956).

In recent years a variety of new drugs—the so-called "tranquillizers"—have been introduced in psychiatric practice, some of which are now being prescribed very extensively—so extensively, in fact, that the American Psychiatric Association has issued a warning against their indiscriminate use, and hospital management committees in this country have expressed concern at the high cost incurred by their use in mental hospitals. For some of these drugs the value in specific conditions has been thoroughly assessed—for instance, in the case of reserpine or chlorpromazine employed for the treatment of chronic disturbed hospitalized schizophrenics. But the widespread use of drugs of this type for the treatment of psychoneuroses in general practice rests on no such secure evidence.

If the preliminary findings of the clinical use of benactyzine prove valid it appears likely that its application may lie mainly in the treatment of certain types of psychoneurotic patients, in which case its chief use would be found in general practice and in psychiatric out-patient clinics. It seems therefore to be of particular

importance that its value in such a type of practice should be rigorously assessed as soon as possible.

None of the clinical papers previously quoted can be regarded as entirely conclusive as an assessment of the value of the drug from the point of view we have in mind. Jensen's series of 110 cases consisted predominantly of in-patients in the Danish Red Cross Sanatorium, since it included only 14 out-patients. From a diagnostic point of view the series is heterogeneous, as it contains many different types of psychoneurotic and some psychotic reactions. Beresford Davies's series also contains patients suffering from many different types of psychoneurotic and psychotic reactions. Of his 110 cases 74 were out-patients, the remainder being in-patients in a mental hospital, some of whom were receiving modified electroplexy at the same time and others drugs of the antihistamine group. (It is not clear whether chlorpromazine was included in this category.) The 13 in-patients studied by Seager and Leitch are diagnostically an extremely heterogeneous group, since they include no fewer than four different types of psychoneurotic syndrome, and the only results presented are those for the group as a whole. Raymond and Lucas, on the other hand, although their series of 43 out-patients contains five different diagnostic groups, present the results for each group separately, from which they conclude that benactyzine had a favourable effect on 12 out of 18 cases of "anxiety neurosis."

Jensen's series includes a "control" group which is said to have been "picked out at random but so that approximately the same types of patients are represented in both groups." It seems to us that there may be a certain incompatibility between the first and second statements in this sentence. It is open to the further objection that the patients in the control group were apparently receiving three different treatments—thiopentone or phenobarbitone, "the latter often combined with bromides"—and that the psychiatrists undertaking the assessments were aware of the treatments which the patients were receiving, except that, at a later stage of the trial, in the case of 40 patients who had responded well to benactyzine, placebo tablets were substituted unknown to the patients' nurses and the colleagues of the author but apparently with the knowledge of the author himself. In Beresford Davies's series no control group was employed, and Ostenfeld's material consists of nine diagnostically heterogeneous case reports without controls. The trials reported by Raymond and Lucas and by Seager and Leitch were both blind and also controlled in the sense that the patients were used as their own controls by the blind alternation of placebo and drug. Unless combined with independent controls this method has, however, the disadvantage of providing no information on the course of the malady in comparable patients who do not receive the drug being investigated.

The method of assessment of the patient's condition is not fully described in any of the papers, except that of Raymond and Lucas (1956). In Jensen's series three general categories—"good effect," "moderate effect," and "no effect"—are employed; Beresford Davies similarly uses two sets of three categories—"worse," "unchanged," and "improved," and elsewhere in his paper "fair," "good," and "marked" improvement. In both these series it appears that different psychiatrists made assessments on different cases. No attempt is made to categorize the degree of improvement shown by Ostenfeld's cases.

In planning our own trial it appeared to us important to eliminate as many as possible of the uncontrolled variables which we have outlined above, or, where they could not be eliminated, to measure the significance of their effect.

Design of Trial

We decided to accept for the trial out-patients between the ages of 20 and 65 suffering from an anxiety state of less than four years' duration. We excluded any patient whose condition merited immediate treatment as an in-patient by reason of the severity of the anxiety, or patients in whom marked depressive symptoms appeared at the outset to be the principal feature. Three psychiatrists participated in the trial. Each patient was seen weekly for at least eight weeks by the psychiatrist who conducted the initial consultation. At the end of the second and fifth weeks—that is, at the third and sixth interviews—a second psychiatrist also saw the patient. Four treatments—A, B, C, and D—were available for prescription. Each psychiatrist was provided with a different list of these treatments arranged in random order, and the treatment prescribed for each new patient taken into the series by a psychiatrist was dictated by the next treatment on his random list.

The three possible combinations of psychiatrists to undertake the double interviews at the end of the second and fifth weeks were allotted in the same way. For any individual patient the third and sixth interviews were conducted by the same pair of psychiatrists. The chief pharmacist at the hospital, without our knowledge, allotted two of the treatments A, B, C, and D to benactyzine tablets, 1 mg., and the other two to placebo tablets of identical appearance.

At the first interview the psychiatrist prescribed for the patient the next treatment code letter on his random list at a dosage of one tablet three times a day. During the first fortnight—the preliminary period—all patients received inert tablets. In this period the fact that the tablets were inert was known to the psychiatrist but not the patient. At the third interview the dosage of the prescription was changed so that during the succeeding week it rose by one tablet a day to a maximum dose of two tablets four times a day. From this interview onwards the pharmacist dispensed tablets according to his code, and it was not known to the psychiatrist or to the patient whether the latter was receiving inert or active tablets. Unless side-effects led the psychiatrist to decrease the dose, the patient continued to receive the tablets at the rate of two tablets four times a day until the sixth interview. At this time all tablets were discontinued for one week. At the end of this week the patient was then placed on "known" benactyzine prescribed by name and continued as an ordinary out-patient at the clinic.

In summary, therefore, the trial provides a preliminary period of two weeks in which the patient is known to be on inert tablets, a test period of three weeks during which it is known only to the pharmacist whether the patient is receiving benactyzine at a dose starting with 1 mg. three times a day rising within five days to 2 mg. four times a day, and remaining at that level until the end of the test period, or, alternatively, is receiving the same dosage of inert tablets. This is followed by a withdrawal period of one week, after which the patient is given "known" benactyzine for at least two more weeks.

The first interview, which lasted about one hour, was devoted to a full psychiatric examination. At the end of this interview an assessment of the patient's symptoms was made in a manner described below. Succeeding interviews varied in length up to three-quarters of an hour. These interviews were devoted to minor psychotherapy and to an assessment of the extent of the patient's symptoms during the preceding week. At the third and sixth interviews a second psychiatrist was present—the external examiner—who made an independent assessment of the patient's symptoms.

The psychiatrist in charge of the case was at liberty to prescribe a nocturnal sedative during the trial if the severity of the patient's sleep disturbance made it imperative. In only one case was this found to be necessary. No drugs other than those under trial were prescribed by day. The psychiatrist was at liberty to reduce the dosage of the drug under trial if side-effects appeared.

Assessment of Symptoms

The method of assessment of the severity of the patient's condition was given considerable attention. The usual method whereby the psychiatrist makes an intuitive global assessment of the patient's improvement under such headings as "fair," "good," or "marked" seemed open to the objection that it is difficult with such assessments to compare with any degree of accuracy the improvement of the same or different patients—in addition, such judgments provide no qualitative information on the nature of the changes in symptoms which might throw light on such matters as general prognostic differences between anxiety states of varying symptomatology or on the type of symptom particularly likely to be relieved by the drug under study. We therefore classified all the symptoms likely to be found in our patients under the following headings: (1) anxious mood; (2) tension; (3) specific fears and phobias; (4) sleep disturbance; (5) intellectual disturbance; (6) depressive features; (7) somatic disturbances (muscular and sensory); (8) cardiovascular disturbance; (9) respiratory disturbances; (10) gastro-intestinal disturbances; (11) genito-urinary disturbances; (12) autonomic disturbances; and (13) manifestations of anxiety in the behaviour at the interview.

A gloss was prepared listing the features to be taken into account in making an assessment under any of these headings. At the interview we rated each of these thirteen items on a five-point scale as follows: 0, none; 1, mild; 2, moderate; 3, severe; 4, grossly disabling.

This rating scale yields a variety of different types of information for each patient, including a "profile" of his symptomatology and, by summing the ratings for all headings, a gross symptom score.

Such in outline is the design of the trial, which provides the means for an intensive study of a small diagnostically homogeneous group of cases to elicit data relevant to many questions. This paper deals with one of those questions—namely, the comparison over a test period of three weeks of two groups of patients suffering from anxiety states, both of which received minor psychotherapy and pills: only in the case of one group, however, were the pills active.

Other matters, such as the extent of agreement between the ratings of different psychiatrists (which proved to be great, $r=0.89$), the prognostic significance of different symptom-patterns, the response of different symptoms to the drug, and the effect of changes in his life situation on the patient's illness, will be dealt with elsewhere.

Nevertheless a word must be said regarding the effect of change in the patient's life situation. While we were still unaware of the coding employed for the tablets, we identified six cases in which it appeared to us that such a factor had been operative and rejected them from the series. In five cases there was considerable improvement (an average of 13 points improvement on the patient's symptom-score during the trial period), which appeared to us to result from very favourable changes in the patient's life situation. In a sixth case a worsening of the patient's life situation appeared to us to be associated with a slight worsening of his condition (two points on his total symptom-score). When the code was broken it was found that the five patients who had improved in this way had all been receiving inert tablets, while the patient whose condition had deteriorated had been receiving benactyzine. It is evident from this that if such factors are not taken into account they may considerably bias the results of drug trials with psychoneurotic patients. In the remainder of our cases, 26 in all, there were, so far as we could tell, no changes

in circumstances during treatment to which any change in condition could be attributed.

To emphasize what we have said regarding the restricted value of global assessments of the patient's condition, such as the term "improved," we show in columns 2 and 3 of Table I our results using the categories "improved" (mean-

TABLE I

Worse	2	0	9
	12	14	22

ing a reduction in total symptom score between the first and second double interviews), "not improved," and "worse." In column 4 we show the results of the 22 cases of "anxious neurosis" treated with benactyzine in the uncontrolled trial reported by Beresford Davies (1956). These data show that, even after the rejection from our series of patients in whom improvement appeared to result from a favourable change in their life situation, three-quarters of the patients receiving inert tablets "improved"—as high a proportion as is attributed to benactyzine in column 4. Although the class frequencies in this table are too small to permit the use of statistical tests, the figures nevertheless make it appear unlikely that valid conclusions can be drawn regarding "improvement" in the treated groups unless the degree of improvement can be assessed in some way.

The improvement of our patients who received inert tablets may be attributed to the benefits of minor psychotherapy or the natural history of the malady, according to the taste of the reader; but, whatever its cause, such an outcome makes it evident that a drug trial in this condition is valueless unless it is controlled, unless the effect of change in the patient's life situation is excluded, and unless it attempts by some means to measure the degree, scope, and nature of the symptomatic improvement. The total symptom-score improvement, as assessed by two psychiatrists on the thirteen-items rating scale, provided us with such a means, although the raw symptom-score might be open to the objection that it does not differentiate between an improvement in a patient displaying one symptom and a more widespread but more modest improvement affecting different symptoms. We have therefore used, in addition, an index of improvement based on the percentage improvement on the patient's original symptom-score as assessed by the two psychiatrists.

Table II shows the data obtained in this way. Columns 1 and 2 show the initial and final symptom-scores during the test period of the patients who received inert tablets, and columns 5 and 6 give similar information for the "benactyzine

cases." Columns 3 and 7 give the net improvement for "control" and "benactyzine" patients as shown by the difference between the initial and final scores. Columns 4 and 8 show the improvement as a percentage of the symptom-score at the beginning of the test period. From this table it will be seen that the average degree of improvement of the patients who received benactyzine was greater than in the case of those who received inert tablets and that this difference can reasonably be attributed to the effect of the drug.

Effect of the Drug

The effect of benactyzine in those cases in which it is evident is to produce a feeling of calmness, and sometimes a sense of detachment from such symptoms as remain, in that it diminishes rumination and preoccupation. It is our impression that it makes some patients more accessible to psychotherapy. In some cases it also appeared to have a favourable effect on sleep disturbance without the administration of any nocturnal sedatives. Patients responding to benactyzine show an improvement within a few days of its administration and, in most cases, a deterioration within a few days of its withdrawal after the comparatively short period of three weeks' medication on which the trial was based.

We found no toxic effects during the period under review, but 8 out of 14 patients receiving the drug, and 1 out of 12 of those on the placebo, showed side-effects of the type reported previously (Jensen, 1955; Beresford Davies, 1956). They complained of dizziness and "muddled thinking" amounting in a few cases to thought-blocking. In most cases these symptoms were very mild; they appeared within 24 hours of the dosage reaching 8 mg. daily and disappeared equally rapidly when the dosage was reduced. Reduction of the dosage to 6 mg. daily was sufficient to abolish the side-effects in all cases except two, in which it was reduced to 4 mg. daily.

During the progress of the trial we were inclined to suspect that an increase in depression might also be a side-effect of the drug. This suspicion was aroused by the fact that, although we had excluded at the outset patients in whom marked depressive symptoms were the predominant feature, we noticed a tendency for our ratings of depression in certain patients to increase during our observation of them.

The data derived from the trial enable the validity of this clinical impression to be examined. The mean depression-scores of the "inert" and "benactyzine" groups at the initial interview were 2.7 and 2.6 respectively. At the end of the preliminary period, during which both groups received inert tablets, the respective mean scores were 2.2 and 2.4. At the end of the trial period both groups had the same mean score of 1.8.

It is evident, therefore, that there was a general tendency for the depression score to fall to the same degree regardless of whether inert or benactyzine tablets were received. There were five patients whose course ran counter to this general tendency in that at some period of the trial their depression-score increased. Three showed such an increase only during the preliminary period while receiving inert tablets. A fourth patient showed an increase only during the trial period while receiving inert tablets, and a fifth showed an increase during the preliminary period on inert tablets and a further increase in the trial period on benactyzine.

Our suspicion that an increase in depression might be a side-effect of benactyzine therefore proves to be without support. The average fall in the depression-scores of those who received this drug is as great as in those who did not. In only one patient receiving benactyzine did an increase in depression-scores occur, and this tendency had already become manifest, before he received the active drug, by a rise in depression-score during the preliminary period.

The increase in the depression-scores may indicate a real and spontaneous increase in the severity of depressive

symptoms, or, alternatively, it may indicate the inaccuracy of assessments of depression made at a single initial interview—an inaccuracy which may diminish with assessments repeated at weekly intervals. It may well be that in some cases the depressive symptoms became more severe, but that in others depressive features became more evident to the observer as anxiety symptoms diminished. We hope to deal with this matter more fully in another communication.

Conclusions

The majority of our "placebo" patients have improved; some, we suspect, by reason of a favourable change in their circumstances, and others, we hope, by reason of the assistance which minor psychotherapy could give to their natural capacity for recovery. Several of our patients showed an increase in depression which proved to be unrelated to benactyzine.

Had our trial not been "blind" and "controlled" we should inevitably have attributed to benactyzine both favourable and unfavourable effects which, it is evident from our data, are not attributable to it; and had we not attempted to assess improvement in both a quantitative and a qualitative manner we should have failed to discern the favourable effects which are attributable to it. This trial has convinced us, firstly, of the misleading findings that may result from uncontrolled drug trials on psychoneurotic patients; we shall in future view with increased scepticism conclusions drawn from such trials. Secondly, we have learnt that, although blind controlled trials are essential, they are exceedingly time-consuming, not only because of the amount of time that must be devoted weekly to the assessment of each patient's condition, but also because a considerable proportion of the patients seen for an initial consultation with a view to inclusion in the trial failed on examination to meet the criteria we had laid down for acceptance. Even when they did meet the criteria there was another source of wastage—namely, their inability (by reason of geography or their employment situation) to attend the clinic weekly for at least eight weeks during working hours. Thirdly, we have learnt that impressionistic global judgments of a patient's condition alone are of little value in assessing the effect upon him of a particular regime, and in attempting to devise a method of symptom appraisal in anxiety states we have been disappointed to obtain little help from past literature with the notable exception of a paper by Cameron (1944). Fourthly, we have been reassured to discover that, with respect to assessment of anxiety states made in the manner we have described, doctors do not differ significantly, at least so far as we three are concerned. And, finally, we have found that, on the average, patients who received benactyzine in this trial showed a greater degree of improvement than those who did not.

Summary

Thirty-two out-patients suffering from anxiety states have received either benactyzine or an inert substance in a double blind controlled trial.

The majority showed "improvement." Six cases in which a change in symptoms appeared to us to result from a change in the patient's circumstances were discarded from the series.

Among the remaining 26 patients the extent of the average degree of improvement as assessed by two independent psychiatrists using a rating scale was greater in the case of the group of patients that received benactyzine than in the control group ($P=0.08-0.06$).

More than half the patients receiving benactyzine, 8 mg. a day, complained of side-effects, usually of mild degree, which disappeared when the dose was reduced.

An increase in depression occurring in five patients was not due to benactyzine.

Double blind controlled trials and improved methods of assessment of the patient's condition are very time-consuming; they are nevertheless essential in studying the effects of drugs on psychiatric patients in order to circumvent the capacity for unwitting self-deception which both psychiatrists and their patients display.

We thank Mr. N. W. Blacow, chief pharmacist of the General Infirmary at Leeds, for supervising the coding and dispensing of the substances under trial; and Glaxo Laboratories Ltd. for the gift of "suavitil" brand benactyzine and the matched inert tablets used in the trial.

ANTILIPAEMIC AGENT WITHOUT ANTICOAGULANT ACTION

BY

E. M. M. BESTERMAN, M.D., M.R.C.P.

AND

JOHN EVANS, M.D., D.Phil.

Institute of Cardiology, London

There is now ample evidence that heparin influences the transport or metabolism of fats in man. When injected after a fatty meal it accelerates the disappearance of visible lipaemia (Anderson and Fawcett, 1950; Oliver and Boyd, 1953). Following heparin administration, analysis of serum lipoproteins by the ultracentrifuge shows a redistribution of the low-density fractions with reduction of the Sf 12-20 and increase of the Sf 6-12 group (Graham *et al.*, 1951). In 1953 Nikkilä reported comparable changes in the electrophoretic pattern of serum lipids after heparin, with diminution of the beta- and increase of the alpha-lipoproteins. However, this quantitative change in the electrophoretic pattern has not been found by all observers. The most constant change is an increase in mobility of both beta- and alpha-lipoproteins with an absolute decrease of the neutral fats and apparent diminution of the beta-lipoprotein (Herbst *et al.*, 1955; Kuo *et al.*, 1955; Besterman, 1957).

Thus heparin tends to rectify the abnormal lipaemia and Sf distribution associated with atheroma. There is as yet no convincing proof that human atherosclerosis will regress with heparin therapy, and to obtain such evidence a prolonged course of treatment would be required. Daily intravenous injection is impracticable, and the anticoagulant action of heparin makes repeated subcutaneous or intramuscular therapy hazardous.

To overcome this difficulty a substance is required which retains the antilipaemic properties of heparin but has no anticoagulant action. Constantinides *et al.* (1954) reported that certain sulphated polysaccharides with negligible anticoagulant action would clear turbid serum in rats, thereby establishing that the antilipaemic and anticoagulant effects were independent properties. Subsequently at the Institute of Seaweed Research Black and

Dewar (1954) showed that laminarin, a relatively homogeneous polysaccharide from the seaweed *Laminaria cloustoni*, could be sulphated to varying degrees. The highly sulphated compounds have an anticoagulant action, whereas the laminarins with few sulphate groups have little or no effect on blood-clotting. The object of the present study was to determine whether either of two lower-sulphated polysaccharides exhibited antilipaemic properties similar to those of heparin as judged by their effect on the electrophoretic pattern of the serum lipoproteins.

Method

The preparations used in this study were two samples of laminarin sulphate, M and N, with a low sulphate content—namely, 0.62 and 0.37 sulphate groups per glucose unit respectively. The anticoagulant activities of these preparations as tested *in vitro* were 1.4 and less than 1.3 international units per mg. respectively. Previous work had shown that laminarin sulphate M and N had very low acute toxicities in mice and guinea-pigs, in contrast to laminarin sulphate K, a preparation with high sulphate content which has been shown to be very toxic to guinea-pigs (Adams and Thorpe, 1957). Toxicity data are shown in the Table.

Acute Intravenous Toxicities of Laminarin Sulphates to Mice and Guinea-pigs

Animal	Substance	I.V. Dose (mg./kg.)	Deaths
Mice	Laminarin sulphate K	1,000	6/10
	" "	1,500	9/10
	" "	4,000	2/12
	" "	2,800	1/9
	" "	3,600	1/5
	Heparin (100 I.U./mg.)	4,000	5/8
Guinea-pigs	" "	1,500	2/10
	" "	2,500	5/5
	Laminarin sulphate K	20	8/11
	" "	40	3/5
	" "	200	0/5
	Heparin (100 I.U./mg.)	200	0/5
	" "	250	0/5

These compounds, comparable to heparin in their low acute toxicity, were considered to be suitable for short-term clinical investigations.

Twelve patients with ischaemic heart disease were given an intravenous injection of 10,000 units of heparin and in 11 the electrophoretic pattern of the serum lipids was significantly altered. Only these 11 patients were subjected to further study. Nine of these patients subsequently received a single intravenous injection of 100 mg. of laminarin sulphate; six were given laminarin sulphate M and three laminarin sulphate N. The remaining two patients were given 100 mg. of laminarin sulphate M by intramuscular injection.

Samples of venous blood were taken from each patient before and at varying times from 10 minutes to 24 hours after injection. Paper electrophoresis of the serum was carried out as described by Dangerfield and Smith (1955). Each strip of filter-paper was divided longitudinally, half being stained for proteins with "light green" and half for lipids with "Sudan black B."

Two of the patients who received laminarin sulphate M had been given a fatty meal four hours before the intravenous injection. The visible turbidity of the serum and the electrophoretic pattern of the lipids were observed. To determine whether laminarin sulphate M or N altered the turbidity or electrophoretic pattern of the serum *in vitro*, 1 ml. of lipaemic serum was incubated at 37° C for one hour with 1 mg. of each of the polysaccharides.

The clotting-time of whole blood was estimated by the method of Lee and White before and after injection in five patients who received laminarin sulphate M and in two who received laminarin sulphate N.

Observations

Heparin. The alterations in the electrophoretic pattern of the serum lipids after heparin consisted of increased mobility of the beta-lipoproteins and less consistency of the alpha-lipoproteins, reduced intensity of staining of the beta-lipoproteins, and clearing of the neutral fat zone (Fig. 1). Changes of variable degree were noted in 11 of the 12 patients. They were fully developed within 10 minutes of the injection and persisted for 6 to 24 hours. The serum proteins were unchanged after heparin save for the appearance of a band ahead of the albumin corresponding in position to the alpha-lipoproteins.

Laminarin Sulphate M. After an intravenous injection of laminarin sulphate M in six patients, the electrophoretic pattern in all cases showed similar changes to those observed following intravenous heparin (Figs. 2 and 4). Increased mobility of the beta-lipoproteins and, to a lesser extent, of the

FIG. 1.—Electrophoretic pattern of serum proteins and lipids before and at varying times after an intravenous injection of 10,000 units heparin. NF=neutral fat; α-L=α-lipoprotein; β-L=β-lipoprotein; A=albumin; α₂=α₂-globulin; β=β-globulin. γ=γ-globulin. Arrow marks, point of application of serum.

FIG. 2.—Electrophoretic pattern of serum proteins and lipids before and at varying times after an intravenous injection of 100 mg. of laminarin sulphate M. (For symbols see Fig. 1.)

alpha-lipoproteins, was noted in each case. The beta-lipoprotein band was decreased and the neutral fat zone, when present, was cleared. As with heparin, the magnitude of the changes varied from patient to patient. These effects were most marked in the serum taken 10 minutes after injection and tended to disappear within four to six hours. The serum and proteins appeared unchanged. Once again a band beyond the albumin fraction was seen in cases with greatly increased mobility of the lipoproteins (Fig. 4). The distribution and mobility of the lipoproteins was not significantly altered in either of these patients, who received 100 mg. of laminarin sulphate M by intramuscular injection. No discomfort was noted locally at the site of injection. The clotting-time of whole blood was slightly prolonged after intravenous laminarin sulphate M in each of the five patients in whom it was measured. The maximum increase was from 9 minutes before injection to 13 minutes after injection. The visible turbidity of the serum was reduced in both patients

given laminarin sulphate M after a fatty meal (Fig. 3). These observations were confirmed on electrophoresis (Fig. 4). The sample taken 10 minutes after injection showed clearing of the heavy zone of neutral fat in addition to marked changes in the lipoproteins. Within four hours neutral fat had reaccumulated and the lipoproteins had reverted to the control pattern.

Laminarin Sulphate N. No changes were observed in the electrophoretic pattern of the serum lipoproteins in any of the three patients given an intravenous injection of laminarin sulphate N (Fig. 5). The clotting-time of whole blood was not prolonged in either of the patients in whom it was measured.

FIG. 3.—Visible turbidity of serum following a fatty meal, before and at varying times after an intravenous injection of 100 mg. of laminarin sulphate M.

FIG. 4.—Electrophoretic pattern of serum proteins and lipids before and at varying times after an intravenous injection of 100 mg. of laminarin sulphate M in a patient who had been given a fatty meal. (For symbols see Fig. 1.)

FIG. 5.—Electrophoretic pattern of serum proteins and lipids before and at varying times after an intravenous injection of 100 mg. laminarin sulphate N. (For symbols see Fig. 1.)

In-Vitro Studies.—The addition of either laminarin sulphate M or N *in vitro* to lipaemic serum caused neither visible clearing of the serum nor any significant alteration in the electrophoretic distribution of neutral fats and lipoproteins.

Discussion

As only small amounts of the two laminarins were available for clinical trial, it was particularly useful that laminarin sulphate N proved to be inert and thus acted as a control for the positive findings following injection of laminarin sulphate M.

A single intravenous injection of the lower-sulphated polysaccharide laminarin sulphate M cleared lipaemic serum, increased the electrophoretic mobility of lipoproteins, and altered the distribution of lipoproteins in the same way as heparin. The changes could be demonstrated almost immediately after injection, and persisted for four to six hours. They were not reproduced by the addition of laminarin sulphate M to serum *in vitro*. It is evident, therefore, that the antilipaemic properties of laminarin sulphate M closely parallel those of heparin, except for the shorter duration of action of the dose used in this study. On the other hand, laminarin sulphate N, a closely related polysaccharide, showed no demonstrable effect on the electrophoretic mobility or distribution of lipoproteins.

No effect was noted when 100 mg. of laminarin sulphate M was injected intramuscularly. It is possible, however, that with larger doses changes may be seen following both intramuscular and subcutaneous injections, and that the duration of the changes will be prolonged by slow release from the tissues at the site of injection. No local reaction resulted from intramuscular injection of the polysaccharide, and no reactions were observed in any patient following intravenous laminarin.

Since laminarin sulphate M possesses the antilipaemic properties of heparin without the hazards of its anticoagulant action, it would appear to be a suitable substance with which to study the effect of prolonged administration of "lipaemia-clearing" substances on the course of atherosclerosis in man. Following the completion of chronic toxicity trials in animals and further information on the optimal dose and most convenient method of administration, a long-term investigation of patients with ischaemic heart disease will be undertaken.

Conclusion

A lower-sulphated polysaccharide of laminarin is described that has antilipaemic properties similar to those of heparin without significant anticoagulant activity. It would appear to be a suitable agent to assess the effect of "lipaemia-clearing" substances on the course of atherosclerosis in man.

We are indebted to Dr. Woodward and his staff at the Institute of Seaweed Research for advice and supplies of laminarin sulphate, and to the Research Department of Boots Pure Drug Company Ltd. for carrying out toxicity trials and the preparation of the material for clinical use. We would in particular like to acknowledge the co-operation and assistance of Drs. E. V. B. Morton, Cobb, and Adams, of Boots. Dr. Paul Wood, Director of the Institute of Cardiology, has throughout provided us with invaluable advice and encouragement, and we are grateful to him and to the other physicians of the National Heart Hospital for their kind co-operation. For untiring technical assistance we are indebted to Miss B. Hall.

DIFFUSION OF RADIOACTIVE SODIUM IN NORMOTENSIVE AND PRE-ECLAMPTIC PREGNANCIES

BY

TREVOR JOHNSON, M.D., F.F.A. R.C.S.
M.R.C.O.G.

AND

C. G. CLAYTON, M.Sc.

From the Department of Obstetrics and Gynaecology, King's College, University of Durham, and the Department of Radiotherapy, Royal Victoria Infirmary, Newcastle upon Tyne

The diminished placental transfer of radioactive sodium which is known to occur in pre-eclampsia (Browne and Veall, 1953; Cox and Chalmers, 1953; Johnson and Clayton, 1955; Clayton *et al.*, 1956) may be due either to a change within the placenta itself or to a reduction in its blood supply from the uterine decidua. This latter possibility has been investigated by Morris *et al.* (1955), who developed a simple method for measuring the effective blood flow in the pregnant uterus. It is based on a determination of the clearance rate of radioactive sodium ions following their injection into the anterior wall of the uterus in the final stages of pregnancy.

It is claimed that the physiological half-life of the injected radiosodium is almost constant in normotensive subjects, whereas in patients suffering from pre-eclampsia there is a very significant reduction in the clearance rate of the isotope. The actual values recorded are dependent upon the clinical severity of the condition as judged by the magnitude of the maternal diastolic blood pressure.

The significance of these results in relation to the possible use of the method in the identification of pre-eclampsia, and to a better understanding of this syndrome, is clear.

We have made similar investigations and have measured the radiosodium clearance rates in normotensive patients, pre-eclamptics, and a group under treatment with a hypotensive drug.

Method

(a) Uterine Muscle

Twenty microcuries of $^{24}\text{NaCl}$ contained in exactly 0.4 ml. of isotonic saline is injected into the antero-lateral aspect of the pregnant uterus between the 34th and 43rd weeks of pregnancy, in the manner described by Morris *et al.* (1955).

The abdominal skin in the region of McBurney's point is infiltrated with a small quantity of 1% procaine, and a hypodermic needle 2 in. (5 cm.) long is introduced into the subjacent myometrium. Localization within the uterine wall is confirmed by asking the patient to inspire, when the needle mount is depressed downwards as the abdominal wall slides over the uterus. Subsequent aspiration with a sterile syringe confirms that the needle point has not punctured the amniotic sac or a large vessel. Experience shows that very careful attention to these details of technique is essential.

After injecting the radiosodium, a gamma-ray G.-M. counter, with the end window screened, held in a delicately balanced support, is located over the injection site. It is kept in position with a thin strip of adhesive plaster. Pressure of only a few grammes is exerted on the skin, and the balancing mechanism enables the counter to ride any abdominal movement which may take place, so that a constant relationship with the injected site is maintained.

FEB. 9, 1957

DIFFUSION OF RADIOSODIUM IN PRE-ECLAMPSIA

BRITISH
MEDICAL JOURNAL 313

The observed counting rates were recorded at half-minute intervals, using a counting rate meter. The radioactivity is expressed in counts per second, and where necessary the final value is corrected for a simultaneous increase in background radiation due to systemic absorption of radiosodium from the injected site.

The reaction time of hydrallazine hydrochloride ("apresoline") in relation to radiosodium clearance in the uterine muscle was also investigated in three cases. Each patient had severe pre-eclampsia. A radiosodium-clearance curve was started, and as soon as the slope of the curve had been established the first treatment with hydrallazine hydrochloride was begun: 20 mg. of the drug was injected intravenously. Observations were continuous and the usual corrections were made. In order to extend the record for as long a period as possible a larger dose of radiosodium (35 $\mu\text{c.}$) was given in these cases. A result typical of the three cases is seen in the Chart.

The action of hydrallazine hydrochloride in increasing radiosodium clearance from an injected site in uterine muscle is seen in Curve A to be significant at approximately 15 minutes after its first injection. Curve B is typical of the 11 cases of untreated severe pre-eclampsia and shows a physiological half-life similar to that of Curve A before the injection of hydrallazine hydrochloride.

(b) Gastrocnemius Muscle

Similar observations have been made over the fleshy portion of the medial head of the gastrocnemius muscle, after intramuscular injection of the same volume and activity of saline as in the uterine muscle experiments. The results obtained in the two series of patients are recorded below.

Material

The above-mentioned studies were carried out on 55 patients between the 34th and 41st weeks of pregnancy. Thirty-eight separate observations were made in the plain muscle of the uterus and 17 in the striped gastrocnemius muscle of the calf.

The patients in these two groups were further subdivided into normotensives, mild pre-eclamptics, and severe pre-

TABLE I.—Numbers of Cases Studied

	Uterine Muscle Clearance	Gastrocnemius Muscle Clearance
Normotensive	14	6
Mild pre-eclampsia (diastolic B.P. 85-95 mm. Hg)	8	5
Severe pre-eclampsia (diastolic B.P. exceeding 95 mm. Hg)	11	6
Severe pre-eclampsia under treatment with hydrallazine hydrochloride	5	

eclamptics, depending on the magnitude of the maternal diastolic blood pressure at the time of experiment (Table I). We have accepted the same standards as Morris *et al.* (1955), and patients with pre-existing essential hypertension were carefully excluded from the study.

An additional group of patients who were receiving intermittent doses of hydrallazine hydrochloride to control the severe hypertension of pre-eclampsia were also included in this study.

Results

The clearance rates observed in uterine and gastrocnemius muscle are set out in Tables II and III. Values are expressed in terms of the physiological "half-life" of the sodium—that is, the time required for half the injected radiosodium to diffuse from the injection site.

TABLE II.—Clearance Rate of Radiosodium from Uterine Muscle

Type of Pregnancy	No. of Experiments	Mean Physiological Half-life (mins.)	Standard Deviation (mins.)	Standard Error of Mean
Normotensive	14 (20)	4.7 (4.1)	± 1.18	± 0.328
Mild pre-eclampsia	8 (10)	8.14 (7.7)	± 3.83	± 1.45
Severe pre-eclampsia	11 (8)	11.6 (15.3)	± 3.60	± 1.1
Severe pre-eclampsia treated with hydrallazine hydrochloride	5	4.5	± 2.72	± 1.21

Values reported by Morris *et al.* (1953) are given in parentheses.

TABLE III.—Clearance Rates of Radiosodium from Gastrocnemius Muscle

Type of Pregnancy	No. of Experiments	Mean Physiological Half-life (mins.)	Standard Deviation (mins.)	Standard Error of Mean
Normotensive	6	24.5	± 4.75	1.9
Mild pre-eclampsia	5	18.7	± 4.41	0.9
Severe	6	24.9	± 7.25	1.2

Discussion

The close correlation which has been found to exist between the magnitude of the diastolic blood pressure in pre-eclampsia and the clearance rate of radiosodium in uterine muscle is in sharp contrast to the results obtained with gastrocnemius muscle, where no significant correlation was observed. The reason for this is not clear, and we have not yet made any investigation beyond that reported, but it is possible that the very different histological texture of the muscle is an important factor. At the moment, however, the lack of any observed correlation in the gastrocnemius muscle seems to be of doubtful importance in diagnosing or understanding the pre-eclamptic condition.

The very significant decrease in radiosodium clearance rate which is seen to occur in uterine muscle in pre-eclampsia can be compared with the similar decrease in radiosodium clearance from an injected site in the placenta and also with the reduction in placental transfer rate of the same isotope in the same condition (Cox and Chalmers, 1953; Johnson and Clayton, 1955; Clayton *et al.*, 1956).

If it is generally accepted that the rate of radiosodium clearance from tissues is a measure of the efficacy of the blood supply (Kety, 1949; Braithwaite *et al.*, 1954), then it may well be that all these observations are an indication of a reduced maternal blood supply to the uterine decidua. If this is so then it is interesting to speculate on the precise environment which prevails in the uterine muscle to cause this reduction, and with the evidence available it is possible to suggest some theory for this mechanism.

Since the radiosodium is injected between the cells and in between the capillaries, the reduced clearance rate must be due to a reduction in the diameter of the open capillaries, a reduction in the number of open capillaries, or a change in the nature of the capillary endothelium itself. The first two alternatives would have the effect of reducing

the total quantity of blood passing through unit cross-sectional area of muscle in unit time. The third possibility—that is, that a reduction in radiosodium clearance rate can also be brought about by a change in the diffusing properties of the capillary endothelium—would result from direct biochemical or toxic activity on the capillary endothelium and would have no effect on blood flow. This latter corresponds to a change in the value of "K," the diffusion constant, in the equation $\frac{ds}{dt} = K.A.(S-S_1)$ (Fulton, 1949).

The first two postulates correspond to a change in "A," the total surface area of capillary available to transfer the sodium ion. S and S_1 are the radiosodium concentrations inside and outside the capillaries.

This postulate of the change in the nature of the capillary bed of the uterus in pre-eclampsia is consistent with the observed change in placental transfer in this condition, for the interchange of electrolytes between mother and foetus depends upon the vascularity of the uterine muscle which supplies the decidua. Furthermore, this capillary injury is not inconsistent with maternal hypertension. In this case the hypertension might be thought of as a consequence of changes in the resistance offered by the capillary bed to the blood flow, and hence of a subsidiary development in the main syndrome. In this event, however, it is not clear why this change in resistance should be confined to the uterus, for the results obtained with the gastrocnemius muscle do not reflect this same change in capillary condition, and blood-flow measurements in several other structures seem to be unaltered in mild pre-eclampsia (Kellar, 1955).

It is possible, however, that similar changes in the capillary bed are taking place in the gastrocnemius and other structures, but an increased clearance rate of radio-sodium in mild pre-eclampsia is not reflected by this method because of the different texture of the muscle.

It is reasonable to expect, however, that in advanced eclampsia with widespread oedema a generalized change in the capillary bed might have been observed, but we have had no opportunity of studying this condition.

It may be, of course, that the whole of the decrease in radiosodium clearance is due to biochemical changes within the myometrium. These may either act directly upon the capillary endothelium or they may be a result of the indirect effect of adrenocortical activity (Venning *et al.*, 1954) which is known to occur in pre-eclampsia and which increases the quantity of extracellular sodium ions causing oedema. The increased intercapillary distances in this latter condition have the effect of reducing the number of capillaries passing through the volume occupied by the injected sodium, and hence are likely to be a contributory factor in determining the clearance rate. Neither the direct nor the indirect of these two hypotheses, however, seems to explain the correlation between uterine muscle clearance and placental transfer rate, or suggest a cause for hypertension. It may be that these intrinsic alterations in the capillary bed are also present in the chemoreceptor organs in the carotid body, which are intimately concerned in the vasomotor control of blood pressure. These structures are well known to be sensitive to local alteration in electrolyte balance and lowered oxygen tension, and capillary injury of the type envisaged may have an adverse effect on this mechanism, with resultant hypertension.

It is felt, therefore, that although the biochemical changes may be contributory to a reduced radiosodium clearance rate they do not fully explain them in the way described above. It is realized, however, that they could be the controlling influence on the change in the nature of the capillary bed in pre-eclampsia.

The effect of hydralazine hydrochloride can be seen from the studies of radiosodium clearance (Table III and the Chart). It is clear that in the patients who were under treatment with this drug and who were suffering from severe pre-eclampsia there was a very significant increase in the radiosodium-clearance rate, which may be interpreted as an improvement in myometrial blood flow.

When hydralazine hydrochloride was first started whilst observation of radiosodium clearance was being made, a gradual increase in the clearance rate was noted. This became significant after about 15 minutes, and is in accordance with the findings of other workers who have measured similar effects upon the cerebral and renal circulations (McCall, 1953; Kaplan and Assali, 1953).

These latter observations add further evidence to the theory that a change in the nature of the capillary bed is one of the observable features of pre-eclampsia. The action of hydralazine hydrochloride in improving the blood flow gives a rationale to its observed therapeutic value in the management of this disease, although it should be understood that if permanent placental injury from pre-existing pre-eclampsia has occurred the use of vasodilator drugs is unlikely to be of value in restoring placental function.

It should be emphasized that the only direct measure of the consequences to the foetus of pre-eclampsia must be by observations on the foetus itself (Clayton *et al.*, 1956), or by measurement of the utero-placental exchange of nutrients and metabolites: a study of decidual blood flow is not necessarily a direct indication of placental function.

Summary

A study of the effective blood flow in the capillary bed of the full-term pregnant uterus in normotensive and pre-eclamptic patients has been made by investigating the clearance rates of isotonic saline containing sodium-24 after injection into the myometrium.

A constant clearance rate of radiosodium in normotensive patients was found to be significantly reduced in patients suffering from pre-eclampsia in proportion to the severity of the disease. We failed to demonstrate a similar correlation in the capillary bed of striped muscle.

The changes in the nature of the capillary bed which condition these observations and their relation to some features of hypertension are considered. It is postulated that a similar alteration in the capillary endothelium of the carotid bodies might be an aetiological factor in the onset of material hypertension in pre-eclampsia.

Hydralazine hydrochloride ("apresoline") administered to pre-eclamptic mothers by the intravenous route was found to restore the reduced myometrial capillary blood flow of this condition, the drug being therapeutically active in approximately 15 minutes from the time of its administration. These findings are in accordance with those previously observed in the cerebrum and kidney.

We gratefully acknowledge the continued support of Professor Harvey Evers, Dr. F. T. Farmer, Mr. C. J. L. Thurgar, and all the patients who willingly co-operated after being told of the research nature of the work. The investigations were made possible by a research grant from the Newcastle upon Tyne Regional Hospital Board. We are pleased to record that the supplies of apresoline used in this study were donated by Ciba Laboratories Limited. We also acknowledge the co-operation of our technical assistant, Mrs. B. S. Crawford.

HEINZ-BODY ANAEMIA IN THE NEWBORN

BY

S. VARADI, M.D.

Consultant Haematologist, City General Hospital and
Wharnclyfe Hospital, Sheffield

AND

E. HURWORTH, M.B., B.Ch., B.A.O.

Pathology Registrar, City General Hospital, Sheffield

Haemolytic anaemia in the newborn is usually due to the transfer of antibodies from the maternal to the foetal circulation (haemolytic disease of the newborn), but such an anaemia may also be the result of an inherent defect, such as congenital spherocytosis. A further haemolytic anaemia occurring in premature infants was reported by Gasser and Karrer (1948) and Gasser (1951, 1953). They described the clinical appearances and haematological findings in 14 infants with this condition, which they called the "spontaneous" Heinz-body anaemia.

The children developed jaundice in the first few days of life, usually between the first and fifth days. Anaemia appeared as the jaundice faded, commonly during the third week. The general condition of the infants deteriorated; they became pale, refused feeds, and were drowsy. At no time could the spleen be felt. Examination of the blood before the development of the anaemia showed the presence of Heinz bodies in 9-45% of the red cells. There were many distorted, disintegrating red cells when the anaemia was severest.

Heinz bodies are intracellular inclusions in the red cells which stain by various supravital dyes, but not by Romanowsky stains. They are thought to be particles of denatured haemoglobin. They occur in man as a result of poisoning with a variety of chemicals, but no such cause could be found in the mothers before or after birth or in the infants.

In the present paper, two unusual cases of Heinz-body anaemia are reported; one patient was a normal full-term infant and the other was not jaundiced at any time during the illness.

Methods.—Haemoglobin estimations were carried out by the oxyhaemoglobin method, using a photoelectric absorptiometer. Red- and white-cell counts were done in a Burk counting chamber. Reticulocytes and Heinz bodies were counted in brilliant cresyl-blue and Nile-blue dry preparations, and the effect of counterstaining with Romanowsky dyes was observed after previous fixation with ethanol. Differential counts were carried out on blood smears stained with May-Grünwald-Giemsa and on bone-marrow smears stained with N.R.G. (Gurr). The osmotic fragility of the red cells was determined both before and after incubation (Varadi, 1951), using the method of Parpart *et al.* (1947).

Case 1

The patient was a full-term male infant, one of non-identical twins, normal delivery, whose birth weight was 3,370 g. (7 lb. 7 oz.). During pregnancy the mother was found to be hypertensive; she had ankle-swelling and was anaemic but not jaundiced, and she had had no known contact with any case of hepatitis. The infant fed poorly from birth and the mother noticed that the baby was jaundiced when he was two weeks old. The twin sister was perfectly

well. The child's motions were loose but not pale. As the jaundice persisted, he was admitted to hospital on October 25, 1954; he was then 3 weeks old.

On examination he was seen to be very jaundiced, quite active, and crying normally. The liver could be felt one fingerbreadth below the right costal margin; the spleen could not be felt; the stools were not pale. No abnormality was found in the cardiovascular, respiratory, and central

nervous systems. The following diagnoses were considered possible: (1) acholuric jaundice, (2) infection, and (3) haemolytic disease. The following haematological examinations were carried out.

Peripheral Blood (Table I, Fig. 1).—This showed the presence of a severe haemolytic anaemia; many distorted red cells and a few spherocytes were present (Fig. 2); nearly one-third of the red cells contained Heinz bodies

FIG. 3.—Case 1. Heinz bodies in nearly one-third of red cells. (x900.)

Monocytes	0.25%		
Promonocytes	1.00%		

(Fig. 3). In the next two days the haemoglobin fell rapidly, numerous nucleated red cells appeared, and reticulocytes increased.

Tibial Puncture on October 29 (Table II) showed an extremely active erythropoiesis with an increased proportion of early cells, findings consistent with haemolytic anaemia.

Osmotic Fragility Test.—This gave a curve with a somewhat wide span. This was due mainly to a "mode" in the

FIG. 4.—Case 1. Osmotic fragility curve in buffered solutions before (continuous line) and after 24 hours' incubation (broken line) at 20° C.

range of the higher saline concentrations (Fig. 4). The mean corpuscular fragility was normal and did not show a pathological increase after 24 hours' incubation at 20° C. The tail of the curve, however, showed a marked shift to the right, caused, no doubt, by the further deterioration of the inferior distorted red-cell population on standing.

Autohaemolysis.—There was a marked haemolysis in the defibrinated blood sample after 24 hours' incubation at 37° C., weaker at 4° C.

Urobilin was strongly positive in the urine (October 27); bilirubin was negative. Serum bilirubin (October 28) was 13 mg. per 100 ml.; direct van den Bergh reaction negative. Direct Coombs test on the child's red cells was negative. Both child and mother were group O, Rh negative, and no incompatibility could be demonstrated between the mother's serum and the infant's red cells by the saline, albumin, or anti-human-globulin methods. The infant's serum did not contain abnormal cold or warm agglutinins or haemolysins. Wassermann reaction and Kahn test were negative. No pathogens were isolated from the faeces.

The child was transfused with 120 ml. of packed cells on October 29: the jaundice rapidly disappeared and was hardly noticeable after two days. The patient's condition remained good, he was gaining weight, and the motions were only slightly more watery than expected at his age. He was discharged on November 18.

Case 2

This patient was a 30-weeks, premature female infant; birth weight 970 g. (2 lb. 2 oz.). The mother's health during pregnancy was good and the delivery was normal. The

general condition at birth was good, and the child appeared to thrive until on the 13th day a soft swelling developed in the left buttock. This swelling increased gradually in size. On the 17th day it discharged spontaneously a few drops of pus and the abscess was incised three days later. About this time the child was noticed to look pale. Haematological examination (19th day) disclosed a severe anaemia (Table III, Fig. 5), with Heinz bodies (Fig. 6) and numerous distorted red cells.

The infant's general condition continued to deteriorate and she became drowsy and very pale. The haemoglobin fell to 4 g./100 ml. on the 25th day. The following day the patient was given a transfusion of 45 ml. of packed cells with very good effect clinically and haematologically. Although the haemoglobin decreased gradually during the next fortnight, Heinz-body formation ceased and haemolytic forms of red cells rapidly disappeared. The abscess healed. The child kept her feeds satisfactorily. She was never icteric and the spleen was not felt. She received no drugs.

Haematological investigations on the peripheral blood showed the

FIG. 5.—Case 2. Results of haematological examination.

typical order in which the red-cell changes develop: peak of Heinz-body formation—morphological alterations—anaemia—outpouring of nucleated red cells—peak of reticulocytes (Table III, Fig. 5).

The mother's blood was group B, Rh positive, the infant's group O, Rh negative. There were no antibodies in the mother's serum. Her Wassermann reaction was negative.

Faecal stercobilinogen (five days' average) was 4.1 g. a day. There was no increase in the urinary urobilin.

The bacteriological examination of the abscess (culture) showed a growth of *Bact. coli*.

FIG. 6.—Case 2. Showing presence of Heinz bodies. (x1,100.)

Discussion

For several reasons we felt justified in recording our two cases. Firstly, as a contribution to the differential diagnosis of haemolytic anaemias in the newborn; secondly, and more important, to point out the excellent effect of transfusion in this type of haemolytic anaemia, because if left untreated the patient may die; and thirdly, to our knowledge the condition has not previously been reported in a normal full-term infant.

The diagnosis of Heinz-body anaemia should not cause any difficulties from the haematological standpoint: the essential thing is that one should think of this diagnosis when faced with a non-obstructive type of jaundice in the first days of life. The patients are not anaemic at birth (Gasser, 1953). After the appearance of the jaundice the first haematological abnormality to be detected will be a rapidly increasing number of Heinz bodies in the red cells during the first and second weeks. As the Heinz bodies become more numerous, red cells that are shrunken, abnormally crenated, and the shape of broken eggshells make their appearance and anaemia develops.

There is a vast literature on Heinz-bodies, to which we refer the reader (see Dacie, 1954; Selwyn, 1955). A variety of aromatic nitro- and amino-compounds and inorganic oxidizing agents known to produce Heinz bodies are listed in reviews of the subject by Webster (1949) and Buckell and Richardson (1950). If the dose of the toxic substance ingested is sufficient to cause a haemolytic anaemia, both Heinz bodies and the above described morphological alterations of the red cells will be present. In the absence of any exogenous toxic cause, the occurrence of Heinz bodies was observed in cases of hypoplasia (Schilling, 1928; Zadek and Burg, 1930; Moeschlin, 1941, 1942) or aplasia of the spleen (Gasser and Willi, 1952), and also in splenectomized individuals (Selwyn, 1955). In such cases the Heinz-body formation is a permanent feature. There are reasons for believing that the spleen either filters off red cells contain-

ing Heinz bodies from the circulation or is in some way responsible for the extrusion from the cells of the bodies which are subsequently phagocytosed by the spleen.

The spontaneous occurrence of Heinz bodies was observed in the newborn in the absence of any exogenous toxic influence and without a demonstrable splenic pathology (Willi, 1947). Out of 1,251 newborn infants, 225 (18%) were found to contain Heinz bodies in over 2.1% of the red cells, and 84% of these 225 infants were premature (Willi and Hartmeier, 1950). Unlike the haemolytic anaemia with spontaneous Heinz-body formation (Gasser and Karrer, 1948; Gasser, 1951, 1953), there were neither disintegrating red cells present in these cases nor signs of an increased haemolysis or of any degree of anaemia.

As Heinz bodies are insoluble in water and red cells "tagged" with them show an increased resistance to lysis by hypotonic saline, the above clinical observations and *in vitro* tests on our Case 1 (saline fragility curve, autohaemolysis test) suggest that the increased haemolysis is due to the presence of the irreversibly contracted distorted red cells.

No satisfactory explanation for the production of Heinz bodies has been found hitherto in the spontaneous Heinz-body syndrome of the newborn. Gasser (1953) suggested that it might be due to a "disturbance of adaptation" ("Anpassungsstörung") of the erythropoiesis in premature infants, and left the question open of whether a fault in haemoglobin synthesis or in the mechanisms normally protecting the erythrocytes from damage or a dysfunction of the spleen is to be blamed. There is a high proportion of twin pregnancies among these cases of anaemia. Five out of Gasser's (1953) 14 premature infants and our first patient were twins.

It would appear that the unknown endogenous factor causes not only Heinz-body formation and disintegration of red cells but also a depression of the erythropoiesis at the time when the changes in the mature red cells in the periphery are the severest (Gasser, 1953). According to Gasser the jaundice is haemolytic and sometimes in part also hepatic in origin. The absence of jaundice in our Case 2 is not surprising in spite of the presence of a severe anaemia associated with morphological alterations of the red cells. Jaundice need not necessarily develop if the function of the liver is unimpaired and the erythropoiesis is depressed to a sufficient degree. Such is the case in the aplastic crisis of acholuric jaundice. It is doubtful whether in Case 2 the abscess of the buttock played any part in the causation of the Heinz-body anaemia; this possibility cannot be ruled out entirely, but is unlikely.

Summary and Conclusions

Two cases of spontaneous Heinz-body anaemia are described. One, a full-term twin of normal birth weight, had both haemolytic anaemia and jaundice. The other, a premature infant, had typical haematological findings, but no jaundice. Both responded well to a single transfusion.

The haematological findings are discussed.

In the differential diagnosis of jaundice in the newborn, Heinz-body anaemia should always be considered, especially if jaundice—not obstructive in character—develops after the first day of life, the Coombs test is negative, and no immune antibodies are present in the maternal serum. It would also appear that Heinz-body anaemia (Case 2) can be present without clinical jaundice: if marked anaemia develops in the premature infant during the second or third week and contracted irregularly crenated erythrocytes are found in the smears, Heinz bodies should be looked for. It is likely that, if these haematological criteria are systematically sought, more cases of this type of haemolytic anaemia will be recognized in the future.

Heinz-body anaemia of the newborn is not only of theoretical but also of considerable practical importance, as transfusions performed in time might save life.

We are indebted to Drs. R. R. Gordon and M. Middleton for permission to use the case notes, and to Mr. J. Bevington, senior technician, and the haematology staff for their assistance.

SOME OBSERVATIONS ON OUT-PATIENT PSYCHOTHERAPY WITH A FOLLOW-UP OF 235 CASES

BY

ROBERT BLAIR, M.D., D.P.M.

JOHN M. GILROY, M.B., D.P.M.

AND

FRANCIS PILKINGTON, M.B., F.R.C.P.
F.R.C.P.I., D.P.M.Consultants in Mental Health, Moorhaven Hospital,
Ivybridge, South Devon

In the minds of most doctors the results of psychotherapy are still clothed in a certain amount of mystery. Yet with the development of the Health Service and the consequent increase in out-patient work it is important to try to estimate the value of this type of treatment. Several questions immediately spring to mind. "Is psychotherapy any good at all?" And if the answer is "Yes," then "How good?" And again, "What sort of cases should it be reserved for?"

Few papers seem to have been written on this subject, and only two will be quoted, both of which are pre-war. In 1935 Luff and Garrod reviewed 500 consecutive patients treated with psychotherapy at the Tavistock Clinic, all of whom had finished treatment at least three years previously. This is a creditable follow-up period, and the patients had had thorough treatment; indeed, half of them had between 20 and 60 interviews. The follow-up was based on information obtained from replies to letters sent out to the patient or the patient's practitioner, though occasionally other methods were used, such as a visit from a psychiatric social worker. Yet it was possible to contact only 70.4%, and there must be serious limitations to the value of a follow-up where only two-thirds of the series were contacted by letter and no patient was personally interviewed by a psychiatrist.

The second paper we quote is by Curran (1937), who records a follow-up of 83 patients. The psychotherapy was carried out under poor conditions (in a dental room of all places) at St. George's Hospital. The only

criterion for selection in Curran's series was that the patients were thought to present psychiatric problems by one of the out-patient physicians or surgeons who referred them to the psychiatric department. These cases were all seen by Dr. Curran at their first interview, though subsequently some were treated by Dr. Eliot Slater. Only 25 of the 83 attended for more than four sessions. It is important to note that these 83 patients represented only 40% of the total circularized. Another 40% did not reply to follow-up inquiry, and the remaining 20% of inquiries were returned "addressee untraced." 40% is a very small percentage of any group to be followed up, and, as Curran says, few deductions are possible. As in Luff and Garrod's series, no patients were interviewed by a doctor.

Present Investigation

Our investigation differed from the two investigations quoted above in that we endeavoured to interview the patients personally. Early in 1954 we studied the case papers and psychotherapy notes of 235 out-patients who had been selected by us as suitable for a course of out-patient psychotherapy from a total of 3,226 out-patients referred to us in Plymouth during the five-year period 1948-52. It should be noted that these 235 patients represented the total number who had been selected for psychotherapy. Thus a few patients had been discharged for nearly six years, while all had been discharged at least 15 months. In about 35% the follow-up period was two and a half years or more. It may be observed at this point that the recovery rates of those patients treated in the earlier years did not vary significantly from the recovery rates of the more recently treated, and also that the percentage of untraced cases did not increase with the passage of time. For the collection of documents we relied on the records department, and there is no reason to suppose that many cases were omitted or that the odd ones left out represented special types.
