that the shoes were indeed modern ones. For some of the models the captions should have been "As worn in old Pekin," or "Hallux valgus guaranteed in three months and bunions in one year." Others again looked guaranteed to cripple in six months. I then realized that I was looking at "fashion shoes of high décor." My mind went back to the anatomy I had learnt and taught, and to the human feet I had seen.

What has happened to women's shoes? Many of the present models have little relationship to the anatomy or physiology of the normal human foot. They produce a self-conscious and stilted gait with hardly any normal movement at the ankle joint, and the slightest wearing of the pencil-point heels produces valgus or varus deformity or wobble of the whole foot during walking. Yet these shoes have become so fashionable that there is a demand that buses, escalators, and gratings should be modified to avoid danger. They must be extremely uncomfortable, since the royal parks in summer are filled with women resting their feet with their shoes by their sides.

There is, however, a practical problem involved. In a certain proportion of my patients I have to take some interest in the type of footwear which is being worn. Over the past few years it has become clear that many women are finding it more and more difficult to get reasonable walking shoes for normal feet. On inquiry I find that they have tried shop after shop without success. Some well-known firms seem to have given up the manufacture of ordinary walking shoes, and at one shop which was, in the past, celebrated for the quality, style, and normality of its shoes, a lady was recently informed that they now only sold high décor shoes and they advised her to go to an orthopaedic shoe-maker. Another lady, who had previously had no trouble at all in getting shoes, recently spent a whole day in London shoe-shops in a completely vain endeavour to get reasonable shoes.

My interest is not merely clinical. I spent the whole of my early life in a county celebrated for its boots and shoes and in a town whose manufacture of these has a world-wide reputation. I have visited many boot factories, I have known hundreds of clickers, finishers, closers, and men in the rough stuff room, and I know the quality of their workmanship. Even years ago, many of the firms took the greatest possible interest in the anatomy and physiology of the foot and made every endeavour to relate this to the design and quality of the footwear they produced. I wonder what the craftsmen think of some of the shoes that are now being produced? The explanation of the present position is that the fashions are entirely commercial. How far is this due to the altered financial structure of the boot and shoe industry? Children's shoes are very satisfactory, but they become more and more abnormal and commercial as the girl of teenage is approached. Many of the women who are wearing contemporary shoes get pain in the calf, oedema of the foot, hallux valgus, and fatigue, to say nothing of the more serious injuries, such as sprains and fractures. It has been estimated that 75% of girls leaving school have hallux valgus. These represent potential patients in the future. All these matters are related to the cost of the Health Service. If animals were treated with the degree of inhumanity to which women now are prepared to subject their feet at the behest of the boot manufacturers, there would be an outcry from all the humanitarian societies in the country. A young doctor, uncertain of the future, might do worse than take up the study of chiropody, for it will obviously be of increasing importance. Eventually he might become a consultant and serve on Government commissions, or an industrial adviser on feet, or he might turn to politics. Whichever course he finally chose, he would have valuable knowledge as to where the shoe really pinches.

As an immediate step, I suggest that the Minister of Health has a talk with the President of the Board of Trade. It might even be necessary to promulgate new sumptuary laws in connexion with women's footwear in order to save the tax-payer and the Treasury.—I am, etc.,

London, W.1.

REGINALD T. PAYNE.

Scapulo-thoracic Crackling in Youth

SIR,—Some time before the second world war, at the German Hospital in London, I was asked by one of the German house staff to see a young Englishwoman living in the neighbourhood of the hospital who had come to the out-patient department. On movement of the shoulder-blades a peculiar kind of crackling could be felt (not heard) over the region of the shoulders at the back of the thorax, apparently unaccompanied by any pain or even disagreeable sensation. This young woman was not in the least afraid nor wished to appear ill, but simply wanted to know the nature of her condition, and whether she ought to do anything about it. On examination the "crackling" seemed clearly to be due to some unusual unevenness of development between the scapulae and the bony cage of the thorax. It could hardly be called crepitous, and certainly there was no actual bony grating, such as may be due to exposed bony surfaces after a fracture. She seemed perfectly normal in every other respect. The chief questions in my mind were whether one was justified in assuming that the abnormality was "rheumatoid" in nature and if it varied at all with the weather. Was it likely to increase or diminish with the age of the patient? Such abnormalities were associated in my mind with changes commonly occurring in later life. One had heard the well-known lines in Dr. Edward Jenner's (the vaccination Jenner) famous poem on the signs of the weather:

"Hark how the chairs and tables crack;
Old Betty's joints are on the rack."

But there were no pains in this case, nor need there be any pain associated with obvious so-called osteoarthritic changes in later life. As a matter of fact, I need go no further than my own person in that regard. Sometimes, on movement of my neck during conversation, a loud crack can be heard, though I feel nothing whatever, and the sound only interrupts my talk. In this young woman, the crackling which one felt with one's hands on her shoulders was obviously of the same nature as crackling which can actually be heard, but I do not know of any other case of crackling like this in youth, or even in elderly people. Minor degrees, I believe, are not rare, though they have attracted very little attention.

On the whole, I thought it better not to advise any special treatment. The young woman was desirous of making a holiday tour in Germany, and, hearing this, the residents of the German Hospital invited her to tea in order to work out the best itinerary for her and her father. It happened that my wife and I met them on the cross-Channel steamer. She introduced us to her father. Her peculiar symptoms remained much the same, and I determined to bring her to a meeting of the clinical section of the Royal Society of Medicine. Mr. Duncan Fitzwilliams was then the president of the section, and I got him to examine her carefully. His commanding figure, great knowledge, and pleasant manner could certainly do no harm. With his hands on her shoulder-blades he said very seriously: "Ah, those are where the wings were amputated." The meeting was a very large one, but beyond this gallant remark I could get no other information worth mentioning. My case was quite rightly not reported in the published account of the meeting.

At the end of the second world war I ascertained by letter that the crackling was still present, apparently neither better nor worse. I now regard the case as a little-known abnormality of development, allied to other conditions, such as camptodactylia of Landouzy, often associated with varying degrees of Dupuytren's contraction of the palmar fascia. Such abnormalities may commence to show themselves as varying ages, often excited by local traumatism; then after reaching a certain stage they tend to remain stationary or regress. In middle age my father, my eldest sister, and myself suffered from a peculiar chronic tenderness about the metacarpo-phalangeal joint of both index fingers, which might have been thought to be of so-called

gouty nature, but in later life it completely disappeared without special treatment. In my own person the Dupuytren's patchy thickenings of the palmar fascia have practically disappeared, though of course the camptodactylia of the fourth and fifth fingers must be expected to remain. I am inclined to think that a congenital bent little finger, with slight webbing to the fourth finger, may be regarded as a non-progressive variety of Landouzy camptodactylia.—I am, etc.,

London, N.W.1.

F. PARKES WEBER.

Hospital Confinement

SIR,—Even although the antenatal period has been uneventful, the position of the foetus normal, and the mother in excellent condition, the actual labour is always an anxious time. Surely, then, it is best to deliver the mother in a maternity unit where all modern resources are immediately available should the need arise, and she should be delivered by the G.P.-obstetrician-midwife team who have supervised her antenatal care. In most cases all will go well, and after an hour or two's rest the mother and baby, accompanied by the midwife, could go home by ambulance. Nursing would be continued as in a domiciliary confinement. The labour would be conducted under ideal conditions, and going home so soon would lessen the risks of cross-infection. Such a scheme, already described in detail,¹ would require the closest co-operation between the G.P.-obstetrician, midwife, and consultant-obstetrician.—I am, etc.,

Bristol.

J. SLUGLETT.

SIR,—Dr. J. P. O'Dwyer states (*Journal*, April 20, p. 947) that "it is so much safer to have a baby in hospital than in the home." It would be interesting to have the facts on which he bases this statement.—I am, etc.,

Newcastle upon Tyne, 2.

FRANK STABLER.

Pulmonary Embolism Following Ear Operations

SIR,—I have recently had two patients who suffered from pulmonary embolism following clean operations on the ear. Neither patient showed any abnormality of the cardiovascular system before operation and a careful search did not reveal any sign of thrombosis in the extremities after operation. In both cases the operations were prolonged, one fenestration and one for bilateral removal of osteomata from the meatus.

In my experience pulmonary embolism is so rare after operations on the ear that I feel that these cases call for comment. I would be grateful for any information as to the experience of others in similar cases and particularly as to whether they were associated with the use of chlorpromazine or similar drugs.—I am, etc.,

Dublin.

V. O. MCCORMICK.

Budgerigars in Wards

SIR,—I should like to reply to Dr. N. A. Thorne (*Journal*, April 27, p. 1008), as one who keeps a variety of birds as a hobby. He makes reference to the danger of psittacosis. In spite of there being a rigid import ban on budgerigars, I personally am very concerned about the manner in which seamen can bring these birds into the country. I am not altogether satisfied that the regulations are observed. Fortunately the disease has not been known in this country for several years, but should it appear it would be extremely difficult to diagnose other than under the title of virus pneumonia.

Although the budgerigar is a most interesting and charming pet, it could be rather a nuisance to the patient who was very ill. Not only that: kept in cages, they are constantly moulting, and there is always a fine dust in and around the cages derived from feathers, skin, food, and excreta. This would adversely affect people allergic to dusts.

In my opinion these pets are not really suitable for general wards, but eminently desirable in outside aviaries where they could be seen from the wards or visited by the patients. I would like to recommend Bengalese or zebra finches as ward pets. They do not create a din; they are tight-feathered and very clean and healthy; they are constantly on the move and are extremely interesting.

I would conclude by stating that in my opinion some type of living creature, such as bird or fish, is very desirable in certain wards, relieving the somewhat drab background.—I am, etc.,

Dalry, Ayrshire.

ALEX. WATT.

Sexing Cells

SIR,—Since 1954 we have been sexing cells.¹⁻³ We have always done so in fresh, unfixed, unstained material—oral, genital, urinary epithelial cells, tumour surface scrapings, amniotic fluid sediment, etc.—observed with the phase-contrast microscope. The method is simple and very rapid.

FIG. 1.—Sex chromatin in epithelial cell of female urethra. FIG. 2.—Sex chromatin in epithelial cell of female urethral polyp ($\times 950$). FIG. 3.—Sex chromatin in cells of thyroid cancer (female) ($\times 950$).

Results are as reliable as those obtained with the observation of stained preparations. Counts of sex chromatin are based only on the presence of planoconvex masses in intimate contact with the inner surface of the nuclear membrane (see photomicrographs).—I am, etc.,

Santiago, Chile.

Thyroid Disorders in the Newborn

SIR,—The paper on thyroid disorders in the newborn by Drs. I. D. Riley and G. Sclare (*Journal*, April 27, p. 979) brought to my mind the case of a former patient of mine, aged 30 years, who in 1924 suffered from a large adenomatous goitre for which she refused any kind of treatment. On two occasions I delivered this woman of a male child; each was born with a well-marked goitre, but each was still-born. From the size of the goitre I believe there is little doubt that the cause of death in each case was respiratory obstruction from pressure by a nodular goitre. This observa-

tion appears to support the views held by Drs. Riley and Sclare, and by the other observers mentioned; furthermore, it strengthens the view that heredity and iodine deficiency are possible factors in the production of the condition. It is interesting to recall that I took a photograph of one of the stillborn children, which showed very clearly the outline of the goitre, and sent it to Sir Thomas Dunhill (then Mr. T. P. Dunhill), of St. Bartholomew's Hospital, who was greatly interested.—I am, etc.,

Cardiff.

T. STENNER EVANS.

Diagnostic Sign of Intussusception

SIR,—I thought that the following sign might be of aid in diagnosis of intussusception. It is one of the most difficult things to feel the lump in the abdomen at times. I would like to suggest that the child is turned in the knee and elbow position, and, as the abdominal wall is usually completely relaxed, the lump is usually felt, because it literally falls into the hand.—I am, etc.,

Dartford, Kent.

E. GANCZ.

Popular Delusion

SIR,—I first heard of the delusion described by Dr. Clifford Allen (*Journal*, April 6, p. 822) in barracks at Aldershot in 1939. A regular Army sergeant who had left his family in married quarters at Catterick one month before explained to me that the bromide took about this time to make its presence felt.

Later on I found that married men on sleeping-out pass did not have any complaints, and it was therefore deduced from this that the culprit was gunfire, or early-morning tea. My physiologist colleagues had explained to me before the war that if I cared to fast in a tub on Blackpool front I would not have any trouble with my appetite after the first 72 hours. I formed the opinion in the Army that, whatever the virtues of the celibate life, its difficulties after three or four weeks could well be exaggerated by anyone who had not been forced to lead it.—I am, etc.,

Dudley, Worcs.

L. H. G. MOORE.

Malignant Melanoma

SIR,—I would like, with your permission, to make the following comments concerning the paper, "Malignant Melanoma," by Sir Stanford Cade (*Journal*, January 19, p. 119).

Sir Stanford Cade states that "the most important recent contributions on the histogenesis and pathology of these tumours are those of Spitz^{1,2} (1948, 1951), A. C. Allen³ (1949), and Allen and Spitz⁴ (1953)" and that their studies reorientated the rationale of treatment. This, I believe, gives more credit to these authors than is their due, even though Allen, in 1954, produced a colossal work dealing in great detail with the subject.⁵ Traub,⁶⁻⁸ Montgomery,⁹⁻¹¹ Sachs and his colleagues¹² (who also quote unpublished notes by Satenstein), Becker,¹³⁻¹⁷ among others (who, unlike Allen and Spitz, are and were clinicians as well as histopathologists), are those mainly responsible for reorientating the rationale of treatment by their studies and findings both prior to and since the above dates. They were the first, to the best of my knowledge, to describe and draw attention to the fact that the junction and/or compound naevus were the only ones that could become malignant. They also were the first to draw attention to the fact that it was safe to perform a partial biopsy of a naevus provided a microscopical report was submitted and acted upon if necessary within 48 hours, preferably within 24 hours. This innovation has since saved many unnecessary mutilations for suspected "malignant melanomata."

They also drew attention to the fact that there was no reasonable proof that a single trauma or injury has ever initiated malignancy in a mole. I see that Sir Stanford Cade has come now to agree with this, since he states on page 122 that "there is no definite evidence, only a

presumption, that these interferences [such as local excision] with a pigmented lesion were actually the trigger action which transformed a benign lesion into a malignant melanoma."—I am, etc.,

Sydney, Australia.

Polyneuritis and Illness in Cats

SIR,—During the last two years I have had three cases of acute polyneuritis of the infective type with raised protein in the cerebrospinal fluid in which the onset of the disease was associated with an acute illness of a cat in the house of the patient. Veterinary surgeons had diagnosed the illness in the cats as "cat influenza." On one occasion the cat died, and on the other two occasions the cats recovered. The association may be entirely coincidental, but, in view of our inability to explain the aetiology of polyneuritis on many occasions, it is worth while considering the possibility that certain cases might be associated with disease in cats. If any other medical men have experience of this kind, I would be grateful to hear their views and to receive any data on any such case.—I am, etc.,

A. M. G. CAMPBELL.

Animal Experiments

SIR,—In an annotation (*Journal*, April 27, p. 999) you refer to Sir Henry Dale's lecture on behalf of the Research Defence Society, and state that "Sir Henry Dale . . . had given a devastating exposition of the untold suffering among men and women and children, to say nothing of domestic animals and pets, that the anti-vivisectionists would have inflicted if they had had their way." This is odd logic. As the anti-vivisectionists have never had their way, such a statement is beyond proof. Indeed, the human organism being what it is, neither Sir Henry nor anyone else could confidently give the name and address of one person upon whom increased suffering or death would have been inflicted in that contingency. I suspect that neither you nor he has much idea of what the "way" of the anti-vivisectionist is. Certainly it is not simply a question of dropping animal experimentation; and in any case the latter is far from being the only means of conducting research, and allopathy is not the only road to health. If vivisection had been ended 50 years ago, it is at least possible that the enormous resources of money, time, and energy thus freed and directed into other channels might have produced quite astonishing results. To deny that this is even possible would be a slight to the intelligence of the medical and allied professions. Apart from this, is it really a good thing that, whenever we are ill, we must "take" something? Modern medicine is riddled with what might be called the "disease-therapeutic complex." The anti-vivisectionist has a number of positive suggestions to make, and not the least among them is the sensible notion that health education should replace a good deal of therapeutics. Time was when the general practitioner was dependent on illness for his living, but it is now entirely in his interests to try to see that people stay well. He can therefore afford

to tell his patients, quite frankly, to smoke less, to drink less, to stop eating too much rubbish, to exercise more, and to behave generally on less pathogenic lines. He could then, perhaps, spare a little time to do battle against what may be called the social or corporate factors of a kind inimical to health.

I read Professor Miles's lecture¹ with much more interest and respect than I did that of Sir Henry Dale; but it is not correct to say that "he neatly turned the tables on the critics of animal experiments." It is obvious that many species have organs and functions related to those in man; but there are wide differences, and one can rarely argue with any confidence from one species to another, or even in some cases from one member of a species to another of the same kind. The kinship is based, not on a similarity of organ or function, but on the two facts that all have conscious life and all can suffer. The more religious would say that all come from God, and that therefore an offence against one of them, whether human or other, is a sin.—I am, etc.,

WILFRID TYLDESLEY,

Secretary,
British Union for the Abolition of Vivisection.

London, S.W.1.

Benactyzine

SIR.—We regret not having included in our paper (*Journal*, February 9, p. 306) the data necessary for the statistical calculation Dr. F. K. Taylor makes in his letter (*Journal*, April 27, p. 1006). The contrast between drug and control was increased by the rejection of four, and decreased by the rejection of two, of the six cases, which, to use Dr. Taylor's model, is equivalent to throwing four heads and two tails in six spins of a coin. P is therefore not 0.016 but 0.34, which is of much lower significance than any of the P values reported in the paper.—I am, etc.,

Leeds, 2.

G. R. HARGREAVES.

Prevention of Tetanus

SIR.—The present correspondence on tetanus and its prevention following the inquest at Hanley on two men who died from post-operative tetanus (*Journal*, April 13, p. 897) revives interest in the unsatisfactory measures employed for the sterilization of rubber gloves, which was discussed in a leading article two and a half years ago (*Journal*, January 15, 1955, p. 156).

The Report of the Central Pathology Committee of the Ministry of Health on the Sterilization of Hospital Equipment, issued in December, 1954, recommended that rubber gloves should first be boiled and then autoclaved at 5 lb. pressure for 30–40 minutes. Your leading article was critical of the details of the process, but you did not condemn the process itself, although you implied disapproval when you spoke of the intolerable position that "gloves, of all things used in an operation, should be of doubtful sterility." Trillwood¹ has recently discussed what happens when steam is admitted to a drum containing rubber gloves and has pointed out the crux of the matter—that rubber is impervious to steam. He concluded that "if surgeons' gloves are required to be sterile a method other than autoclaving is indicated."

Surely the time has come to consider whether the solution to this problem may not be a re-examination of surgical techniques. If rubber gloves cannot be sterilized by autoclaving, and if sterilization by chemical means is uncertain (there are additional dangers if rubber is in contact with phenolic solutions), then may not the only alternative be a change in surgical procedure? One could make several suggestions: (1) a no-touch technique, almost impossible in most types of surgery; (2) the use of dry "clean" gloves, washed with a detergent and finally rinsed in a long-acting antiseptic, or smeared with chlorhexidine cream (where this is not contraindicated, as it is in brain surgery); (3) if tetanus is the biggest risk, a careful search for its source in hospital and the immediate banning of such common offenders as talc and tow; (4) the prophylactic protection by tetanus toxoid of

all patients for operation, and not just those with accidental injuries as suggested by Dr. J. W. Myles (*Journal*, May 4, p. 1064).

There are of course many other facets to this problem, but these suggestions may provide a basis for a useful discussion.—I am, etc.,

Oxford.

Dimenhydrinate in Chicken-pox

SIR.—Dr. G. I. Watson, in his article on infectious diseases in general practice (*Journal*, January 5, p. 39), mentions the use of mepyramine maleate in chicken-pox. In January, 1956, while suffering from chicken-pox, the irritation drove me to trying antihistamines because of the reasonable theoretical proposition that the great irritation is due to release of histamine. The most effective proved to be dimenhydrinate 50 mg. twice a day with pentobarbitone 1½ gr. (97 mg.) in the morning. Mepyramine maleate 100 mg. alone made me sleepy and depressed. In August, 1956, I used dimenhydrinate 50 mg. with pentobarbitone ½ gr. (50 mg.) on 57 children between 2½ and 12 years old. There were ten children additionally who were siblings and also had chicken-pox; these were used as controls. The results were striking, because the treated children became quite happy and tractable. Further, because there was no cause for scratching, there was only one case of secondary infection of the pocks, yet other doctors in the same district were much troubled by secondary infection. Later, in another area of Sydney, it seemed that dimenhydrinate 50 mg. was sufficient for children up to 5. However, in the older children pentobarbitone did relieve them from worrying about their pocks. Since chicken-pox is a dangerous, a depressing, and a disfiguring disease, it should be worth while having several clinical trials in general practice.—I am, etc.,

Tasmania.

MICHAEL V. PERKINS.

Local Analgesia and Kielland's Forceps

SIR.—Drs. J. S. Scott and R. L. Gadd have made a very useful contribution to the art and technique of forceps delivery (*Journal*, April 27, p. 971). I read their paper on the use of local analgesia and Kielland's forceps with great interest, but was surprised to find myself quoted as giving 70 lb. (31.8 kg.) as the critical level of traction force.¹ When I looked over my old paper I was even more surprised to find I had been quoted correctly, for I had forgotten my first efforts to find some guide to the safety of traction force.

The figure of 70 lb. (31.8 kg.) was based on theoretical considerations and some experimental work which was not very convincing. Over the years I have acquired a considerable experience of measured traction force, but I still do not know the level of critical traction. It probably varies from foetus to foetus, and a fixed figure is extremely unlikely. I have found that a force of 100 lb. (45.4 kg.) may be used with safety provided the foetus is at term, the blades of the forceps applied along the cheeks or mento-vertical diameter of the fully flexed head, and traction force applied slowly through a spring handle. I have little experience and no data relating to forceps delivery of premature infants. The excessively moulded head of the term foetus may not withstand the same compression force as the unmoulded head, and I have always assumed that the compression force is proportionate to the traction force and is supplied by the resistance of the maternal tissues. To commit oneself to the forceps operation when the head is at the mid-cavity station or higher, without due consideration of all the factors involved, is to court disaster, and, it seems to me, no rule of thumb can ever replace obstetrical judgment and the technical skill which come with experience.

Anyone who has used a recording instrument for the obstetrical forceps operation must have been rather shocked at the ease with which the magnitude of the traction force

can be raised, and alarmed at the effects such force might have on the foetal brain. Seated on a sterilizing drum 10 in. (25 cm.) high, and pulling with one hand, 100 lb. (45.4 kg.) is the maximum force which I can exert with the Milne-Murray axis-traction instrument. A powerfully built man may exert a much greater force under the same conditions. Infants delivered with a force of this magnitude have been examined at intervals up to 10 years of age, and nothing has been found to suggest that such force has been harmful.

The great majority of these difficult forceps cases were due to contraction at the pelvic outlet. The rickety flat pelvis which was common in this locality 20 years ago has gradually been replaced by a type of contraction more difficult to detect because more often it involves the outlet. This preponderance of outlet contraction has been confirmed by x-ray pelvimetry. About 30% of the women admitted to this hospital are under 5 ft. (1.5 m.) in height, and many of these have some degree of outlet contraction. In the past we usually allowed trial of labour in this group and had little trouble when the foetus was no more than 6½ lb. (3 kg.). Not infrequently, however, when the foetus was larger, we were faced with the unhappy choice of delivery by caesarean section after the head had become deeply engaged, or by a difficult forceps operation. In recent years we have been inducing labour more often in this group, and the difficult forceps delivery has become something of a rarity.

When dealing with persistent occipito-posterior and deep transverse arrest positions, I have always preferred manual rotation followed by application of the Milne-Murray instrument. My objections to Kielland's instrument include the difficulty of accurate application of the blades along the cheeks and the greater traction force apparently required to effect delivery. This latter is merely an impression, but it has seemed to me that infants delivered with Kielland's forceps show more bruising due to the impress of the blades. I have a device which allows attachment of a spring recording handle to the Kielland's instrument, but have collected no useful data. Scott and Gadd are on rather thin ice when they argue traction force on the basis of one case of brow presentation. From the position of the head in their illustration delivery would be effected by the movement of flexion alone, and if more than slight traction force had been required after complete flexion was reached the blades would probably have slipped. Moreover, the head must have been small to rotate from the brow to the vertex position when so low in the pelvis. This movement of the head between the blades was probably due to the fact that the blades were not designed for application to the short arm of the head lever in the biparietal diameter, and the authors were fortunate to deliver so easily, for this application is dangerous. Some years ago I produced an indented fracture with a somewhat similar application and I have been careful to avoid it ever since. Movement of the head between the blades properly applied to a vertex presentation occurs for very different reasons and is disturbing because it presages slipping of the blades. I attempted to demonstrate these reasons some time ago.² However, there can be little doubt that in the hands of competent operators different types of obstetrical forceps produce equally good results.

During the war years we began to use local analgesia for the forceps operation in the Rankin Memorial Hospital. We have gradually increased this practice, and in recent years we have been performing over 90% of these operations using no other analgesia or anaesthetic. This has required a variation in technique which has developed along much the same lines as those described by Scott and Gadd, although we deliver face to pubis when this can be easily accomplished—a technique which at one time we regarded with some suspicion and generally avoided. In all cases we perform a generous episiotomy before applying the blades.—I am, etc.,

Greenock.

SIR.—Our experience at Perivale Maternity Hospital fully confirms that of Drs. J. S. Scott and R. L. Gadd (*Journal*, April 27, p. 971) regarding the safety and efficiency of local analgesia combined with the use of Kielland's forceps. Two hundred and twenty-three of the last 231 forceps extractions were done using local analgesia alone. Of these, 184 were simple outlet extractions, 23 were forceps rotations and extractions for deep transverse arrest, and 16 a similar

manœuvre for persistent occipito-posterior position. Ninety-seven per cent. of all forceps extractions were done using local analgesia.

Of the eight cases requiring general anaesthesia, four were extremely agitated mothers who would probably have responded well to the supplementary sedation suggested. Otherwise trichlorethylene self-administered with the "emotril" or "cyprane" inhaler has been adequate here. Three were delivered by temporary residents not practised in the technique. One was a compound presentation requiring much intravaginal manipulation. A straight sacrum is almost the only common pelvic abnormality in this area. This may explain our higher percentage of delivery under local analgesia alone.

We found that the technique of injection as described by Gate and Dutton¹ was effective but complicated by formation of paravaginal haematomata in a fair number of cases. Latterly we have had excellent results by the simple injection transvaginally around the pudendal nerve of 10 ml. 1% lignocaine on each side, using a technique similar to that described by Wilds.² Only two injections are required in all.—We are, etc.,

A Verbal Shock

SIR.—The English in the *British Medical Journal* is usually exemplary, witness your insistence on the correct spelling of "disk" and "connexion," and therefore any lapse comes as a shock. In your annotation on the M.R.C. report on emmetropia (*Journal*, April 27, p. 1000), the last word (if it may be called such) is "emmetropization." I hope that this is indeed the last appearance of this word. Such neologizations should be blue-pencilled.—I am, etc.,

Liverpool, 1.

JOHN MATTHEWS.

Congenital Ring Constrictions

SIR.—I am at present working on a hypothesis of the cause of congenital ring constrictions of the limbs and body. I should be most grateful if anyone who is in attendance at the birth of a child with this condition would send the placenta and membranes in a jar containing 10% formal saline to the morbid anatomy department, the Hospital for Sick Children, Great Ormond Street, London, W.C.1. Any expenses incurred will be paid with thanks.

I should also like to hear from anyone who has seen one of these congenital constrictions round the trunk, or any part of the body excluding the limbs.—I am, etc.,

London, W.1.

DENIS BROWNE.

Post-maturity

SIR.—The article by Professor F. J. Browne on foetal post-maturity and prolongation of pregnancy (*Journal*, April 13, p. 851) draws attention once again to the divergence of opinion in relation to post-maturity. There is one aspect of the subject which does not appear to be covered by his article, so you will perhaps excuse me if I draw attention to it.

In my experience post-maturity is only of serious obstetric significance if it occurs in association with what De Lee aptly termed the "dystocia dystrophica syndrome."¹ In this syndrome we find stocky, obese women, who are often about 5 ft. (1.5 m.) in height, with short thighs, broad shoulders, and a short thick neck. It is said that these women exhibit certain well-marked and unfavourable clinical features. First, the cervix is small and the vagina narrow and rigid. Secondly, there is a far greater tendency to pre-eclampsia. Thirdly, pregnancy commonly continues for a week or more beyond full term. Fourthly, primary uterine inertia, slow dilatation of the cervix, and early rupture of the membranes

are frequent. Fifthly, interference with the placental circulation by utero-foetal pressure follows. Sixthly, there is a high incidence of uterine sepsis. Lastly, these patients commonly exhibit the so-called android pelvis of Caldwell and Moloy.³

Some years ago, Miss Meave Kenny⁴ wrote an interesting paper on the x-ray findings in 1,000 suspect pelves, which she had collected from some 10,000 consecutive pregnancies at the British Postgraduate Hospital, Hammersmith. Among these 1,000 suspect pelves were some 450 pelves with android features in the hind pelvis. The outcome was as follows (there is some reduplication): caesarean section, 115; mid-forceps delivery, 176; low-forceps delivery, 69; occipito-posteriors, 67; deep transverse arrest, 50. But that is not the whole sad story. Speaking from memory she found an incidence of both pre-eclamptic toxæmia and of puerperal infection, which was six to nine times that of the patients who had not android pelves. And the incidence of puerperal infection was not necessarily related to interference. Mal-presentations occurred in 25% of cases.

What is even more interesting is to note that, in the seven cases of post-maturity from hospital F, quoted by Professor Browne, five had conditions that one associates with android pelves—deep transverse arrest of the head, transverse lie, accidental haemorrhage, toxæmia of pregnancy, and, lastly, a case of intrauterine sepsis.

Every stillbirth is a complicated problem in detection. It may be due to faults in the powers, passages, or passenger—not forgetting diseases affecting the mother and the child. I, for one, am not in the least convinced by Dr. Walker's work in Aberdeen.⁴ I cannot recall a single stillbirth or intrauterine death which might have been the result of post-maturity where there was not some complicating factor such as one associates with the dystocia dystrophica syndrome.—I am, etc.,

Praa Sands, Cornwall.

Smoking and Lung Cancer

SIR.—It is known that the ash of cigarettes contains on the average the following inorganic substances: 29.1% K, 3.2% Na, 36% Ca, 7.4% Mg, traces of Rb, etc.¹ In all potassium there is 0.012% of the radioactive isotope ⁴⁰K. The half-life of this isotope is 1.3×10^{10} years, the beta energy has the maximum value of 1.36 MeV and the gamma energy is of the order of 1.5 MeV. In total rubidium there is 27.2% of the radioactive isotope ⁸⁷Rb. The half-life of this isotope is 6×10^{10} years, the electron energy has the maximum value of 0.13 MeV, and the gamma energy is of the order of 0.13 MeV.² It has been shown that the exposure of living tissues to long-life radioactive isotopes may initiate the onset of a malignant neoplasm.

Mulvany³ filled a geiger counter (M₀) with cigarette or cigar ash and found a radioactivity varying from 70 to 170 counts per minute against a normal background of 12, and concluded from this: "There would appear to be no doubt that radioactive particles are actually deposited in the bronchial tree; and, absorption here being very slow, these tissues must be continually subjected to bombardment by active beta particles. This fact would seem to support the statistical evidence linking inhalation of cigarette smoke with carcinoma of the lung by heavy smokers."

I have tested the cigarette ash of Greek and Virginia tobacco for radioactivity with a similar geiger counter shielded by 2 in. (5 cm.) of lead (lead castle). I filled this M₀ tube with the ash of 10 cigarettes and found a reading varying from 80 to 126 counts per minute against a background count of 10 ± 1 (the variation depended on the particular type of cigarettes examined). I therefore agree with the above measurements of Mulvany, but, at the same time, I think that the existence of radioactivity in the cigarette ash

is not sufficient to prove that there is any relation between this radioactivity and the lung carcinoma.

I think that before any significance can be attributed to the radioactivity of inhaled cigarette smoke as a factor in the aetiology of lung cancer, it must be demonstrated that the radioactive isotopes ⁴⁰K and ⁸⁷Rb are inhaled as an aerosol and deposited in the bronchial mucous membrane. I therefore decided to find out whether the radioactive isotopes ⁴⁰K and ⁸⁷Rb were present in the water of a wash-bottle after cigarette smoke had been passed through it. The velocity at which the smoke entered the bottle was about the same as in natural smoking. The radioactivity of 10 ml. of the water from the washbottle after the artificial smoking of 100 Greek cigarettes (total quantity of water in the washbottle being 20 ml.) was 10 ± 1 counts per minute against a background count of 8 ± 1 ; in other words this was really 2 ± 1 counts per minute, and equivalent to the radioactivity of the water of Athens.

I also examined the radioactivity of 10 ml. of water from a narghile (total quantity 100 ml.) after passing the smoke from a coarse Persian tobacco through it. There were 10 ± 1 counts per minute against a background of 9 ± 1 (almost the same as the radioactivity of water of Athens). That I did not find more radioactivity in the water of the washbottles after artificial smoking than in the water of Athens shows that the radioactive isotopes ⁴⁰K and ⁸⁷Rb cannot be deposited in any form in the bronchial mucous membrane. Therefore I think that it is improbable that the radioactivity of cigarette smoke is an aetiological factor in bronchial cancer.

I wish to thank Assistant Professor Ninis for providing the facilities for the experiments.—I am, etc.,

Athens, Greece.

Mental Performance in Chronic Anoxia

SIR.—With reference to the article on mental performance in chronic anoxia by Dr. Raymond Greene (*Journal*, May 4, p. 1028), during some twenty years of medical practice I have frequently encountered serious mental deterioration in men of good social and professional standing. All of them had two things in common: they suffered from considerable reduction in the alveolar capacity of their lungs for several decades; and they were in their 50's when deterioration became very obvious. Some had been gassed during the first world war, others had suffered from extensive pulmonary abscesses during the second and third decade of their lives, or smoked over 60 cigarettes per day. They all lost the greater part of their livelihood, as they became cantankerous, erratic, and offended consistently against the code of conduct in their social setting.—I am, etc.,

London, S.W.3.

E. F. BLUMBERG.

Transfusion Service

SIR.—Recently I have been greatly disturbed by the serious shortage of blood which is available for blood transfusion purposes. On more than one occasion I have been obliged to contact other hospitals in the region in order to ascertain whether they were in a position to supply us with one or two pints of blood when we have had seriously ill patients and the blood bank has been depleted. I am wondering whether other hospitals have experienced a similar shortage and whether this is a particular problem of the S.E. Region. If so, the time should seem ripe for an appeal to the public for more blood donors.—I am, etc.,

London, S.E.5.

T. KRAFT.

Obituary

G. A. AUDEN, M.D., Ph.D., F.R.C.P., D.P.H.

Dr. G. A. Auden, school medical officer to the City of Birmingham from 1908 to 1937 and a former professor of public health in the University of Birmingham, died at Repton on May 3, aged 84.

George Augustus Auden was born on August 27, 1872, the son of the Rev. John Auden, of Burton-on-Trent. From Repton he won a scholarship to Christ's College, Cambridge, where he was Porteus gold medallist and took first-class honours in the natural sciences tripos. For his clinical training he went to St. Bartholomew's Hospital, where he won the Kirkes and Lawrence scholarships and gold medals. Qualifying in 1896, he graduated M.B., B.Chir. in the following year, proceeded to the M.D. in 1900, and took the M.R.C.P. in 1909 and the D.P.H. in 1910. After qualification he held resident appointments at Bart's and became resident medical officer and physician to out-patients at the General Lying-in Hospital. In 1898 he moved to York, and was appointed physician to the York County Hospital, where he developed his interest in the care of sick children. He also took part in the public life of the city, serving on the education committee, and consequently, when he went to Birmingham in 1908, he well knew of the need for the school medical service and of the increasingly important part it would play in the work of education authorities. All through his professional life he was particularly interested in the psychological problems of children, including those resulting from infections such as encephalitis, and he was appointed to the staff of the Birmingham Children's Hospital as honorary psychologist. During the first world war he served in the R.A.M.C. in Egypt, Gallipoli, and France, and on his return to Birmingham he was elected F.R.C.P., an unusual honour for a whole-time school medical officer. For many years he was lecturer in public health in the University of Birmingham, and in 1940, some years after his retirement from the post of school medical officer, he was appointed professor of public health. He was also sanitary adviser to the governors of Rugby School.

A scholar all his life, Dr. Auden had a European reputation as an expert on early Scandinavian history. He was a foreign member of the Society of Northern Antiquaries of Copenhagen, and he translated into English the guide to the prehistoric collection of the National Museum at Copenhagen as well as F. Rathgen's monograph on *The Preservation of Antiquities*.

Dr. Auden married Miss Constance Rosalie Bicknell in 1899 and had three children. One of his sons is W. H. Auden, professor of poetry in the University of Oxford.

Dr. MALCOLM ALLAN writes: I first met Dr. Auden when he returned to Repton in 1949. He had previously resided in the Lake District, but the call of his early associations in Horninglow, Burton-on-Trent, and of his old school, Repton, was a combination too strong for even him to resist, and so he returned to spend the last years of his already crowded life in the village. If anyone assumed he came to rest from his labours they were quickly disillusioned. His was a strictly disciplined life, and his day was methodically apportioned, beginning at 6 a.m. with breakfast, and as I regularly passed his home at 8 a.m. he was always seated at his desk. He kept up a most voluminous correspondence with friends, medical and lay, all written in his own hand, and it distressed him so much when he had perforce to employ an amanuensis. At the suggestion of the vicar he wrote a series of more than a dozen articles for the parish magazine on the history of Repton from before the ice-age up to recent times. Such a series involved much research and labour, but how he enjoyed it! Naturally he continued his long and keen interest

in archaeology by his studies of ancient camps on Askew Hill, St. Joseph's Well, and earth mounds by the River Trent. Another task was to keep a lengthy list of old Reptonians carefully annotated and up to date.

A heart attack about two years ago shook him badly and for long we despaired of his recovery, but his robust constitution and his determination asserted themselves. Can it be said of any other similar versatile scholar that he was also a craftsman? It amazed me when he said that nearly all the furniture in his room had been made by himself, including the bed he slept on. Just behind the door of his room was a carved wooden screen, and on it an inscription in Greek which being translated read, "Live as on a mountain." Naturally his conversation was mostly of interests in the past, but until very recently he kept himself abreast of advances in medicine, especially in public health, and had very decided views on the recent negotiations with the Minister of Health.

Gone now from our village streets is the old familiar slight figure with his most faithful of companions, his dog "Biddy," but his comparatively short time amongst us has made a deep impression, and his zest and enthusiasm for life have been a great inspiration, especially as he struggled manfully with his failing physical and mental powers. The final lines of Tennyson's *Ulysses* might well have been written about him:

"One equal temper of heroic hearts,
Made weak by time and fate, but strong in will,
To strive, to seek, to find, and not to yield."

Dr. A. A. E. NEWTH writes: At the beginning of the century there were several doctors of outstanding calibre who foresaw a great future for the school medical service—George Newman, Ralph Crowley, James Kerr, and Ralph Williams—and Auden was one of them. He undertook the pioneer work in Birmingham in 1908 with enthusiasm, and quickly established such a reputation that school medical officers throughout the country thinking of starting some new scheme went to Birmingham to see what he was doing there. Auden had had a brilliant academic career, and his profound knowledge of medicine backed by a close attention to detail was the secret of his success. For instance, at his residential school for rheumatic children at Baskerville he had the children dressed in different-coloured shirts or jerseys according to their stages of convalescence, so that the lay staff could be under no misunderstanding as to what physical activities were allowable, and when he started a school for partially sighted children he personally rooted round the second-hand book shops of Birmingham to pick up church bibles and other books with large type, as at that time specially printed educational books for the partially sighted were unobtainable. Auden was one of the first to realize the importance of child guidance, and the Birmingham clinic was one of the earliest outside London; but he was no believer in the vocational guidance on psychological lines which was attracting so much attention at one time. His knowledge of psychiatry was wide, and he contributed many authoritative articles to the *Journal of Mental Science*. His familiarity with the classics enabled him to write with authority on the history of medicine, and his paper on "The Madness of Ajax, as Conceived by Sophocles, Clinically Considered," written in 1926, was a masterly treatise. He was a great man of very considerable charm, and one is proud but at the same time humbled to have had the privilege of knowing him.

BERNARD MYERS, C.M.G., M.D., F.R.C.P.

Dr. Bernard Myers, consulting physician to the Royal Waterloo Hospital, died at his home in London on May 9. He was 85 years of age.

Bernard Ehrenfried Myers was born at Thames, Auckland, New Zealand, in 1872, and was educated at Wellington College and at Auckland Grammar School. On leaving school he studied chemistry at University College, Auckland, and

became analyst to the family brewery. In 1894 he decided to study medicine in Britain, and spent three years at Edinburgh University before going on to St. Bartholomew's Hospital for his clinical training. He took the London Conjoint diploma and the Edinburgh degrees of M.B., C.M. in 1898, and two years later he proceeded to the M.D., with commendation. Becoming a Member of the Royal College of Physicians of London in 1912, he was elected to the Fellowship in 1933. After graduation Myers held the appointment of junior house-physician to Sir Dyce Duckworth at St. Bartholomew's Hospital, and then became clinical assistant at the Coombe Hospital for Women, Dublin. He obtained the Dublin L.M. in 1899. After a trip to New Zealand and back as a ship surgeon, he settled in practice in London, becoming a well-known consultant physician in children's diseases, and a popular member of the staff of the Royal Waterloo Hospital for Women and Children. He wrote a number of papers on infant feeding and was the author of a *Practical Handbook of Diseases of Children*. In 1915, during the first world war, he was appointed officer commanding the 2nd New Zealand General Hospital at Walton-on-Thames, with the rank of lieutenant-colonel, and in 1918-19 he was A.D.M.S. of the New Zealand Expeditionary Force in the United Kingdom, with headquarters in London. For his war services he was appointed C.M.G. in 1917.

From 1932 to 1934 Myers was president of the Clinical Section of the Royal Society of Medicine, and he was president of the West London Medico-Chirurgical Society in 1935, the year in which he attended the New Zealand Biennial Conference as the delegate of the British Medical Association. Keenly interested in the work of the Red Cross, in 1937 he became commissioner of the New Zealand Red Cross Society in the United Kingdom, and two years later commissioner to the Joint Council of the Order of St. John and the New Zealand Red Cross Society. He was also a consultant physician to the New Zealand Government in London. During the second world war he represented New Zealand on the technical advisory committee on medical supplies and services of the Allied Post-war Requirements Bureau. Dr. Myers was a widower, and is survived by three daughters.

J.L.C. writes: "Bernie," as Myers was affectionately called by his friends, was noted for his kindness and geniality. He had a quiet and gentle manner, but when questions of high principle arose it was swiftly apparent that he was also made of very stern moral fibre. Another facet of his character was his intense loyalty to his country and the Crown, and he placed himself entirely at their disposal whenever occasion demanded. He was very fond of his work as a paediatrician, and his writings show an extraordinary depth of knowledge of his specialty. In dealing with children he showed a vast clinical wisdom as well as skill in handling them. He was greatly esteemed by colleagues and nursing staff. A lovable character, he was courteous and considerate, and for these qualities he will long be remembered. He died after a short illness, having enjoyed several years of retirement. Our sympathy goes out to his three daughters.

E. St. J. WHITEHOUSE, M.B.E., M.R.C.S., L.R.C.P.

Dr. E. St. J. Whitehouse, a well-known general practitioner at Solihull, Warwickshire, died peacefully at his home on April 18. He was in his 90th year and had practised in Solihull for 62 years. The late Bishop Chavasse of Liverpool was his uncle, and Dr. Noel Chavasse, the double V.C. of the first world war, was his cousin.

Born at Sedgley, Staffordshire, on October 30, 1867, Edwin St. John Whitehouse graduated from St. John's College, Cambridge, and received his medical training at Mason's College, Birmingham. He qualified M.R.C.S., L.R.C.P. in

1893 and then became house-surgeon to his uncle, Sir Thomas Chavasse, at the General Hospital, Birmingham. Later he was appointed resident surgical officer and resident medical officer at the Children's Hospital. In 1895 Dr. Whitehouse became a partner of Dr. A. V. Bernays, who had been practising in Solihull for over ten years: the practice flourished to such an extent that at the time of his death Dr. Whitehouse was head of a partnership of nine general practitioners. He was appointed medical officer to the old fever hospital and smallpox hospital at Sheldon and was instrumental in the building of the new Catherine de Barnes Fever Hospital. Before the first world war he organized and became the first doctor to attend the Solihull welfare centre, and later, together with other trustees, bought and equipped the first Solihull maternity home. He did the work of three general practitioners during the first world war and also found time to look after 150 wounded soldiers housed at the Hermitage. For this work he was appointed M.B.E. in 1920. During the second world war, in spite of advancing years, he worked as hard as ever and was in command of the medical section of the local civil defence organization.

He belonged to the old school of doctors, and besides being an excellent physician he had a wide knowledge of law and a deep sense of religion. Always very interested in the younger generation, he was a member and, later, chairman of the board of governors of Solihull School; subsequently he became chairman also of Malvern Hall School for Girls (now the Solihull High School). Whatever he undertook, whether in the hospital, in the committee room, or in the countryside, he did with all his considerable might, and neither at work nor at play did he allow matters to drift. A man of wide interests, he had a good singing voice and was excellent at games and field sports. He had been a first-class golfer and a keen fisherman, and with his keen sense of humour he brought a boyish enthusiasm into everything he did which made him a delightful companion and friend. His passing reduces the ranks of the great characters in medicine who have upheld professional traditions in present-day circumstances. He was a power of strength to all, ever ready to help anyone in trouble. He will be sadly missed by all those to whom he was doctor, friend, and counsellor.—P. Q.

D. J. THOMAS, M.R.C.S., L.R.C.P., D.P.H.

Dr. D. J. Thomas, who died at Salisbury on May 4 in his 85th year, was for more than 30 years medical officer of health for Acton.

David Jones Thomas qualified M.R.C.S., L.R.C.P. from the London Hospital in 1899, and, after acting as house-surgeon to Sir Frederick Treves, took the D.P.H. of the English Royal Colleges in 1900 and was appointed medical officer of health at Merthyr Tydfil. In those days there was more drama in public-health work: outbreaks of smallpox and typhoid fever were commonplace, and Dr. Thomas even had to combat an epidemic of typhus. In 1907 he was appointed medical officer of health for Acton, and held the appointment until 1940. During these years he saw great changes not only in the physical appearance of the town but in the whole structure of the preventive-medical services, which he himself did so much to develop. He was one of the pioneers who popularized diphtheria immunization and published several papers on the subject.

Dr. Thomas was born at Newcastle Emlyn, Carmarthenshire, on October 4, 1872, and will be remembered as an intensely patriotic Welshman, as a man of deep religious convictions, and as a distinguished freemason. His life was one of hard work and unselfishness. His hobby was the study of early parochial registers. He married Gwladys Roberts, the Welsh singer, and devoted himself to caring for her during her long illness until her death last year. They had four children, two of whom are doctors.

Medical Notes in Parliament

HEALTH SERVICE CONTRIBUTIONS

The National Health Service Contributions Bill, which was read a second time on May 8 by 303 votes to 230, sets up a separate Health Service contribution (as distinct from the existing system in which this forms part of the National Insurance contribution) and approximately doubles the rate of payment.

The proportion of the cost of the Health Service financed by direct contribution is also increased. Mr. DENNIS VOSPER, Minister of Health, moving the second reading, said that although much of the increase in the total cost of the Health Service (from about £450m. in 1949-50 to an estimated £690m. this year) was due to higher earnings and prices, there had been a substantial increase in real terms. The estimate of £690m., when adjusted to changes in the consumer price index since 1949-50, became £515m.—an increase of about 15%. Of the estimated current cost of £690m. about £550m. would have fallen on the Exchequer, compared with £345m. in 1949-50. This was about 80% compared with the 72% estimated when the original calculations were made in 1946. The Government had therefore decided that this heavy and growing burden was more than the taxpayer could reasonably be expected to bear.

No service could be allowed to impose a completely unlimited annual charge on the Exchequer. It would have been possible to reduce the scope of the Service or to impose further charges on patients. Rather than do this, they had decided that the proper course was to increase the direct contribution in accordance with the rise in earnings and costs. It was better that people should be asked to contribute when well towards the cost of the burden when they were sick. Further, the share of the total cost met from the existing Health Service contribution was now far less than was ever contemplated. When the original Health Service Bill was before Parliament it was expected that the contribution from the Insurance Fund would pay about 20% of the gross cost of the Service. In 1956-7 it provided approximately 6% only; the contribution had remained unchanged at approximately £40m. a year over the past ten years. When the new rates came into force they would be providing only 11½% of the total cost—considerably less than the 20% originally estimated before the Service started. Average earnings to-day were about twice what they were in 1946.

Misunderstanding

The opportunity was also being taken to remove the frequent misunderstanding that all, or none, of the Health Service was financed by weekly contributions. When this Bill was law about three-quarters of the cost would still be found by the taxpayer, and the remainder from contributions, charges, and rates. A single stamp would continue to be used, but on each stamp there would be overprinted the rate of the Health Service contribution. When a new stamp design was introduced words would be incorporated to make it clear that there were separate insurance and health contributions. The same criteria for liability had been adopted as applied to the existing weekly payments—whenever the National Insurance contribution was paid a Health Service contribution would also be collected. The existing Health Service elements were—for a man 10d., a woman 8d., and a juvenile 6d.; for employed persons 1½d. of this was payable by the employer. The new rates were to be man 1s. 8d., woman 1s. 4d., juvenile 1s., with 3½d. of these amounts payable by the employer. Altogether the increased contributions would provide roughly £80m. a year, compared with the present £40m.

Regressive Poll Tax

Miss MARGARET HERBISON (Lanarkshire, North, Lab.) expressed the Opposition's dissent from these proposals, which they regarded as a regressive poll tax. This increased

contribution was only one of many similar actions by the Government, including school meals, welfare foods, and food subsidies, which taken altogether might well mean that families of lower-paid workers would suffer in health because of the resulting lower standard of living, and thus put an additional cost on the Health Service. If the increase in the population and the increase in the number of aged people were taken into account the rise of cost in real terms would be seen to be much lower than the figures the Minister had given.

Dr. DICKSON MABON (Greenock, Lab.) looked forward to the day when there would be no contributory element in the Health Service. Such a contributory principle was all wrong. Socialized medicine rested its case entirely on the concept that the country provided the money according to its ability, and that people in need could go to the Service and obtain it without immediate cost.

Dr. DONALD JOHNSON (Carlisle, Con.) regarded the Bill as a necessity, if a disagreeable one. The effect of making people pay more, and in more direct fashion, for the Health Service would, he hoped, lead to an increasing interest and informed opinion about economies in the Service. General practitioners' surgeries were no longer filled with instruments of healing but were places with files, "in" trays and "out" trays containing specialists' letters from hospitals. The B.M.A. had pointed out that practitioners were complaining that there was a tendency for hospitals to retain unnecessarily patients sent to them for consultation. This was one of the mysteries of the Health Service. Why busy hospitals wished to take on more and more work when they were already stretched to capacity he did not know. Perhaps the most difficult and intractable item in rising costs was drugs. There was undoubtedly an advertising pressure on the general practitioner, which tended inevitably to replace his naturally acquired skill in prescribing and in using what he learned as a student. The problem he thought arose in the medical schools, in the lack of pharmaceutical training.

Mr. JAMES GRIFFITHS (Llanelly, Lab.), in the final Opposition speech, hinted that there might be a case for the State manufacturing drugs, and expressed the Labour Party suspicions that the Government did not merely seek to get £40m. from contributors, but really wanted to establish the Health Service as a contributory system. One of these days there would be an award on doctors' salaries which would probably increase the cost of the Service substantially. Was that to be paid for by the taxpayer, through the Exchequer, or by an increased contribution?

Radio-strontium and Tumours

Dr. BARNET STROSS (Stoke-on-Trent, Central, Lab.) asked the Prime Minister on May 7 about the possibility that there might be no threshold dose for radio-strontium, and that tests of nuclear weapons might already be responsible for some 50,000 cases of bone tumour in the future, and if he would therefore postpone the proposed British tests.

Mr. R. A. BUTLER, Home Secretary and Lord Privy Seal, who replied, said he assumed that Dr. Stross had in mind certain statements in a report recently published by the Atomic Scientists' Association. He would draw his attention to the very careful reservations made by the authors of this report. They stated that, apart from the considerable margin of error due to lack of adequate data, the estimates were based on the as yet unproved hypothesis of a proportional relationship applying to very small doses; from this point of view they represented the most pessimistic approach. He was informed that the estimates made in this report from the Atomic Scientists' Association were interpretations of factual evidence which was available last year to the Medical Research Council's special committee, but that the latter did not consider it an adequate basis to justify their making such calculations. In these circumstances the Government were not prepared to postpone the proposed tests.

Dr. STROSS said that while there was some doubt the benefit of it must be given to posterity. They had no right to be optimistic about this. The only possible approach was by pessimism. Mr. H. GAITSKELL (Leeds, South, Lab.) suggested that in view of the time that had elapsed since the M.R.C. report, and the statements since made by scientists in various countries, the Council could be asked for a further report to bring the matter up to date. Mr. BUTLER said he was ready to do that, and would discuss it with the Prime Minister, but no relevant new fact had become available, so far as the Government were aware, since that report was published.

Bomb Tests

In the House of Lords on the same day Viscount THURSO asked how many hydrogen bombs had been exploded by Russia and the United States during 1956, and so far this year; the sites of the explosions; the approximate number of people living within 750,000 square miles of them; whether the Government's attention had been drawn to the estimate by the American scientist, Dr. Linus Pauling, that if the British bomb was exploded this year it would result in the deaths of at least 1,000 people; and whether they had any idea of the number of deaths caused by the Russian and American explosions.

The EARL OF HOME, Lord President of the Council, stated that from the beginning of 1956 to the present time 14 nuclear tests by the U.S.S.R. had been reported, and the United States authorities had announced that they had carried out one test series. He could not say how many thermonuclear explosions were included in these tests. The Russian tests were believed to have occurred in south-west Siberia. The U.S. tests took place in the Marshall Islands. It was impossible to give even a rough estimate of the number of people living within 750,000 square miles of the test sites in either case. The Medical Research Council, to whom the Government looked for advice on radiation hazards, took the view that there was insufficient evidence to justify making the kind of estimate which had been attributed to Dr. Linus Pauling. The Government had no information that any deaths had been caused by the U.S.S.R. and/or U.S. explosions during 1956-7.

Lord Cherwell's Strictures

Uninformed comment on the risks to health from hydrogen bomb tests was roundly criticized by Lord CHERWELL in the House of Lords debate on defence on May 8. He said the argument that Britain ought to have thermonuclear weapons but ought not to test them displayed such a degree of technological innocence that discussion was difficult. The argument that the British tests constituted a danger to the health of humanity was unmitigated nonsense. They could not in any circumstances cause any significant increase in the number of stillbirths or in leukaemia or cancer. The excitable and sometimes hysterical people who rushed forward to stop the British tests left out of account that this would prevent Britain having the deterrent which would probably save her from a war costing millions of lives. The highest authorities who had investigated the alleged dangers had stated that the risks were negligible or non-existent. Yet for some reason people tended to believe the views of less knowledgeable men, whose assertions were circulated as though they were the last word on the subject. It was very undesirable that tendentious views, clearly based on wishful thinking and directly at variance with the conclusions of the International Commission on Radiological Protection, should be promulgated as though they were authoritative.

The so-called leading scientists who objected to the British tests should have explained to the Labour Party the distinction between fission of the heavy nuclei, which did form radioactive products that might in sufficient quantities be obnoxious, and the fusion of hydrogen nuclei, which could not in any circumstances produce fall-out emitting rays harmful to man or beast. The gamma rays to which people were exposed from the fission products of all tests

up to date were 150 times weaker than the radiation to which everybody was exposed in the course of nature. To frighten people by making out that this slight increase—two-thirds of 1%—was going to increase the mutation rate by an appreciable fraction was deliberately dishonest. About 10,000 times the amount of gamma radiation caused by the tests to date would be needed to cause sterility in women and about 15,000 times in men.

Strontium-90 seemed to frighten people because it had been linked with the hated word cancer. According to the Medical Research Council's investigations the amount which people had absorbed up to date was 1,000 times less than the amount they considered safe for people working where radium was used. The amounts of ordinary radium in the soil were 60 times greater than the amount of strontium-90 that had been deposited there, and radium was about 10 times as obnoxious as strontium-90. Though radium did not enter the food chain in the same way as strontium, it was, to say the least, striking that 600 times the effective activity appeared to be harmless. Only those with detailed knowledge of the design of the bombs, who knew how much strontium would be produced in the detonation or blanket, could form any idea of the amount that the Christmas Island test would add to the atmosphere. It was monstrous that, lacking this essential datum, anyone should allow the assertion to appear in the press that the debris of every megaton equivalent would kill 1,000 people. He would agree to the United Kingdom not carrying out more tests than the Americans or the Russians, but it would be criminal folly to limit her to fewer tests, and worse than that to delay those on Christmas Island.

Evidence of Strontium Hazards

Mrs. B. CASTLE (Blackburn, Lab.) asked the Minister of Health what further evidence he had received from the Medical Research Council on strontium hazards since its report in June, 1955. Mr. VOSPER stated that he was advised by the Medical Research Council that the present evidence did not lead them to modify the conclusions published in their report in June, 1956. The Council were supporting an increased programme of research on the biological effects.

Mrs. CASTLE said that two scientists, Professor Haddow and Professor Penrose, who signed the Medical Research Council report, had since signed a report by a committee of the Atomic Scientists' Association on strontium hazards in which they stated that new evidence seemed to support the view that there was not a threshold below which there was no danger, but that there was a proportional relationship between each extra fall-out of radioactive material and the number of bone cancer cases. In view of this new report, would the Minister ask the Medical Research Council officially to reconsider the matter with a view to amending their own report? Mr. VOSPER said the Lord Privy Seal had already indicated that he would consider whether the Council should prepare a further report, but the fact remained that all the evidence available about the level of radioactive strontium was that there had been no appreciable increase in the past few months. Dr. EDITH SUMMER-SKILL (Warrington, Lab.) asked whether the Minister's attention had been drawn to the public controversy during the week-end between eminent authorities on ionizing radiation, and whether it was not desirable to reconvene the committee of the Medical Research Council to reconsider the subject. Mr. VOSPER said he was aware of the controversy, but he was advised that there had been no appreciable increase since the report was published.

Alcoholism.—1,053 certified patients were admitted to mental hospitals in 1955 in consequence of alcoholic psychosis or alcoholism. No figures of this kind were available before 1949, when the number was 438.

Clean Air Council.—The Clean Air Council has been constituted, with 29 members. Among them are Dr. L. I. Roberts, Medical Officer of Health of Sheffield, and Professor A. B. Semple, Medical Officer of Health of Liverpool.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending April 27 (No. 17) and corresponding week 1956.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available.

The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.

† Includes primary and influenza pneumonia.

§ Includes puerperal pyrexia.

Vital Statistics

Week Ending May 4

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 480, whooping-cough 2,399, diphtheria 1, measles 23,188, acute pneumonia 447, acute poliomyelitis 60, dysentery 574, paratyphoid fever 1, and typhoid fever 2.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1948-56 are shown thus ----, the figures for 1957 ———. Except for the curves showing notifications in 1957, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

The largest rises in the notifications in England and Wales during the week ending April 27 were 5,173 for measles, from 21,787 to 26,960, 347 for whooping-cough, from 1,890 to 2,237, and 43 for acute pneumonia, from 382 to 425; the largest falls were 304 for dysentery, from 874 to 570, 73 for food-poisoning, from 207 to 134, and 25 for scarlet fever, from 567 to 542.

63 cases of acute poliomyelitis were notified, and these were 18 more for paralytic and 3 more for non-paralytic cases than in the preceding week. The largest returns were Essex 16 (Colchester M.B. 6, Brightlingsea U.D. 5), Sussex 9 (Brighton C.B. 9), London 7 (Wandsworth 2), and Yorkshire West Riding 5.

Rises of 100 or more in the number of notifications of measles were reported from 16 counties. The towns with large increases included 334 in Birmingham C.B., from 905 to 1,239, 245 in Nottingham C.B., from 115 to 360, 212 in Sunderland C.B., from 227 to 439, 212 in Coventry C.B., from 333 to 545, 115 in Bristol C.B., from 213 to 328, 113 in Ealing M.B., from 98 to 211, 110 in Swindon M.B., from 96 to 206, and the largest decreases were 112 in Liverpool C.B., from 356 to 244, and 91 in Dewsbury C.B., from 180 to 89. The largest rises in the incidence of whooping-cough were 46 in Durham, from 72 to 118, and 44 in Kent, from 143 to 187. The largest declines in the number of notifications of scarlet fever were 25 in London, from 55 to 30, and 24 in Yorkshire West Riding, from 67 to 43. 7 cases of diphtheria were notified, the same number as in the preceding week; 2 of the cases were notified in Plymouth C.B.

No further cases of dysentery were notified from Surrey, Chertsey U.D., where 108 cases were recorded in the preceding week. The other large fall in the number of notifications of dysentery was 106 in Yorkshire West Riding. The largest returns of dysentery were Lancashire 132 (Manchester C.B. 45, Liverpool C.B. 18, Ashton under Lyne M.B. 13, Blackpool C.B. 12), Yorkshire West Riding 107 (Bradford C.B. 31, Leeds C.B. 12, Rotherham C.B. 12), Northumberland 50 (Newcastle upon Tyne C.B. 16, Newburn U.D. 16, Longbenton U.D. 15), Cheshire 49 (Hyde M.B. 25, Stalybridge M.B. 13), Durham 27 (South Shields C.B. 12, Sunderland C.B. 12), London 26, Yorkshire East Riding 24 (Kingston upon Hull C.B. 20), and Essex 20 (West Ham C.B. 11).

In Scotland the number of notifications of dysentery increased by 88, from 235 to 323. The largest returns were Glasgow 154, Lanark county 47, Edinburgh 31, Midlothian county 25, and Aberdeen burgh 17.

Universities and Colleges

UNIVERSITY OF LONDON

The following degrees were awarded by the Senate on March 27:

M.D.—E. A. Boyse, Margaret R. Dix, P. W. G. Tasker.
M.S.—W. J. Atkinson.

UNIVERSITY OF GLASGOW

The following degrees were conferred on April 27:

M.D.—A. S. Douglas (with honours).
Ch.M.—J. W. Sutherland (with honours).

Medical News

Scottish House of the Association.—During the past few years the Scottish House of the Association at 7, Drumsheugh Gardens, Edinburgh, has been undergoing a lengthy process of renovation. The extensive alterations have now been completed, and the President of the Association, Dr. ALEXANDER HALL, officially reopened the House last Tuesday afternoon. About 150 guests were present at the ceremony by invitation of the chairman, Dr. W. M. KNOX, and members of the Scottish Committee.

Bath Hospital for Rheumatic Diseases.—The British Rheumatic Association held a press conference on May 13 to draw attention to the dilapidated condition of the Royal National Hospital for Rheumatic Diseases, Bath. Mr. TOM WILLIAMS, M.P., chairman of the B.R.A., presided at the conference, which was held at the Royal College of Surgeons. The hospital was opened in 1742 and enlarged in the nineteenth century. In 1938 money for new buildings was collected, but rebuilding was prevented by the outbreak of war, states the B.R.A. During the war a wing was destroyed by bombing. When the hospitals were nationalized in 1948 £130,000 of the hospital's endowment funds, including £89,000 subscribed specifically for its rebuilding, was appropriated by the Ministry of Health for the central hospitals endowment fund, and this money is now said to have "lost its identity." In spite of this, and of approaches to both the Ministry of Health and the South-western Regional Hospital Board, no decision has yet been taken about financing the hospital's rebuilding. "It is obvious to all connected with the hospital," states the B.R.A., "that it cannot continue to serve the community in its dilapidated state. If the hospital is to continue its unique specialist functions in the future, either one of two actions is of the utmost urgency: (a) the regional board to give it top priority for immediate rebuilding as a regional operation, or (b) the Minister of Health to direct—as he is empowered to do—that the hospital shall be rebuilt, as a first priority, from central finances."

More Children Eligible for Polio Vaccination.—The Minister of Health has now sanctioned the vaccination of children born in 1955 and 1956. In a circular to local health authorities, acquainting them of this and of his decision to continue the distribution of the vaccine during the summer polio season (see p. 1178 of this issue), the Minister states that the Central and Scottish Health Services Councils' joint committee on poliomyelitis had advised that these children, and those born in the years 1947-54 and not so far registered, were those to whom vaccination should next be offered. As, however, continues the circular, there is unlikely to be enough vaccine for some time to come to provide for all the children in these categories whose parents desire their vaccination, a two-phased operation is suggested. First, authorities should find out how much vaccine will be needed for the children born in 1955 and 1956, notifying the Ministry by August 1. This amount of vaccine will then be supplied as soon as the inoculation of the originally registered children has been completed. Then would come the turn of the children born between 1947 and 1956 who were not registered during last year's campaign. The precise timing of these children's vaccination will depend on the availability of vaccine and local arrangements.

Perinatal Mortality Survey.—The National Birthday Trust Fund is planning a nation-wide survey designed to throw light on the aetiology and prevention of perinatal deaths. After obtaining the sanction of all concerned with the maternity services—hospital boards and committees, local health authorities, general practitioners, and relevant professional bodies—the Trust will ask midwives and health visitors to collect data on births in England, Wales, and Scotland during a week in November. It is hoped that pathologists will also assist by providing necropsy reports on perinatal deaths during this period. Information will be sought on

such factors as previous obstetric history, antenatal supervision (including pelvic radiography) and abnormalities detected, the course of labour, post-natal progress, etc. The survey is being directed by Dr. NEVILLE BUTLER, a paediatrician, assisted by a steering committee under the chairmanship of Miss JOSEPHINE BARNES, F.R.C.O.G. The steering committee includes representatives of the B.M.A., the Royal College of Obstetricians and Gynaecologists, the College of General Practitioners, the Society of Medical Officers of Health, and the Royal College of Midwives, as well as observers from the Health Ministries and the Central Midwives Board. Dr. J. W. B. DOUGLAS, director of the National Survey of the Health and Development of Children and a senior lecturer at Edinburgh University, will supervise the survey in Scotland. Further information about the survey will be sent to those concerned during the next few weeks.

Tenth World Health Assembly.—Professor JACQUES PARISOT, the out-going president, honorary dean of the medical faculty at Nancy, opened on May 7 the Tenth World Health Assembly in Geneva. After Professor Parisot's speech of welcome, Mr. DAG HAMMARSKJÖLD, secretary-general of the United Nations, addressed the Assembly, drawing attention to the close relationship between W.H.O.'s work for health and the efforts of the United Nations and its other specialized agencies against poverty, ignorance, injustice, and war. "Medicine," he said, "is more and more concerned with the whole man, the physical and psychological unity in its total environment." The Assembly was attended by delegations from most of W.H.O.'s 88 member States. On May 8 the Assembly met in plenary session to hear Dr. S. H. AL-WAHBI's presidential address and to discuss the report of the director-general of W.H.O., Dr. M. G. CANDAU (see *Journal*, May 4, p. 1071). Dr. Al-Wahbi, a former Minister of Health for Iraq, is at present director of Karkh Hospital, Bagdad; last year he was chairman of W.H.O.'s executive board. Among other officers elected by the Assembly were Dr. DONALD A. CAMERON, the Australian Minister of Health, as one of the three vice-presidents; and Dr. B. M. CLARK, deputy chief health officer, South Africa, as chairman of the programme and budget committee. At the close of his speech introducing his report on W.H.O.'s work in 1956, Dr. Candau gave a special welcome to the delegation from Ghana, admitted a member State on April 8.

London Fluoridation Council.—Dr. J. L. PATTON, M.O.H. for Hendon, Mr. R. B. D. STOCKER, a London dentist, and Dr. J. GREENWOOD WILSON, M.O.H., City and Port of London, under the title "London Fluoridation Council," are asking for the support of local householders in lodging a complaint about the low level of fluorine in London's water. According to the Fluoridation Council's circular letter to householders, the Metropolitan Water Act of 1852 provides "that the Minister of Housing and Local Government may appoint a person to inquire into any complaint by 20 or more householders as to the quantity or quality of the water supplied. If the complaint appears to be well founded the Minister must notify the Board (Section 12), which must then remove the grounds for complaint (Section 13)." The letter states that the fluorine concentration of London's water is below 0.3 part per million, "which is practically negligible." Householders are asked to sign a declaration, addressed to the Ministry of Housing and Local Government, complaining that the water supplied by the Metropolitan Water Board contains less fluorine than one part per million. The address of the London Fluoridation Council is given as 73, Harcourt Terrace, London, S.W.10.

Suggestions to Authors.—The *Biochemical Journal* has just issued a revision of its "Suggestions to Authors" on "Chemical Nomenclature and Abbreviations, Symbols, Usages, and Conventions." This 16-page reprint will be most helpful to many medical writers, and to editors of medical and scientific journals. Copies can be obtained on application to *The Biochemical Journal*, The Lister Institute of Preventive Medicine, Chelsea Bridge Road, London, S.W. (price 1s. 6d. post free).

British Hospital in Paris.—Lady ALEXANDER, wife of Field-Marshal Lord Alexander, reopened the former Hertford British Hospital in Paris on May 4 as a British military hospital. The hospital was closed in 1952 owing to lack of funds, but it has since been reconstructed and now has 60 beds. Although a military hospital, with a permanent R.A.M.C. staff, civilian members of the British community in Paris will have access to beds and out-patient facilities.

F.R.F.P.S.—At a meeting of the Royal Faculty of Physicians and Surgeons of Glasgow on May 6, the following were admitted fellows: *Qua* physician, V. Benjamin and J. W. Howie; *Qua* surgeon, B. T. Hammond, J. D. L. KIRSTEIN, C. J. Longland, and M. S. Tin.

British Association of Physical Medicine.—About 80 members attended the association's annual meeting, which was held at the Middlesex Hospital on April 5 and 6. Dr. P. BAUWENS, the president, was in the chair. On the first day the principal event was a discussion on the treatment of poliomyelitis, but in addition five short papers were read. Two of these concerned lesions of the tendons in rheumatoid arthritis. Dr. J. H. JACOBS (St. Stephen's Hospital, Chelsea) described seven cases in which tenosynovitis was the primary manifestation of the disease, four of which had been operated upon before the true diagnosis became apparent. Dr. D. A. BREWERTON (King's College Hospital) had found a history of trigger finger in just over a third of 300 patients with rheumatoid arthritis. Usually the condition cleared up spontaneously, but he emphasized how commonly minor lesions of the flexor tendons in the hand gave the first clue to a diagnosis of rheumatoid arthritis. On the second day clinical cases were shown. The annual dinner was held at the Royal College of Surgeons on April 5 (see *Journal*, April 13, p. 899).

The Brompton Hospital.—Sir CLEMENT PRICE THOMAS, presiding at the sixth annual dinner of the Brompton Hospital Association on May 10, paid a warm tribute to the memory of those pioneers of chest surgery, Mr. TUDOR EDWARDS and Mr. J. H. ROBERTS.

British Occupational Hygiene Society.—Dr. P. PRINGLE, chief medical officer of the Central Electricity Authority, assumed office as president during the Society's seventh conference, held in London on April 16 and 17. He succeeds Dr. C. G. WARNER, of the National Coal Board. At the conference eight papers were read on instruments used in safeguarding the health of industrial workers. A full report of the conference will appear in the June issue of *Instrument Practice*, extra copies of which may be obtained from the Society's scientific secretary, Dr. D. J. TURNER, M.R.C. Laboratories, Holly Hill, Hampstead, London, N.W.3.

Birmingham Medical Institute.—The Institute is closing its library and office at 154, Great Charles Street, and reopening on May 27 at 36, Harborne Road, Edgbaston. The regional office of the B.M.A., the Birmingham office of the Medical Insurance Agency, and the Birmingham local medical committee are among other organizations moving to 36, Harborne Road at the same time. From June 1 the facilities of the library of Birmingham University will be available to members of the Institute.

Assistant D.-G. of W.H.O.—Dr. W. A. TIMMERMAN has been appointed assistant director-general of W.H.O. in charge of central technical services. He succeeds Dr. H. S. GEAR. Until his appointment in 1950 as director of W.H.O.'s division of therapeutical substances, Dr. Timmerman had been for 16 years director of the Netherlands National Institute for Public Health.

Professor Arne Tiselius was one of four distinguished scientists elected as foreign members of the Royal Society on May 9. Dr. Tiselius has been professor of biochemistry at Uppsala University, Sweden, since 1938 and has made important contributions in the field of physicochemical analysis.

COMING EVENTS

Tissue-grafting.—Discussion on research, B.B.C. Third Programme, May 22, 8.25 p.m., repeated May 23, 6 p.m. Professor P. B. MEDAWAR, F.R.S., will be the chairman, and among the panel will be Professor M. F. A. WOODRUFF, F.R.C.S., and Dr. J. F. LOUIT.

Fourth European Congress of Dietetics.—Madrid, September 26–28. Details from the secretary-general, Dr. E. A. VALLEJO, Dirección General de Sanidad, Plaza de España, Madrid. Apply before June 1.

Institute of Dermatology.—June 5 to 29, semi-permanent exhibition on "The Xanthomatoses."

International Society for the Welfare of Cripples.—Seventh world congress, London, July 22–26, followed by annual study tour (July 27–August 3). Details from Mr. D. GUTHRIE, 34, Eccleston Square, London, S.W.1.

NEW ISSUES

British Journal of Venereal Diseases.—The new issue (Vol. 33, No. 1) is now available. The contents include:

EDITORIAL.
OCCURRENCE OF LATE SYPHILIS IN UNTREATED SYPHILITIC PATIENTS. József Tówpik.
COMPARATIVE STUDIES ON THE HISTO-PATHOLOGY OF SYPHILIS, YAWS, AND PINTA. C. M. Hasselmann.
CONGENITAL SYPHILIS IN ONE OF TWINS. Sydney M. Laird.
ON THE TREATMENT OF EARLY FORMS OF SYPHILIS. N. S. Smelov.
PRELIMINARY REPORT ON A COMPLEMENT-FIXATION TEST FOR TREPONEMATOSIS (TWR). J. N. Orpwood Price and M. J. Whelan.
FURTHER ASSESSMENT OF CARDIOLIPIN ANTIGEN BY PARALLEL TESTING AGAINST STANDARD ANTIGEN IN ROUTINE WASSERMANN REACTIONS. Sidney Shaw.
COMPARISON OF THE RESULTS GIVEN BY A COMPLEMENT-FIXATION TEST FOR SYPHILIS USING THE REITER TREPONEMA AS ANTIGEN WITH THE TREPONEMAL IMMOBILIZATION TEST. A. E. Wilkinson.
LUMBAR PUNCTURE HEADACHE IN RELATION TO SEX, AGE, AND CEREBROSPINAL FLUID FINDINGS. C. B. S. Schofield.
GONOCOCCAL INFECTION IN TEEN-AGED GIRLS AND MATURE WOMEN. Leopold Z. Goldstein.
BENZATHINE PENICILLIN G IN THE CONTROL OF GONORRHOEA. Carl E. Hookings and L. M. Graves.
TREATMENT OF NON-GONOCOCCAL URETHRITIS. E. E. Prebble.
LYMPHOGANGLIOMA INGUINALE IN THE MALE IN LIVERPOOL, ENGLAND, 1947–1954. C. D. Alergant.
TREATMENT OF NON-GONOCOCCAL URETHRITIS WITH NOVIOICIN. R. R. Wilcox.
EXTRACT FROM THE ANNUAL REPORT OF THE CHIEF MEDICAL OFFICER FOR THE YEAR 1955.
BOOK REVIEWS.
ABSTRACTS.

Issued quarterly; annual subscription £2 2s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

Abstracts of World Medicine.—Issued in the first week of each month, this journal contains abstracts of important papers selected from the current medical literature of the world. Annual subscription £4 4s., single copy 8s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, May 20

LONDON UNIVERSITY.—At Wright-Fleming Institute Lecture Theatre, St. Mary's Hospital Medical School, 5 p.m., special university lecture in medicine by Professor G. W. Thorn (Harvard): Studies on Aldosterone Secretion in Man.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Dr. W. S. C. Cope-man: Steroid Treatment in Rheumatoid Arthritis.

Tuesday, May 21

DUBLIN UNIVERSITY.—TRINITY COLLEGE.—At Anatomy Theatre, 4.30 p.m., John Mallet Purser Lecture by Professor A. H. Schultz (Zurich): Past and Present Views of Man's Specializations.
LIFORD MEDICAL SOCIETY.—At King George Hospital, 8.45 p.m., annual general meeting followed by cocktail party.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. D. O'Neill: Emotional Aspects of Skin Diseases (I).
LIVERPOOL UNIVERSITY.—FACULTY OF MEDICINE.—At Surgery Theatre, Old Medical School, 5.15 p.m., Professor J. B. S. Haldane, F.R.S.: Idiocy, syncrasy, or Genetics and Medicine.
LONDON UNIVERSITY.—At Wright-Fleming Institute Lecture Theatre, St. Mary's Hospital Medical School, 5 p.m., special university lecture in medicine by Professor G. W. Thorn (Harvard): Some Effects of Adrenal Cortical Steroids on Intermediary Metabolism.
MEDICAL RESEARCH COUNCIL.—At National Institute for Medical Research, Mill Hill, N.W., 5 p.m., Dr. Paul C. Zamecnik (Boston): Recent Studies on Protein Synthesis.
MIDDLESEX HOSPITAL.—4 p.m., Sanderson-Wells Lecture by Dr. R. F. Milton, Ph.D., F.R.I.C.: Trace Elements in the Biological Relationship of Soil, Plant, and Animal.

SOUTH-WEST LONDON MEDICAL SOCIETY.—At Bolingbroke Hospital, Wandsworth Common, S.W., 8.30 p.m., Bolingbroke Lecture by Professor C. G. Rob: Advances in Cardiovascular Surgery.
UNIVERSITY COLLEGE LONDON.—At Chemistry Theatre, Gower Street, W.C., 5.30 p.m., Walter VanDyke Bingham Lecture by Sir Cyril Burt: Inheritance of Mental Ability.
WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Mr. L. C. Oliver: Surgical Aspects of Head Injuries.

Wednesday, May 22

BIRMINGHAM MEDICAL INSTITUTE: SECTION OF PSYCHIATRY.—8 p.m., symposium by Dr. A. M. Spencer, Dr. C. A. H. Watts, and Dr. G. A. Wray: Who Should be Sent to a Mental Hospital?
BRITISH ASSOCIATION OF SPORT AND MEDICINE.—At London Hospital Medical College, 5.30 p.m., Sir Adolphe Abrahams: Stitch and Cramp.
EUGENICS SOCIETY.—At Royal Society, Burlington House, Piccadilly, W., 5.30 p.m., Mr. C. M. Stewart, F.I.A., F.S.S.: Population Problems in the British Caribbean.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. I. A. Magnus: Epidermal Energy Relationships in Health and Disease.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. J. Smart: Pleural Neoplasms.
KING'S COLLEGE.—5.15 p.m., Halliburton Lecture by Professor A. von Muralt (Berne): Chemical Aspects of Nervous Excitation.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Dr. B. A. D. Stocker: Heritable Transformations of Bacteria.

Thursday, May 23

HONYMAN GILLESPIE LECTURE.—At Anatomy Theatre, University New Buildings, Edinburgh, 5 p.m., Professor J. C. Goligher: Surgery of Ulcerative Colitis.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. D. O'Neill: Emotional Aspects of Skin Diseases (II).
LONDON JEWISH HOSPITAL MEDICAL SOCIETY.—At Medical Society of London, 8.30 p.m., Mr. M. A. Falconer: Advances in Surgical Treatment of Temporal Lobe Epilepsy.
NUFFIELD ORTHOPAEDIC CENTRE.—At Winfield-Morris Orthopaedic Hospital, 8.30 p.m., Mr. W. Waucho: Pathology of the Tarsal Navicular: A Clinical and Laboratory Study.
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Institute, 5 p.m., Dr. S. Udenfriend (U.S.A.): Biogenesis and Metabolism of 5-Hydroxytryptophan.

Friday, May 24

BIOCHEMICAL SOCIETY.—At Department of Biochemistry, Physiology Institute, Newport Road, Cardiff, 2 p.m., 362nd meeting.
●INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. J. S. Pegum: clinical demonstration.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. F. H. Young: clinical demonstration.
INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—3.30 p.m., Mr. G. H. Howells: Sinusitis.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—10 a.m., Mr. E. G. Muir: Pathology, Treatment, and Results in Malignant Disease of the Large Bowel.
●ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS.—5 p.m., William Blair-Bell Memorial Lecture by Mr. C. W. Taylor: Mesodermal Mixed Tumours of the Female Genital Tract.
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Institute Theatre, 5 p.m., Mr. S. Bender: Obstetric Problems in General Practice.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Herbertson.—On April 27, 1957, at Cambridge, to Margaret and Basil Herbertson, a son—Michael Jonathan.
MacTaggart.—On May 4, 1957, at Torbay Hospital, Torquay, to June M.B., Ch.B., D.P.H., and Douglas MacTaggart, M.B., Ch.B., D.P.H., of Broadwater, Preston, Paignton, Devon, a son.
Quamina.—On April 13, 1957, at the Colonial Hospital, San Fernando, Trinidad, B.W.I., to Dr. Elizabeth (formerly Smith), and Dr. David Quamina, a daughter—Jacqueline.
Rainford.—On May 5, 1957, at Aughton, Lancs, to Janet, wife of Dr. F. A. Rainford, a daughter—Alison Jean.
Smith.—On May 10, 1957, at West Hill Hospital, Dartford, Kent, to Pat (formerly Frisby), M.B., B.S., wife of the Reverend R. Allington Smith, M.A., a son—Jeremy Richard.

DEATHS

Auden.—On May 3, 1957, at Repton, Derbys, George Augustus Auden, M.D., Ph.D., F.R.C.P., D.P.H., aged 84.
Condon.—On April 30, 1957, in London, Gerald Fitzgerald Aloysius Condon, L.R.C.P. & S.I. & L.M., Lieutenant-Colonel, I.M.S. (retired), late of Ballyshannon, Co. Donegal.
Cory.—On May 5, 1957, at Bournemouth, Hants, Evan James Trevor Cory, O.B.E., T.D., M.D., Lieutenant-Colonel, R.A.M.C. (retired), formerly of 38, Hyde Park Gate, London, S.W., aged 95.
Couppland.—On May 1, 1957, at Winchester, Hants, James Alane Couppland, M.B., F.R.C.S.
Fry.—On May 1, 1957, the result of an air accident, Richard Oswald James Fry, M.R.C.S., L.R.C.P., Major, R.A.M.C., aged 35.
Harris.—On April 26, 1957, Louis Harris, M.B., B.Ch., of 141, Castelnau, London, S.W.
Hughes.—On April 16, 1957, Clement Alston Hughes, M.D., of Bolton-le-Sands, Lancs, formerly of Liverpool.
Murray.—On April 28, 1957, Percy Hope Murray, M.B., C.M., of Oakhurst, Hambledon, Hants, aged 88.
Panton.—On April 26, 1957, at The Court Nursing Home, Malvern, Worcs, Henry Forbes Panton, D.S.O., M.C., M.B., Ch.B., Colonel, late R.A.M.C., retired, of Ham Court, Upton-on-Severn, aged 71.
Pratt.—On April 24, 1957, at 35, Chartfield Avenue, Putney, London, S.W., Eldon Pratt, M.D., aged 87.
Randolph.—On May 1, 1957, William Henry Randolph, M.R.C.S., I.R.C.P., of Wiveliscombe, Somerset.
Wilson.—On April 27, 1957, in hospital, William Wilson, M.D., of Cald, Marine View Crescent, Rhos-on-Sea, Denbighshire, formerly of Manchester.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Cause and Treatment of Stitch

Q.—What are the causes, treatment, and prevention of stitch? A boy of 16 finds his efforts at cross-country running frustrated by this symptom, particularly in the more important races.

A.—Stitch probably results from a tugging of the diaphragmatic attachments of the peritoneal ligaments which suspend the liver, spleen, and stomach. Sinclair¹ has ably reviewed the evidence for this conclusion and confirmed such previously known facts that shoulder pain may be associated with stitch, that it may shift from right to left following a meal, and that it is provoked by deep expiration and relieved by deep inspiration; it is also relieved by assuming the upside-down posture.

There are no measures that can guarantee freedom from stitch, which sometimes troubles the most experienced runners. It occurs less frequently if the subject is well trained for the distances over which he is racing, if he avoids a lengthy and hence a bounding stride, and does not eat a meal within three hours of racing. When stitch occurs it may sometimes be eased by breathing more deeply, but it may be necessary to stop racing and bend the trunk forwards for some seconds until the pain eases and running may be resumed.

Agranulocytosis from Drugs

Q.—When giving drugs under domiciliary conditions which are known to carry a risk of agranulocytosis, how often should a blood count be done and what other precautions should be taken? To what level may the leucocyte count safely be allowed to fall before stopping the drug?

A.—There seems to be no practical way of predicting whether a particular patient will develop serious agranulocytosis when treated with a drug known to produce this complication. The reason for this is that in the majority of cases bone-marrow depression leading to agranulocytosis appears to come on suddenly. There seems to be little information on how rapid is the consequent decline in the leucocyte count in the circulating blood, but it seems likely that the neutrophil count falls from normal levels to a few hundreds, or less, per cubic mm. within 48 hours. This means that leucocyte counts carried out at intervals of a week or more can seldom be expected to detect agranulocytosis before it actually happens. More frequent counts are no doubt impracticable. Indeed, unless counts are done daily there seems little point in carrying them out at all. A better course would seem to be to impress on the patient that should he develop any new symptoms or untoward reaction—e.g., sore throat, temperature, skin rash, etc.—he should immediately stop taking the drug and report without delay to the doctor supervising the treatment, who could then arrange for a blood count to be carried out. The drug should be withheld until the result is known.

Certain drugs—e.g., sulphanilamide and thiouracil—as well as producing acute agranulocytosis, have been shown to produce not infrequently moderate (and apparently harmless) degrees of symptomless leucopenia. Even so, the total leucocyte count rarely fell below 3,000 per cubic mm. The sulphonamide derivatives and antithyroid drugs now in use may do the same. However, it was found that the moderate leucopenia produced by thiouracil might become less severe

even if the patient continued taking the drug, and that the development of leucopenia did not by any means mean that the patient might develop serious agranulocytosis (or that patients who did not develop leucopenia might escape agranulocytosis). The undertaking of routine blood counts in order to detect symptomless leucopenia thus does not seem to be a useful procedure.

Cancer in Chronic Alcoholics

Q.—How does the incidence of cancer at different sites differ in chronic alcoholics from that found in the general population? Are there any types of cancer known to be less frequent in alcoholics?

A.—The incidence of cancer at different sites in the body has not been fully studied in relation to chronic alcoholism, and statistical analysis has up to date been incomplete. There is a correlation between cancer of the pharynx and cancer of the larynx and alcoholism; these forms of cancer seem to be commoner in those who take alcohol habitually and in excess than they are in abstainers. Cancer of the mouth also seems commoner in those addicted to spirits than in others, a view supported by evidence provided by Professor E. L. Wynder and Dr. I. D. Bross elsewhere in this issue (p. 1137). It has been suggested, also, though it has not been clearly proved, that carcinoma of the oesophagus is commoner in spirit drinkers, and a similar relationship has sometimes been thought to exist in cancer of the stomach.

A cirrhotic liver is more prone to malignant disease than is a liver free from cirrhosis, and consequently a relationship might be predicted between chronic alcoholism and primary liver cancer, though the relative rarity of this last disease in this country makes it unlikely that the increased risk of cancer of the liver to which the chronic alcoholic is exposed is a very important or notable hazard here.

Amateur Boxing Queries

Q.—What are the points to look for in deciding whether a boxer who has taken several counts should be allowed to box on? If a boxer is unable to walk back to his corner after a knock-out, should the M.O. insist on his being removed from the ring on a stretcher? Is adrenaline still the best haemostatic to use for cut eyebrows, etc.?

A.—If a boxer is knocked down and on rising is obviously unable to defend himself, the bout should be stopped immediately. It should also be stopped if he staggers on rising or hangs on to the ropes. If a boxer is unable to walk back to his own corner after a knock-out he should be carried to his corner, and if he is unable to leave the ring on his own he should be removed on a stretcher.

Adrenaline solution is still the safest haemostatic to be used for cut eyebrows.

The London Amateur Boxing Association (69, Victoria Street, London, S.W.1) issues full notes on the treatment of boxing injuries and the physical standards for amateur boxing. These will be sent gratis to any doctor applying for them.

Prolonged or Repeated Courses of Cortisone

Q.—In using cortisone for an acute exacerbation of a chronic condition how long is it wise to continue the drug, and what risk is there attached to repeated courses? Similarly, how advisable are repeated applications of cortisone by nasal spray for allergic rhinitis?

A.—Cortisone may often be given for long periods without harm, provided overdosage is avoided. This may be indicated by oedema, low serum potassium, mental changes, or deterioration in other ways. The greater dangers arise at the end of the course, when too sudden withdrawal may lead to a flare-up of the original condition or to a state of temporary adrenal deficiency. The latter is due to the fact that prolonged cortisone medication leads to adrenal cortical atrophy; when the drug is withdrawn, the patient's

own adrenals are for a time unable to produce the normal supply. Stoppage of the drug should therefore be gradual, the dose being progressively reduced over one or two weeks.

There is no additional risk from repeated courses. Some disorders respond less well a second time, but sensitivity to the drug does not develop.

The amount of cortisone absorbed from a spray in allergic rhinitis would be small and unlikely to have any adverse systemic effects.

Mental Exercise

Q.—What is the general educational value, in terms, for example, of increased mental agility and ease of association, of regular attempts to solve difficult crossword puzzles? Has there been any research work on this so far as children are concerned?

A.—How much does doing one thing help us to do something else? The answer used to be, "A great deal." But this is not so any longer. One of the arguments advanced in favour of the old type of classical education was that translating from and into an ancient language was good "mental exercise." Similarly, geometry was good practice in reasoning and so on. William James carried out one of the early investigations on transfer of training, as it is called, at the close of the nineteenth century. His subjects were used to discover whether memorizing one thing made people any better at memorizing other things. His results were entirely negative. More recent work has, on the whole, given similar results, and the whole argument seems to have been based upon the fact that the abler pupils tended to have a more rigorous academic course at school, and tended to do well in after life whatever their job might be. They did well, however, not because of their rigorous schooling but because of their ability. As one research worker in this field put it, "If the abler pupils should all study physical education and dramatic art, these subjects would seem to make good thinkers. These were, indeed, a large fraction of the programme of studies for the best thinkers the world has produced, the Athenian Greeks."

It is, however, true that common elements and techniques exist between many different kinds of task. Through these common elements and techniques one field of study may produce valuable results in another. So far as crossword puzzles are concerned, it is clear that by doing them we enlarge our vocabularies, though the words we learn may not come readily into ordinary conversation or writing. We should also acquire a certain resourcefulness in trying out different kinds of solution. This would certainly help us in decoding a cipher, and the persistence and ingenuity required might confer still further general benefits.

To sum up, we should not look for too much of general educational value from our crossword puzzles, but we may expect something. In any case, they are good fun and worth doing for their own sake.

Vocational Guidance for the Mentally Retarded

Q.—Where may skilled advice be obtained on the type of employment likely to be suitable for a patient who is somewhat mentally retarded? What agencies exist to help such people find the type of employment recommended?

A.—Many institutions for the care of mental defectives now make it their chief aim to train these patients in simple industrial tasks and to help them to become self-supporting members of the community. Psychological assessment and vocational advice are given at out-patient clinics run in conjunction with these hospitals. For those who are not in institutions but who are too severely handicapped to enter normal employment there exist some 272 occupation centres which provide training in manual skills. These are controlled by the local health authorities (in London, by the Mental Health Department of the L.C.C.). Where the handicap is less severe, advice on suitable employment can

be obtained at the local youth employment bureau of the Ministry of Labour. Older patients should first be registered as disabled persons, after which they can receive advice and preferential employment through the disablement rehabilitation officer at the Labour Exchange. Advice on special cases can also be had from the National Association for Mental Health, 39, Queen Anne Street, London, W.1.

"Wind" in the Young of Mammals

Q.—Human infants are distressed if their "wind" is not brought up after feeds, and often this is a laborious process which makes a sleepy child restless and irritated. Other mammals seem to suckle their young without such troubles. Has the human body some peculiar defect to account for this, or is the difficulty with our infants due to some departure in our habits from the natural?

A.—It is probable that most mammals swallow air when eating and drinking. It is difficult to see how it could be otherwise, and indeed calves have been observed to belch after suckling.

It is possible that the problem is more acute in the human baby because in its case a full meal is taken in a limited time. Many other mammals are suckled intermittently, so that the amount of air and food in the stomach at any time is likely to be less, and a fully distended stomach, such as must commonly occur in the human baby after a full feed, must be rare. The wind can be brought up without much trouble in most human babies if it is done after about two-thirds of the full feed and again at the end of feeding. It is uncommon for a baby to have difficulty in eructating air, but if it does the infant will then often be uncomfortable. There is no reason to suppose that such a difficulty is due to any aberration in human anatomy or habit.

NOTES AND COMMENTS

No Diastolic Reading.—Dr. F. M. RIFKIN (Salford) writes: I was interested in the question on the diastolic reading ("Any Questions?" April 6, p. 840). This is a phenomenon that every doctor notices and is unable to explain. I have found from my own experience that a low diastolic pressure of between 40 and 60 mm. Hg can be obtained in nearly if not all of these cases by using extremely light pressure with the stethoscope on the brachial artery. I have come to the conclusion that where people have these "soft" pulses with low diastolic pressures, even medium pressure with the stethoscope can continue to act on the brachial artery in place of a sphygmomanometer cuff. This is a simple matter to prove, because in cases where it is impossible to obtain a diastolic reading, even if it is 80 or 90 mm. Hg, if one puts a stethoscope on the brachial artery without using the sphygmomanometer cuff and listens, gradually increasing the pressure of the stethoscope on the brachial artery, one will hear the diastolic come through.

Correction.—Last week on p. 1133 we wrongly stated that Dr. H. L. Glyn Hughes had retired as S.A.M.O. of the South-east Metropolitan Regional Hospital Board. He retires on October 31.

Books of "Any Questions?" and Refresher Course Articles.—The following books are available through booksellers or from the Publishing Manager, B.M.A. House. Prices include postage. *Any Questions?* Volumes 2 and 3 (8s. each); *Refresher Course for General Practitioners*, Volumes 2 and 3 (26s. 6d. each inland, 26s. overseas); *Clinical Pathology in General Practice* (22s. 3d. inland, 21s. 9d. overseas).

Countless thousands...every day

It is a sobering revelation that over 50 per cent of the average practitioner's patients can be said to suffer from some degree of anxiety neurosis. This means that hundreds of thousands of such cases present themselves every day in Great Britain alone. A massive problem—yet one which has been vastly simplified by the advent of MILTOWN meprobamate. Uniform in action, and remarkably free from side reactions, MILTOWN acts safely and selectively to calm restlessness and irritability of anxiety states. It eases emotional and muscular tension without autonomic effects, and shows marked advantages over conventional sedatives. By day, MILTOWN secures true sedation; by night, it brings natural sleep without narcosis.

Tablets of 400 mg.; bottles of 50 and 500

RECENT WORK ON LEUKAEMIA IN MAN*

BY

L. J. WITTS, M.D., F.R.C.P.

Nuffield Professor of Clinical Medicine, University of Oxford

In this lecture I shall confine myself to human leukaemia, and in particular to recent work on the aetiology, course, and treatment. This work has been mainly inspired by two events. The first is the apparent steep rise in the incidence of leukaemia in Western Europe, North America, and Australasia. The second is the discovery of new and powerful drugs for the treatment of acute and chronic leukaemia. Connecting these two events is the use of the numerical or statistical method to study the incidence of leukaemia at different epochs and in different places, to define the natural history of the disease and its individual variations, and to control the large-scale trials which have proved to be necessary if methods of treatment are to be satisfactorily evaluated.

Classification of Leukaemia

So far I have talked about leukaemia, but in fact we should talk about the leukaemias, for the different forms of leukaemia differ from each other at least as much as the different forms of malaria. The classification of leukaemia offers difficulties, some of which are semantic and others technical. The two parameters used in classification are the acuteness of the disease process and the type of cell involved. Demographers are not fond of the words "acute" and "chronic," and it must be confessed that the definitions given by the Committee for Clarification of the Nomenclature of Cells and Diseases of Blood-forming Organs in 1950 have not proved entirely adequate to deal with the subsequent course of events. With modern therapy an occasional acute leukaemia may last for more than five years, or longer than many patients with chronic leukaemia.

The type of cell involved in acute leukaemia is also sometimes difficult to decide. Fashions in the diagnosis of myeloblastic, lymphoblastic, monocytic, and erythroblastic leukaemia have changed too often for one to have much confidence in *ex cathedra* statements based on a look down the microscope. It is probable that in atypical cases a group of characteristics should be determined before a decision is made—the microscopical appearances of the cells, their physical, histochemical, and immunological reactions, and their cultural characteristics. This would be impracticable as a routine procedure, but it might be of value if it was used as a method of sampling from time to time to keep a check on working diagnoses.

In the seventh revision of the *International List of Causes of Death* leukaemia is classified under the headings of lymphatic leukaemia, myeloid leukaemia, mono-

cytic leukaemia, acute leukaemia, and other and unspecified leukaemias. Acute leukaemia includes all forms of acute leukaemia whether the type of cell is specified or not, with the exception of monocytic leukaemia, which is treated as a separate entity. This is probably as far as the demographers are justified in going at present, and it must be left to the haematologists to discover methods of differentiating the subgroups of acute leukaemia which will stand up to statistical appraisal.

Incidence of Leukaemia as a Whole

With this knowledge in mind we can now turn to recent figures for overall death rates from leukaemia. The rate of increase of leukaemia as a recorded cause of death in Western Europe and North America has been greater than that of any other disease except lung cancer and coronary thrombosis. The figures of the

FIG. 1.—Death rates per million from leukaemia and pernicious anaemia for all persons in England and Wales over the years 1920-55. The data are taken from the Registrar-General's *Statistical Reviews*.

Metropolitan Life Insurance Company of New York (1955) show a rise from 1.8 to 4.7 per 100,000 in their policy-holders between 1930 and 1951. In England and Wales the incidence was more than two and a half times as high in 1953 as in 1931 (Hewitt, 1955) (Fig. 1). Nevertheless, the fear of leukaemia should not blind us to the fact that it is an uncommon disease. In 1955, 2,224 people died of leukaemia in England and Wales, as compared with 17,569 deaths from cancer of the respiratory system and 20,869 from violence. Indeed, something like three times as many children died from accidents as from leukaemia.

*The Gwladys and Olwen Williams Lecture delivered in the University of Liverpool on February 19, 1957.

Men and women have been equally affected by the increase in leukaemia, so that the cause is unlikely to be smoking, cosmetics, or occupation. The upward trend has been visible for at least twenty-five years and cannot be explained by recent events such as the introduction of the sulphonamides and antibiotics. The main correlation is with the standard of living. Hewitt noted that as between different countries the incidence followed the order U.S.A. and Denmark; England, Wales, and Scotland; Western Germany and Ireland. As between economic strata, leukaemia is more frequent in the rich than the poor, and in the United States it is more frequent in the white than the non-white. As between different regions of England it was higher in the south than the north, and over the period of observation the south of England had been more prosperous than the north. In the United States the contrary is true, and there leukaemia is commoner in the north than the south.

Incidence of Different Types

It is not easy to demonstrate how changes in the incidence of leukaemia as a whole are related to changes in the incidence of the different types of leukaemia, for until recently the International Classification of Diseases and Causes of Death did not distinguish between acute and chronic forms of the disease. Moreover, crude figures for deaths from leukaemia have little meaning unless we know also the age and sex structure of the population, because leukaemia occurs with increasing frequency over the age of 50 and because males are affected more often than females. Two studies have recently been reported in which a high level of ascertainment and diagnosis of leukaemia was combined with a full knowledge of the structure of the populations under study. MacMahon and Clark (1956) analysed the incidence of leukaemia in the Borough of Brooklyn, a city with a population of 2,700,000, over the ten-year period 1943-52. Hospital records were available in 87% of the cases and marrow puncture or necropsy records in 63%. Gunz and Hough (1956) carried out a similar analysis of deaths from leukaemia over the quinquennium 1950-4 in New Zealand, where the population is just under two million and the level of medical care is high.

In Brooklyn the overall distribution of cases was, acute leukaemia 53%, chronic lymphatic leukaemia 26%, and chronic myeloid leukaemia 21%. Acute leukaemia falls from a level of 44.3 per million in the first decade to 11.9 per million in the decade 20-29. It then rises steadily to

FIG. 2.—Age incidence of the leukaemias in Brooklyn. The data are taken, by permission, from the article by B. MacMahon and D. Clark (*Blood*, 1956, 11, 871).

reach levels over 50 per million in the seventh and eighth decades. Acute lymphatic leukaemia shows an exaggeration of this tendency of the acute leukaemias to occur at the extremes of life. Acute myeloid leukaemia was the commonest form of acute leukaemia except in the first few years of life, but too much reliance should not be placed on the differentiation of the various types of acute leukaemia. Chronic myeloid leukaemia rises steadily from an incidence of 1 per million in the first decade to 39.4 per million in the eighth. Chronic lymphatic leukaemia rises from less than 1 per million in the first three decades to 114 per million in the eighth.

The figures for the relative frequency of acute and chronic leukaemia are in agreement with those of Gunz and Hough, who found that the proportion of acute cases was almost 100% in the first five years of life, falling to about 60% in the forties, and 40% over the age of 75. Noteworthy features in both surveys are the sharp rise in the death rate from all forms of leukaemia over the age of 50, the frequency of chronic lymphatic leukaemia in the aged, and the high proportion of acute leukaemias even in the oldest age groups. Acute leukaemia in later life is often atypical, with few signs pointing to affection of the haemopoietic system, and the diagnosis can easily be overlooked if the blood is not examined. Other observers have confirmed the relative decline in frequency of chronic myeloid leukaemia in the West (Gauld, Innes, and Robson, 1953).

Racial and Geographical Differences

Much less accurate information is available about the racial and geographical incidence of leukaemia, though

FIG. 3.—Mortality rates from leukaemia in males in the U.S.A. and Japan from data collected by the World Health Organization (1955).

there is a general impression that leukaemia is less common in the indigenous populations of Africa and Asia, particularly chronic lymphatic leukaemia. An analysis of the mortality from Hodgkin's disease and leukaemia in different countries has recently been made by the World Health Organization (1955). Unfortunately, the only non-Western country is Japan, but separate figures are given for the white and the non-white population of the United States of America. The contrasts are striking. The overall mortality from leukaemia in men is 7.5 per 100,000 in the white population of the United States, 3.9 per 100,000 in the non-white, and 2.0 per 100,000 in Japan (Fig. 3). In the age group 60-69 the mortality from leukaemia in men is 22.0 per 100,000 in the white population of the United States, 13.8 per 100,000 in the non-white, and 2.5 per 100,000 in Japan.

Causes of Increased Incidence

If these differences in the incidence of leukaemia in time and place are real, they suggest that it resembles cancer of the lung, the liver, and the scrotum, and that environmental factors must be important in its causation. If the differences are spurious, we should have to rank leukaemia with

carcinoma of the breast and the stomach as one of those forms of malignant disease whose incidence we are unlikely to be able to modify until the general problem of neoplastic disease is solved.

Part of the increase is due to the ageing of the population; but this is not the whole story, because not only the absolute numbers but the incidence of leukaemia in the later decades has increased. Cooke (1954) showed that the crude incidence of leukaemia increased from 2.1 to 5.5 per 100,000 in the U.S.A. between 1930 and 1949. At all ages up to 54 the incidence had uniformly doubled, but above age 54 there had been a much sharper increase. In 1949 there were over 23 deaths per 100,000 from leukaemia in patients over 70, which was about four times the figure in 1930. Of these 23 cases one can calculate from MacMahon and Clark's data that 11 were chronic lymphatic leukaemia, 5 acute leukaemia, 4 chronic myeloid leukaemia, and 3 unspecified.

The main correlation of the death rates is with the standard of living. People with a high standard of living have a greater probability of detection of leukaemia owing to better medical attention, and a larger proportion of patients in the older age groups where leukaemia is especially common. I can look back on my own experience as a student and recollect cases which were diagnosed as oral sepsis or haemorrhagic fever, and which would nowadays be almost certainly shown to be leukaemia. A high proportion of acute leukaemias occur at the extremes of life, and if laboratory facilities are not easily available they are apt to be diagnosed as infections in infancy and as cardiovascular or renal disease in later life. It seems certain that a big factor in the increase of deaths attributed to leukaemia is the more frequent recognition of the disease at all ages, particularly in later life.

It is, nevertheless, difficult to believe that enough cases of leukaemia were misdiagnosed in the past, particularly in middle life, to account for the total increase in notifications. In this country a notable improvement in the facilities for the diagnosis of blood disorders was initiated by the expansion of the Hospital Laboratory Service between 1939 and 1948, and this was soon reflected in a fall in the mortality from pernicious anaemia (see Fig. 1). If the increased incidence of leukaemia was entirely a matter of better ascertainment, one would have expected that the curve of deaths from leukaemia would have risen even more sharply about fifteen years ago and then flattened out, but this did not happen.

It looks as if the rise is not just a matter of greater availability of medical care. An improved standard of living seems to contain elements which bring about a real increase in leukaemia. In our discussions together, Alice Stewart has suggested that, as a result of the greatly reduced mortality from infections, people who have sustained leukaemogenic damage to the bone marrow survive to develop leukaemia after the appropriate incubation period. However that may be, it would be complacent at present to assume that the increase in leukaemia is entirely a matter of better notification, and we must continue searching for factors in our greatly changed environment which may have contributed to the increase.

Chronic Lymphatic Leukaemia

The variation in the incidence of chronic lymphatic leukaemia, a disease with manifest clinical signs, is particularly hard to explain by failure of detection. In a recent visit to India and the Far East I saw many cases of acute leukaemia and myeloid leukaemia but none of chronic lymphatic leukaemia. Acute leukaemia and myeloid leukaemia occurred in typical and atypical forms, and it was not unusual to see myeloid leukaemia of the chronic myelocytic type in children. Aplastic anaemia, which is probably related in aetiology to leukaemia, was not infrequent.

Anaemias of all kinds are so common in hospital patients in Africa and Asia that the absence of chronic lymphatic

leukaemia is especially noteworthy. Pernicious anaemia, which is likewise a disease of the later decades, is even less common. Otsuka *et al.* (1956) report that only 309 cases of pernicious anaemia have been described in Japan in the last fifty years. They were atypical in age distribution, occurring most often in the age group 20-40, and a proportion were undoubtedly due to pregnancy or to gross lesions of the intestine. Otsuka and his colleagues emphasize that the Japanese medical profession has been keenly interested in haematology throughout this period and that the rarity of pernicious anaemia contrasts with the frequency of aplastic anaemia.

As already mentioned, the age structure of the populations is very different from ours. In Singapore, for example, 50% of the population are under age 21 and anyone over 45 is described as old. In the absence of written records, the age of middle-aged and elderly people is often unknown to the individual and cannot be determined, but the populations of the Oriental countries are so numerous that in absolute figures there must be large numbers of people in the sixth, seventh, and eighth decades, where chronic lymphatic leukaemia has its greatest incidence with us.

Reasons for a failure to recognize chronic lymphatic leukaemia and pernicious anaemia may be that elderly people are less likely to be referred to hospital for diagnosis or to be admitted for treatment when the pressure of the younger age groups is so great. The proportion of doctors to the population in Eastern countries is rarely higher than one in ten thousand, and certification of the cause of death cannot be expected to be precise, particularly at the extremes of life. Owing to religious prejudices post-mortem examinations are hardly ever made except in persons who have died a violent or unnatural death. In parenthesis, one cannot resist commenting on this failure of Oriental peoples to contribute their quota to our knowledge of the morbid anatomy of disease. When all is said and done, however, one is left with the feeling that there is a real difference in the incidence of leukaemia and pernicious anaemia in elderly people in the West and the East, which might be due to genetic factors or to environmental factors such as differences in diet.

Observations of the kind just made are useful only in so far as they serve as hypotheses for further work. Obviously one thing to be done is to try to improve our statistics of leukaemia. In this country it must be unusual, now, for any patient, however old, to develop a chronic illness like lymphatic leukaemia and die without the blood being examined. In Asia and Africa a comparable standard of diagnostic facilities is unlikely to be achieved for some time, and by then other differences between the two populations, which are at present playing a part in the differing incidence of leukaemia, may have been obliterated. In other words, we are faced with something like Heisenberg's principle of uncertainty. As the incidence of all forms of leukaemia is only about 5 per 100,000 per annum, a pilot survey would be impracticable. In this state of affairs it would be reasonable to act on the hypothesis that there is less chronic lymphatic leukaemia in the East than the West, to enumerate the differences in environment between Asian and Western peoples, particularly in reference to diet, and to study them experimentally.

Aetiological Factors in Human Leukaemia

When a disease occurs in only 5 out of every 100,000 people, it suggests that either the make-up of the patient or his experience has been unusual. The inheritance of leukaemia is still controversial, and it is unusual to find cases in more than one member of a family. Videbaek (1947), who analysed the family histories of 209 patients with leukaemia and a corresponding number of controls, concluded that the chance of a relative of a patient with leukaemia getting leukaemia was 1 in 250 as compared with 1 in 4,000 of the control population. It will be interesting to see if the current survey by Alice Stewart and her co-workers (1956) confirms these ratios. As regards

environmental factors, the only one known for certain is the somewhat unusual one of exposure to large doses of x rays.

This story has so often been recapitulated in the last few years that I shall summarize it briefly. Leukaemia has probably been unduly frequent in doctors and nurses who work with x rays. It has occurred after x-ray treatment of non-malignant diseases such as ankylosing spondylitis in adults and enlargement of the thymus in infants. It is also occurring with abnormal frequency in the survivors of the atomic-bomb explosions in Hiroshima and Nagasaki who were within range of the ionizing radiations. In all these instances there is reason to believe that the dosage was high, usually more than 100 r over a short period of time or more than 200 r over a longer period.

The total normal background radiation over a generation in man amounts to about 3 r. The ordinary chest film exposes the patient to only a fraction of a roentgen, but a gastro-intestinal examination with the apparatus commonly used at present may expose the patient to 15 r a minute if full precautions are not taken. Children are more susceptible to x-radiation than adults, and in their preliminary communication Stewart *et al.* (1956) reported that about twice as many of the mothers of children who died of leukaemia or malignant disease before the age of 10 in the years 1953-5 had had an x-ray examination of the abdomen during the relevant pregnancy as the mothers of a group of control children. Many of these x-ray examinations were probably for pelvimetry, in which it has been stated that a radiation dose of only about 2.5 r is received by the foetus (Rabinowitch, 1956).

While genetic damage is accounted for by a relatively few sites of examination, principally the hip, the lumbar spine, the lower abdomen, and the pelvis, it seems probable that extensive radiation over any part of the trunk or the proximal ends of the long bones would increase the likelihood of leukaemia. The committee appointed by the Medical Research Council (1956) to report on the hazards to man of nuclear and allied radiation considered that there would be little increased risk of leukaemia if an individual received a total dose of 200 r in his lifetime in addition to radiation from the natural background, provided that the dose was distributed over tens of years and that the maximum weekly exposure, averaged over any period of thirteen consecutive weeks, did not exceed 0.3 r. However, there is probably no threshold below which x rays are harmless, and even with small doses ill effects will be seen if a sufficient number of people are observed. In the survivors of the atomic-bomb explosion at Nagasaki who had been most severely irradiated, the incidence of leukaemia has been 1 in 80 or over. At the other extreme of dosage, Court Brown and Doll (1957) suggest that a dose of 1 r averaged over the red bone marrow of the whole body would cause about one case of leukaemia annually in a population of a million people.

It is axiomatic that we should exercise the greatest care in exposing ourselves, our patients, and above all the pregnant woman to x rays and radioactive agents. Nevertheless, it is probable that the contribution made by x-radiation to the total incidence of leukaemia is small. From the figures of Stewart *et al.* (1956) it would appear that 50 children a year may have developed leukaemia or malignant disease because their mothers had an abdominal x-ray examination during pregnancy. All the leukaemias so induced may not yet have appeared, but at the very most the figure for leukaemias induced by x-ray examinations *in utero* is unlikely to exceed 50 per annum. If the number of adults developing leukaemia from diagnostic or therapeutic x-radiation is of the same order as the number of children, x-radiation is unlikely to account for more than 15% of the total deaths from leukaemia.

Most of the leukaemias occurring after radiotherapy for spondylitis have been acute or subacute myeloid leukaemia. Of 92 cases in Hiroshima and Nagasaki, 39 were chronic myeloid leukaemia and only one was chronic lymphatic

leukaemia; the remainder were acute and subacute leukaemias, with the myeloid form predominating and the younger age groups more severely affected (Moloney, 1955). The study of post-irradiation leukaemia thus throws little light on the apparent increase in spontaneous leukaemia, which affects more heavily patients over the age of 50 and which has been largely of the chronic lymphatic type.

Finally, we must balance the risks of x-ray diagnosis and therapy against their benefits. The amount of radiation received by a patient who has a chest film is exceedingly small, and it would be unfortunate if people refused to participate in mass x-ray programmes because of a possible risk of leukaemia. It is protracted screening over the trunk which is dangerous, and the amount of radiation is likely to be greatly reduced by more stringent precautions and improved apparatus. The possible 50 cases of leukaemia a year from x-radiation *in utero* must be set against 439 deaths of mothers in childbirth, 15,829 stillbirths, and 9,750 deaths in the first week of life in 1955. Obstetricians and radiologists believe that the mortality of mother and child may be significantly reduced by appropriate x-ray examinations in pregnancy, and that they can save more lives than are likely to be lost from leukaemia, appreciating as they now do the hazards of x-radiation. Similarly, the death rate from leukaemia after radiotherapy for ankylosing spondylitis is only 3 per 1,000, and, though this is at least ten times as high as the usual incidence of leukaemia in this age group, it is a good deal lower than the mortality of 13 per 1,000 for interval partial gastrectomy for peptic ulcer in the best hands.

Important as has been the discovery of the leukaemogenic effects of x rays in man, their role does not seem to be comparable with cigarette smoking in cancer of the lung or saturated fats in coronary thrombosis. The search for other aetiological factors must be intensified. Alice Stewart and her colleagues are shortly extending their survey to leukaemia in adults, and it is to be hoped that those in charge of patients with leukaemia, especially in hospitals, will give them full co-operation in their important task.

Natural History of Leukaemia

The recent introduction of new remedies for leukaemia and the consequent need for therapeutic trials have attracted the attention of statisticians to the course of the disease and the effect of treatment on it. It is the old story that when we begin the intensive study of a disease we commonly find that we do not know as much as we thought we did about its natural history. For example, a question we want to answer is whether the initial treatment of chronic myeloid leukaemia should be by x rays, radioactive phosphorus, nitrogen mustard, or busulphan ("myleran"), and the data are not yet available.

In leukaemia there are two factors which make therapeutic trials difficult. The first is the great variation in the length of survival in all forms of leukaemia. The second is the occurrence of spontaneous remissions in acute leukaemia. The times of survival in leukaemia, as in other forms of malignant disease, do not have a symmetrical distribution about a mean but are skew—that is to say, the majority of the patients die relatively soon after the onset of the disease but a few live a surprisingly long time. This variable course of the disease is something we are already familiar with in non-lethal diseases such as infective hepatitis, and it means that we require a lot of cases and a long period of observation for therapeutic trials. Numbers required are further increased by the necessity to match cases by type of leukaemia and age of the patient.

The remissions of acute leukaemia are one of the most remarkable phenomena in the natural history of malignant disease. They occur typically in acute leukaemia and they may be complete or partial. In a complete remission all signs and symptoms of the disease disappear and the bone marrow becomes practically normal: a partial remission is substantial improvement but something less than this. Remissions may be spontaneous or induced. Swaen (1954),

who reviewed 97 spontaneous remissions in acute leukaemia, occurring in the days before chemotherapy, thought that the remissions were not, in fact, spontaneous but that they usually followed an infection, probably a virus infection. He thought that the infection caused necrosis of the leukaemic cells, and cancer and leukaemia have been treated by deliberate infection of the host with non-lethal virus diseases, though unfortunately with only scant success.

Spontaneous remissions are not common, at any rate complete ones, occurring probably in less than 5% of cases (Southam *et al.*, 1951). The great discovery of the last decade in leukaemia research has been the ability to provoke remissions by treatment. In acute lymphatic leukaemia in childhood remissions can be induced in 85% of cases. Two main groups of remedies have been used—corticoid hormones, and chemotherapeutic agents which act by blocking the synthesis of nucleic acid. At present three subgroups of the chemotherapeutic agents are available—antagonists of folic acid, purine, and glutamine respectively—but the synthesis of nucleic acid goes through so many stages and research in this field is so active that other agents are certain to be discovered.

The average duration of spontaneous remissions is about four months, and then some of the damaged cells recover and the disease rapidly recurs. Induced remissions may last longer because the therapeutic agent can be continued, but relapse eventually occurs owing to the development of resistance. This may be circumvented by alternating different remedies, and in this way life may be prolonged well over a year, even as long as five or six years. Theoretically, resistance could be postponed by using different drugs in combination. The chemist's dream is that if he can block one stage of the synthesis of nucleic acid so effectively that only, say, one in ten milliard cells becomes resistant, and if he can do the same at other stages, the odds against resistance or recurrence will finally become astronomical.

Nothing quite comparable with the spontaneous remissions of acute leukaemia occurs in chronic leukaemia, though almost all signs of the disease may be temporarily banished by effective therapy. Moreover, the remedies used in acute leukaemia are ineffective in chronic leukaemia, and vice versa. Arsenic, x rays, busulphan do harm and not good in acute leukaemia. Nevertheless, in both types of leukaemia the working hypothesis is that the remedy has a disproportionately lethal effect on the leukaemic cells and works very much as the sulphonamides and the antibiotics do in bacterial infection. The development of strains of resistant cells is likewise used as the explanation of the ultimate failure of treatment. Of course, not all haematologists share these views. Some believe that treatment does something to the defence mechanisms of the body rather than to the leukaemic cells.

Therapeutic Trials

Remedies must first be synthesized, then screened in experimental animals for efficiency in leukaemia and new growth, next studied pharmacologically, and finally tested in human leukaemia. Therapeutic trials are taking on the same shape as in tuberculosis, though it is difficult to get comparable numbers of cases. Survival is estimated from the onset of the first symptom that is identifiable as due to leukaemia—splenomegaly, adenopathy, or bleeding. We may in addition measure survival from the time of diagnosis or the onset of therapy. In analysing and comparing the data the mathematician uses the logarithms of the survival times because these have a normal distribution. For ordinary purposes it is not necessary to make any calculations, as the survival data can be represented graphically by the use of log-probability paper. For comparing different groups of cases, the time at which 50% and 10% remain alive can be read to the nearest half-month. By appropriate statistical methods it is possible to calculate the median survival, the standard deviation of a series, and the standard error of the mean, and in this way to test the significance of the differences between the various groups of cases. If a series con-

tains both living and dead patients, it is necessary to construct a life table such as is used in vital statistics and by insurance companies.

Satisfactory statistical studies of the natural history of the leukaemias are now available. Tivey (1952), who pioneered these studies, showed that of children with acute leukaemia treated only by supportive measures, without antibiotics or specific therapy, 50% will die within a period of approximately four months from the onset of symptoms but 10% will live as long as eleven months. There is no evidence that the prognosis in children with acute myeloid or monocytic leukaemia differs from that of children with the more common lymphatic leukaemia when no specific treatment is given. Haut and co-workers (1955) were unable to find any trials in which patients treated with the new remedies were compared with simultaneous untreated controls, which was perhaps not surprising, but there is good evidence that when patients are treated with the new remedies 50% live for twelve months and 10% for two years.

Tivey (1954) found no difference in survival between chronic myeloid and chronic lymphatic leukaemia. Half the patients will die 1.6 years after beginning therapy or 2.65 years after the first symptom. Ten per cent. will live 7 years after the onset of the disease and 1% will live for 15 years. Treatment has little or no effect on the length of survival, though the period of useful life is almost certainly increased. Additional criteria such as time spent in usual activities, time in hospital, and freedom from pain, could be used to measure the value of treatment.

The position reached in therapeutic research on leukaemia is that we now have full knowledge of the course of the disease and accurate methods for comparing different forms of treatment. Large numbers of cases and long periods of observation are necessary if new remedies are to be promptly evaluated. In England and Wales there were 2,224 deaths from leukaemia in 1955, of which just over half must have been acute leukaemia. No single centre can see enough cases for a therapeutic trial, and co-operative studies must therefore be planned on a national or international basis. Apart from the inertia which affects all of us, resistance to therapeutic trials comes from two quarters. Some physicians believe they can do better for their patients by individual treatment than by including them in a therapeutic trial. As trials in leukaemia nowadays consist in a comparison of remedies or of combinations of remedies this belief is not well founded. Some research workers believe that therapeutic trials mean the expenditure of a great deal of time and money for a relatively small return and that our resources would be better devoted to basic research in the laboratory. However, the expenditure is trifling compared with the national drug bill, and much of the work can be done by practising doctors and public health workers.

Conclusion

The exciting feature of research on human leukaemia in the last decade is that it has passed from the phase of description and classification to a study of the disease as it affects the community as a whole, its apparent increase, and the action of new remedies which relieve the symptoms and, in acute leukaemia at any rate, prolong life. As a side-effect we have learned what a lot can be achieved by co-operative endeavour within the framework of the National Health Service. The work of Abbott, Court Brown, Doll, Lea, and others on the occurrence of leukaemia after x-ray treatment of ankylosing spondylitis could not have been completed without the help of radiologists, physicians, records officers, and others in widely separated areas. Alice Stewart and her colleagues have shown how much the public health services can contribute to the mass study of a disease like leukaemia, reducing a problem of daunting size to manageable proportions. Therapeutic trials in tuberculosis and ulcerative colitis have shown how cases can be pooled and treated on a central plan.

Leukaemia is a hard nut to crack, and we shall have to wait for further fundamental scientific discoveries before we can greatly modify its frequency and mortality. In the meantime current interest in the incidence of leukaemia and in new forms of therapy can contribute significantly to the welfare of the unfortunate victims of the disease. My experience of therapeutic trials is that they arouse an enthusiasm for treatment which might otherwise be lacking and produce an improvement in results quite apart from the specific remedy. Indeed, as in the famous Hawthorne experiment at the Bell Telephone Works, community studies on the incidence and treatment of disease may sometimes have side-effects which are just as important as the original aim of the investigation.

Summary

Acute leukaemia is becoming commoner than chronic leukaemia, and chronic lymphatic leukaemia commoner than chronic myeloid leukaemia.

Important factors in the increase in the incidence of leukaemia in Western Europe, North America, and Australasia, and in the higher incidence of leukaemia in these countries than in Asia and Africa, are greater availability of medical care with consequent improvements in diagnosis and ageing of the population, leukaemia being more frequent in later life. It is nevertheless unlikely that these factors account for the whole of the increase, and the search for aetiological factors in leukaemia associated with the rise in the standard of living should continue.

Man-made ionizing radiations such as x rays can induce leukaemia, but there is no evidence that they can account for the considerable increase in notifications of leukaemia in the later age groups, which is largely of the chronic lymphatic type, whereas leukaemia after irradiation has so far been predominantly myeloid.

The risks of irradiation may be greater in the foetus than in the adult, and stringent precautions should be taken when x-raying pregnant women. These risks should be carefully balanced against the reduction in maternal mortality, stillbirths, and perinatal deaths which can be secured by the intelligent application of radiography.

Our recently discovered ability to provoke remissions in acute leukaemia, and the accelerating development of powerful chemotherapeutic remedies and new methods of administering ionizing radiations, have made it essential to organize therapeutic trials in leukaemia. Owing to the spontaneous variations in the course of the disease large numbers of cases are required for valid trials, which must therefore be organized on a co-operative basis.

Although we shall have to wait for further fundamental scientific discoveries before we can greatly modify the frequency and mortality of leukaemia, there is no doubt that current interest in the incidence of leukaemia and in new forms of therapy has contributed materially to the welfare of the unfortunate victims of the disease.

TREATMENT OF STONE IN THE COMMON BILE DUCT

BY

JOHN HOSFORD, M.S., F.R.C.S.

Surgeon, St. Bartholomew's Hospital, London

There are few conditions so disappointing to patients and their doctors as a recurrence of biliary colic following an operation on the biliary tract. I am concerned not so much with the case in which there has been a simple cholecystectomy for stones and a stone has been overlooked in an unopened common duct, as with the case in which there has been a careful exploration of the duct and removal of stones or mud, and at a later date colic has occurred. There is no doubt that surgeons open the common duct much more often than they used to, perhaps because it is easier owing to better anaesthesia and the better general condition of patients, and perhaps owing to information gained from experience and possibly also from cholangiography.

When small stones or biliary mud have been sought and found it is easy to leave some more behind in the lower part of the duct or even in the upper part, be the search ever so careful. They may later pass into the duodenum, though they are more likely to remain in the duct and increase in size or amount and cause further trouble. This may take the form of pain and/or jaundice, or it may only show as recurring attacks of "chills" due to cholangitis. To repeat the operation of exploration and evacuation of the common duct alone is neither sound nor satisfactory, and it is wise to establish some larger opening from the common duct instead of the small lumen at Oddi's sphincter. This may be made at the lower end by some form of sphincterotomy (perhaps combined with a long-armed T-tube) or plastic operation on the duct, or it may be made higher up by a new anastomosis between the common duct and the duodenum. One of the purposes of putting forward this brief communication is to make a plea for the wider use of the latter operation—choledochoduodenostomy. Most surgeons will have done this operation a number of times, some very readily, others less readily, being uncertain of the later results. There are several points connected with the operation about which one may be anxious: whether duodenal contents will get into the common duct and cause infection or other trouble; whether stones or debris may collect in the part of the duct distal to the stoma and set up inflammatory changes or obstruct the main duct of the pancreas; or whether, indeed, the stoma may close.

I have been so well satisfied with the results of the operation over a period of some years that it seemed worth while making a few remarks about it. These are based on an experience of 21 cases.

The subject of division or injury of the ducts is not considered here, but only cases in which the duct is still intact but obstructed from within. Nor do I propose to argue here whether stones and mud found in the duct at a second operation were necessarily overlooked at the first, or whether they had formed since then. In all probability the correct answer is that it is sometimes one and sometimes the other.

It is not possible to give exact indications for the operation, but it is hoped that from the following account of one's experience and cases the place and usefulness of the operation may be gathered.

At first I did a choledochoduodenostomy only when there had been a previous operation and when the obstruction had recurred owing to biliary mud or sand; but since finding how good the results are I have done it as a first operation for common-duct stones when these were associated with much mud or sand, and particularly when the duct was thickened and somewhat rigid from inflammation as well as dilated from obstruction.

I have been most gratified with the singular freedom from symptoms these patients have afterwards. There is a free way between the duodenum and the common duct, as can be shown by a barium meal being seen to enter the biliary tree. A plain x-ray film of the region in many of these cases after operation shows the common duct, and sometimes branches of the hepatic duct as well, outlined by air. A "biligrafin" x-ray film does not show up the ducts, probably because it passes through them too quickly, but one can see the dye in the duodenum. I imagine that, provided fluid and solid particles can get out of the common duct as easily as they can get in, it does no harm and neither obstruction nor liver infection occurs: certainly the patients remain in good health without pain or jaundice or fever. The first part of the duodenum is probably sterile in healthy people on a normal diet.

Technique

There are certain points about the technique of the operation which I think are worth mentioning.

The common duct is approached by whatever route the surgeon favours, and this may, of course, be very difficult if there have been several previous operations on the duct. I usually use a modified Kocher's subcostal incision or a paramedian, and approach the duct from the antero-lateral aspect. I have no experience of the postero-lateral approach through the bed of the tenth rib, which is advocated by some surgeons in cases that are likely to prove difficult. If the common duct is largely covered over by the duodenum, as is sometimes the case in a virgin operation and frequently so in a second operation, the first part of the duodenum must be mobilized by careful dissection and drawn downwards, and the blood vessels which are usually present ligated and divided. If it is the type of case in which it is thought that choledochoduodenostomy may be required the duct is opened by the usual vertical incision, but this should be low down very close to the point where the duct passes behind the duodenum.

When the duct has been fully explored, and if it has been decided to do a choledochoduodenostomy, a vertical incision is made in the duodenum as shown in Fig. 1, the upper end of the incision being very close to the lower end of the incision in the common duct. If the edges of the opening in the common duct are held gently apart by stay sutures the anastomosis, which is done with interrupted sutures of fine catgut, is not difficult. The first suture joins the lower end of the incision in the duct to the upper end of the incision in the duodenum. Sutures are then put in on each side alternately from below upwards, each being

tied as it is put in and so arranged that the cut edges are inverted as shown in Fig. 2. The stoma is about 2 cm. in length, and six or seven sutures are placed on each side. A few reinforcing sutures are put in on each side through any

FIG. 1.—The vertical incisions in the common bile-duct and duodenum for a choledochoduodenostomy.

FIG. 2.—The first five catgut sutures placed in making the anastomosis.

conveniently placed tissue. A corrugated rubber drain is introduced through a stab wound down to the site of the anastomosis.

Most of the descriptions of this operation are of a horizontal stoma, the opening being placed transversely in the common duct, but I prefer the vertical stoma described above and have found it very satisfactory from the technical point of view as well as functioning well. What is more, when the operation is begun a decision on whether an anastomosis will be done or whether the duct will be closed or drained has not always been made, and the usual vertical stoma for the exploration of the duct can be used for the anastomosis provided it has been placed far enough down the duct adjacent to the duodenum.

Case Reports

Five out of the 21 cases are described. They have been chosen to illustrate different typical points: in three there had been previous operations on the biliary tract, and in two it was the first operation. The ages are those at the time of the choledochoduodenostomy.

Case A.—A housewife, aged 64, began to have attacks of biliary colic in 1930. In 1932 she was operated on elsewhere, but apparently it was possible to remove only a part of the gall-bladder, with stones in it, owing to extensive adhesions and inflammation. In 1939 she had attacks of jaundice and pain. At operation in November, 1940, the remains of the gall-bladder were removed and the common duct was opened. It was dilated, and stones and much mud were removed. A choledochoduodenostomy was performed. She had no further trouble until 1944, when she developed a carcinoma of the stomach which a colleague removed, doing a Billroth-I type of operation. She lived for another ten years, dying in 1954 with metastases in the liver at the age

Fig. 3.—Case A. Radiograph following a barium meal 11 years after choledochoduodenostomy. Barium is clearly seen in the common bile-duct and smaller ducts higher up.

of 78. During the 14 years she lived after the choledochoduodenostomy she had no symptoms referable to the biliary system, and a barium meal examination 11 years after the operation showed that barium very readily entered the common duct (Fig. 3).

Case B.—A man aged 46, the manager of an English firm in Lisbon, had had occasional attacks of pain in the upper abdomen for three years; they were never very severe, but on one occasion had been accompanied by a shiver. There had never been any jaundice. He was a very fit man, and nothing abnormal was found on examination. Cholecystograms in 1947 and 1950 showed no filling of the gall-bladder, but in the 1950 films air could be seen in the bile passages in the liver, and a tentative diagnosis of a fistula between the gall-bladder and duodenum was made. Operation was performed in November, 1950. A dense mass of adhesions surrounded the gall-bladder and common duct. A fistula found between the shrivelled gall-bladder and duodenum was divided and the opening in the duodenum closed. The common duct was much dilated and thickened, and was filled with a soft stone about 1.5 by 3 cm. The lower part of the duct immediately distal to the stone was contracted. As this part had so thick and rigid a wall, and the upper dilated part was also thick and rigid from chronic inflammation, it was thought wise to do a choledochoduodenostomy. The patient made an uninterrupted recovery, and in 1955 he

wrote from Lisbon saying, "Since my operation I have enjoyed perfect health so far as my digestive organs are concerned."

This is an example of a choledochoduodenostomy being done at a first operation on the biliary passages. The large mass of soft stone in the duct had been able to form quite quietly, as there was an adequate escape for the bile through the gall-bladder into the duodenum.

Case C.—A very remarkable man of 87, a doctor of science who worked six days a week as a research chemist, was first seen in 1954. The history was that he had had an attack of obstructive jaundice in 1934 for which a cholecystostomy was performed. He remained well until 1953, when he had attacks of biliary colic and nausea. A cholecystectomy was performed elsewhere. The lower end of the common duct was said to be stenosed. In 1954 the pain recurred and he became jaundiced. At operation in February, 1954, a grossly dilated and thickened common duct was found to contain biliary mud and small stones. As the duct was large and thickened and it was the third operation on his biliary tract a choledochoduodenostomy was performed. His recovery was interrupted by a severe chest infection, but he got perfectly fit and returned to his full work six days a week. He has remained in excellent health, but as he is now in his 91st year he works only five days a week. In 1956 he enjoyed to the full the good fare provided on a Mediterranean cruise.

Case D.—A housewife of 72 began to have attacks of biliary colic, vomiting, and jaundice in 1949. In 1951 at operation a macroscopically normal gall-bladder without stones in it was removed. Several stones and some mud were removed from the common duct, which was then drained by a T-tube. She remained well until 1954, when there was a recurrence of pain and jaundice. At operation in August, 1955, the common bile-duct was so dilated that it admitted the thumb. A large stone and some mud were removed from the duct and a choledochoduodenostomy was performed. Apart from a mild infection of the wound with a coliform bacillus there was an uninterrupted recovery. She has remained well and free from symptoms since the last operation.

Case E.—A man aged 82, a retired confectioner, had an attack of mild upper abdominal pain followed by jaundice in January, 1955. In March, 1955, there was a return of the jaundice but no pain. A biligrafin x-ray film showed a very dilated common duct with filling defects in it. In April, 1955, at operation the gall-bladder was found to be small and to contain a few stones, and was removed. The common bile-duct was grossly dilated and had a thick wall; it contained much biliary mud and stones. A choledochoduodenostomy was performed. There was a clostridium infection of the outer end of the wound which cleared up well with penicillin. He has remained in good health apart from spinal arthritis, an old trouble of his.

This was a case in which it was thought right and proper to do a choledochoduodenostomy at the first operation, in view of the patient's age and the very dilated and thickened condition of the duct.

Results

A choledochoduodenostomy has been performed on 21 patients (12 men and 9 women) for obstruction of the common bile-duct by stone or biliary mud. In all the cases the duct was dilated, and in most of them it was thickened and rigid. Sixteen of the patients had had one or more previous operations on the biliary system, but in five cases there had been no previous operation. One patient died from a massive pulmonary embolus on the fourth day after the operation: the other patients all left hospital well recovered from the operation. One, aged 73, died suddenly from coronary thrombosis five months after the operation. Most of the patients were rather old, the average age being 66. Two men were over 80, one being a remarkably sprightly doctor of science who was 87 at the time of the operation (Case C) and another was 82 (Case E). The youngest was aged

46 (Case B). As the majority of the patients were in an old age group it is not surprising that three more have died, 15 years, 4 years, and 2 years respectively after the operation, apparently from conditions unassociated with it.

There were no particular complications in the post-operative period. In four of the cases there was some infection of the abdominal wound. In one the organism was a clostridium: the patient was not ill with it, but it delayed healing of the wound by about 10 days.

In none of the cases was there any apparent leakage at the anastomosis.

I have been a little surprised at the freedom from symptoms shown by these patients since operation. None has had jaundice or chills. A few have had some abdominal discomfort occasionally, and one man who had had four operations in all had a severe pain lasting three to four hours ("just like my old pain") 16 months after his choledochoduodenostomy. Three patients noticed a slight dragging feeling in the right hypochondrium after a big meal: whether this was due to distension of the common duct, to a pull on the anchored duodenum, or to adhesions it is impossible to say.

There are no apparent digestive or duodenal symptoms following this operation. Three patients said their motions were looser than previously.

In a number of cases, post-operatively, air can be seen in a large part of the biliary passages. A barium meal can be seen to go into the ducts for a considerable distance, but it soon comes out again. In one of the patients, who had a barium-meal examination post-operatively, the radiologist made the interesting observation: "Barium meal: in the erect film the biliary tract is outlined by air. As soon as the patient was placed in the supine position, the barium refluxed up the bile duct, which is rather dilated." One wonders whether this observation by the radiologist should prompt us to advise patients who have had a choledochoduodenostomy not to lie down after a meal until sufficient time has elapsed to allow the stomach to empty. I have not done so. Another thought that has passed through my mind is whether mud or stone forms in the duct distal to the anastomosis or whether food collects there. I do not know the answer to this; but trouble, so far as fresh symptoms are concerned, does not seem to arise.

Conclusions and Summary

A vertical, supraduodenal choledochoduodenostomy is an operation which gives good results with a surprising freedom from symptoms afterwards.

It is very valuable in cases in which there are recurrent stones or biliary mud in a thickened, dilated common bile duct when previous operations have been done.

It is also probably sound practice to do the operation in any patient in whom the duct, in addition to being dilated from obstruction by stones, is thickened and rigid from chronic inflammation, even though no previous operation has been done. It is not advised when the duct appears healthy, even though it contains stones.

Twenty-one cases in which this operation has been performed for stone are referred to.

Some points in the technique of the operation are mentioned.

The results and post-operative radiographic appearances are discussed.

The 113th annual issue of the *Medical Directory* is now available from Messrs. J. & A. Churchill Ltd., 104, Gloucester Place, London, W.1 (2 parts, 84s.). It contains 87,122 names, nearly 2,000 more than last year.

Defects in the function of many organs in the body may be detected by chemical analysis of blood or of secretions, such as gastric or intestinal contents, faeces, or urine. The collection of specimens for such analyses can be done by nurses or technicians, and their analysis is usually accepted as a routine by departments of clinical chemistry.

The situation is quite different in testing lung function. Impairment of the lungs' action as a bellows can be assessed from study of their ventilatory reserve by measuring the maximum breathing capacity either directly, by asking the patient to hyperventilate maximally for a given period of time, or indirectly from a spirometric tracing of a single forced expiration. This measurement is relatively simple and is becoming an accepted clinical investigation; nevertheless it requires trained observers. But the study of defects in pulmonary gas exchange usually demands analysis of expired gases. The taking of gas samples for such analysis, either at a specific time in the breathing cycle or from a collection of gas expired over even a short period of time, requires intricate or bulky apparatus, while the established methods of chemical analysis of the gases so collected are tedious, time-consuming, and beyond the routine capacity of many laboratories. Before most of the tests of defects in gas exchange can be accepted as part of routine clinical study simpler and more rapid techniques of gas sampling and analysis are needed.

Automatic gas-analysers such as the infra-red analyser for carbon dioxide or carbon monoxide, the spectrophotometric nitrogen analyser, the para-magnetic oxygen analyser, the katharometer for helium or nitrous oxide, etc., have simplified some of these tests sufficiently for them to be performed routinely in specialized laboratories. But advances have been limited, and the problems of gas sampling have remained because none of these instruments, except the nitrogen meter and some forms of infra-red carbon dioxide analyser, can continuously record the changes in gas concentration occurring within the breathing cycle. Their response time is too slow and the gas flow required for their operation is too large a fraction of the total breath expired. Moreover, each instrument can estimate only one gas, whereas simultaneous analyses of several gases is required for many purposes.

It has long been realized by workers seeking new methods of gas analysis that the mass spectrometer is a versatile instrument, theoretically capable of overcoming

*Working with the aid of a grant from the Medical Research Council.

all these difficulties, but machines commercially available are designed mainly for isotope separation or for hydrocarbon analysis in the oil industry, and even if modified for respiratory use, as some have been in the U.S.A., they are not entirely satisfactory. Some have been designed for continuous analysis for one or for two gases (Hitchcock and Stacy, 1948; Miller *et al.*, 1950), but none has fulfilled the requirements of respiratory work. A new type of instrument was required for this purpose which was also reliable enough for daily routine use, and one has been designed by one of us (K.T.F.). We propose to describe it briefly and to show some of its potentialities in clinical investigation and physiological research. A full technical description will be published elsewhere.

The Respiratory Mass Spectrometer

Specifications.—The instrument was designed to fulfil the following requirements: (1) It should provide a continuous analysis of inspired and expired gases drawn either from a mouthpiece or from within the bronchial tree at bronchoscopy. (2) It should simultaneously record concentrations of at least four gases, including oxygen, nitrogen, and carbon dioxide, and some other foreign gases of physiological interest. (3) It should present the analysis both as meter deflections and continuous traces on a direct-writing recorder. (4) It should require a sample not greater than 15 ml. per minute, which is a negligible fraction of the respiratory minute-volume. (5) It should have a response-time short enough to follow accurately changes in gas concentrations throughout the respiratory cycle. Full deflection in 0.1 second was required. (6) It should be stable and accurate enough to detect 1% change of concentration. (7) It should be readily transportable from the laboratory to ward, theatre, clinic, or field survey. This meant dispensing with the running water and dry ice required to maintain the vacuum system of existing machines.

Principles of Operation.—Analysis in a mass spectrometer is performed by separation of the molecules in the gas sample according to their molecular weight. This separation is achieved by bombarding the gas molecules entering the machine with a beam of electrons so that the molecules are ionized, and then deflecting the ions with a magnetic field. This field is at right angles to the direction of travel of the ions, so that they are deflected into circular paths. The deflection is greater for light than for heavy ions, so the stream splits up into beams of different molecular weight, any of which can be caught on a suitably placed collecting electrode. As each ion carries a positive charge, the number in any beam can be found by measuring the minute electric current which it carries to the collector. The proportion of molecules of different weights in the gas sample can thus be found, and a complete analysis of the gas sample can be made provided that all the constituent gases have different molecular weights, which is usually the case in respiratory work. These processes are conducted in a high vacuum, normally produced by water-cooled pumps and vapour-traps cooled by liquid air or dry ice.

Description

In this instrument (see Fig. 1) a small fraction (0.1%) of the patient's exhaled breath is drawn continuously and at high velocity through a length of hypodermic tubing into the spectrometer by a sampling pump. An even smaller fraction (0.01%) of this sample passes through a molecular "leak"

into an ionization chamber where the gas molecules are charged (ionized) by bombardment with a transverse stream of electrons. The charged molecules (ions) diffuse out of a slit in the chamber wall and are accelerated by being attracted towards a plate (P_2) to which a negative accelerating voltage is applied. A similar slit in this plate permits

Fig. 1.—Diagram of the mass spectrometer. (B.=ion beams of different mass; C.C.=collector cup; C.S.=collector slit; D.T.=dispersion tube; E.B.=electron beam, at right angles to plane of diagram; G.M.=gas molecules within ionization chamber; L.=molecular leak; P_1 and P_2 =accelerator plates; P.M.=permanent magnet; S.T.=sampling tube.)

many of the accelerated ions to stream as a narrow pencil into a magnetic field at right angles to their course so that they are deflected and separated into a fan-like pattern of beams of different molecular weight.

The position of this pattern of ion beams may be altered by changing the velocity with which all the ions enter the magnetic field. This velocity is controlled by the voltage which accelerates them from the ionization chamber; by variation of this voltage it is possible to move the "fan" and so direct a beam of ions of a given mass on to one collector. An analysis can thus be performed by varying the accelerating voltage from its maximum to its minimum value, thus "scanning" all the ion beams across the collector. The collector current therefore rises to a series of peak values representing the abundance of ions in each beam in turn, and falls to zero between them.

The scanning process is in practice made repetitive at 25 cycles per second. The pulses of current thus brought to the collector, as the array of ion beams swings across it, are amplified and displayed on a cathode-ray oscilloscope running synchronously with the scanning accelerating voltage. The current pulses are thus spread out as a series of peaks in an apparently stationary "mass spectrum" (see Fig. 2). The horizontal position of a peak identifies the molecular weight of a gas in the sample, and the vertical height of a given peak is proportional to the abundance of molecules

Fig. 2.—Drawing of mass spectrum as seen on the oscilloscope screen with the instrument sampling expired air. (N_2 , O_2 , A, CO_2 =peaks of nitrogen, oxygen, argon, carbon dioxide, respectively; S_1 , S_2 , S_3 , S_4 =light spots for "tuning" pen-recorder to following variations in height of any peak.)

of that gas at a given instant, and hence its partial pressure. Thus, when air is being drawn down the sample tube the nitrogen (mass 28) is represented by a tall peak on the left, next the oxygen (32), then the argon (39), and finally the carbon dioxide (44). On exhaling over the end of the sampling tube the oxygen peak will fall and the carbon dioxide peak will rise immediately the expired gas from the lungs enters the instrument. During breathing the heights of the peaks

Fig. 3.—Photograph of mass spectrometer (M.S.), electronic measuring equipment (E.), and four-channel pen-recorder (R.). (S.T.=entrance for sampling tube; M.=monitoring meters; O.=oscilloscope displaying mass spectrum.)

fluctuate as inspire or expire passes the sampling point. The height of one or more of the displayed peaks can be automatically reproduced on a multichannel pen-recorder, so giving a continuous trace of the variations in partial pressure of a gas against time.

The selection of the peak or peaks to be recorded is done with the aid of a number of brightened spots (Fig. 2) which may be moved along the baseline of the oscilloscope trace by their respective control knobs on the electronic selector cabinet (Fig. 3, E) so that they climb the required peak. When the spot is tuned to the apex of a peak, as determined by the monitoring meters (Fig. 3, M.), one of the pens will automatically follow the variations in height of that peak. For instance, to measure oxygen concentration the operator positions one spot on the top of the peak corresponding to mass 32, and one pen of the recorder will then continuously record the changing partial pressure of this gas. As many "selector" channels as required can be incorporated; four are used on this machine, and it is thus possible to analyse simultaneously for any four constituents of the gas mixture. A pen of the recorder actually jumps each 25th of a second to the new height of the peak revealed as the ion beam of the relevant mass crosses the collector. This time is sufficiently brief in comparison with the respiratory cycle for the record to appear continuous.

Sampling Tubes

The sampling tube for general use consists of

about 3 feet (91 cm.) of fine (0.5 mm. outside diameter) hypodermic stainless-steel tubing. This is heated electrically to 70° C., to prevent condensation of water vapour, and covered with a protective, thermal insulating cover. The end of the tube goes into a taper plug so that it can be sited accurately at the centre of a gas stream, usually in a mouthpiece, as a push-fit (Fig. 4, A).

For use regionally within the lungs at bronchoscopy an alternative 4½-ft. (137-cm.) sampling tube is used, on the end of which different sizes of "cage" (Fig. 4, B) can be screwed so that the end of the sampling tube can lie centrally within the lumen of the chosen segmental bronchus. Three cages (of 5, 9, and 13 mm. diameter, respectively) have been made for us by Dr. B. M. Wright so that they fit different parts of the bronchial tree as determined initially from a precision cast of the tree made in plastic (Tompsett, 1952). The wire to carry the heating current is replaced by wider-bore hypodermic tubing (electrically insulated from the sample tube itself). This wider tubing makes the whole sample tube more rigid for manipulation down the bronchoscope, a short flexible end being left, as shown in the diagram, for bending as required. The outer hypodermic tube is finally covered with heat-insulating plastic. Sampling tubes can be changed for sterility between cases or in the event of blockage during sampling, and the instrument brought back into operation within two minutes.

Dimensions and Performance Data

The general appearance of the instrument is shown in Fig. 3. It consists of three mobile cabinets: the spectrometer itself (2 ft. 6 in. by 2 ft. 6 in. by 3 ft.—76 by 76 by 91 cm.), the electronic measuring equipment (2 ft. 6 in. by 2 ft. 6 in. by 4 ft. 6 in.—76 by 76 by 137 cm.), and finally the four-channel "Sanborn" pen-recorder (2 by 2 by 3 ft.—61 by 61 by 91 cm.). Each selector channel of the electronic equipment is on a plug-in separate chassis allowing immediate replacement. The case of the spectrometer is rapidly removable for servicing.

The instrument is designed so that potentially any stable gas of molecular weight between 18 (water vapour) and 80 (krypton) can be analysed. In practice the instrument is normally set for the mass range 25 to 50, thus including most gases of physiological importance, except helium (mass 4) which, because of its insolubility, has often been used for measuring the lung volume and distribution of ventilation within the lungs (Meneely and Kaltreider, 1949; Gilson and Hugh-Jones, 1949, 1955; Bates and Christie, 1950; Briscoe *et al.*, 1951). To have included helium would have meant more complex design and cost, using high-potential electrical components; moreover, neon (mass 20) is an almost equally insoluble inert gas available in substitute.

If the gas concentration at the tip of the sampling tube changes abruptly there is a constant "delay time" before the pens start to respond to the change, of 0.10 to 0.15 second, depending on the length and bore of the sampling tube in use. The pens then rise to the new level, 95% of the movement being completed in 0.10 second. It is this latter "response time" which is important in following fast gas-concentration changes. The delay time which is small may usually be ignored; it simply means that events are recorded slightly later than they occurred. If precise time relationship with other events is required the gas concentration tracing may be moved back by the required time interval.

The machine is normally left in a "stand-by" condition, with only the vacuum pumps running. To put it into operation the ionizing electron beam is turned on, the sample pump is started, and the electronic valves are warmed up. An air sample flow is then admitted and sufficient time allowed to elapse for the temperature and pressure conditions in the ionization chamber to stabilize. Our experience has been that one hour is sufficient time to prepare the machine for use. The various selector spots on the oscilloscope trace are positioned on the relevant peaks and the

Fig. 4.—Diagrams of ends of sampling tubes: A, with taper plug (P.T.) for routine use in a mouthpiece; B, with protecting interchangeable cages (C.), sizes from 5 to 14 mm., for use at bronchoscopy. (H.W.=wire carrying heater current; H.T.=0.5-mm. bore hypodermic steel sampling tube; S.T.=outer steel tube for rigidity; I=electrical insulating coating; P=plastic covering.)

sensitivity of each channel is adjusted to give a known and convenient full-scale deflection, by using standard mixtures of the gases to be included in the analysis. Stability is affected by conditions in the ionization chamber, which are changed slightly if widely different gas mixtures are used. An overall control of the sensitivity of all channels together is therefore provided to make any minor corrections necessary during operation, using room air or a known mixture as standard.

At any time the trace has an absolute accuracy within 3%, though relative variations can be determined within 1%, of the full-scale deflection selected. Exact full-scale deflection is selected for convenience to the work in hand, and may be given by gases whose partial pressure is anything from 3% to 100% of the total.

Clinical Use of the Spectrometer

The instrument's ability to provide a continuous analysis for several gases should remove the difficult problem of gas sampling for routine clinical tests, and facilitate advances in research on the mechanism of gas exchange in the lungs.

Lung-function tests are rapidly proving their value in clinical medicine. With their help the mechanism of a patient's signs and symptoms, such as breathlessness or cyanosis, can often be understood from a quantitative measure of such factors as the relation between the distribution of gas and blood in the lungs, or of any barrier to the normal diffusion of gas between the alveoli and the blood. Such an assessment not only provides a basis for logical therapy, but repeated tests enable the physician to follow the efficacy of treatment. Measurement of all the different aspects of lung function aids the surgeon in gauging the likely functional effects of proposed operation. But lung-function tests are of no value in making a diagnosis of chest disease in terms of morbid anatomy or histology, with the notable exception of making a positive diagnosis of the presence and degree of emphysema.

The likely uses of the spectrometer in lung-function testing can best be considered under two headings: (1) studies of expired gases sampled at the lips; and (2) regional analysis within the bronchial tree.

Analysis of Expired Gases at the Lips

Multiple Breath "Wash-out" Data

The well-established procedure for determining the degree of inequality of gas distribution in the lungs by "washing-out" the nitrogen in them with successive breaths of oxygen or, alternatively, "washing in" a foreign inert and insoluble gas can readily be done. Part of a typical tracing taken from the spectrometer is shown in Fig. 5. Nitrogen is being washed out of the lungs by the inhalation of a mixture of argon and oxygen, the spectrometer being set to record the concentration of argon and nitrogen at the lips. Before the point marked S in Fig. 5 the subject is sitting breathing air, fluctuations in the nitrogen concentration between inspiration

Fig. 5.—Assessment of uneven ventilation in the lungs by the "gas wash-out" technique. (Part of a record in a normal subject showing the nitrogen in the lungs being washed out by a mixture of argon and oxygen, as described in text. Tap turned in expiration following point S; puff of gas to clear apparatus dead space at P. E and I=expiration and inspiration, respectively. Ordinates, relative gas concentrations. Paper speed 10 mm. per second.)

and expiration being caused by the effect of the respiratory quotient and of the different moisture content of inhaled and exhaled air. During the expiration after S, a tap is turned so that the subject will breathe the argon-oxygen mixture in the next inspiration, the brief spike of the records at P. being caused by a puff of argon-oxygen mixture used to flush the dead space in the tap. In each subsequent breath as nitrogen is washed out argon is washed in, so that finally the exhaled argon is at the same concentration as that inhaled, while nitrogen almost disappears from the expirate. The steplike changes in concentration of these two gases are virtual mirror images.

The usual analysis of these curves is to plot the change in concentration of either gas on a logarithmic scale against the number of breaths. When the gas distribution in the lungs is "even," as in normal subjects, a nearly straight line is obtained on this semilogarithmic plot, since the wash-out process is approximately a simple exponential one. If

Fig. 6.—Nitrogen concentration in each successive expiration during a period of breathing a nitrogen-free gas mixture of a patient with emphysema (left) compared with a normal subject (right), plotted on a logarithmic scale against the number of breaths on a linear scale.

ventilatory inequality exists, as in emphysema, a biphasic exponential process becomes more obvious, and the semilogarithmic plot is curved (Fig. 6). The procedure is simple and rapid with the spectrometer. The continuous analysis throughout each breath will make it possible to find the effect of sampling at different times during the expirate and hence assess the results that were obtained when using some of the older methods of gas analysis; while the effect of using gases of different solubility or of nitrogen excretion from the blood to the lungs during the process can be determined.

Single-breath Data

Useful as the spectrometer is for "wash-out" tests, the information it will provide from analysis of a single breath is much more useful. By analysis of a single expiration with this instrument it should be possible not only to elucidate the unevenness of gas distribution but also to determine the way in which blood is distributed in the lungs in relation to gas distribution, and to estimate the diffusion barrier between blood and alveolar gas. This multiple information from analyses of single expirations is obtainable in no other way.

Nitrogen Analysis

Nitrogen analysis in a single expirate following an inspiration of oxygen (Fig. 7, bottom tracing) gives information similar but supplementary to that obtained from the "wash-out" data. Initially, oxygen from the upper respiratory dead space is exhaled so that there is a negligible amount of nitrogen in the record (phase 1), then an S-shaped portion (phase 2) appears which represents dead-space oxygen dilut-

Fig. 7.—Analysis of a long expiration following a single breath of oxygen. Tap turned from air inspiration to oxygen at point marked O₂. Lower two tracings: concentration of CO₂ and N₂ sampled at the lips. Upper two tracings: concurrent rate of flow of expired gases from pneumotachograph, and gas volume, from electrical integration of flow. Paper speed 5 mm. per second.

ing alveolar nitrogen, and finally a plateau of alveolar nitrogen (phase 3). The slope of the alveolar plateau gives a measure of the inequality of gas distribution, for a difference in concentration at the beginning and end of the alveolar plateau results from nitrogen being preferentially diluted by the breath of oxygen in some parts of the lung at the expense of others (Fowler, 1948). But this slope must depend not only on the uneven distribution of gas to the different parts of the lung but also on the timing of emptying of these parts. If all the regions, with different dilutions of nitrogen in them, emptied together, the alveolar plateau would be horizontal. By combining data from the nitrogen wash-out and single-breath experiments it may be possible to obtain measure both of inequality of gas distribution and of the relative timing of emptying of the different parts.

Carbon Dioxide and Oxygen Analysis

Carbon-dioxide and oxygen analysis will provide even more important data. Although inequality of gas distribution is important in itself (for example, in diagnosis and assessment of emphysema), from the functional point of view the significance of this factor depends on the relative distribution of blood to the well and badly ventilated parts of the lungs. If air is sent to parts of the lung which are poorly perfused with blood there is wasted ventilation, while blood flow through poorly ventilated parts causes "venous admixture" in the arterial blood. In fact, the distribution of ventilation-perfusion ratios in the lung determines the gas tensions which can be maintained in the blood, and likewise those appearing in the exhaled breath. Since there is practically no carbon dioxide in the inspired air, that exhaled

must come from the blood, and the concentration of this gas in the alveolar phase of the expiration is an indication of the uniformity of the ventilation-perfusion ratio (Comroe *et al.*, 1955). Unfortunately, other factors besides the ventilation-perfusion ratios affect the carbon-dioxide curves. However, the respiratory quotient is also a function of the ventilation-perfusion ratio, and a simultaneous record of oxygen and carbon dioxide in a long exhalation following an ordinary inspiration of air can readily be got from the spectrometer, on a tracing similar to that in Fig. 7, and hence the variation in respiratory quotient during expiration can be measured.

Calculations from the respiratory quotient with the aid of the oxygen-carbon-dioxide diagram (West *et al.*, 1957) will enable an estimate of the variation in the ventilation-perfusion relationships throughout the lungs to be made, and provide a simple test of this factor for routine clinical use. This measure, not hitherto available in a form simple enough for clinical use, may be of great help in understanding the behaviour of the lung in such conditions as asthma and emphysema, besides being an important measure for determination of the cause in patients who exhibit cyanosis or carbon-dioxide retention.

Carbon Monoxide

Carbon monoxide has recently been used increasingly for studying the readiness with which gases diffuse between gas in the alveoli and the blood. It has such a high affinity for haemoglobin that its rate of uptake is primarily a function of this diffusion. This test of carbon-monoxide uptake readily permits the detection of a barrier to diffusion caused by pathological change in the alveolar wall ("alveolar-capillary block" of Cournand, 1952) in diseases such as sarcoidosis, scleroderma, etc., or from any reduction in the effective surface area of the lung. It can be performed by either the multiple-breath (Filley *et al.*, 1954; Bates *et al.*, 1955; Gilson and Hugh-Jones, 1955) or the single-breath (Forster *et al.*, 1954) technique. Infra-red gas analysis has made it a clinically practicable procedure, but the infra-red analyser has a response time too slow and needs a gas sample too big to observe accurately the "alveolar plateau" for carbon monoxide. The new spectrometer would be ideal for the analysis, especially as for many calculations it is really necessary to know the distribution of an inert insoluble gas given concurrently with the carbon monoxide, were it not that nitrogen has the same molecular mass (28) as carbon monoxide, hence they both contribute to an identical peak in the mass spectrum. However, it may be possible to wash out the nitrogen in the lungs with, say, argon-oxygen mixtures and then record a single breath of carbon monoxide together with another inert gas, say, neon, as a tracer for gas distribution.

Since this spectrometer can record the analysis of a gas mixture for four gases concurrently there seems no reason why, ultimately, the degree of inequality of ventilation, of ventilation-perfusion ratios, and of perfusion (the latter from the relation between the first two) should not be measured at the same time as the diffusing capacity from single expiration measurements following the inhalation of a suitable mixture of gases.

Regional Analysis at Bronchoscopy

Gas analysis, similar to that of the expirate sampled at the lips, can be used to determine ventilation and perfusion relationships in individual lobes and segments. A special sampling tube (Fig. 4, B.) is introduced at routine bronchoscopy so that the appropriate cage holds the tip of the sampling tube itself centrally within the required branch of the bronchial tree. The small (0.5 mm.) tube causes little obstruction to the air flow from lobar or even segmental bronchi. When the sampling tube has thus been sited under direct vision, the bronchoscope (redesigned with a side arm proximally and an inflatable cuff near the distal end) can be withdrawn just above the main carina, and its cuff inflated.

By closing the usual inlet of the bronchoscope round the sampling tube, gas is washed out through the side arm, while a record is taken on the pen-recorder of the changes in gas concentration from the lung segment under exploration. We have not yet done detailed investigations within the bronchial tree, though tracings from the main bronchi show the procedure to be quite practicable.

From such tracings it should be possible to calculate the ventilation, ventilation-perfusion relationships, relative blood flow, and gas uptake of any portion of the lung which can be individually probed. Even a knowledge of the respiratory quotient, which can be measured from a continuous tracing of oxygen and carbon dioxide taken with an unmodified bronchoscope at routine diagnostic bronchoscopy (Fig. 8), will provide a measure of differential lung

FIG. 8.—Continuous gas analysis within the bronchial tree at diagnostic bronchoscopy. Upper tracing, carbon dioxide (5-cm. full-scale deflection $\equiv$ 75 mm. p.p. CO_2); lower tracing, oxygen (F.S.D. $\equiv$ 250 mm. p.p. O_2). Paper speed 5 mm. per second.

function without bronchospirometry (Armitage and Taylor, 1956), and since this can be done segmentally with the mass spectrometer it should provide useful information for the surgeon before local resection is contemplated. For example, if the respiratory quotient of a part of the lung is unchanged by a pathological process there may be no functional indication for resection of this part, since there would be no venous admixture or wasted ventilation caused by it.

Applications in Medicine and Surgery

The procedures which we have described would be quite impracticable without the mass spectrometer. With its help they may well become practicable as routine diagnostic procedures. They demand but little effort and co-operation from the subject, and neither the complex apparatus for "snap" gas samples nor the bulky apparatus for gas collection are necessary.

Both prognosis and treatment of the large group of chronic chest diseases at present lumped together within the general terms of asthma or bronchitis and emphysema are unsatisfactory and empirical. The mass spectrometer should enable large series of such cases to be submitted to frequent functional testing, which by clarifying the functional disturbance should place prognosis and treatment on a more rational basis. Moreover, since the instrument is transportable, it could be used in field survey work, such as that designed to enlarge our knowledge of the evolution of chronic chest diseases.

The regional assessment at diagnostic bronchoscopy will be of obvious value to the surgeon as an indication of the advantages or danger of subsequent lobectomy or pneumonectomy. Perhaps in this field the *ad hoc* advances with the instrument will be greater than in any other. Regional continuous gas analysis within the lungs should also open up wide research possibilities in the elucidation of the changes in pulmonary blood flow associated with heart disease, such as mitral stenosis, and congenital abnormalities, and help in the study of the mechanism of pulmonary hypertension.

By contrast the use of the spectrometer in anaesthesiology will be limited, since the complex organic gases employed in modern anaesthetics are not readily analysed by this type of machine. It could be used for such simple purposes as

checking the level of carbon dioxide in the patient's breath during an operation, but there are other much simpler and less expensive instruments available for doing this. On the other hand, the spectrometer can prove very useful in checking the efficiency of oxygen masks, detecting leaks in equipment, rapidly checking the calibration of gas-delivering equipment, and so on.

Finally, the spectrometer can provide the most elegant and convincing demonstrations, for teaching purposes, of many classical experiments in physiology. The effects of breath-holding, hyperventilation, carbon dioxide narcosis in emphysema from oxygen inhalation, and many other phenomena can be beautifully demonstrated.

Summary

A mass spectrometer has been made, specifically for clinical practice and research, which will continuously and automatically analyse a gas mixture containing components of molecular weight in the range 18–80; this includes the majority of gases of physiological importance. It requires only electricity for operation, is transportable, and draws its gas sample (at a rate of 15 ml. per minute) through about 4 feet (122 cm.) of fine (0.5 mm.) hypodermic steel tubing.

The uses of this instrument are described. It will make the study of the gas exchange of the lungs as simple as measuring their ventilation for many clinical purposes. Analysis of single expirates and "wash-out" curves will enable measurements to be made of the inequality of gas distribution in the lungs, of the relation between distribution of gas and blood, and of the efficiency of gas transfer between alveoli and blood. These measurements are of value in making a positive diagnosis of emphysema, in elucidating the nature of the functional changes in chronic lung disease, in determining factors causing effects such as breathlessness, cyanosis, and carbon dioxide retention, and in following the efficacy of treatment in lung disease.

By passing the fine sampling tube into the bronchial tree, at diagnostic bronchoscopy, individual lobes and segments of the lung can be explored and local function examined; this should open new possibilities in cardio-respiratory research, and should be of considerable help to the thoracic surgeon.

The instrument provides a continuous record of the constituents of the gas sample as a series of peaks on an oscilloscope screen; the horizontal position of the peaks represents their identity as nitrogen, oxygen, carbon dioxide, etc., and their vertical height is directly proportional to their partial pressure in the mixture. Up to four components can be selected independently and simultaneously from this display, which represents their varying partial pressures, and these are recorded continuously on a direct-writing multi-channel pen-recorder. Pneumotachygraphic, electrocardiographic, or other information can be recorded simultaneously.

The response time when one gas is changed to another is such that 95% of full-scale deflection with the new gas is given in less than one-tenth of a second. The sensitivity is such that full-scale deflection may be obtained for partial pressures of anything between 3% and 100% of the total. The absolute accuracy is within 3%, though incremental changes can be measured within 1%, of the full-scale deflection selected.

The cost of construction and work with the spectrometer has been borne by the Medical Research Council, to whom we are most grateful. We would also like to record our thanks for the help and encouragement given by Dr. D. K. Hill, Director of

Bio-Physics Laboratory, and by Professor John McMichael and Dr. C. M. Fletcher, of the Department of Medicine of the Postgraduate Medical School. Dr. J. West, of the Medical Research Council's staff, has made valuable contributions in the initial use of the instrument. Mr. C. Lawden and Mr. T. Neal were responsible for construction of the instrument in the Postgraduate Medical School workshop.

COMPARISON OF SIDE-EFFECTS AFTER PARTIAL GASTRECTOMY AND VAGOTOMY AND GASTRO-ENTEROSTOMY*

BY

H. T. COX, M.D., F.R.C.S.Ed.

Consulting Surgeon, Withington and Wythenshawe Hospitals, Manchester

AND

D. F. KERR, M.B., Ch.B.

Late Registrar, Wythenshawe Hospital, Manchester

Partial gastrectomy is a well-established procedure with a low mortality rate and a low incidence of anastomotic ulcers. Dissatisfaction with it correctly centres in its side-effects—that is, those symptoms not due to ulceration. The figures for mortality rates and anastomotic ulcers are easily definable, but the side-effects prove a difficult field to chart. Numerous surgical procedures have been devised with the object of reducing or eliminating them: fixing the gastric stump, changing the position of the stoma, the combination of vagotomy with practically every known variant of partial gastrectomy, and, more recently, Billroth I for duodenal ulcer. If gastric operations, in an attempt to reduce side-effects, are not to show a discouraging tendency to rotate in popularity, the results of different procedures must be compared with a fixed standard.

This fixed standard should be a simple clinical yardstick which illustrates principles rather than catalogues symptoms and which omits comparative terms as a basis or aid to comparison.

This paper compares the side-effects in 100 patients who have had partial gastrectomy for duodenal or anastomotic ulcer with the side-effects in 100 cases of duodenal ulcer treated by vagotomy and posterior

gastro-enterostomy. Each type of operation was carried out in comparable and unselected cases.

No case included in this report has been operated on during the past 12 months. As long-term results of vagotomy and posterior gastro-enterostomy are still unknown, it was decided to limit to 100 the number of cases in which this operation was carried out as a routine.

Facts have been collected in respect of the following points; (1) biliary regurgitation; (2) ability to take a normal-size mixed meal; (3) ability to take a one- or two-course meal; (4) the presence of selective impairment of digestion; (5) the incidence of dumping; and (6) the existence of any interrelation between the above.

All 200 patients have been personally interviewed on more than one occasion. The above questions were evolved with the object of demonstrating underlying principles.

PARTIAL GASTRECTOMY FOR DUODENAL ULCER

This operation was carried out for duodenal ulcer in 83 cases and for anastomotic ulcer in 17 cases (after posterior gastro-enterostomy 16, after pyloroplasty 1). Gastric section in all cases was carried out after division of the left gastric artery at the point at which it gives off the descending branch and after division of the lower two vasa brevia. Reconstruction was as follows: antecolic with spur, 85 cases; Polya, 8; Moynihan 1; Schoemaker 5; and Finsterer, 1. The afferent loop was made as short as possible consistent with the avoidance of tension.

Follow-up—Ninety-eight cases were operated on between 1947 and 1953, inclusive, and two in 1954. The average time between the date of operation and the date of this follow-up was four years five months. Eleven patients did not attend for review; the next 11 were therefore reviewed.

Biliary Regurgitation

Investigation into the incidence of biliary regurgitation in 100 patients gave the following results:

Nil	74 patients
Definite	5
(1) $\frac{1}{2}$ pint (285 ml.) once a day	1 patient
(2) " " (285 " " " week	1 "
(3) " " (285 " " " in two months	1 "
(4) Half a cupful (85 ml.) three times a week	1 "
(5) (85 " " once a month	1 "
Negligible (less than a mouthful once a week)	21 patients

Regurgitation of bile was therefore nil or negligible in 95 patients. Of the five patients with definite biliary regurgitation four had an antecolic partial gastrectomy with a spur and one had a Polya gastrectomy; four were females and one was a male.

Ability to take a Normal-size Mixed Meal

By this is meant the ability to take the normal-size two-course meal, whether in the evening or midday, composed of meat or fish and potatoes as the first course, and milk puddings, steamed puddings, etc., as the second course. The patient was asked to compare the size of the meal with the size of the corresponding meal prior to the development of the ulcer. No account has been taken of any patient's inability to take a large meal.

Group A: 55 patients were able to take a normal-size mixed meal.

Group B: 45 patients were unable to take a normal-size mixed meal.

In just under 50% of patients, therefore, there is a quantitative reduction in the food taken in this meal. An inability to take a normal-size meal may be a major handicap. The underlying problem has, we believe, not been pursued to its logical conclusion. A patient who is unable

*Based on a paper read before the Section of Surgery of the Manchester Medical Society on March 13, 1956.

to take a normal-size meal may be found to be omitting either course or to be taking a reduced amount of each course.

Ability to take a One- or Two-course Meal

The patient was asked whether he was taking a one- or two-course meal, and if the former, which course he now omitted. The patient was also asked to compare this with his ability to take a two-course meal before the development of the ulcer. Of the 100 patients under consideration, 35 were found to have been deprived by partial gastrectomy of their ability to take a sweet course. The distribution of these 35 patients in the two groups is as follows:

Group A: of the 55 patients able to take a normal-size meal, only 6 did not take a sweet course.

Group B: of the 45 patients unable to take a normal-size meal, 29 did not take a sweet course.

No patient had been deprived of his ability to take a meat or fish course.

The actual figures obtained were:

Sweet Course			
Group A		Group B	
Yes	46	Yes	13
No	6	No	29
No (and no pre-ulcer)	3	Occasionally (daily pre-ulcer)	3

It will be seen that 46 patients were taking a normal-size meal with a sweet course and 29 were not taking a normal-size meal or a sweet course.

Selective Impairment of Digestion

Patients were asked to compare their ability to take milk, as such, milk puddings, eggs, fatty foods, chocolates, and pastries at the time of the follow-up, with their ability to take the same foods prior to the development of the ulcer. These foods—fatty, sweet, and sweet fatty—were chosen as representing the constituents of the second or sweet course; any patients being deprived of the ability to take these foods would also be deprived of the ability to take a sweet course in virtue of what may be termed—for want of a particular phraseology—a selective impairment of digestion.

Group A

Selective Impairment of Digestion in 46 Patients Having a Normal-size Meal with a Sweet Course

Ability to Take	Yes	No	No/No	Uncertain
Milk	25	9	5	1
Milk puddings	41	3	3	2
Fatty foods	40	1	3	2
Eggs	42	1	2	1
Chocolates	31	7	6	2
Pastries	31	8	5	2

Six patients in addition stated that they could take milk but that they did not require it.

The word "No" in the tables indicates that the patient has been deprived of the ability to take the food in question because of the production of clearly defined symptoms after ingestion: nausea, palpitation, weakness, vertigo, sweating, marked flatulence, or a feeling of marked distension. Occasionally a definite dislike only has led to the omission of these particular foods.

"No/No" indicates that the patient did not take the particular food prior to the ulcer or after gastrectomy. Under the heading "Uncertain" are placed those few patients who gave uncertain or conflicting answers or who were not asked the question under consideration.

Of the 46 patients in this group having a normal-size meal and a sweet course, 25 were taking all of the following: milk, milk puddings, fatty foods, and eggs. (These include three patients who usually did not drink milk because they felt they did not need it but who could do so if they wished.) Not one patient out of the 46 had been deprived by partial gastrectomy of his ability to take all of the following: milk, milk puddings, fatty foods, and eggs.

Group B
Selective Impairment of Digestion in 29 Patients Not Having a Normal-size Meal or a Sweet Course

Ability to Take	Yes	No	No/No	Uncertain
Milk	9	16	2	—
Milk puddings	6	22	—	3
Fatty foods	8	16	2	2
Eggs	12	15	—	4
Chocolates	6	16	3	4
Pastries	8	16	1	4

Two patients in addition stated that they could take milk but they felt they did not require it. Similarly one patient could take milk puddings if he wished.
One patient included in the nine taking milk was taking cold but not hot milk. The statistics relating to the ability to take cold but not hot milk may be fallacious owing to the small number of patients taking hot milk by itself.

The diagram compares the selective impairment of digestion in those patients who can and those who cannot take a sweet course.

Of the 29 patients not taking a normal-size meal or a sweet course, only two were taking milk, milk puddings, fatty foods, and eggs. Five patients in this group had been deprived by partial gastrectomy of their ability to take all of the following: milk, milk puddings, fatty foods, and eggs; in addition 10 had been deprived of their ability to take three of these four foods.

There is an impressive difference in selective impairment of digestion between those patients who can and those who cannot take a sweet course. This indicates clearly that the main reason why the patient cannot take a sweet course is a failure of digestion for the sweet fatty foods which constitute this course. The attempt to digest these foods produces unpleasant symptoms, and they are therefore omitted from the diet. The facts set out in these tables cannot be accounted for solely by a reduction of reservoir or holding capacity. For example, a reduction of this holding capacity sufficient to allow a patient to take meat and potatoes but not a sweet course would be quite inadequate to account for the inability of the same patient to take the same quantity of fatty foods and eggs or to drink milk with the stomach empty, especially when he can drink the same quantity of water, tea, or beer.

There is much confusion between sweet and sweet fatty foods, the fat element usually being overlooked. One patient stated that she never took anything sweet. This on further questioning was found to mean that she never ate chocolates but was very fond of barley sugar or sugar in tea. Six patients had been deprived by partial gastrectomy of their ability to take fatty foods, chocolates, and pastries and yet were taking substantial amounts of sugar in tea. This suggests that it is the fat in reputedly sweet things—that is, chocolates and pastries—either by itself or in combination with the sweet element which determines the inability to digest.

This selective impairment of digestion has occurred after the following types of partial gastrectomy—antecolic with spur, Polya, Schoemaker, and Moynihan.

It should be emphasized that the average time of follow-up after partial gastrectomy was four years and five months.

Varying accounts have been given of the incidence of the pulmonary tuberculosis after partial gastrectomy. The correct answer is surely the most obvious. The main difference in any patient after partial gastrectomy and, for example, cholecystectomy, or in the same patient before and after partial gastrectomy, is the severe quantitative and qualitative reduction in food intake that may follow this latter operation. This must at times be responsible for lighting up a latent tuberculous focus. One patient who had been deprived by partial gastrectomy of the ability to take milk, milk puddings, fatty foods, chocolates, and pastries for five years developed pulmonary tuberculosis with a cavity and a positive sputum.

Incidence of Dumping

By dumping is meant attacks consisting of most or all of the following symptoms: vertigo, weakness, palpitation, and sweating. The total number of patients dumping was 19. This bald statement, however, conveys nothing of the underlying physiological defect or of the handicap imposed. It is essential, where possible, to establish what precipitates the attacks.

In six patients the attacks bore no ascertainable relation to any particular food; in two of these the dumping attacks came on after a large meal irrespective of the type of food consumed. In two patients the attacks were not related to meals at all. In one patient moderate attacks of dumping occurred on entering a warm room. In one patient there was no dumping for two years; attacks of dumping then came on, and were worse after exercise. In four patients, therefore, the attacks bore no relation to meals or any particular food.

The largest number of patients dumping—13 in number—all fall into one well-defined group. In every patient in this group the dumping attack was directly induced by one or more of the following: milk, milk puddings, fatty foods, eggs, chocolates, and pastries. In three of these patients the dumping was, in addition, produced by a large meal. The relation of dumping to a large meal, however, was not specifically asked for in each case. If a patient has dis- covered that attacks of dumping are directly induced by certain foods it is reasonable to suppose that these foods would be omitted from the diet. An inquiry into the diet of these 13 patients reveals the following:

	No	Yes
Normal-size meal	11	2
Sweet course	12	1

The selective impairment of digestion in these 13 patients was as follows:

	No	Yes	Doubtful
Milk	10	3	—
Milk puddings	12	1	—
Eggs	8	4	1
Fatty foods	11	2	—
Chocolates and pastries	12	1	—

The conclusion to be drawn from these tables is clear—in order to avoid attacks of dumping the patient has omitted from his diet those foods that produce them. In other words, the main handicap of dumping in these patients is the handicap imposed by avoiding it. It should be again emphasized that these findings do not relate to the early post-operative period in which dumping may more often follow a large meal and in which the patient has not had time to sort out those foods particularly associated with dumping.

On further questioning, all these 13 patients have stated that, with particular care in avoiding the foods that produce dumping, the attacks of dumping have been eliminated. The number of patients, therefore, who were actually experiencing unavoidable dumping attacks was four—that

is, those patients already referred to whose attacks bore no relation to meals or any particular food.

In order to confirm statements that attacks of dumping followed ingestion of certain foods, patients have been brought to the out-patient department and given a glass of hot milk containing two eggs. It had previously been ascertained from the patients that attacks followed these foods. Attacks of dumping have followed and have been directly observed. The production of dumping by a glass of milk with two eggs, the fatty meal of the cholecystogram test, with its known hormonal action, may eventually put the dumping syndrome on a firm physiological basis. It will also be recalled that systemic disturbances in a case of argentaffinoma have been provoked by fatty foods (Bleehen, 1955).

A loss of reservoir or holding capacity and an inability to take sweet foods does undoubtedly occur after partial gastrectomy; an inability to take purely sweet foods is no material handicap or hardship to anyone; a loss of holding capacity is undoubtedly responsible for a definite reduction in food intake, but has previously been allowed to over-shadow in importance the effect of selective impairment. An inability to take milk, milk puddings, fatty foods, and eggs is a determining factor in the production of the post-gastrectomy defects—inability to take a normal-size meal, inability to take a sweet course, and attacks of dumping. The cause must be physiological; it is therefore difficult to understand how this digestive disability can be reduced or eliminated by such advocated procedures as fixing the gastric stump or changing the position of the stoma from the lower third to the middle third in Billroth II modifications.

It will have been noticed that no attempt has been made to place patients into categories determined by the use of comparative terms—that is, "good" or "bad" results—or to give the number of "satisfied" patients. This classification so frequently distorts the truth because it hides it, and it is no substitute for factual statements.

VAGOTOMY AND POSTERIOR GASTRO-ENTEROSTOMY

Routine abdominal vagotomy and posterior gastro-enterostomy with the stoma in the pyloric antrum was carried out.

Follow-up—Ninety-six cases were operated on between 1948 and 1953 inclusive and four in 1954. The average time between the date of operation and the date of this follow-up was two years and nine months. Nine patients did not attend for review; the next nine patients were therefore reviewed.

Biliary Regurgitation

The following were the results of investigation into biliary regurgitation in 100 cases:

	67 patients
Nil	8
Definite	1 patient
(1) 1 pint (285-570 ml.) twice a week	1
(2) 1 cupful (170 ml.) daily before breakfast	1
(3) Half a cupful (85 ml.) twice a week	1
(4) Half a cupful (85 ml.) after fats only	2 patients
(5) One mouthful three times a day	2
(6) One mouthful almost daily	25
Negligible (less than a mouthful once a week)	—

Evaluation.—Seven cases more have regurgitated bile after vagotomy and gastro-enterostomy than after partial gastrectomy. In each of these seven cases not more than a mouthful of bile was returned at once. There was no material difference in major biliary regurgitation after partial gastrectomy and after vagotomy and gastro-enterostomy.

Ability to take a Normal-size Mixed Meal

Group A: Seventy-seven patients were able to take a normal-size mixed meal.

Group B: Twenty-three patients were unable to take a normal-size mixed meal.

Evaluation.—Comparing the above figures with those after partial gastrectomy it is clear that there is an overwhelming advantage in favour of vagotomy and posterior gastro-

enterostomy, 45 patients being deprived of their ability to take a normal-size meal by partial gastrectomy as against 23 by vagotomy and gastro-enterostomy.

Ability to take a One- or Two-course Meal

Of the 100 patients under consideration, nine were found to have been deprived by vagotomy and gastro-enterostomy of their ability to take a sweet course. The distribution of these nine patients in the two groups is as follows:

Group A: of the 77 patients able to take a normal-size meal, only one did not take a sweet course.

Group B: of the 23 patients unable to take a normal-size meal, eight did not take a sweet course.

The actual figures obtained were:

Sweet Course			
Group A		Group B	
Yes	69	Yes	13
No	1	No	8
No/No	7	No/No	2

"No/No" indicates that the patient did not take a sweet course prior to the ulcer or after operation. It was found that 69 patients were taking a normal-size meal with a sweet course and eight were not taking a normal-size mixed meal or sweet course.

Evaluation.—The advantage here is overwhelmingly on the side of vagotomy and gastro-enterostomy, 35 patients being deprived by partial gastrectomy of their ability to take a sweet course as against nine similarly deprived by vagotomy and gastro-enterostomy.

Selective Impairment of Digestion

Group A

Selective Impairment of Digestion in 69 Patients Having a Normal-size Mixed Meal With a Sweet Course

Ability to Take	Yes	No	No/No	Uncertain
Milk	52	2	7	—
" puddings	63	3	2	—
Fatty foods	58	8	3	—
Eggs	59	7	3	—
Chocolates	55	5	7	—
Pastries	58	5	6	—

In addition to the above, eight patients did not drink milk and one did not take milk puddings; both could have done so had they wished.

Group B

Selective Impairment of Digestion in Eight Patients Unable to Take a Normal-size Mixed Meal or a Sweet Course

Ability to Take	Yes	No	No/No	Uncertain
Milk	3	5	—	—
" puddings	1	6	1	—
Fatty foods	1	6	—	1
Eggs	3	4	—	1
Chocolates	3	3	1	1
Pastries	2	5	1	—

The selective impairment of digestion in the 100 patients treated by partial gastrectomy and the 100 patients treated by vagotomy and gastro-enterostomy was as follows:

	No Milk	No Milk Puddings	No Fatty Foods	No Eggs
After P.G.	30	32	25	20
" vag. and P.G.E.	7	10	17	14

Evaluation.—These figures show a clearly defined advantage on the side of vagotomy and gastro-enterostomy.

Incidence of Dumping Attacks

The total number of patients with dumping was 12. In six these attacks were not related to meals. This group is constituted as follows: one patient with dumping attacks approximately once a month after exercise; one patient

with dumping attacks twice a week associated with emotion and exercise; one patient with dumping attacks occasionally after emotion; two patients with dumping attacks once a month with no ascertainable cause; one patient with three attacks of dumping in eight months with no ascertainable cause.

In the six patients in whom dumping attacks bore a definite relation to meals the record is as follows: two had dumping after hot milk, one after "horlicks"; one slightly after fatty foods; one after the midday meal irrespective of its nature; and one had two attacks a month, usually after breakfast.

Evaluation.—The incidence of dumping after vagotomy and gastro-enterostomy is less than after partial gastrectomy. The attacks are less often associated with particular foods, and there is therefore not the same necessity to restrict the diet in order to avoid the attacks.

Summary

There is no material difference in the incidence of biliary regurgitation after partial gastrectomy and that after vagotomy and gastro-enterostomy; the incidence of dumping is less after vagotomy and gastro-enterostomy; the outstanding advantage of vagotomy and gastro-enterostomy over partial gastrectomy is in the nutrition of the patient; more patients take a normal-size meal, more patients take a sweet course, fewer patients suffer from a selective impairment of digestion—and the difference in all three points is substantial.

It is a pleasure to thank the South Manchester Hospitals Management Committee for financial assistance in carrying out this work. The diagram was produced by the department of medical illustration.

CLINICAL EVALUATION OF THREE ANTICOAGULANTS IN THROMBO-EMBOLIC DISEASE

BY

J. McE. NEILSON, M.B., M.R.C.P., M.R.C.P.Ed.
D.P.H.

AND

A. W. MOLLISON, M.B., B.Sc., F.P.S.

From the Departments of Medicine and Clinical Biochemistry, Stobhill General Hospital, Glasgow

Although anticoagulant therapy is at present widely accepted as being of value in thrombo-embolic disorders, there is less agreement on the best agent for inducing a therapeutic degree of prolongation of the one-stage prothrombin time.

The most commonly used oral anticoagulants in this country are ethyl biscoumacetate ("tromexan") and phenindione ("dindevan"), both of which rapidly produce an effect of comparatively short duration. The former is apt to produce frequent wide fluctuations in the prothrombin time, particularly during the first ten days of treatment (Barker, 1952). Toohey (1953) has reported favourably on the actions of phenindione. A third anticoagulant, cyclocoumarol ("cumopyran"), or 3,4-(2'-methyl-2'-methoxy-4'-phenyl) dihydropyranocoumarin, has become available in this country recently. It was first synthesized by Ikawa in 1942 in Link's laboratory during an investigation of substances chemi-

cally related to dicoumarol. Under the name of anti-coagulant No. 63 it has been experimentally and clinically assessed in America (Battle *et al.*, 1950; Brambel *et al.*, 1950; Rotter and Meyer, 1951, 1952; Barker *et al.*, 1952), but so far no account of its effects has been published in this country.

In this paper the results obtained in treating 57 patients with cyclocoumarol, 125 with ethyl biscoumacetate, and 179 with phenindione are analysed and compared.

Methods

In general, in estimating the initial dosage, attention was paid to the age and weight of the patient and to evidence of cardiac failure and renal or hepatic disease. Any history of recent dyspepsia, especially in patients known to have been sufferers from peptic ulceration, and any source of bleeding were considered contraindications to the use of anticoagulants.

Patients given ethyl biscoumacetate or phenindione received 10,000–15,000 units of heparin intravenously every six hours for the first 24 hours of anticoagulant therapy. Because of its slower effect on the prothrombin time, those given cyclocoumarol received the same dosage of heparin six-hourly for 48 hours.

Each of the three drugs was given by mouth in divided doses at 2 p.m. and 10 p.m. An initial prothrombin time was estimated only when there was any reason to suspect that it would be abnormal. Subsequent dosage was dictated by the prothrombin time. For this purpose blood was withdrawn each day at 9 a.m. and the prothrombin time (Quick's one-stage clotting-time) was estimated, using as a source of thromboplastin a carbol-saline extract of human brain (Toohey, 1950). A control prothrombin time was done daily on a suitable subject, and all results were expressed in seconds. The control prothrombin time varied between 14 and 16 seconds. If the control prothrombin time exceeded 16 seconds it was discarded as unsuitable and a fresh control was selected. A patient's prothrombin time was regarded as being within therapeutic limits if it lay between two to three times the control value.

We decided to avoid converting the patient's prothrombin time into a percentage of normal prothrombin activity by the use of a calibration curve of the prothrombin times of serial dilutions of normal plasma. The use of such a percentage figure—the so-called "prothrombin concentration"—makes comparisons between the results from different laboratories using dissimilar sources of thromboplastin difficult and leads to the misconception that prothrombin activity is measured by the prothrombin time.

All dosage was controlled by us and by the consultant clinical biochemist. The urine of each patient receiving cyclocoumarol was examined daily for microscopic haematuria.

Results

The age, sex, and weight distributions of the three series were similar. Table I shows the diagnoses in the respective series. The initial dosages of the three substances were:

Ethyl Biscoumacetate.—The usual initial dose was 600 mg. followed eight hours later by a further 600 mg. On the second day of therapy two doses of 300 mg. were most

TABLE I.—Diagnoses in the Three Series

Diagnosis	No. of Cases		
	Ethyl Biscoumacetate	Phenindione	Cyclocoumarol
Coronary artery disease	56	76	42
Venous thrombosis	53	83	11
Pulmonary embolism	2	10	—
Arterial	12	4	4
Cerebral thrombosis	2	5	—
Post-operative prophylaxis	—	1	—
Total	125	179	57

frequently used. The total amount given in the first 48 hours, however, varied from 300 to 2,400 mg.

Phenindione.—The most common dosage schedule was 200 mg. divided into two doses on the first day with two 50-mg. doses on the second, but again there was a wide variation in the amounts used. The sum of the doses given in the first 48 hours varies from only 125 mg. to as much as 650 mg.

Cyclocoumarol.—Two 75-mg. or two 50-mg. doses on the first day were found to be adequate for most cases. On the second day two 12.5-mg. or two 25-mg. doses were most often necessary.

Initial Response.

—The Graph shows the initial responses achieved in each of the three series. Within 48 hours of the first dose of ethyl biscoumacetate the prothrombin time of 85% of patients had reached therapeutic levels; the corresponding figure for phenindione was 76% and for cyclocoumarol only 40%.

Daily Maintenance Dose.—The ranges of the daily maintenance doses are shown in Table II. These daily maintenance doses were calculated only for those patients who

TABLE II.—Daily Maintenance Doses

Anticoagulant	Daily Maintenance Dose in mg.	No. of Patients
Ethyl biscoumacetate	Less than 150	11
	150–300	34
	300–450	25
	450–600	16
	600–750	8
	750–900	5
	900–1,050	2
Phenindione	1,050–1,200	2
	More than 1,200	1
	Less than 25	11
	25–50	38
	50–75	56
	75–100	33
	100–125	22
Cyclocoumarol	125–150	4
	150–200	1
	200–300	2
	Less than 12.5	12
	12.5–25.0	23
	25.0–37.5	9
	37.5–50.0	1

received anticoagulants for a sufficient length of time. No close relationship was found between the daily maintenance dose of any of the drugs and the age, sex, or weight of the patients.

Time Spent within Therapeutic Limits.—After exclusion of the prothrombin times affected by the initial dosage, the number of days under treatment during which the prothrombin time was within therapeutic limits was calculated for each patient. Table III compares the three series. Although the figures shown seem to reflect a poor degree of control of the prothrombin time, it should be emphasized that, whereas in practice one is satisfied when the patient's prothrombin time is within one or two seconds of two to three times the control prothrombin time, strict interpreta-

TABLE III.—Comparison of Time Spent Within Therapeutic Limits

Percentage of Days During which Prothrombin Time Lay between Therapeutic Limits	Percentage of Patients		
	Ethyl Biscoumacetate	Phenindione	Cyclocoumarol
80–100	42	75	45
Over 60	79	95	71

Initial response obtained in each of the three series. The therapeutic range is between two and three times the control prothrombin time.

In these studies of men examined before national service, records were collected from a variety of centres. In view of most of the evidence given above, it was surprising to find that the proportion of men who had been operated on was much higher in a group of men drawn from Clydeside and the West of Scotland (Clydeside A in Table II) than it was in similar groups drawn from North-west London and the Home Counties. In my studies the rates found in North-west London and in the Home Counties agreed well with those found by Stewart (1955) in Southend, Northampton, and Leicester. These are also given in Table II. To check

TABLE II.—Proportion of Men Who Had Undergone Appendicectomy Before Their Pre-Service Medical Examination. By Area

Area:	Part of Home Counties (1)	North-west London (1)	Leicester (2)	Northampton (2)	Southend (2)	South-east Lancashire (1)	Clydeside A (1)	Clydeside B (3) (4)
Proportion of men who had undergone the operation	4.0%	4.8%	4.4%	4.0%	3.9%	5.0%	6.4%	7.2%
No. of men examined	1,823	460	4,870	4,387	4,424	602	271	587

(1) Previously unpublished data from studies of the findings of the medical boards that examined young men before military service in 1953-4. The numbers given refer to the actual examinations reported, and are not reconstructed populations. 63% of these men were aged 18, and almost all the rest were under 23.

(2) These figures are from Stewart (1955). The men were examined during the war, and were aged 17 to 19.

(3) These figures are from the special study made at the boards to check the high appendicectomy rate in young men found in this area. The men were aged 17-18½ in 1955. This was a study specially directed towards appendicitis. This may explain the slightly higher value than Clydeside A, the data for which were taken from a general survey of all diseases. However, Webb (1955) showed that appendicectomy scars were reliably recorded by those boards.

(4) Because of the different conditions under which the various data used in the calculation of the different rates were collected, no formal tests of significance have been used. However, with samples of this size it is unlikely that the variations are entirely due to chance.

TABLE III.—Death Rates from Appendicitis. Greater London and Glasgow Area.* Per 100,000 Per Annum Over the Period 1945-54

Ages:	0-14	15-44	45-64	65 and Over	All Ages
Males					
Glasgow Area	Deaths 94	90	90	76	350
	Rate 3.5†	2.0	4.2	9.5	3.5
Greater London	Deaths 220	265	402	441	1,328
	Rate 2.5	1.5	4.3	12.7	4.4
Females					
Glasgow Area	Deaths 59	87	89	64	299
	Rate 2.2	1.8	3.6	6.3	2.7
Greater London	Deaths 169	187	270	419	1,045
	Rate 2.0	1.0	2.4	7.7	2.9

* As defined in the text.

† The excess of the Glasgow rate over the corresponding London rate is unlikely to be due to chance: $\chi^2=6.92$; $P<0.01$.

that the Scottish figures were reliable a further special study was made of the records. The figures are given in Table II as Clydeside B. Thus there seems to be, for young males, an operation rate substantially higher in Clydeside than in London.

Mortality from Appendicitis in Males

These variations in the geographical distribution of the operation in young men are not closely reflected by the total death rates from appendicitis, taking all ages together. This is not surprising, since in the latest series of hospital admissions published (collected in 1951) only 15% of the admissions of males were over the age of 44, while during the same period in this country 62% of the deaths in men from this condition occurred at greater ages than this (Registrar-General, 1953, 1955a). However, if the age-specific death rates are taken—here it has been done for Greater London and the Glasgow area*—we get a different pattern (Table III). There is a definite excess in Glasgow of deaths in the younger age groups.

Thus substantially higher operation and death rates from appendicitis have been demonstrated in the Glasgow area in

* A better comparison would be between the two conurbations of Greater London and Central Clydeside. This is not possible, as the figures have not been available for Clydeside for long enough to give stable rates. An approximation to this area has been made by taking the counties of Lanark, Renfrew, and Dunbarton, with their burghs, and adding their experience and population to that of Glasgow City. This was necessary as the boundaries of the conurbation cut across the older administrative units, in terms of which the figures are given. The population of this composite area was 2,103,000 in 1951. At the same census the population of the Central Clydeside Conurbation was 1,758,000.

young men. In view of the evidence that this disease is associated with high social and economic status, and that the proportion of people in social classes I and II is lower in Glasgow than it is in London (Registrar-General, 1952), this finding seems to indicate that there must be a further independent environmental factor in the causation of the disease, at least in the young.

The contrasted ways in which the appendicitis death rate behaves in young and old people are shown as we examine the rates for England, the Glasgow area, and the rest of Scotland. These are given in Table IV. The excess death rate of young people in the rest of Scotland is unlikely to be

TABLE IV.—Death Rates from Appendicitis by Ages. England, the Glasgow Area, and the Rest of Scotland. Males. Per 100,000 Per Annum Over the Period 1945-54*

	England	Glasgow Area†	Rest of Scotland
Ages under 15			
Deaths	1,079	91	110
Rate	2.6	3.7	3.3
Ages over 64			
Deaths	1,667	68	130
Rate	10.1	9.5	10.7

* Excepting in each case 1950, the figures for which year for England have not been published in this form.

† As defined in the text.

the result of the distance that some of them live from surgical facilities, for it is also found in the Glasgow area. Further, this excess is not found in old people in the rest of Scotland. The excess death rate from appendicitis in males under 15 in the rest of Scotland suggests that the factor, whatever it is, is not confined to Glasgow. A similar excess is found in Wales.

Discussion

The operation of appendicectomy is performed both in the acute stage of the disease and when it is more chronic. There is controversy over the usefulness of the latter type of operation (British Medical Journal, 1955), and the practice of different surgeons varies widely. Thus it might be expected that substantial variations in the operation between different areas would not reflect real differences in the disease. But the differences demonstrated here apply to the death rates as well as to the operation rates. They are thus likely to reflect actual differences in the disease, and not in its treatment.

The geographical and social variations of the disease discussed here relate only to the fairly homogeneous population of this country. With greater differences in conditions—as when people in the West Indies or tropical Africa are compared among themselves or with Europeans—much greater differences in the prevalence of the disease emerge, which do not seem to be related to differences in the surgical care available (Leacock, 1952; Karn, 1952; Barker, 1952).

The geographical variation found in Britain seems to fit in with the evidence that there is a link between appendicitis and duodenal ulcer. The prevalence of duodenal ulcer seems to be high in young men in Glasgow (Doll, 1952), and “duodenal ulcer proved to be an important fallacy in the diagnosis of chronic appendicitis” in a series reported from Glasgow (McLennan and Watt, 1954). Further, the hospital admission rates among troops in the U.K. for these two conditions have moved in a similar way. From 1946 to 1952 both rates rose, at a time when the general level of sickness fell, and since then they have both fallen a little (War Office, 1954a, 1956).

No information is given by these inquiries about the distribution of the operation among females. It is known that the incidence of the operation is very high in young women (Ferguson, 1950b; War Office, 1954b; Ministry of Pensions and National Insurance, 1955). There is no rise in the death rate of young women, to correspond with this high operation rate (Table III). The mortality of females under the age of 15 is greater in the Glasgow area than it is in London, but the excess is not so great as for males.

INFLUENCE OF VITAMINS UPON SOME TERATOGENIC EFFECTS OF RADIATION

AN EXPERIMENTAL STUDY

BY

D. H. M. WOOLLAM, M.D., M.R.C.P.

C. W. M. PRATT, M.B.

AND

J. A. F. FOZZARD, M.A., F.R.P.S., M.S.R.

Department of Anatomy, University of Cambridge

Developmental malformations may readily be produced in the embryo by exposure of the dam to ionizing radiation during pregnancy (Hicks, 1953). Extensive investigations have been carried out upon chemical agents which either increase or diminish the radio-sensitivity of the tissues, but little attention has been paid as yet to the possibility that the teratogenic effects of radiation may be modified in a similar fashion. Wolff and Kirmann (1954), however, have shown that certain substances, such as cystamine, protect the developing tissues to some extent from the effects of x-radiation, and thus reduce the incidence of malformations in the offspring of dams exposed to x-radiation during pregnancy.

A large body of evidence has now accumulated which indicates that the induction of a maternal hypovitaminosis or hypervitaminosis is an effective method of producing a wide range of deformities in the embryo. The literature has recently been reviewed by Woollam and Millen (1956). Alteration of the maternal vitamin intake produces deformities in the young remarkably similar to those which occur when the dam is exposed to ionizing radiation during pregnancy. Defects of the eye and hydrocephalus which are readily produced by radiation (Hicks, 1953) also occur when the dam is subjected to the effects of hypovitaminosis or hypervitaminosis A (Giroud, 1955). The question naturally arises whether alteration of the vitamin intake of the dam during pregnancy might not have some effect in increasing or reducing the sensitivity of the young to the teratogenic action of radiation. The present communication deals with a group of experiments in which the effects of a combination of vitamins on the radiosensitivity of the foetus were studied.

Material and Methods

Preliminary Investigations.—It was considered necessary to concentrate on a single deformity, the presence or absence of which could be demonstrated unequivocally. Anophthalmia fulfilled this criterion satisfactorily. Preliminary experiments were therefore conducted to establish the time of administration and level of dosage of x-radiation which would produce a suitable standard incidence of anophthalmia.

Experimental Details.—Virgin female white rats of the Wistar strain were divided into four groups of 12 each as follows: Group 1 received radiation and vitamins; group 2 received radiation only; group 3 received vitamins only; and group 4 (controls) received neither radiation nor vitamins. Pregnancy was dated by vaginal smears taken daily at 9 a.m.; the day on which sperm was found in the smear was taken as Day 1. Animals in groups 1 and 3 received the following vitamins by parenteral injection at 2 p.m. on Day 1: vitamin A, 10,000 i.u.; vitamin D₂, 50,000 i.u.; α -tocopherol acetate, 60 mg.; aneurine hydrochloride B.P., 70 mg.; nicotinamide, B.P., 45 mg.; riboflavin B.P.,

The mortality from appendicitis is still far from negligible (969 deaths in 1954 in England and Wales) although it is falling. Allowing for changes in the age structure of the population, the mortality of the males is 27% of what it was in 1938 (Registrar-General, 1955b).

Age, sex, social class, and place of residence probably affect the incidence of the disease, and these and other factors certainly affect the incidence of appendicectomy and the death rate from appendicitis. The distinction between (a) the distribution of the disease, (b) the distribution of the operation, and (c) the mortality rate is necessary at the present time, as nothing is known about possible variations in the minor forms of the condition. The variety of factors that influence the operation and death rates, and interact in a complex way, seems to rule out the possibility of there being a single cause for the disease. At the present time we are almost entirely ignorant of what these causes may be. Fuller knowledge, while valuable for its own sake, might well lead to better treatment or rational prophylaxis. Thus the use of purgatives is still very common among young people—a problem to which Reid (1956) has recently drawn attention.

What is the geographical and social distribution of the use of these drugs? Is appendicitis related to their routine or sporadic use? The operation rate is very high in young women, while the death rate is very low. What proportion of these appendixes removed from young women show good evidence of inflammation? Is the severe disease commoner here, or do these young women have an excess of the minor forms of the disease? If they do, why is this so? Children and young people in certain areas seem unduly exposed to the disease. Is the disease process different from that found in old people, when the social distribution may be quite different? These and many other problems of the disease could be approached by epidemiological methods.

Summary

Young males are more likely to be operated on for appendicitis and to die of the disease in the Glasgow area than they are in London. This is an unexpected finding, in view of the association between appendicitis and high economic and social status. The existence of a further factor in the causation of the disease is postulated.

I am grateful to Dr. J. N. Morris and Mr. J. A. Heady for their interest and help, and to the latter for statistical advice. I am indebted to Mrs. V. P. Hall for much of the calculation. The Ministry of Labour and National Service made certain of the studies possible, and I am grateful to them. The opinions expressed are personal.

1 mg.; pyridoxine hydrochloride B.P.C., 15 mg.; calcium pantothenate, 1.5 mg.; benzyl alcohol B.P., 40 mg.; and ascorbic acid B.P. as sodium ascorbate, 150 mg.

The animals of groups 1 and 2 received x-radiation on Day 2 at 9 a.m. The details of the radiation are as follows. Each animal received a single dose of x-radiation. The animal was placed in a lead tube which had an aperture $1\frac{1}{2}$ by $1\frac{1}{2}$ in. (3.8 by 4.4 cm.) situated over the anterior abdominal wall so as to expose both cornua of the uterus to the rays. A beam of x rays was used at a potential of 85 kV.P., filtered through 1 mm. of aluminium at a tube current of 8 mA and exposure of 2 minutes; the skin dose, as measured with a Baldwin-Farmer substandard dosimeter at focal skin distance of 10 cm., was 258 r. The animals were killed on Day 20. The young were removed and weighed. The heads were preserved in Bouin's solution. Celloidin sections of heads were later prepared and the presence and dimensions of each eye accurately ascertained.

Findings

There were no significant variations in the weights of the young in the four groups. The incidence of anophthalmia, microphthalmia, and hydrocephalus in the four groups is given in Table I.

In Table II the incidence of anophthalmia and microphthalmia in the hydrocephalic young of groups 1 and 2 is shown.

TABLE I.—Incidence of Anophthalmia, Microphthalmia, and Hydrocephalus in the Four Groups

Group No.	No. of Dams	No. of Young	Anophthalmia. No. of Absent Eyes	Microphthalmia. No. of Eyes Less than 1.5 mm. in Diameter	No. of Hydrocephalic Young
1	12	88	47	36	8
2	12	81	15	30	3
3	12	100	0	0	0
4	12	88	0	0	0

TABLE II.—Incidence of Anophthalmia and Microphthalmia in the Hydrocephalic Foetuses of Groups 1 and 2

No. of Hydrocephalic Young in Groups 1 and 2	Anophthalmia. No. of Absent Eyes	Microphthalmia. No. of Eyes Less than 1.5 mm. in Diameter
11	13	8

A litter of 5-week-old rats; the dam was exposed to 258 r on Day 11 of pregnancy.

Nature of the Deformity.—Only the neuro-ectodermal elements of the eye were affected, the muscles and lacrimal apparatus being present and well differentiated. Anophthalmia was more commonly bilateral than unilateral. In the preliminary experiments, in which the young were allowed to survive for one month after birth, bilateral anophthalmia was more rarely encountered (see Fig.), suggesting that some anophthalmic foetuses were either born dead or destroyed at birth by the mother. Hydrocephalus was invariably associated with stenosis of the cerebral aqueduct.

Discussion

The findings of this investigation indicate that the administration of vitamins A, B, C, D, and E to the pregnant rat increases to a marked extent the incidence in the young of anophthalmia induced by x-radiation. The incidence of anophthalmia in group 2 (10.8%) contrasts markedly with that in group 1 (37.4%). The absence of anophthalmic young from the control group (group 4) suggests that genetic factors are not in any way involved. Moreover, since there were also no anophthalmic young in the group which received vitamins alone (group 3), the possibility can be ruled out that the increased incidence of anophthalmia in group 1 over group 2 represents an additional teratogenic effect of excess of one of the vitamins.

It seems, therefore, that the action of the vitamins in the combination administered is to sensitize the cells of the developing eye to the destructive action of radiation. It is tempting to associate this effect with the part played by the vitamins in the metabolism of the cell, and to contrast the findings of this experiment with the observation of Wolff and Kirmann (1954) that the protective action of cystamine applied equally to the developing foetus as to the adult.

The finding that the development of the lacrimal apparatus and other structures associated with the eye are not affected by radiation administered on Day 11 confirmed the report of Hicks (1953). Hicks also noted hydrocephalus in the young of dams irradiated on this day, and attributed its occurrence to stenosis of the cerebral aqueduct. Although the present investigation confirms the association between hydrocephalus and stenosis of the aqueduct, it is far from certain that stenosis of the aqueduct invariably bears a simple causal relationship to hydrocephalus when both are present (Millen, Woollam, and Lamming, 1954). It was particularly interesting to find that, whilst deformity or absence of the eye occurred frequently in association with apparently normally developed brains, hydrocephalus when present was almost invariably associated with absence or severe retardation of development of the eye. It is important to note, however, that in the case of hydrocephalus due to maternal hypovitaminosis-A the appearance of hydrocephalus may be delayed for some weeks after birth (Millen and Woollam, 1956). It is possible that the association between hydrocephalus and anophthalmia would have been as constant as that which occurs in the young of female rats subjected to experimental vitamin-B₁₂ deficiency (Ransdell, 1956) if the anophthalmic young had been allowed to survive for some weeks after birth.

It would be most satisfactory if subsequent investigation were to disclose that a single vitamin was responsible for the effects described in this paper. There is, however, much evidence of interaction between the vitamins in the development of the foetus. Lefebvres-Boisselot (1951), for example, has shown that the teratogenic effects of a maternal deficiency of pantothenic acid are greatly enhanced if the diet is supplemented with an excess of nicotinic acid. It therefore appears that the effects of the administration of a wide range of vitamins do not represent a simple summation of the individual actions of the vitamins but result from a complex interaction in which the relative amounts of each vitamin given may be of considerable significance. In following up the present study, therefore, and in attempting to find an explanation for the phenomenon described in this paper, the effects of combinations of the various vitamins in various proportions as well as the influence of individual vitamins on the teratogenic effects of radiation will require investigation.

Summary

The effect of the combined administration to pregnant rats of vitamins A, B, C, D, and E upon the incidence of anophthalmia produced in the embryo by subsequent x-radiation has been studied.

The incidence of anophthalmia in the group receiving radiation and vitamins (37.4%) is in strong contrast with that in the group receiving radiation alone (10.8%).

We are grateful to Professor J. D. Boyd for his encouragement in the preparation of this paper. We thank Messrs. Vitamins Ltd. for advice and for the preparation and supply of vitamins. Thanks are also due to Mr. R. Smith and Miss I. Dean for technical assistance. This work was supported by a grant from the Nuffield Foundation.

HYPERTENSION AND TUBERCULOUS RENAL LESIONS

BY

J. P. LAVENDER, M.B., M.R.C.P.Ed.

Registrar, Royal Masonic Hospital, London

Since the first demonstration of hypertension resulting from clamping of renal vessels by Goldblatt *et al.* (1934) and the subsequent report of a case of renal hypertension treated with nephrectomy by Butler (1937), great interest has been shown and large numbers of papers have been written on the subject. Reviews of the literature have been given by Abeshouse (1941), Langley and Platt (1947), Pickering and Heptinstall (1953), and others. The literature on tuberculous renal lesions and hypertension, however, is surprisingly small, and it is intended to review the published cases in the literature and to report two further cases.

Literature

The first reference I can find to renal tuberculosis as a possible cause of hypertension is Leadbetter, who is quoted by Mulholland (1940) as having performed nephrectomy on two cases of unilateral renal tuberculosis with initial blood pressures of 160/100 and 180/100; in one of these patients the blood pressure returned to normal after operation.

Braasch *et al.* (1940) referred to a series of 158 patients operated on for renal tuberculosis of whom 12 were hypertensive. He also reports a group of 37 patients with "auto-nephrectomy" due to tuberculous renal lesions of whom five were hypertensive. In discussing the reasons for this low incidence of hypertension in patients with extensively damaged kidneys he points out that these patients tend to be from a lower age group and also that "vascular sclerosis is uncommon in the presence of the renal pathological changes which occur with tuberculosis." He also noted that there was no greater incidence of hypertension in bilateral disease. Of the 11 cases which were traced, only two showed no fall in blood pressure post-operatively, and seven maintained a normal blood pressure on follow-up.

Abeshouse (1941) reviewed the literature concerning renal tuberculosis and hypertension and quoted details concerning five cases of tuberculosis of the kidney and hypertension which were operated on with successful cure of their hypertension. He adds three cases of his own, two of which are not quoted here, for although they had a fall in blood pressure the initial diastolic pressures were at no time above 96 mm. Hg.

Goidsenhoven (1947), in a review of 92 cases of renal tuberculosis, found six with hypertension, of which two only had a nephrectomy, both with subsequent fall in blood pressure. Barker (1951), in reporting a series of 100 patients with hypertension and unilateral renal disease, quoted nine cases of renal tuberculosis (some of which had been pre-

viously reported by Braasch), five of which were reported as successful two years post-operatively, two fair, and two unsuccessful.

In the accompanying Table are shown the cases reported in the literature. Seventeen of these are from series of five or more cases, and therefore give an indication of the actual success rate.

* From series of five or more cases.

Case 1

The patient, a boy of 17, was admitted to hospital on May 4, 1955. His story was that he had had a tuberculous thoracic spine at the age of 4 and for the year prior to admission he had complained of frequency, haematuria, and right-sided renal pain. Three months before admission he had been found to have a lesion in the right retina which was diagnosed as being a tuberculoma.

On examination he was seen to be small for his age. He had an angular kyphosis of the thoracic spine. His blood pressure was 210/180, but there were no other abnormal cardiovascular signs.

Investigations.—Blood urea, 36 mg. per 100 ml.; haemoglobin, 78%; leucocytes, 13,500 (polymorphs 78%). Urine culture showed the presence of tubercle bacilli in two out of three specimens examined. An intravenous pyelogram showed a non-functioning kidney on the right side.

As a result of these findings cytoscopy was carried out on May 11, when a diffusely inflamed bladder was seen and both ureteric orifices were partially occluded. It was impossible to pass catheters up either of the ureters because of the inflammation.

Following this investigation he began to develop severe headaches, blurring of vision, and slight but definite papilloedema. Furthermore, his blood urea rose from 36 to 59 mg. per 100 ml. and it appeared that his hypertension had entered the malignant phase. In view of this, a right nephrectomy was performed on May 28, when a kidney extensively damaged by tuberculosis was removed.

Following this his blood pressure came down from 210/180 to 136/90 and has remained at this level for the seven months that he has been at this hospital (see Chart). During this time he has received antituberculous therapy, but while on this he developed a cold abscess on the sternum.

Examination of the resected kidney showed caseating tuberculosis accompanied by secondary pyelonephritis. There was considerable fibrosis of Bowman's capsule, leading in many instances to partial or complete obliteration of the glomeruli. The interlobular arteries showed fibroblastic thickening of the intima and the larger arteries medial hypertrophy.

Case 2

A 49-year-old man was admitted to hospital on October 16, 1954, complaining of shortness of breath of 18 months' duration. Together with this he had had a cough productive of white sputum. There was also a history of orthopnoea and retrosternal tenderness on exertion.

On examination he was ill and cyanosed. The blood pressure was 240/160; there was pulsus alternans and a presystolic gallop rhythm at the apex. The heart was enlarged to the left, the apex beat being in the fifth left space in the anterior axillary line. The fundi showed the presence of early papilloedema.

Investigations.—A specimen of urine contained albumin and a deposit of epithelial cells and scanty hyaline casts. Blood urea; 100 mg. per 100 ml. An intravenous pyelogram showed good concentration of the dye in the right kidney. The left renal pelvis, however, was not outlined. Three specimens of urine cultured for tubercle bacilli gave negative results.

On October 29 cystoscopy showed that the right ureteric orifice was normal, as was the rest of the bladder. The left ureteric orifice was scarred and prevented the passage of a catheter. A further intravenous pyelogram done when his condition had improved showed that the left kidney was, in fact, non-functioning and there was no excretion of dye. Also, calcification was present in the upper part of the kidney.

In view of the severe hypertension and the non-functioning left kidney, nephrectomy was performed on November 17. A tuberculous left kidney was removed. Following this the blood pressure, which prior to the operation was 210/110, came down to 120/80 and remained at or under 150/100 until he was discharged.

Three months later he was readmitted for hypotensive drug therapy as his blood pressure was again 210/110. He was stabilized on reserpine 0.25 mg. three times a day and pentolinium tartrate ("ansolysen") 40 mg. twice daily by mouth. On this dose his blood pressure was controlled in the neighbourhood of 155/95 and he was again discharged.

He was seen again in the out-patient department when the dose of these drugs was readjusted because his blood pressure was once again increasing. In May, 1955, despite further antihypertensive therapy, he died in cardiac failure.

Pathological examination of the resected kidney showed areas of fibrosis and calcification. There was advanced glomerular fibrosis, and the arterioles showed intimal and medial proliferation.

Discussion

Hypertension occurring in patients suffering from renal tuberculosis seems to be rare, and it is doubtful if it differs from the incidence of hypertension in normal people of the same age group. In a series of 40 patients with renal tuberculosis who have been subjected to nephrectomy and therefore had fairly extensive disease, I have found only the two cases of hypertension reported above. This low incidence of hypertension is of interest in that renal tuberculosis causes progressive complete destruction of renal substance, and the fact that this process is not associated with the production of hypertension suggests that some other factor is responsible. This question of the relation between the renal lesion and the hypertension has, of course, been discussed since the original observations were made, but no very satisfactory conclusion has been reached. Attempts to relate specific vascular lesions to the onset of hypertension have not met with any real success (Longcope, 1937), nor has any specific

pathological change been found in those kidneys removed from hypertensive patients compared with similar changes not associated with hypertension. It would seem, then, that simple destruction of renal substance is not related to the incidence of hypertension, as is shown in its low incidence in tuberculous lesions.

The results of nephrectomy in these cases seems to be very satisfactory. Langley and Platt (1947), in a review of cases with various renal diseases, quote four successes in 18 in hydronephrosis, six successes in 16 in calculus and pyelonephrosis, and 17 successes in 27 in pyelonephritis, with a total success rate of 44%, which may be compared with 15 successful cases in 23 in this collected series from the literature. These collected results undoubtedly give a rather optimistic estimate of the position, since they include isolated case reports of successes without mentioning the concomitant failures, but 17 of the total of 23 come from series reporting five or more consecutive cases and therefore should be representative. It seems likely that this success rate can be related to the age group of these patients (83% of the series of Braasch *et al.* were under the age of 50), for in all these cases one is studying hypertension in a person suffering from a renal lesion, and a causal relation can only be assumed in cases where the blood pressure falls. In the older age groups there is an increasing incidence of patients with "essential hypertension" who also have a renal lesion and in whom nephrectomy causes no change in the blood pressure.

The two cases related above are of interest in that they both had malignant hypertension. Schroeder and Steele (1939) reported two cases of unilateral renal tuberculosis associated with malignant hypertension as shown by fundal exudates and haemorrhages, and a case reported by Pickering and Heptinstall (1953) had fundal exudates and was found to have arteriolar necrosis on section of the resected kidney. Otherwise this condition does not appear to have been reported. In Case 1, since the malignant phase developed while the patient was under observation, it is known to have been of short duration, whereas in Case 2 unfortunately no record of blood pressure was made before October, 1954. Case 1 is also of interest in that the patient undoubtedly had bilateral lesions, and in spite of that had a prompt and excellent response to nephrectomy. It has been stated by Platt, Pickering, Barker, and others that bilateral lesions are a contraindication to nephrectomy in the treatment of hypertension of renal origin. In renal tuberculosis, however, the remaining lesion is treatable by chemotherapy. It would seem justifiable to consider nephrectomy as treatment for the hypertension even in cases where there is bilateral disease but good renal function remains.

As mentioned in the pathology of the two cases here reported, there was evidence of a secondary pyelonephritis in addition to tuberculous renal lesions, and it seems likely that this is a factor, and possibly the chief one, in causing the few cases of renal hypertension in renal tuberculous lesions.

Finally, in this discussion of the subject I would like to emphasize the good results obtained in these cases. A still very commonly held opinion is that renal hypertension responding to nephrectomy is frequently talked about but rarely seen at first hand. Of series quoting all cases, successful and unsuccessful, hypertension is completely and permanently abolished in between one-third and one-half of the cases. In the cases with tuberculous renal lesions these figures are even better.

Summary

The literature concerning tuberculous renal lesions and hypertension is reviewed and cases which have had nephrectomy performed are reported. Of the total of 23 cases, 15 had a fall in blood pressure to normal levels following operation, two had a fall but a subsequent rise in blood pressure, and in six there was no alteration.

Two further cases are reported here, both having malignant hypertension, one responding to nephrectomy and one not.

I am grateful to Dr. Horace Joules and Dr. R. A. J. Asher for permission to report cases admitted under their care. I am also grateful to Dr. J. H. O. Earle for his help in the pathological examination of these cases.

A CASE OF MYOTONIA CONGENITA WITH HYPOTHYROIDISM

BY

A. F. WADE, M.B., B.S.

Late House-Physician, Medical Unit, University College Hospital, London

Symptoms and signs suggestive of myotonia have been described in association with hypothyroidism. Since these are relieved by treatment of the thyroid condition, they have been regarded as part of the hypothyroid state (Hoffmann, 1896; Debré and Sémelaigne, 1935).

This paper records a case in which myotonia congenita (Thomsen's disease) and hypothyroidism were present simultaneously and in which the myotonia was not completely relieved even when the patient was made hyperthyroid.

Myotonia congenita is a hereditary disease of muscle characterized by prolonged involuntary contraction following a voluntary contraction (active myotonia) or mechanical stimulation (mechanical myotonia). The condition was first described by Leyden (1874), and Thomsen later published his classical account (Thomsen, 1876).

Case Report

A man aged 20 was referred to University College Hospital in September, 1954, for assessment of his myxoedema, diagnosed nine months earlier. He stated that at the age of 5 he had suffered from stiffness in the legs. This did not greatly trouble him and disappeared after two years. At 12 years the stiffness reappeared. It was more severe and extensive than previously. His main difficulty was in starting a movement, especially if sudden, owing to stiffness of the muscles. The calves and forearms were particularly affected. He noticed that the muscle became prominent and hard and was occasionally painful. After performing a movement repeatedly the stiffness wore off. He was sometimes unable to move a limb for some seconds. The symptoms were worse in the mornings and when cold.

His athletic abilities, previously excellent, fell off markedly, and by the time he was 13 he had given up sport completely, though doing well at his studies. At 14 he was becoming slower physically and mentally. He gained weight rapidly and complained of lethargy and difficulty in concentrating,

and his work deteriorated, so that instead of being near the top he was now near the bottom of his class.

At 18 he joined the Army and was constantly in trouble on account of slowness and clumsiness. On a cold morning he was almost incapacitated. While on sentry duty he once "went stiff all over" and fell to the ground when an officer unexpectedly appeared.

He next complained of frontal headaches, constipation, and occasional double vision. On investigation at that time he was puffy about the eyes, his skin was cold and dry, his pulse 55, his basal metabolic rate -25%, and serum cholesterol 470 mg. per 100 ml. A diagnosis of myxoedema was made and he was treated with thyroid. His weight decreased, the headaches became less severe, and the stiffness was less marked.

When first seen at University College Hospital there was, in the absence of full details, some doubt about the diagnosis, and thyroid therapy was discontinued. A month later, on admission, there was slight puffiness around the eyes, his skin was cold and dry, his temperature 97° F. (36.1° C.), his voice low-pitched, his pulse 44, and blood pressure 130/80 mm. Hg. The thyroid was not clinically enlarged. The muscles were well developed, the calves appearing abnormally bulky; tone was normal and there was no wasting. The arm-, knee-, and ankle-jerks were sluggish, and direct percussion of the calf muscles and forearm extensors produced a contraction lasting about five seconds with marked grooving at the site of percussion. Following a firm handshake there was considerable delay in relaxation of the grip.

Investigations.—Plasma cholesterol was 275 mg. per 100 ml. (later 370 mg.). His basal metabolic rate was -30%; radioactive iodine uptake at 24 hours was 5% of total dose. The electrocardiogram showed a rate of 39 with normal voltage curves. The blood sodium, potassium, chloride, calcium, magnesium, and inorganic phosphate were all normal. His intelligence quotient was 100.

Electromyography (Dr. W. D. Fletcher).—"The strength-duration curves of the right extensor carpi radialis were quite normal, although the type response was rather sluggish. Electromyography with needle electrodes, however, revealed trains of high-frequency oscillations on insertion of the needle and on mechanical stimulation of the muscle. These findings, taken together, are typical of myotonia congenita."

Improvement, objective and subjective, followed the administration of quinine. There was no urinary creatine. The creatine tolerance was high (71% retained) and administration of creatine had no observable effect on the myotonia. These findings are in keeping with other recorded observations in Thomsen's disease (Milhorat and Wolff, 1938; Poncher and Wade, 1938).

While under investigation the patient became more myxoedematous and his myotonia more marked. Thyroid therapy resulted in an improvement in both conditions. Correction of the hypothyroidism, however, was not accompanied by abolition of the myotonia, although active myotonia became less obvious.

He was discharged from hospital on December 3, 1954, taking 0.4 mg. of sodium L-thyroxine daily. Six weeks later he was readmitted for observation. He stated he was physically and mentally more agile, but complained of perspiring hands and palpitations. He had been less troubled by stiffness.

On examination he had lost a stone (6.4 kg.) in weight since taking thyroxine. His pulse was 68 a minute and regular. Active myotonia was not observed, the grip relaxing rapidly, but there was still marked mechanical myotonia, particularly of the calf and forearm extensors. His basal metabolic rate was now +53% and plasma cholesterol 247 mg. per 100 ml. No urinary creatine was detected. Electromyography showed no change, being still typical of myotonia; the electrocardiogram showed no significant change. Slit-lamp examination revealed no lens opacities.

Histology of calf-muscle biopsy showed well-developed muscle fibres with no muscle atrophy. In spite of the weight

loss, arm and leg volumes showed no significant change since his first admission. He was discharged on 0.2 mg. of sodium L-thyroxine daily.

Family History.—The mother, a maternal aunt, and her daughter all gave a history of myotonia and were found on clinical and electromyographic examination (Dr. Fletcher) to exhibit myotonia. The mother's father had had an operation for a cataract at the age of 74. Another sister of the mother had suffered from "Derbyshire neck."

Discussion

The history and findings are so characteristic of myotonia congenita and of hypothyroidism as to leave no real doubt that this patient suffers from two separate conditions.

The early age of onset of myotonia and the prolonged muscular contractions, worse in the morning, when cold, and becoming less marked on repeated movement, are typical. Difficulty in relaxing a grip following a handshake is a usual complaint. His falling "muscle bound" on being suddenly surprised recalls the behaviour of myotonic goats who suffer from a condition which completely resembles myotonia congenita in man (Levin, 1934; Brown and Harvey, 1939). Further, the bulky calf muscles exhibiting mechanical myotonia, the electromyographic records, and the strong family history indicate that this is a case of myotonia congenita. The diagnosis of hypothyroidism cannot be in doubt, and the history suggests that the myotonia preceded the hypothyroidism by about nine years.

Very few cases of the two diseases occurring together seem to have been described. Gordon *et al.* (1952) reported four cases of myotonia congenita in a family, one of whom had a basal metabolic rate of -20% and a blood cholesterol of 371 mg. per 100 ml.

The reason for stressing the existence of two separate conditions is that a number of cases have been described in which myotonoid symptoms and signs were due to hypothyroidism.

Hoffmann (1896) described a syndrome in which myxoedema was associated with hypertrophy and slow action of the muscles. Electromyography in such cases is not typical of myotonia (Nevin, personal communication; see Poncher and Woodward, 1936), and the condition responds completely to thyroid therapy (Malloret and Sigwald, 1939). Debré and Sémelaigne's cases exhibited the combination of myxoedema, muscle hypertrophy, and retarded growth. The condition occurs chiefly in young children (Thomsen, 1948) and responds completely to thyroid (Debré and Sémelaigne, 1935). Thomsen (1948) described a similar case to that recorded here, but the electromyographic records were not those of myotonia congenita, there was no family history, and all symptoms responded completely to thyroid therapy. Goldstone and Ford (1955) described the cases of two patients who developed severe myotonia as a complication of post-operative thyroid deficiency. The symptoms were completely relieved by the administration of thyroid extract.

The relief of myotonia with thyroid, noted in this case, is interesting, but cannot be a specific effect, for myotonia could still be demonstrated when the patient was hyperthyroid.

Thyroid therapy has been tried in uncomplicated cases of Thomsen's disease with either no effect or a worsening of the myotonia, and one case of Thomsen's disease with hyperthyroidism was improved by thyroidectomy (Thomsen, 1948).

Summary

A case in which myotonia and hypothyroidism co-existed is reported and reasons are put forward for believing that the patient suffers from two distinct diseases, myotonia congenita and myxoedema.

Treatment with thyroid brought improvement in both conditions. With correction of the hypothyroidism, however, myotonia could still be demonstrated.

I am grateful to Dr. W. D. Fletcher for performing the electromyographic studies; to Dr. D. R. Laurence and Dr. T. Geffen for their advice; and to Professor M. L. Rosenheim for his help and encouragement and for allowing me to publish the case.

Medical Memoranda

Sensitization Reactions to Tulle Gras Dressing, B.P.C.

After the conquest of Peru in the sixteenth century balsam of Peru was introduced into European medicine. It is obtained from the trunk of the tree *Myroxylon pereirae*, and contains cinnamic and benzoic acids.

Fuller (1730) says it has many uses; for instance, in treating coughs, spitting of blood, and dysentery, or with bees burnt, mouse dung, and honey for baldness. Graham (1832) states that the balsam is a stimulant and tonic, cleansing and stimulating foul and indolent ulcers.

More recently balsam of Peru has been used as a mild antiseptic. In the *Extra Pharmacopoeia* (1952) it is said to have a slight irritant local action and to stimulate epithelial regeneration, being employed, diluted with castor oil, for bedsores and chronic ulcers, and as an ointment for skin diseases such as eczema and pruritus. It is also mentioned as a treatment for scabies. Bloom and Lorincz (1954) used balsam of Peru, 10% in petrolatum, as a remedy in three cases of dermatitis repens; they found, using *in vitro* tests, that the balsam had bacteriostatic effects in similar concentration on several pathogenic bacteria commonly found in skin lesions.

The commonest use of balsam of Peru at present is in curatio carbasi paraffini B.P.C., otherwise known as tulle gras dressing. This consists of bleached cotton cloth impregnated with yellow soft paraffin containing balsam of Peru, 1 part in 80. Several identical proprietary brands are made as well as tulle gras with the addition of sulphanyl-amide, etc.

It is known that balsam of Peru may cause sensitization reactions. Andrews (1954) states that balsam of Peru may cause dermatitis when incorporated in perfumes (it has been used in brilliantine); Schwartz, Tulipan, and Peck (1947) mention the balsam as a cutaneous irritant. Alexander (1955) says: "The constituents of this drug [balsam of Peru], once so widely used, are largely cinnamoin with esters of cinnamic and benzoic acids. It was an ingredient of a large number of proprietary preparations. According to Engelhardt, sensitivity to it was first described in 1880. It is a strong contactant, and if applied freely may sensitize some 10% of patients. Patch tests are readily secured. Which of its constituents is the determinant allergen is unknown, but both cinnamon and benzoic acid have the capacity to sensitize the skin."

Tulle gras dressing is widely used, and sensitization of the skin to the balsam of Peru may be overlooked. Sensitization is probably more likely to occur, and more easily overlooked, when the material is applied to already diseased skin.

Recently two examples have been seen. Both patients were women with hypostatic eczema of the legs; following the application of tulle gras there was increased soreness and exudation. Patch tests with tulle gras were strongly positive,

whilst control patches (in one case of plain gauze and in another of gauze impregnated with yellow soft paraffin) were negative.

When such untoward reactions may occur, however rarely, it seems reasonable to doubt whether the continued incorporation of balsam of Peru in tulle gras dressing B.P.C. is justified; moreover, its beneficial effects are probably slight.

I thank Dr. Brian Russell for his help and advice in preparing this report.

Haemolytic Disease of Newborn: Delivery at Term of Living Affected Infant after Previous Stillbirths

A rhesus-negative woman whose husband is homozygous rhesus-positive, and who has had one or more infants still-born owing to haemolytic disease, is usually told that the chance of having a live infant from any future pregnancy is virtually nil. However, this view has been challenged by Watson, Crosse, and Hatchuel (1954), and by Watson (1956); they advocate premature induction of labour in such mothers, or delivery of the infant by caesarean section if foetal movements are diminishing. Williams (1956) described one case successfully managed by induction at the 34th week of pregnancy, followed by immediate exchange transfusion of the infant. The mother in question had previously had three stillbirths. Watson (1956) also mentions two other similar cases in which the infants were saved by inducing labour at the 36th week. Buffa, Francois, and Davidsohn (1956), in studying the outcome of pregnancy in 167 women whose sera contained immune Rh antibodies, reported that of 15 mothers who had had previous stillbirths five were delivered of affected but living infants, all of whom survived after treatment. They comment that these findings contradict the extreme pessimism often expressed to such mothers on the likelihood of their having a liveborn infant.

A further case is described which supports the new-found optimism expressed by these writers. It is of interest partly because the mother, after two previous stillbirths, was delivered at term of a liveborn affected infant, successfully treated, and partly because the mother's antibody titre in any pregnancy, whether it produced an affected live or stillborn infant, was relatively low throughout.

CASE REPORT

The mother's previous obstetric history is summarized as follows. 1941: caesarean section (India) for disproportion. Given 2 pints (1,140 ml.) of blood at operation; infant liveborn and normal. 1943: normal delivery; infant liveborn, no transfusions; severe jaundice for over a week; retarded development with incontinence and ataxia until death at 2½ years, presumed kernicterus. 1947: normal delivery; infant liveborn, jaundiced; simple transfusion first day; generalized spasticity and incoordination of movements, diagnosed as kernicterus by paediatrician; died at 4 years. 1949: normal delivery; exchange transfusion (Salisbury); infant alive and well. 1951: pregnancy terminated at 4 months, reason unknown. 1952: macerated stillbirth at 36 weeks. 1953: macerated stillbirth at 36 weeks. 1954: spontaneous abortion at 16 weeks.

She became pregnant again in November, 1955. Her attendances at the antenatal clinic were irregular, and,

although induction of labour at 36 weeks was considered, she did not present herself for admission until term: labour was induced surgically and a liveborn male infant weighing 6 lb. 15 oz. (3,150 g.) delivered.

Serology.—This woman was group O cde/cde; her husband was group B, cDE/cDE (presumptive). Antibody tests had been done at frequent intervals in her various pregnancies. The highest titre was 1/20 either in albumin or by indirect antiglobulin techniques. In her fourth, fifth, sixth, and seventh pregnancies no saline antibodies were demonstrated; but in 1956 an antibody titre of 1/20 in saline was detected in March, and remained at this level, as did the titre in albumin, until delivery. The specificity of the antibodies (both in 1953 and in 1956) was anti-D only. It is probable that this woman's sensitization dates from her blood transfusion (probably Rh-positive blood) in 1941.

The baby at birth (August, 1956) looked normal, but within an hour jaundice at the base of the cord was noticed. Cord blood findings were: haemoglobin, 13.9 g. per 100 ml.; serum bilirubin, 5.7 mg. per 100 ml.; direct Coombs test positive; group B, Rh (D) positive; blood film showed erythroblastemia. Exchange transfusion was carried out within three hours of birth, 306 ml. of blood being withdrawn, and 296 ml. of compatible (saline, albumin, and indirect antiglobulin techniques) blood injected. Samples of cord blood immediately before and after this exchange showed bilirubin levels of 8.7 and 7.8 mg. per 100 ml. respectively. Twelve hours later the infant was deeply jaundiced, and the bilirubin level was 24 mg. per 100 ml. (heel prick). A further exchange transfusion was therefore given, 400 ml. of blood being withdrawn and 380 ml. injected (O Rh negative); immediately after the exchange the bilirubin was 10.3 mg. per 100 ml., and haemoglobin 13.6 g. per 100 ml. The next day (40 hours) the haemoglobin was 15.8 g. per 100 ml. and the jaundice not increased; thereafter the jaundice faded rapidly during the next three days.

COMMENT

This case clearly demonstrates that it is possible for an Rh-negative woman, having had previous stillbirths due to Rh incompatibility, to have a liveborn affected infant at term. It is generally agreed (Mollison and Walker, 1952) that premature induction of labour is not indicated in most mothers with antibodies. However, induction of labour at the 36th or even 34th week in certain selected cases—that is, those who have had previous stillbirths due to haemolytic disease—is the treatment of choice, followed by immediate and large exchange transfusion of the infant. That the infant described here required two exchange transfusions within 12 hours is almost certainly due to the relatively small first exchange. Preliminary investigations here (J. R. H. P.) based on estimation of percentage of foetal haemoglobin before and after exchange transfusion, show that the efficiency of exchange transfusions is not as high as is generally supposed, even with exchanges of 50–60 ml. per lb. (110–132 ml. per kg.) of body weight. It seems desirable to aim at 80 ml. per lb. (176 ml. per kg.) for the more seriously affected infants.

We are indebted to Mr. J. G. Reynolds, under whose care the mother was admitted, for permission to describe this case; to Dr. G. H. Tovey, Director, South-west Regional Transfusion Centre, for confirmation of some of our serological findings; and to Dr. H. E. Harding for much advice.

Reviews

THE INFANT CEREBRAL CORTEX

The Postnatal Development of the Human Cerebral Cortex. By J. LeRoy Conel. Volume V. *The Cortex of the Fifteen-month Infant.* (Pp. 220; 109 plates. £5.) Cambridge, Massachusetts: Harvard University Press. London: Oxford University Press. 1955.

This is the fifth volume of a series in which certain histological features of the immature cerebral cortex are described in great detail. Between 30 and 40 cytoarchitectonic areas are treated separately, and each in terms of such criteria as the depth of the entire cortex and of individual laminae, the density and size of the cells, the development of Nissl substance, of neurofibrillae, of nerve fibres, and so on. The quantitative results are given in tables, and the actual material is fully illustrated in the plates. Comparisons with younger brains are made, so that conclusions about the growth which has occurred in the different areas and laminae can be drawn.

This work will provide a useful cytoarchitectonic atlas of the cortex of a 15-month infant. The photographs of the Nissl preparations are good and form a standard for comparison with sections from specimens of other ages. It is doubtful, however, whether the detailed descriptions and quantitative estimates will serve any very useful purpose. The methods used are open to serious criticism. Measurements of the maximum and minimum diameter, in one plane, give only a poor idea of the size of the cell, and no information is given of how large the samples measured were or how the range of cell size was distributed within them. The width of laminae is given to the nearest 0.005 mm., but the uncertainty about their boundaries must be much greater than this, and none of the usual statistical methods have been applied to the results to assess their level of significance. The estimates of the degree of development of Nissl granules or of neurofibrillae are very largely subjective, and may be affected by technical variations which cannot be accurately controlled. Taking all this into consideration, one cannot feel great confidence in the more detailed conclusions which the author draws about the differences between the present observations and those made in younger specimens, particularly since variations in the amount of shrinkage affect all the quantitative estimates to a serious degree. This is the more important when, owing partly to the laborious character of the work, only very few specimens can be examined (the description at 15 months is based on three), so that little account can be taken of individual variation.

Sections prepared by the Cox-Golgi and a Cajal silver impregnation method have also been studied. Though beautifully reproduced, the photographs of these are almost valueless as illustrations, and it is difficult to see what purpose is served by publishing them in such numbers. The drawings from the Cox-Golgi preparations are good, but, to judge only from the photographs, they seem to bear little relation to the actual sections. In general, one must conclude that neither the material nor the methods used in its examination are capable of giving precise and detailed answers to the questions asked. It is as if the magnification had been raised with no corresponding increase in resolving power, so that the information obtained remains on the same approximate and imprecise level as before, and subject to the same uncertainty of interpretation. It is only fair to point out, however, that nothing similar dealing with the immature human brain is available. It is to be hoped that the author will at some future date publish a critical summary of those features of the growth of the human brain which can be observed in the material on which he has done so much work, and where the really significant results are not obscured by the presence of excessive detail of doubtful validity.

F. GOLDBY.

THE CHILD'S SKELETON

Das Skelett des Kindes: Entwicklung, Bildungsfehler und Erkrankungen. By W. Swoboda. (Pp. 184+xii; illustrated. D.M. 48.) Stuttgart: Georg Thieme. 1956.

This volume on "The Skeleton of the Child," which forms one of the series in "Advances in the Field of X Rays and Nuclear Medicine," maintains the high standard of its predecessors. It fills a gap very conveniently in providing the paediatrician with a full radiographic reference work of normal and abnormal skeletal development. This inevitably means some compression, and there is still room for a book detailing fully the variants in growth and radiological appearances of the normal child, though the subject is successfully handled in the first 32 pages of this volume. The next 32 pages are devoted to the systemic disturbance of bone growth of hereditary, congenital, or developmental origin. In this section there is one serious omission—the disturbance of epiphyseal growth first described by David Trevor as tarso-epiphyseal aclasis (*J. Bone Jt Surg.*, 1950, 32B, 204) and more recently enlarged upon by T. G. Fairbank (*ibid.*, 1936, 38B, 237). Localized skeletal areas of maldevelopment such as hemivertebrae and coxa vara are then discussed, and next endocrine disturbance of the skeleton and disorders associated with general disease—for example, renal rickets. Osteochondritis juvenilis is included in the latter section, as it is considered secondary to disease of the epiphyseal vascular system. Inflammatory and toxic diseases are next described, then diseases of the reticulo-endothelial system producing secondary skeletal changes, and finally and briefly there is mention of tumours of bone and infantile fractures.

The positive radiographic illustrations throughout are beautifully clear and carefully chosen. Their limitation in number is probably on the grounds of cost, as there is obviously no shortage of clinical material; this is regrettable, as their perusal will be a source of pleasure to the experienced akin to that of visiting one's own National Gallery, and, for those unacquainted with radiographic appearances, of a first tour of the gallery. Brief clinical and radiological notes accompany each disease mentioned, and the grouping of the diseases is stimulating and thought-provoking. The volume would make a valuable preliminary study to Sir Thomas Fairbank's *Atlas of General Affections of the Skeleton*. It is unfortunate that no English translation is available, but no difficulty will be found in extracting the core of the information provided, which is essentially visual.

J. G. BONNIN.

MODERN SURGERY

Modern Operative Surgery. Edited by the late G. Grey Turner, LL.D., D.Ch., M.S., F.R.C.S., F.R.A.C.S., F.A.C.S., and Lambert Charles Rogers, V.R.D., M.Sc., M.D., F.R.C.S., F.R.A.C.S., F.A.C.S. Foreword by Sir Gordon Gordon-Taylor, K.B.E., C.B., M.A., LL.D., Sc.D., M.D., M.S., F.R.C.S., F.R.C.S.Ed., F.R.C.S.I., F.R.A.C.S., F.A.C.S. Fourth edition, Volume II. (Pp. 1231-2614+xii; illustrated. 75s.) London: Cassell and Company Ltd. 1956.

The second volume of this well-known work on operative surgery contains over 1,200 pages of text, which bring the number of pages for the two volumes to a total of 2,475—truly a magnum opus. There are over 1,000 illustrations, of which 600 are in this second volume; they are mostly clear, but some (as Figs. 715 and 716) are not easy to make out. This volume contains some very fine accounts of the surgery of special regions. The chapter on hernia was written by Grey Turner himself and is full of practical wisdom, though it may not find favour with the modern anti-Bassini school. Mr. Naunton Morgan compresses the whole of rectal surgery, and does it very efficiently, into the small compass of under 70 pages. Operations on the ear, eye, nose, pharynx, jaws, tongue, and hare-lip and cleft palate are described by recognized experts in the surgery of those parts. Mr. John Howkins covers the field of

gynaecological operations in a competent manner. For urological operations the accounts of Mr. Ogier Ward and of the late Mr. Everidge have been ably supplemented by revisions undertaken by Mr. Badenoch, Mr. David Wallace, and Mr. Henry Vernon. Professor Windeyer has written an excellent chapter on radiotherapy in malignant disease. Plastic surgery is dealt with in a masterly manner by Sir Harold Gillies, who has been assisted by Mr. Barron. The name of Sir Geoffrey Keynes is sufficient to guarantee the accuracy and the clarity of the section on surgery of the thyroid and thymus. We reserve for final mention the 100 pages devoted to the surgery of the skull and brain written in inimitable style by Sir Geoffrey Jefferson. The question is sometimes discussed whether, failing the opportunity actually to see an operation performed, one can learn more from a series of illustrations or from a well-written account of the operation. If everyone could write as Sir Geoffrey does we believe the written description would win. One could almost say that he wrote pictorially, and he also manages to get in, almost as an aside, some excellent principles of general application. For example: "Neurosurgery demands an apprenticeship in which the neophyte learns to regard all lesions as exercises in applied physiology and all operations as experiments, to be carried out with the greatest caution and solicitude for the welfare of the patient." If the word "surgery" were substituted for "neurosurgery," I doubt whether a better motto could be devised to be put up in large type over the door of every operating theatre. As the writer so truly adds, such principles cannot be forgotten without detriment.

ZACHARY COPE.

MEDICINAL CHEMISTRY

Medicinal Chemistry—Volumes II and III. A series of reviews prepared under the auspices of the Division of Medicinal Chemistry of the American Chemical Society. Volume II, edited by F. F. Blicke and C. M. Suter (Pp. 311+vi, 80s.) Volume III, edited by F. F. Blicke and R. H. Cox. (Pp. 346+vi, 84s.) New York: John Wiley and Sons, Inc. London: Chapman and Hall, Ltd. 1956.

These volumes maintain the high standard of accuracy of the first volume (which appeared in 1951) and are even more elegantly produced on better paper. Each volume contains four chapters. Apart from one chapter in Vol. 2 on some chemical aspects of the cardiac glycosides by A. Stoll, each chapter aims to include references to all the compounds that have been tested for a particular pharmacological activity. The chapters are therefore compilations of information rather than review articles, and their chief virtue lies in their comprehensiveness. Tables of compounds and reference lists occupy about two-thirds of the pages in these books, and the tables enable the reader to track down quickly what compounds have been tested and what activities have been reported for them. The remaining text gives an account of synthetic methods, of screening tests and of structure-action relationships. The treatment of structure-action relationships is naturally the most uneven of the aspects discussed, since it involves a more critical approach to published information on pharmacological activities, but some chapters reach a very high standard, particularly those on β -haloethylamine adrenergic-blocking agents by G. E. Ulyot and J. F. Kerwin and on synthetic analogues of physostigmine by A. Stempel and J. A. Aeschlimann.

Both volumes appear to cover the literature up to the end of 1952, but some chapters contain supplementary reference lists (with titles) for 1953. It would seem, therefore, that these volumes have taken three to four years to be printed and published, a circumstance which must be disheartening to the authors of chapters, and which raises the question whether speedier production in a less expensive form might not better fulfil the objects which the editors have in view. In future volumes it would be helpful if the date up to which the literature is covered was clearly stated at the beginning of each chapter. In the present volumes some, but not all, chapters contain this information.

The subjects dealt with, apart from those already mentioned, include synthetic oestrogens, arylpiperidine analgesics, methadone and related analgesics, quaternary ammonium germicides, and non-mercurial diuretics.

H. R. ING.

HISTAMINE IN ANAPHYLAXIS AND ALLERGY

Histamine: Its Role in Anaphylaxis and Allergy. By M. Rocha e Silva, M.D. Foreword by Carl A. Dragstedt, M.D. (Pp. 248+xii, 54s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1955.

The author of this monograph, at the Department of Biochemistry and Pharmacodynamics at São Paulo, Brazil, is internationally known for his many contributions to this subject. In his preface he points out that "many different threads must be followed simultaneously in order to clarify details of the mechanism of any physiological or pathological phenomena." The threads of the histamine problem are certainly most tangled, and after reading this book it is obvious that "even now, in spite of intensive and inspiring work . . . all the pieces of this jigsaw puzzle do not fit. We are still looking for missing parts which would give us the whole picture." In allergy histamine is only a part of the picture, for other substances undoubtedly have their place, but here also the boundary-line is indistinct.

The book is described on the jacket as being designed to interest clinicians, investigators, and students. It should indeed attract the attention of clinicians and investigators and all who are interested in histamine and the part it plays or may play in anaphylaxis and allergy. It is largely a compendium of experimental work. Not much space is given to the clinical aspects of the subject of the book; and here there is not enough critical discussion, some observations being of doubtful clinical value. Clinicians and investigators might well like to have this volume as a convenient reference book to experimental work, but one doubts its value to medical students.

D. A. WILLIAMS.

IMMUNOLOGY AND SEROLOGY

Immunology and Serology. By Philip L. Carpenter. (Pp. 351+viii, 45s. 6d.) London: W. B. Saunders Company Ltd. 1956.

The average student has little time to systematize and integrate into a pattern the knowledge he has gained from books, lectures, and demonstrations relating to the subject of immunology and serology. For years there has been a demand for the type of book under review by those who have reached the level, as the author so aptly puts it, of advanced undergraduate or early graduate status. The book is well produced and of reasonable compass, and the subject-matter is presented in an easy and readable manner. The emphasis is undoubtedly on serology, and the student is initiated, without too many of the details of technique, into the principles and practice of this fascinating subject. He is shown how serology is used in the furtherance of our knowledge of immunity as well as in the diagnosis, control, and treatment of disease. In a concise and interesting style the author lucidly expounds the generally accepted present-day views on immunity, allergy, antigens, antibodies, and antigen-antibody reactions *in vitro* and *in vivo*. If as a result of reading this book the student feels impelled to pursue his studies of this subject he will find useful lists of references at the end of each chapter.

This is not a manual of serology, and therefore the inclusion of the appendix might well be questioned. Nevertheless, it is clear that the book should prove to be of great value to those students for whom it has been written. As it stands it is excellent, and it is to be hoped that in future editions the author will not be tempted to expand the work so that it becomes neither a book for the student nor yet one for reference.

I. N. ORPWOOD PRICE.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY MAY 25 1957

DISSEMINATED SCLEROSIS

The cause or causes of disseminated sclerosis remain unknown, but it is possible that there may be a clue in the geographical incidence of the disease. C. C. Limburg,¹ who compared the mortality rates in different countries, concluded that the colder the climate the higher the crude death rate from the disease, and in comparing death rates in the American states and Canadian provinces he found that all the states or provinces with high rates either touched or were north of the fortieth parallel. Although statistics are lacking, it is probable that the disease is rare in China² and in India,³ while in South Africa G. Dean⁴ searched the records of the principal hospitals for the years 1939 to 1948 and found records of only 36 cases and states that the disease is unknown among the native and coloured peoples of South Africa. Two most careful regional surveys have been carried out in the United Kingdom in the past few years by R. S. Allison and J. H. D. Millar⁵ in Northern Ireland and by J. M. Sutherland⁶ in Northern Scotland, the great majority of the suspected cases being personally examined. In Northern Ireland the prevalence rate for the disease was found to be 7.9 per 10,000 of population for all groups over the age of 20: there was no evidence to suggest that the disease was more prevalent in any one district or that there was any tendency to focal distribution of cases. In the survey of the seven northern counties of Scotland the overall prevalence of probable cases was 5.5 per 10,000 of population, but in studying the local distribution Sutherland found in Shetland the surprisingly high figure of 11.3 per 10,000 and in the Western Isles (including Skye) only 3.4 per 10,000. He suggests that there may be a constitutional vulnerability to the disease in people of Nordic extraction in

Shetland as compared with the more Celtic population of the Western Isles. R. Swank^{7, 8} has suggested that the geographical distribution of the disease might be related to the amount of fat in the diet, and thought that there was some confirmation of this in a survey of cases which he made in Norway. On this assumption he has treated patients with disseminated sclerosis by a low-fat diet and has published several reports on the results.⁹⁻¹¹ In his last report he gave an account of 47 patients who had been on such a diet for at least seven and a half years and 107 for a somewhat shorter period. Unfortunately he had no comparable control series, but took the three years before the diet was started as a control period. He states that it is increasingly evident that the low-fat diet alters the course of the disease, and that there is a substantial decrease in both frequency and severity of exacerbations. The better results were obtained when the diet was started early in the disease, while in late progressive cases deterioration continued. Swank is very restrained in his claims for the treatment, admitting that this may be the natural course of the disease, but in view of the apparent benefit he is preparing to continue with the diet in his patients for a further four years.

In a recent number of this *Journal* Dr. Douglas McAlpine¹² has put forward once more the possible allergic origin of disseminated sclerosis, and suggests that this implies more than one factor in the aetiology. There does appear to be a slight familial tendency to the disease: in a survey of 310 cases from the Middlesex Hospital¹³ a familial incidence of 6.5% was found, a finding similar to that of Allison and Millar in their study of cases in Northern Ireland, while Sutherland in Northern Scotland gives the figure of 11%. In these familial cases siblings are affected more often than parents or children of the patients. The genetic factor is clearly a small one. A recent investigation at Oxford¹⁴ suggests that there may be a disorder of the normal immunological processes in disseminated sclerosis. This suggestion is based on the response to intrathecal injection of a purified protein derivative of tuberculin (P.P.D.). As a control, a similar injection was given to a number of chronic psychotic patients who had no signs of progressive neurological disease and in whom the cerebrospinal fluid was normal. The psychotics and the patients with disseminated sclerosis (when both were positive to the Mantoux test) responded quite differently to the injection. In the psychotics the initial response in the C.S.F. was the appearance of many hundreds or thousands of polymorph cells; these disappeared in the course of two to four days, to be replaced by a considerable increase of lympho-

cytes. In the patients with disseminated sclerosis the initial polymorph response did not occur, and, in addition, the correlation found in the psychotics between the intrathecal reaction and the result of the Mantoux test and the dose of P.P.D. injected was not present. The authors believed that the reaction was a true antibody-antigen response and that the consistent distortion of the pattern in disseminated sclerosis indicates that the normal immunological processes are disordered.

As to treatment of disseminated sclerosis, McAlpine states that no drug can be relied on to prevent relapses or modify the course of the disease. Nevertheless he advocates the use of arsenic—four courses of intravenous neoarsphenamine a year, with Fowler's solution in between the courses, the treatment to be continued for five years or more—because he believes that this treatment may modify the frequency and severity of relapses and so delay or even prevent the stage of progression. N. D. Compston,¹⁵ also working at the Middlesex Hospital, in a careful study of the effects of treatment in 57 patients given artificial pyrexia and arsenic, found no significant difference in the relapse rate before and after treatment. Many physicians would take the view that in a disease for which up to now no specific treatment has been discovered it is wiser to avoid a drug such as arsenic, which, whether given in inorganic or organic form, may cause toxic symptoms. The difficulty of assessing treatment in this disease is well illustrated in a short report from Gothenburg, where L. H. Blomberg,¹⁶ reporting on a small series of patients, found that those receiving a placebo showed greater subjective improvement than those given a substance which it was thought might influence the disease.

AMERICAN POLIO VACCINE

Public opinion now seems to be rather in favour of staking a claim for some of America's exportable surplus of poliomyelitis vaccine, though last year many parents declined to register their children for inoculation with the British vaccine, a product that is known to have passed the strictest tests of safety. It is now also known to have an antigenic efficacy equal to the best of the American vaccines¹ and better than some. Encouraging reports from the U.S.A., combined with the present rather high incidence of the disease in Britain, have raised public demand. But the medical pros and cons have hardly been argued—at least in public. No doubt those medical men who have the most expert knowledge of the subject are making their advice available to the Ministry of Health in official or semi-official ways, and they may,

understandably, feel restrained from simultaneously making it known to a wider audience. In consequence public opinion, and indeed ordinary medical opinion, is in some doubt about the possible benefits or disadvantages that must be considered.

Perhaps the main reason why the Government has not yet ordered American vaccine to supplement our own is that the same warranty for its safety cannot be given as the Glaxo product receives from the Medical Research Council's tests. Though the chances may be remote that live virus will contaminate any vaccine supplied to the public nowadays, the fact that this did apparently once happen is enough to impose caution. The Mahoney strain used for the type-1 antigen is many times more virulent than the Brunenders strain used in Great Britain, so that if by mischance some in a live state reached the public the results could be serious. Regulations for testing the American vaccine were tightened up in 1955, and, so far as the public health authorities there know, about 100 million injections have been given without serious misadventure; apart from the disaster in 1955, about 25 cases of poliomyelitis are suspected of being associated in some way with the vaccine or its injection. But those responsible for the surveillance of the American vaccine would concede that their knowledge of its effects in the vast population which have now received it, though considerable, is not necessarily complete. Apart from infection by live virus, some other possibly related ill effects have been reported to the authorities. These include about a dozen neurological cases varying from transient meningism to permanent paralysis of a non-poliomyelitic type. A few cases of allergic reactions have been reported, but there is little evidence of any haematological or renal reactions. The risk of provoking poliomyelitis by injection, discussed in these columns last week,² is exceedingly small. In general, American opinion seems to be that significant reactions to the vaccine must be occurring at a very low frequency. Against that must be set the difficulty of detecting any that might occur in Britain if some millions of doses were injected during a short period of perhaps rising incidence of the disease. Yet immediate detection is essential if a faulty batch is to be stopped before great damage has been done. A second reason for caution in importing American vaccine is that the antigenic potency of the products of different manufacturers varies. While some are excellent, some are not, and

clearly it would be desirable to specify which brands are wanted.

In considering the benefits to weigh against the possible, if remote, risks of using American vaccine, the epidemiologist may have a slightly different viewpoint from the family doctor or parent—and they may have something to learn from each other. There may or may not be an epidemic this summer; the present incidence of the disease cannot be interpreted either way; but, as M. Agerholm³ emphasized last week, no one can be certain that there will not be one. The protection conferred by the American vaccine, which seems to have been measured only in the mass and not by separate products, is impossible to express with any great precision. The estimate on the original trials was 60–90%.^{4–5} A recent one from the U.S. Department of Health, based on 1956 data which were not so rigorously controlled, is that, when a large proportion of the vaccinated population have received fewer than the recommended three doses, the vaccine prevents about 75% of the paralytic cases that would occur in an unvaccinated population. In the Hawaii epidemic in 1955–6⁶ statistically significant differences in severity were not found between the vaccinated and unvaccinated patients who had paralytic disease, though the figures suggested that the vaccinated patients did better. In the Chicago epidemic in 1956⁷ the figures were again in favour of vaccination. The difficulties in collecting valid data when a large-scale vaccination campaign is rushed through are evident in the reports on these two outbreaks, and many of the inoculations were given too soon for the vaccine to have its full effect. It is reasonable to conclude, though, that at least two doses of the American vaccine, and certainly the best brands of it, confer a fairly high degree of protection against the paralytic disease. Protection against the non-paralytic disease is probably slight.

No one can say that the Government and its advisers have an easy task in finding the best way through the maze of probabilities, favourable and unfavourable, that surround this question. But it has a duty to explain more fully than it has done the thoughts that animate it,⁸ for they are open to dispute. There is certainly a strong argument for importing the best brands of American vaccine, if that is possible. If the arguments against doing so outweigh it, they would be all the better for public discussion.

LUNG CANCER AND CHROMATES

The first reports of lung cancer among chromate workers came from Germany in the 1930's.^{1,2} At least 62 cases are now known to have occurred in that

country, but the size of the population at risk is not known with accuracy, and the existence of a specific industrial hazard was not established until after the second world war, when the data for the American industry were published. These data concerned the workers at seven chromate plants; the mortality from lung cancer among them was some 30 times greater than would have been expected from either the national mortality data or the records of other industrial employees of corresponding ages.^{3,4} In contrast, the mortality from other types of cancer among the chromate workers was similar to that recorded for all men throughout the country.

No suspicion of a risk had been raised in the British industry, and both management and men were so confident that none existed that attempts began to be made to explain the different experiences in the three countries by an analysis of differences in the techniques of manufacture. A preliminary clinical and radiological examination of 724 men employed in the three British plants engaged in the manufacture of chromates from chromite ore revealed only one case.⁵ Such a finding showed only that it would be necessary to observe the men for a long period before a conclusion could be reached, and a continuing study of the health of the employees was therefore initiated by P. L. Bidstrup and R. A. M. Case.⁶ As a result, 15 cases have been discovered in a little under six years. Of these, 12 occurred among the group of 723 men who had previously been x-rayed by Bidstrup; the affected men had all died before the end of the follow-up period and their deaths had been certified as due to lung cancer. Of the other cases, one had been found by Bidstrup at the initial x-ray examination and had consequently been excluded from the study, another was found to have lung cancer at a repeat x-ray examination at the end of the inquiry, and the third was an employee who had not been included at the initial examination. If the men who were studied had experienced the same mortality from lung cancer as other men of the same ages in Britain, the number of deaths from lung cancer would have been about 3 (actual calculated number 3.3), and the observed mortality was therefore more than three and a half times the normal. The mortality from other causes was, in contrast, close to the normal; 9 deaths were recorded from other types of cancer against 7.3 expected and 38 deaths from all other causes against 36.3 expected. Thus the men were not unhealthy in general, and the excess mortality from lung cancer must be attributed to some specific factor. The size of the excess is such that it cannot reasonably be explained by residential or social factors or by differences in smoking habits, and it seems that it must be due to a specific hazard in the industry. At first sight it might appear that the extent of the risk in Britain was substantially less than in the U.S.A., but this is probably

¹ Pfeil, E., *Dtsch. med. Wschr.*, 1935, 61, 1197.

³ Machle, W., and Gregorius, F., *Publ. Hlth Rep. (Wash.)*, 1948, 63, 1114.

⁴ Brinton, H. P., Frasier, E. S., and Koven, A. L., *ibid.*, 1952, 67, 835.

⁵ Bidstrup, P. L., *Brit. J. Industr. Med.*, 1951, 8, 302.

⁶ — and Case, R. A. M., *ibid.*, 1956, 13, 260.

⁷ Baetjer, A. M., *Arch. Industr. Hyg.*, 1950, 2, 487.

not so. The "normal" mortality with which the mortality of the American workers was compared was recorded at a time when mortality from lung cancer was less than half as common as it was during the period of Bidstrup and Case's study, and "normal" American mortality is, moreover, only about half the British. The fact that the risks may be much the same is illustrated by the proportion of the total deaths which were attributed to lung cancer in both countries. Out of 193 deaths from all causes W. Machle and F. Gregorius³ found 42 attributed to lung cancer (22%), whereas Bidstrup and Case found 12 out of 59 (20%).

Apart from the cases of lung cancer, three other cases of respiratory cancer have been described among chromate workers.⁷ All occurred in the nose, but they did not arise from the nasal septum and were unrelated to previous perforation of the septum. It seems, therefore, that the perforation of the septum commonly found among all types of chromate workers, like the chrome ulcer of the skin, does not predispose to malignancy. One of the three cancers arose from the inferior turbinate and the two others from the maxillary antrum. These cases are reminiscent of the nasal cancers—principally ethmoid or antral in origin—which together with lung cancer have been a major hazard to men employed in the refining of nickel in South Wales. In view of the rarity of nasal cancers in normal conditions, it seems likely that the reported nasal cancers among chromate workers are also industrial in origin.

Evidence of the exact nature of the substance responsible for the induction of cancer is conflicting. No cases have been reported among miners of chromite ore, and the ore itself might therefore be considered innocuous had it not often been shown that an important cause of cancer can easily be overlooked. Apart from men engaged in the manufacture of chromates from the crude ore the only other group reported to have suffered a high mortality from the disease is a group of men engaged in the manufacture from dichromates of chrome pigment (that is, lead and zinc chromate). Machle and Gregorius, on the other hand, found no cases of lung cancer in one of the plants which they studied, in which the men were exposed only to dichromates and chromic acid. Apart from two cancers in rabbits which followed the intrafemoral injections of metallic chromium, animal experiments have so far proved negative, and it has not been possible to isolate the carcinogen by this means. The consensus of opinion is that the carcinogen will probably prove to be trivalent chromium in the form of acid-soluble–water-insoluble compounds. However this may be, it appears that one further example must certainly be added to the list of relatively simple inorganic substances which, under suitable conditions, can cause cancer of the respiratory tract.

MASS SPECTROMETRY

A spectrometer is an instrument for the quantitative measurement of radiations of different wavelengths. Various means, such as quartz prisms, diffraction gratings, and crystals, are used for dispersing the light

rays into their component spectra. The mass spectrometer utilizes the same principle for the analysis of a mixture of gases, the individual molecules being first ionized and then dispersed by means of a powerful magnetic field. The greater the molecular weight (mass) of a particular gas the less will be its deflection in the magnetic field. Thus the stream of ionized molecules will be split up into beams of different molecular weight, the electrical charge of which can be measured. Physicists have used mass spectrometry for thirty years, and it has been applied to the industrial separation of radioisotopes and hydrocarbon gases. But only a few attempts have been made—notably in the United States—to extend its use to the biological sciences. This week we publish an enthusiastic account by Mr. K. T. Fowler and Dr. P. Hugh-Jones of the value of the mass spectrometer in the study of respiratory function in man. The instrument has been designed and built entirely in the workshops of the Postgraduate Medical School at Hammersmith Hospital—a notable example of the contribution which electronic engineering is making to clinical medicine.

A pump draws air either from the mouth or from a bronchus during bronchoscopy through a fine stainless-steel tube into an ionizing chamber, where the gas molecules are bombarded by a beam of electrons. The ions are then accelerated by means of a negatively charged plate, through which they stream into the magnetic field. Here they are deflected in a circular pathway towards a collecting plate, which is connected to a cathode-ray oscilloscope. By varying the accelerating voltage it is possible to obtain a continuous scan of the different beams, so that the oscilloscope shows a series of peaks, the horizontal positions of which indicate the molecular weight and hence identity of the component gases. The abundance (partial pressure) of each gas can be determined from the height to which the peak rises. A continuous tracing of variations in partial pressure with time can be obtained by connecting the spectrometer with a multichannel recorder. The present instrument is capable of continuously analysing up to four different gases during the whole of the respiratory cycle. It requires a negligible fraction of the respiratory minute volume, has a response time of less than a tenth of a second, can detect changes in concentration of 1%, and is readily transportable. It has been designed to detect gases of molecular weights ranging from 18 to 80, which includes those of physiological importance as well as certain inert gases which are useful in this type of work.

The advantages of such a device will be appreciated by anyone engaged in investigating lung disease. Most methods for measuring respiratory gases depend on laborious chemical analysis of samples obtained at a particular time in the respiratory cycle. Automatic gas analysers are available for continuous sampling, but they can be employed in the study of only one gas at a time.

One of the most puzzling aspects of lung function at present is the manner in which exchange of gas takes place in the lungs. The mass spectrometer can provide information about the distribution of inert gases and

therefore will detect any inequalities of ventilation. It can be used to assess the relationship between ventilation and blood flow through the lungs, the so-called ventilation-perfusion ratio. In addition it should be capable of measuring the ease with which gases diffuse between the alveoli and the blood. Such measurements are of great importance in the study of chronic lung diseases, such as emphysema and asthma, and serial readings would help in assessing the results of treatment. The advantage of mass spectrometry over existing techniques is that it can simultaneously provide simple, rapid, and accurate estimations of several different variables in pulmonary gas exchange. Time will show whether it can supply the answers to some of the many problems which confront the chest physician.

RESCUE WORK IN MINES

For purposes of study, mines provide a situation typical of hot working environments. Physiological research in mines has recently been renewed, and there have been reports from the deep mines of the Rand¹ and of the Gold Coast,² and now a Medical Research Memorandum³ from the National Coal Board draws attention to a different aspect of the same problem. This study is concerned not with the miner himself and the maintenance of thermal equilibrium, but with rescue workers who when saving life or fighting underground fires must endure conditions well beyond the usually accepted limits of human tolerance. Any environment may be tolerated for a period: clothed men at rest can withstand temperatures of 240° F. (115° C.) in dry air (relative humidity 1.5%) for 20–25 minutes before suffering "intolerable discomfort"⁴; in mines temperatures are not so high, usually below 113° F. (45° C.), but the air is near saturated and still, and rescue personnel must work extremely hard, carrying the added burden of equipment for oxygen breathing. The tests were carried out with the assistance of the Medical Research Council's Unit for Research on Climate and Working Efficiency on members of the rescue teams employed in mines. Preliminary screening trials were performed at Oxford; the men were not exposed in these to severe conditions, nor were they worked hard. Older men (39 to 45 years) reacted more sharply than did the younger men (19 to 31),⁵ with higher skin and body temperatures and greater circulatory changes. But these differences were not large, and men in both age groups were exposed to more severe conditions in the National Coal Board's testing chambers at Doncaster. In these trials men carried out the sort of work they might have to do during rescue operations, building sandbag stoppers, at a mean

metabolic rate of 200 kilogram calories per square metre of body surface per hour in saturated environments at temperatures ranging from 85 to 100° F. (29–38° C.) with an air movement of less than 20 ft. (6 m.) per minute. They were withdrawn when their rectal temperatures reached 101.8° F. (38.8° C.). Tolerance time was not affected by age, nor did it differ with occupation. But it did vary according to the type of breathing apparatus worn; at 100° F. (38° C.) men wearing the "aerophor" equipment could tolerate these working conditions for 32 minutes, but with the "proto" they lasted only 29.5 minutes. At 85° F. (29° C.) the corresponding figures were 64.5 and 54 minutes. These differences were associated with the higher temperatures from the inspired air when wearing the proto equipment. Further tests were carried out at higher temperatures in unsaturated environments and included observations on "vigilance." The tolerance times finally recommended by the authors and incorporated in an Information Bulletin⁶ from the National Coal Board are 10 minutes less than those determined experimentally in order to allow a safety margin for any rescue workers who might be unduly susceptible to heat. The recommendations extend to temperatures up to 120° F. (49° C.) dry bulb, 95° F. (35° C.) wet bulb.

This is probably the first time that such high rectal temperatures have been regarded as permissible: 101.8° F. (38.8° C.) is beyond the point at which sweating diminishes with further rises in rectal temperature,⁷ but in saturated atmospheres evaporative cooling is minimal, and the effects of the inevitable rise in body temperature are a calculated risk that must be taken. The men can cool down only when they return to their "fresh air base," but no recommendation has been made about the temperature of the base; presumably the authors did not consider this necessary, as E. F. DuBois⁸ has shown that an unclothed inactive man has difficulty in maintaining his body temperature even at 80° F. (26.7° C.), and it is unlikely that any "fresh air base" in Britain would be warmer than this.

GROWTH IN CHILDHOOD

The physiological processes of growth are so complex that studies of deviations from the normal may be developed in a great variety of conditions. Heredity, antenatal disorders affecting the foetus, and prematurity have all been—and still are—subjects of intensive research. Normal variations in pattern throughout childhood are well recognized, and the introduction of such aids to evaluation as the Wetzel grid has done much to stimulate the study of these individual differences. It is, however, in disease that deviations become particularly evident and the natural inherent struggle to maintain or regain normal growth can be seen. The problems have been approached in many different ways, and three recent papers have contributed to our knowledge of childhood reactions to some adverse factors.

¹ Sheldon, W., *Gt. Ormond Str. J.*, 1956, 8, 31.

² Hubble, D. V., *British Medical Journal*, 1957, 1, 601.

³ Ansell, B. M., and Bywaters, E. G. L., *Ann. rheum. Dis.*, 1956, 15, 295.

The effects of coeliac disease on growth have been known since the condition was first described over seventy years ago. Coeliac dwarfism was a well-recognized condition. Now that the aetiology is established and a means of control is available, studies of the effect of withdrawing, and of subsequently reintroducing, gluten into the diet of affected children have shed light on the prognosis, particularly for growth. W. Sheldon¹ analysed 86 cases of coeliac disease and found that in 64 growth continued normally after the reintroduction of ordinary (that is, gluten-containing) diet; in 5 there was a prompt recurrence of symptoms, which again subsided when gluten-free diet was given. The remaining 17 were an interesting group, for in these the only sign observed after the reintroduction of gluten to the diet was retardation of growth. Subsequent withdrawal of gluten was followed by increase in growth. In none of the 86 cases was growth accelerated when the children were on a normal diet; indeed, this resulted in an overall diminution in the rate of growth. The cause of this effect on growth of gluten intolerance remains to be explained.

D. V. Hubble² considered the problem of growth from the point of the hormonal influences—the competition between protein anabolizers (growth hormones, thyroxine, insulin, and androgen) and catabolizers (chiefly the adrenal cortical compound F)—and discussed the effects of certain pituitary and adrenal dysfunction on growth. He constructed an ingenious "hormonal formula" to explain the features of these endocrine, and of some metabolic, disorders. The annual percentage increase in height, he suggested, offered a clinical index of the activity of the protein-anabolic hormones when disease and malnutrition were absent. He stressed particularly the metabolism of protein in relation to growth and considered that the anabolic hormones were in the ascendant during active growth phases, when the growth hormone, about which little is yet known, may be directly stimulating tissue synthesis from amino-acids.

Rheumatoid arthritis in childhood afforded B. M. Ansell and E. G. L. Bywaters³ an opportunity to study the changes in growth caused by this disease. They followed up 119 cases over several years, studying particularly height, weight, and bone development and the effects of testosterone and cortisone on the growth and maturation of the children. In this careful investigation they found that slowing in rate of growth in height was common during periods of active disease but that growth was rapidly resumed and indeed returned to normal rates during quiescent periods. The weight similarly varied. Abnormalities of bone development were the result of the general retardation of growth due to the chronic disease, together with local changes in the neighbourhood of affected joints. Treatment with testosterone stimulated a rapid increase in weight, particularly when the disease was becoming less active, and cortisone produced a slowing in growth which was maintained even when the disease was well controlled clinically; increase in height was resumed only after the dose of cortisone had been reduced to 50 mg. a day or less.

These three papers may be considered complementary to one another in their approach to an understanding of

how disease may affect growth in childhood. Each in its different way helps to clarify the subject and will well repay study by all who are interested in the vagaries of growth, normal and abnormal.

WELLCOME TRUST

Henry Solomon Wellcome was born in Wisconsin, U.S.A., in 1853, and it was as a traveller for an American pharmaceutical firm that he first landed in Great Britain. As a pharmaceutical student he had met Silas Mainville Burroughs, a fellow student, at Philadelphia, who conceived the idea of developing a British market for compressed tablets containing accurate doses of drugs. These two young men joined forces in 1880 to found the firm of Burroughs Wellcome and Co. It was not long before what started as an importing business grew to be a large manufacturing firm, and "tabloids" became familiar to almost everyone in the country. Burroughs died of pneumonia in 1895, and Sir Henry Wellcome, as he became in 1932, built up the firm while retaining all the capital in his own hands. All his life interested in a wide variety of researches, many of which he financed on a generous scale, he founded in 1924 the Wellcome Foundation Ltd., to provide more formal arrangements for financing them from the profits of Burroughs Wellcome and Co. On his death in 1936 trustees¹ appointed by his will took over these affairs, and the first report of the Wellcome Trust, from which these biographical notes are taken, has now appeared.² It covers the twenty years 1937–56, twenty years of most discerning and fruitful help to medical (and some other) research.

In recognition of Wellcome's own interests the trustees early decided to support research in pharmacy and pharmacology, tropical medicine, and veterinary medicine. Among the ventures it has endowed in one way or another are a professorship of clinical tropical medicine at the London School of Hygiene and Tropical Medicine, a professorship of pharmacy at the School of Pharmacy, London, research fellowships in veterinary medicine, biochemistry, and anaesthesia, grants to the Universities of Oxford, Leeds, and St. Andrews to improve their departments of pharmacology, and special sums to buy expensive apparatus such as electron microscopes. Large sums have also been given to all three Royal Colleges in London and to the Royal Society of Medicine to help to expand their libraries and museums. These are only a few of the many benefactions that this remarkable trust has been able to make in pursuance of its policy of "giving support to enterprises of which the merits were endorsed by the best available scientific opinion, but which, for one reason or another, had not so far received the support which they needed." It is evident from this report not only that Wellcome was a man of far-seeing vision but that his trustees have served him well.

¹ The present trustees are Sir Henry H. Dale, O.M., F.R.S., L. C. Bullock-M. Price, Lord Piercy, and Brigadier J. S. K. Boyd, F.R.S.

PREVENTION OF RECURRENCES OF RHEUMATIC FEVER

BY

E. G. L. BYWATERS, M.B., F.R.C.P.
KATHERINE HALLIDIE-SMITH, M.R.C.S.
D.C.H.

AND

G. T. THOMAS, M.B., M.R.C.P.

From the Special Unit for Juvenile Rheumatism, Canadian
Red Cross Memorial Hospital, Taplow, Maidenhead,
Berkshire

Each attack and every recurrence of rheumatic fever is preceded by infection of the throat with group A beta-haemolytic streptococci. If this infection could be prevented or eliminated by early treatment, rheumatic fever and rheumatic heart disease would be exterminated. This is now almost universally accepted. It is, however, not feasible to prevent all group A beta-haemolytic streptococcal infections in the general population, and, while it is theoretically possible to eliminate such infection in the individual by early treatment, this is difficult in practice in more than a small proportion of patients. A more limited objective is the prevention of rheumatic fever recurrences.

Prophylaxis of Proved Value

It is 18 years since sulphonamides were first used for the prevention of rheumatic fever recurrences by Thomas and France (1939) and Thomas *et al.* (1941), and almost simultaneously by Coburn and Moore (1940). All subsequent studies and all those conducted using penicillin in a similar way have confirmed the value of these measures (Houser and Eckhardt, 1952; Bywaters, 1952, 1954). Experts agree on their value (Mortimer and Rammelkamp, 1956), and on the amount of invalidity and suffering that could be avoided were these measures used throughout the world. Experienced observers hold that "the extent of cardiac damage appears to increase with the number of recurrences" (Wilson, 1940), and "the degree of disability and the ultimate longevity of those with injured hearts are largely influenced by the frequency, duration, and severity of recurrences" (Bland and Jones, 1952).

Yet in this country it is an exception to find children or adults who have recently had rheumatic fever protected in this way against further attacks. Apart from some paediatric teaching centres, few of the teaching hospitals and fewer of the non-teaching hospitals use this measure. It is true that only a small number of rheumatic fever cases are now admitted, compared with, say, 50 years ago, yet in notifying areas 0.027% of schoolchildren are attacked by rheumatic fever each year (Leff, 1956) (taking the mean of the last three years, 1951-3, for all areas). If this rate applies to all the children of England and Wales, we can calculate that each year about 2,000 children develop rheumatic fever and need protection for an average period of five years. It becomes important, therefore, to find out why this well-established prophylactic measure is not being used in this country either by consultants in the hospitals or by general practitioners in the home. Some of the reasons have been uncovered by a review of our own prophylactic scheme and the extent to which it has been implemented when the patient returns home.

Why Prophylaxis is Abandoned

Prophylaxis has been undertaken in this unit since 1951, using either sulphadiazine or triple sulphonamide 0.5 g. b.d. or penicillin G 200,000 units b.d. All patients with proved or probable rheumatic fever or chorea since then have been

discharged from hospital on this regime. They are given a supply to last three months and a letter is sent to the family doctor suggesting that this should be continued until the age of 20. The patients are seen at 6- or 12-month intervals at our own follow-up clinics. Erythrocyte sedimentation rate and antistreptolysin O titre are measured and urine tests for sulphonamide made at each attendance. Results of such follow-up examinations and recommendations are incorporated in letters to the family doctor and school medical officer. Sulphonamide is dispensed in the clinics in amounts to last six months. If the patient has finished the supply before his next visit, he may either write in for more or obtain them from his own doctor. Penicillin is given by prescription for three months at the follow-up clinics or is supplied by the family doctor; patients may write directly to the hospital for further supplies.

By inquiry of patients, parents, and doctors we have found that most parents co-operate to a variable extent, depending upon their conscientiousness, ability to control their children, their comprehension of the measure, and their trust in the doctor: others are apathetic, and still others appear to be confused by the difference between their own doctor's instructions and those of the hospital doctor. Many doctors approve of the scheme and co-operate well, but others are apathetic, and others oppose this measure.

The difficulties we have encountered may be summarized as follows:—(1) *Parental*: (i) apathy, (ii) lack of supervision. (2) *General practitioner opposition* on account of: (i) swelling the drug bill, (ii) making children hypochondriacs, (iii) lack of knowledge of its value, (iv) fear of toxic reactions, (v) fear of bacterial resistance developing, (vi) fear of penicillin loss of potency over three-month periods and subsequent too frequent (monthly) prescribing, and (vii) the fact that the disease is now uncommon and diminishing.

Medical Opposition Examined

It must be admitted that most of these reasons for medical opposition have some element of validity in them, but the measures advocated have been tested out practically and successfully over a prolonged period of time. For reasons often stated before, we consider, in common with the American Heart Association (1953), recently reviewed in this *Journal*, that the advantages greatly outweigh the possible disadvantages. To take the medical objections serially:

1. Cost per day (based on hospital costs).

	Dosage	Daily cost
Crystalline penicillin G*	200,000 units b.d.	3.68d.
Phenoxymethylpenicillin (penicillin V)	120 mg. b.d.	8.8d.
Sulphadiazine	0.5 g. b.d.	2.04d.
Tab. trisulphonamide ("sulphatriad")	0.5 g. b.d.	1.62d.
Sulphafurazole ("gantrisin")	0.5 g. b.d.	4.60d.

This seems a small price to pay for protection against a second attack of rheumatic fever and possible further cardiac damage.

2. Hypochondriacs are made, not by pills but by parental attitudes.

3. Failure to realize the value of prophylaxis is widespread and bears no relation to the excellence or otherwise of the physician in general.

4. Toxic reactions are rare with sulpha drugs, and if they occur they usually do so within the first three months of prophylaxis—i.e., with our own patients usually while they are still convalescent under observation in hospital. In a five-year period with about 500 patients discharged on prophylaxis—mostly a sulphonamide but some on penicillin—we have had only one serious (but not fatal) reaction, a patient developing agranulocytosis after sulphadiazine for eight weeks. Others have shown transient leucopenia (2 cases) or urticarial rash of doubtful aetiology. Renal damage will not occur in this dosage and with these drugs. Rarely, reactions have occurred with therapeutic dosage, after a prior period on prophylactic dosage. Penicillin sensitivity (mainly skin reaction) is rare on prophylactic

*Benzathine penicillin is only long-acting intramuscularly, and offers no commensurate advantage for its extra cost by mouth.

dosage, and also occurs in the early convalescent period. We have had very few, none severe.

5. Streptococcal resistance to sulphonamides develops only under epidemic conditions, in closed institutions: it is not serious, since change can be made to penicillin, to which streptococci remain sensitive. Staphylococcal resistance to penicillin can be a nuisance, but again emerges in this country usually only under institutional or hospital conditions, not at home. We have had no trouble in this institution over the last five years. If staphylococcal-resistant strains appear, other antibiotics are available.

6. Loss of potency of penicillin tablets may occur on exposure to moist air, but penicillin should last at least three months unimpaired if stored in an air-tight bottle in a cool place. Some brands are packed in metal foil as an additional protection against humidity.

7. This is no reason for not protecting those particularly susceptible.

8. Another objection, more difficult to meet, is that another method of prophylaxis exists—that of treating promptly every sore throat in such patients with bactericidal doses of penicillin. This is useful should a sore throat develop in a rheumatic child because of omission of prophylaxis, but it is not always successful and it is not practical as a general measure, since all group A streptococcal infections are not manifest as sore throats, all children do not complain, all parents do not go to the doctor, and all doctors do not use this method. We consider routine daily prophylaxis safer.

The prevention of first attacks of rheumatic fever in a susceptible population also needs attention but is another and separate problem.

Conclusions

We conclude that measures should be taken in this country to acquaint physicians in general with the advantages to be gained from routine daily prophylaxis against rheumatic fever relapses. Opportunities exist at meetings of learned societies and in medical publications. Full discussion of possible disadvantages is needed together with accounts of practical experience in this field. Lay education should not be neglected.

TERMINOLOGY OF THE HEREDITARY HAEMOGLOBINOPATHIES WITH HAEMOGLOBIN VARIANTS

BY A WORKING PARTY* OF THE COLONIAL MEDICAL RESEARCH COMMITTEE

The following recommendations are based on immediate practical requirements rather than on fundamental theoretical considerations, and are put forward at the present time solely with the aim of discouraging the growth of ambiguous systems of terminology until an agreed international system has been devised.

General Recommendations

(a) The term *sickle-cell disease* should be used to denote any pathological condition which is, in part, attributable to sickling of the red cells. The term *sickle-cell anaemia* should be reserved to denote the presumably homozygous state. Its use is (strictly) conditional upon the demonstration of homozygosity from family studies.

(b) Foetal haemoglobin is excluded from the present discussion of terminology, though its persistence in varying degree is an often-observed feature of states involving the haemoglobin variants. Statements regarding its occurrence should be made as part of the biochemical findings.

(c) The working party appreciates the desirability of having a complete statement of the haemoglobin variants actually present, preferably in order of decreasing proportions, leaving the clinician to decide if an actual (or potential) pathological situation needs to be described, and the geneticist to state how the observed combination of haemoglobin variants has arisen. The working party also appreciates the undesirability of using a terminology with genetic implications in the absence of family studies.

(d) The term *haemoglobinopathy* should be used to denote a condition in which the production of normal adult haemoglobin (Hb-A) is partly or wholly suppressed and it is partly or wholly replaced by one or more haemoglobin variants, which may include foetal-type haemoglobin (Hb-F).

Specific Recommendations

(a) The term *sickle-cell* should be hyphenated when used as an adjective.

(b) Excluding Hb-F from consideration, the biochemical state involving Hb-A and any other one haemoglobin variant (Hb-X) should be described as *Hb-X trait*.

(c) The term *disease* and not the term *anaemia* should be used generally to denote pathological conditions associated with haemoglobin variants.

(d) The term *thalassaemia* should be retained because the genetic variants of thalassaemia present themselves as such. These variants should be described as *Hb-C/thalassaemia*, *Hb-E/thalassaemia*, etc. The term *thalassaemia* should be used rather than the terms *Cooley's anaemia*, *microcythemia*, etc. The qualifying terms *major* and *minor* are in practice used to denote the presumably homozygous and heterozygous states respectively, but their use in this way is (strictly) conditional on supporting evidence for the nature of the genotype from family studies.

(e) A morbid condition, not presenting itself as sickle-cell disease or as a variant of thalassaemia, but produced by any one or two Hb variants, in the absence of Hb-A, should be described as a *disease*—e.g., *Hb-C disease*, *Hb-C/Hb-D disease* (hypothetical). It is appreciated that some of the possible combinations are not yet known to produce morbidity in adults.

Examples of Known Haemoglobin Combinations

(Note.—In these examples the haemoglobin variants given in parentheses are not always found).

A	..	..	..	Normal adult
A+F	..	..	..	Infants
A+F	..	..	..	Thalassaemia
S+F	..	..	..	Sickle-cell anaemia
A+S	..	..	..	Sickle-cell trait

*The Colonial Medical Research Committee's working party on sickle-cell trait and sickle-cell anaemia, which prepared these recommendations on terminology, consists of the following: Professor A. W. Woodruff (*chairman*), Dr. A. C. Allison, Professor P. C. G. Garnham, Dr. H. Lehmann, Dr. R. Lewthwaite, Professor B. G. Macgrath, Dr. A. E. Mourant, Dr. A. B. Raper, Dr. J. C. White, Dr. G. H. Beaven (*secretary*).

PROFESSIONALISM AND BUREAUCRACY

MR. GRAHAM HUTTON'S ADDRESS TO
WINCHESTER DIVISION

This year's "Winchester Address" was given on May 15 by Mr. GRAHAM HUTTON, the economist, before a large audience of members of the Winchester Division and their ladies, and guests. Dr. J. T. ROWE, chairman of the Division, presided.

Changes in Human Societies

Mr. Hutton said that the title of his talk, "Professionalism and Bureaucracy," although topical, in fact summarized a problem of human organization which had regularly reared its head throughout the history of civilizations. During this twentieth century—a paradoxical century of the two worst wars, and the most rapid rise in humanity's material standards of well-being in peacetime—this problem of professionalism and bureaucracy had reared its head higher and higher. "Let us begin," he said, "by looking carefully at what has been happening in all kinds of human societies, organized in differing states and civilizations, during this century, and to the individuals in those societies. Let us try to trace the nature of changes, the direction of change, and the rate of change."

First Change

The threefold nature of the change in all human societies would not provoke much dispute among sociologists, economists, anthropologists, social psychologists, and other such. First, the techniques of human control over the powers of Nature, and therefore over men, had immeasurably multiplied and accelerated. These powers were humanity's means to its differing ends: means to produce more; means to influence, communicate, and convey more, communications of goods and of ideas and of rules and regulations; means to develop and use more human faculties and potentials, and thereby to put more strains and stresses on both individual and collective humanity; means to exert power over other men, which also put new strains and stresses on human tolerances; and, finally, means to lighten mankind's burdens, ease and lengthen human life, and further develop mankind's powers over environment. Most, if not all, of these rapidly extending human powers were as potent for evil as for good. "But," Mr. Hutton said, "we must not get long-run things into short-term perspectives. It is good that human powers over inhuman powers are being so rapidly increased. It is a bad thing that increased human power is used—or, I should say, abused—to stress human beings beyond their normal tolerances, or to frustrate their natural modes of expression and development, or to dehumanize them by compelling them to behave as machines or automata at the bidding of other human beings."

Second Change

The second great change in society was that, whereas the course of last century, all over the world, was towards the liberation of individuals from collective restraints that had endured for many centuries, the course of the twentieth century everywhere had been towards more and more collective powers and restraints over individuals and their self-expression. Everywhere, this century, and never more so than in the past decade or two, the State had steadily increased its power over almost every walk of individual life. This had occurred in the arts and sciences, in education and medicine, in the everyday lives of households and families, in business and travel, in the means and uses of leisure and pleasure, in the totality of laws and administrative regulations within which individual life must be lived and self-expression sought.

It was true, keeping things in perspective, that this second or political change, the greatly increased powers of the State, had brought both material and non-material benefit to millions of human beings in many nations. Many old evils had been removed: slums, real poverty below subsistence

level, exploitation of the masses who work for a living. But in the same perspective it must be observed that, whether in democracies or dictatorships, power over individual and family lives had been immeasurably magnified and concentrated in a more and more centralized form of State apparatus. From there it is more and more exerted, through more and more agencies and agents of central political power—functionaries (as the French call them), bureaucrats (as rude Americans call them), and *apparatchiki*, or "apparatus-boys," as the Russian Communists call them.

So, while leisure increased and the means for self-expression and creative realization of human potentials increased, on the other hand "the political revolution of our time cribs, cabins, cramps, and confines the freedoms of individual life." To-day economic, professional, trade union, legal, travel, and other freedoms were narrower, not at the administrative centres of these sectors of life, but on the periphery where the individual members live and operate. Even apart from the centralizing political power of the State, these other sectors of individual life—in business, trade unions, professions, vocations, sport, commercialized pleasures and leisure, and media of publication and radio communication—were all of them more centralized, more collectively organized in larger administrative units, in which what was once an outstanding British advantage (namely, individual originality and even eccentricity) was scarcely any longer permissible, tolerable, or indeed observable.

"Make no mistake," Mr. Hutton said; "all this blanketing, by administrative centralization of a standardizing power, is a political manifestation, in the proper sense of the word 'political.' It stems, as it always has in history, from the exercise of collective, social power over the individual citizen's life." The manifestation of centralized administrative power was quite as clear—though, luckily, not as repressive, yet—on our own side of the Iron Curtain as on the other. It was a phenomenon of all human societies now. As the first or technical change had shrunk the whole world and crammed the human race cheek by jowl, so had the second or political change unfolded everywhere—"the concentration of vastly enhanced social or political power in the hands of the few over the lives of the many, and the once-vaunted 'rule of Law' has given way everywhere to the contemporary rule of laws and regulations affecting more and more of individual life."

Third Change

The third great change in all human societies was also a result of widening, increasing, and accelerating human techniques and controls over the powers of Nature. It was the resulting, and at the same time the causing, of ever-deepening, ever-narrowing specialization in all human knowledge. This accelerating process showed up in the arts and sciences, in leisure and pleasures, as well as in the everyday economic business of life, public administration, professions, and vocations, young persons' education, industrial and professional training, and all other kinds of instruction, experimentation, or research. It was found on both sides of the Iron Curtain, in America as in Russia, in democracies as in dictatorships, in the world's most developed and in its least developed societies. Allied to the other two great social changes in our time, this third change still further weakened the powers, potentials, and freedoms of the individual citizen. It still further strengthened the tendency of all political and administrative power to be centralized, because the individual learner, researcher, operative, technician, professional man, trade unionist, or manager tended in parallel to become submerged by an ever-expanding, ever-more-powerful collectivity which ruled and regulated more and more of his functional or working or professional life. He tended to become so submerged because his craft, or expertness, or profession, expanded its technical scope at an accelerating rate, and he saw his own individual mastery of only a little part of a widening field becoming smaller and smaller; in short, he himself became ever more dependent upon the end-results of other individuals' current work, without his being able

either to understand or to control their operations. This process could be traced with equal clarity among experts of all kinds—medical men, physical scientists, economists, accountants, lawyers, engineers, business managers—and among the skilled and less skilled operatives on a factory floor, in transport, or even in public and private administration and government itself.

Tensions, Strains, and Stresses

Complaints about this third change in mankind's social process arise, Mr. Hutton pointed out, on both sides of the Iron Curtain, in America, in Russia, in India, in Africa, in school and university and other training curricula, in religions, castes, social classes, and income brackets of all levels. "The burden of complaint is one and the same—namely, that the individual's distinguishing individualities are tending more and more to be ironed out, that differentials and varieties are being flattened into standard and more rigid moulds or types, and that frustration of human potentials follows upon such a narrowing specialization." Following such a sense in individuals and technical or vocational groups of being ever more compulsorily and collectively circumscribed bad social outbreaks occur: the inevitable tensions, strains, and stresses in the society, the malaises and maladjustments, cause something like social earthquakes. One stratum slips as against another. One grouping, one profession, one social class reacts, in time explosively, against others. Next the system of law and custom, rights and duties, sentiments and beliefs and values, begins to lose its binding force, and the whole social fabric is threatened. Law, political power, the State and its agencies and agents, the rulers (whether they are despots or elected democrats)—all these equally quickly come into contempt. Men begin to rebel, to become "anti-minded," against their own society. They begin openly to set law, custom, morality, religion, all the ingredients of the necessary social mortar, in defiance. "That is why such changes—changes of phase—are rightly called social revolutions, whether human blood flows or not. And that is the stage, or phase, wherein all human societies now wander. The same new stresses and strains impinge on the older, familiar tolerances, in all kinds of human society to-day, for the first time in recorded human history. The phase, the era of social revolution, is world wide for the first time. It is far, far wider than that temporary 'class warfare' imagined by Karl Marx over a century ago—for that was virtually confined by him to industrial countries already possessing an urban, industrial proletariat. Our contemporary time of troubles involves all mankind."

Communist Russia

Mr. Hutton thought the most significant event of the post-war era would prove to be the working-out of these same revolutionary social changes inside Communist Russia after forty years of Communist Party dictatorship. We others of the West could learn a lot from what had gradually, remorselessly, inevitably unfolded inside the Russian social laboratory, under totalitarian rule, in the last decade or two. Not since the time of the ancient pyramids, perhaps, had there been so totalitarian, so compulsive a society as that of Russia in the past forty years. It began dedicated to equality. It soon took away all powers, rights, and privileges of trade unions, professions, vocations, and other self-governing voluntary and functional groupings; and it fell back on naked force, even for forced slave labour. "But then see what happened, just as Plato said it did over 2,000 years ago. Because of the technical needs of society—of all society, everywhere, in our time as in Plato's—a new set of groupings, orders, castes, classes, and functional *élites* speedily came about under a dictator, nearly all of them necessarily organized on the lines of the former professional and other functional groups. But this time the bureaucrats—the State's agents, or the 'apparatus-boys'—gradually lost their power and prestige, their privileges and esteem. As modern techniques advanced in all walks of life—in economics, science, medicine, the arts—it was the profes-

sions, not merely the State's agents or functionaries, who gathered and accumulated esteem, powers, and privileges. To-day a qualified engineer, economist, medical scientist, doctor, or ballerina, for that matter, can exert more power than a mere Russian functionary, whose unpopularity stems in direct line from old Tsarist Russia."

Lessons to Learn

This paradox compared very badly with our own society in Britain, whatever you care to call it—half Socialist, half egalitarian, half State-run, half baked. Mr. Hutton asked his hearers to consider the long-term significance of one feature of the convulsions in Russia and other Communist lands during the past three years. It was that the profound uprush of protest against flattening and standardization by the omnipotent State, against unqualified egalitarianism, and against the tyrannies of an all-pervasive bureaucracy in Russia after nearly forty years, and in other Communist lands after only a decade or so, had occurred in the ranks of the experts, the artists, the technicians, the professional men, the people with long-acquired and long-trained vocations, the people of whom a really up-to-date, progressive modern society needed more and more. The State and its agents had had to perform in public the most extraordinary intellectual and verbal acrobatics, in a pathetic effort to preserve merely the semblance of consistency in their outworn and exploded myths, slogans, and dogmas. "And there is one heartening, encouraging feature of all this ferment in Communism," the speaker continued, "for us who have not—or not yet—become 100% State-run and State-ordered in our individual lives—namely, that the old-line Communists, even after forty years of despotism and bureaucracy, have utterly failed to standardize the reactions and the actions, the beliefs and the desires, of the young generation of Communists." It was among these—among the experts and artists, the technicians and the professional persons above all—that the ferment of dissatisfaction with the bureaucracy was at its height.

We on this side of the Curtain ought to learn that the lesson, which Messrs. Bulganin and Krushchev and others were even now publicly proclaiming inside Russia, was in effect that modern industrial, technical, progressive societies must not over-centralize; they must not subject the skilled, the expert, the scientists, the trained persons, the professions, the *élites* without whom no society could progress or could even be run decently, to the dogmas, myths, slogans, and fantasies of ignorant—and often of psychopathological—bureaucrats, politicians, State agents, power-boys, or (as the Russians so neatly put it to-day) "apparatus-boys."

Penalizing Ability

It must be asked why it had developed this way in other societies, and to an alarming extent among ourselves of the West. Why, for example, did both the major political parties in Britain tacitly and substantially agree to penalize outstanding abilities in the professions, in management of all kinds, in science and the arts? It was an odd reflection that in a Communist country the children of outstandingly responsible, able, and therefore highly privileged and highly paid experts—in any walk of life—were encouraged by the State to secure a better education, and at the State's expense, in special (what we would call private) schools; while in Britain, even if the child of such an outstanding contributor to the nation's welfare won a scholarship, and even if there were 10 children in the one surtax-paying household, he or she was not allowed to have it, though it was gained on merit in open examination. "I know," and Mr. Hutton expected his audience knew, "cases in which the young person in such a family has point-blank refused to allow the parents to undergo the penalty prescribed for them by our State, and has either emigrated or by-passed a university and gone into another walk of life, but socially and politically embittered, and dedicated to a kind of adult vengeance at some time or other upon a society that treats a decent and responsible family that way. That has become—till

the Budget of a month ago, the effects of which private persons will not feel for another 18 months, by which time the cost of living will have wiped out its concessions to them—increasingly common in this country."

The speaker wished some scientists and medical men would report on the myth, dogma, and fantasy that individual mammals are either born equal, or ought to be treated as equals, and that societies of them are in some unexplained way better if they are so treated. All the evidence of human history that he had found showed the precise opposite, and that any societies who tried to secure such equality of treatment of their members had to be despotisms, and did not long endure. Yet the ravages of these myths and dogmas persisted among us, while they had long since been abandoned by the Communist States.

So at both the superficially seeming opposite poles of world politics to-day, in North America and in Soviet Russia, really substantial differential rewards for differential responsibilities and differential expertnesses were the order of the day; while British society lagged behind those in material progress and was mixed up between them in social and political organization. It was a social phenomenon yet to be adequately explained, but some justification better than the mere mouthing of myths and slogans was long overdue.

Burden on Minority

Mr. Hutton said it might shock his audience if he stated one simple economic fact in a rather unpleasant, and certainly unusual, way; it needed saying in our confused society to-day. "It is this: all the material sacrifices due to the last war's effects upon us—all the material losses of warfare, the burdens of becoming a debtor nation for the first time in centuries, the loss of our overseas investments, the cost of running the swollen national debt and heavy defences and rebuilding our economic potential and developing our associates in the Commonwealth and sterling area—all material sacrifices thus entailed upon the British people have fallen, net and on balance, only upon roughly one-fifth of our people; and that fifth includes not only the one-twentieth who can be termed rich in personal property, but another three-twentieths who are the old and retired at all levels of income (some very poor and on National Assistance), and all the skilled, trained, and responsible paid leaders of the nation in all its branches of activity. The others—the four-fifths of our people represented by the wage-earners and lower-salaried groups and their families—have made no sacrifices at all in material terms; they are living better than ever they did, for easier work."

He did not say this was even wrong. In one sense, it was the goal of all human endeavour to create so much productive capital that human lives, the lives of individuals, should be made longer, healthier, fuller, better, and wiser. "But just as an examination and a justification of equality of treatment for everybody is long overdue in our political and social system, so is an examination of the distribution of rewards for responsibilities." After all, the locomotive engineer, among trade unionists, bemoaned the fact that inflation and social or political policies had eroded his long-standing "differential" over the earnings of the less-skilled railwaymen. He, and others like him in the ever-more-complex hierarchy of industrial functions, could organize to keep abreast of this inflation and these new social or political policies. "But somewhere around the current figure of £1,000 to £1,500 a year gross for a breadwinner—no matter what his training or responsibilities, or how big his family, or what his hours of work or conditions of service—British society seems to shut up shop in consideration of him."

How, asked Mr. Hutton, could our society ever match the rates of technical progress, the massive educational, medical, and other social experimentation going on in North America and Russia, their concentration on creating more productive capital equipment and research apparatus of all kinds and for all purposes, individual and social? We knew how badly starved the whole field of British medicine was for equipment and buildings and research. But so

were many other departments of our national life on which our progress depended. If we added these together we should better appreciate the overriding need not to penalize, but positively to stimulate and increase differential rewards for any and every citizen who could command such enhanced rewards in virtue of his abilities, responsibilities, and social contributions. "And we might do well to remember that, while an overworked doctor or engineer or manager in Britain ends up his day helping his wife at the kitchen sink, his opposite number in North America (probably without any servant either) has a labour-saving house fully equipped with cheap domestic capital equipment, while his opposite number in a Communist country may well have servants allotted to him by the State."

Radical Rethinking

In terms of the older professions, and all the younger functional groupings now organized or being organized on the basis of special training and responsibilities, this accelerating technical and social revolution meant that much radical rethinking, much radical reform, much reorganization, and much imaginative planning for the future had got to be done in Britain. There was no doubt in the speaker's mind that this process had got to extend to the State itself, the political parties, the press, and all other influencers and media of public opinion. What we had undergone in the last 11 post-war years, in a world of technical revolution, had merely been a revolution in the apparatus of the State and in its administration. We had had no post-war revolution of thought and ideals and imagination. "The future of this country, to most of our people and their politicians in all parties, in my judgment, is still limned far too much—pathetically and perilously too much—in terms of old ideals, slogans, and myths, of 'far-off things and battles long ago,' of cosy and familiar British notions for an enfeebled nation growing rapidly older, and with most of its people's eyes glued on leisure and retirement: a pension-minded, past-orientated people; glad to escape from anything approaching an effort to the womb-like warmth of a darkened room and the 'telly'—a womb with a view," as one of my young medical friends put it." But we now depended 50% more than we did before the war upon competitive international trade for our people's standards of life. That demanded savings and efficiency and endeavour and skilled leadership before they could be applied and developed for our own use. Certainly the State and its political parties had to reshape their thinking and look more to the future than to the past.

Mr. Hutton here put in a word of praise for "our leading agents of the State, our responsible civil servants." It was not their fault that they were so often opposed to, or put in conflict with, the professions and the other functional or vocational groups in the country. They, too, were overworked, underpaid, and loyal to their political chiefs; and they often, nowadays, had to do their best to carry out policies with which they did not and could not agree, but on which they could not publicly comment. "No; the blame must be placed fairly and squarely where it belongs—namely, in our democracy, on the people, and their influencers, and their politicians, who are to a very great—perhaps an overwhelming—extent the people's influencers. Without a proper elite, any society, any people, will fail."

Role of Professions

But meanwhile we could not dance attendance upon the State and political parties, waiting for a wind to change, Mr. Hutton said. We had still in our hands the power to change the contents of professional training, to publicize, to protest, to go direct to the public through its media of communication, to put pressures on Governments and politicians, to get together with our opposite numbers in other countries and profit from current trends there. "But if our British professional bodies are to play the part they are equipped, and deserve, to play in the reshaping of our people's thought and the reform of our national institutions, they must first be sure that on balance what they propose to

do will not only benefit themselves but will primarily benefit the community or communities they serve in their professional capacities."

The justification for a profession which guarded its own standards of training could only be that in so doing it constantly proved its contributive power to the community was kept at top pitch. "Any profession will lapse in public esteem if either it fails to do that or fails to make public why the State or some other factor beyond its power prevents it from doing it. The great power of our professions still resides in their vocational mission, their safeguarding of training and education, and their role—quite apart from their particular skills—in turning out the well-rounded, socially adjusted, contributory, and responsible leaders of the nation in all its walks of life. It is perhaps this last role which is so often overlooked in our land to-day. Without wise leaders, without a widely trained and humanistic elite, any society on earth, both to-day and in the even more technical complexity of the future, will perish. It is as much the function of our professions—and pre-eminently of yours—to turn out members of such a national elite as it is to turn out technically qualified young men who are certified as able to perform certain skills adequately."

Time to Build Anew

"Our time of troubles in this world," Mr. Hutton concluded, "is vexatious, but exciting and capable of eliciting much enthusiasm. It is a time of pulling down the old and building anew. Many of us—the older ones naturally—regret much in all this. Mistakes are bound to be made. New tensions, between social groupings and political groupings and professions and State agents and all down the echelons of a country's economic organization, arise all the time. But we must, as I said, look not to the extremes but to that centre, that middle of the road, at which British common sense and sobriety and stability have always come to rest. They may have come to rest a bit too long sometimes. It is a time now for them to be up and doing more. But if we look to the hectic experimentation, often wildly successful, often over-costly, in North America at one extreme and in Russia at the other, we need not despair or repine. Technically it is well within our scope to succeed, in any sector of social life, as well as they, if not better. There is, believe me, no economic reason why we should not. It depends on us, and on no one else. We are, we need be, the creatures or dependants of none. If we bring it off in our nation it will primarily be due to leadership; and that must still come largely from our professions. It is therefore up to them to set their own standards, and then to fight for them until they prevail. There is nothing wrong in that for the nation. On the contrary, I think this nation has everything to gain from it. And if our professions are not prepared to do that, then they cannot complain if they are overwhelmed by a bureaucracy; and the people of the nation must take the consequences—perhaps, like the Russians, for forty years in a wilderness. But, even then, professional leadership has to come back."

FROZEN-TUMOUR BANK

In the last report of the Imperial Cancer Research Fund,¹ Dr. JAMES CRAIGIE, F.R.S., reviewed briefly his work on the preservation of transplantable tumours in the frozen state. He described among other things the frozen-tumour bank he has built up at the Fund's central laboratories. This frozen-tumour bank is believed to be unique. Its aim is to provide a representative collection of experimental tumours for research workers. The tumours are not frozen simply as part of some relatively temporary study, but for long-term storage. At present about 50 types of transplantable tumour are available, and they are listed below. The variety of strain-specific mouse tumours is limited at the moment by

¹ See *British Medical Journal*, April 27, p. 1004.

the number of colonies of different strains of mice maintained, but it is hoped to add to them as time goes on. Tumours still being studied experimentally in the Fund's laboratories are not included in the bank.

Research workers from at home or abroad wishing to obtain tumour samples from the bank should write to the director, Imperial Cancer Research Fund central laboratories, Burtonhole Lane, The Ridgeway, Mill Hill, London, N.W.7.

List of Available Tumours

In this list ascites tumours are marked with an asterisk.

Mouse Tumours.—(a) *Not strain-specific.* Ehrlich carcinoma,* S 37 (1906-08),* T 2146* (originally a tar-induced epithelioma), 63* (Bashford, 1907; originally a mammary carcinoma). (b) *Strain-specific.* C_H tumours: mammary carcinoma, SM/B 26; epithelioma, Bp/Ep/S₁*, sarcoma, L/β*, Bp 1, Bp 3, Bp 8,* Bp 9, Bp 10, Bp 17, A/Bp, HA/Bp, HK/Bp, Q/Bp; hepatoma, H 10 R; fibrosarcoma, H 10 X; ascites tumour, DR/7/54.* **Strong A tumours:** Lung carcinoma, L/α; sarcoma L/ξ; mammary carcinoma, L/ε. C_s tumours: mammary carcinoma, L/γ; squamous epithelioma, T/Ep; sarcoma, MC_s; leukaemia, EL 4.* **R III tumours:** mammary carcinoma, F 11/52 and L/α; mammary adenocarcinoma, T VI/21; squamous-cell carcinoma, C 1/3; sarcoma, BRT*; fibrosarcoma, L/φ. C_s × R III tumour: F/BR 16.*

Rat Tumours.—Jensen rat sarcoma (1907), Walker rat tumour (1928), Yoshida* (ascites tumour), Murphy* (lymphosarcoma).

Rabbit Tumour.—Brown-Pearce.

Guinea-pig Tumour.—Daels (radium-induced sarcoma).

Fowl Tumours.—RPL 12, RPL 16, RPL 19, Rous, Fujinami, MH₁, MH₂, Erythroblastosis.

Preparations and Appliances

FOOT-REST FOR LABOUR BED

Dr. DAVID BOWER, formerly of the Derby City Hospital, writes: It is observed that patients lying upon the labour bed find most ease with the hips and knees flexed. However,

this position is difficult to maintain owing to lack of friction between the patient's heels and the surface of the bed, the legs constantly tending to extend. The device here illustrated is extremely simple, and, by providing a transverse bar for the feet, allows the patient to rest in a comfortable position between contractions. The footpiece is a 1½-in. (3.8-cm.) tube of mild steel, and is supported at either end by two 1-in. (2.5-cm.) tubes at right angles to each other. At the lower ends of the supporting tubes are welded curved sections of mild steel, which fit over the longitudinal tubes of the bed frame. One of the curved sections on each side of the device has a hole drilled through, and this is tapped to ½-in. (0.8-cm.) Whitworth thread. Along this thread is passed a brass thumbscrew which when tightened locks the footrest to the bed frame. The device was constructed by a local light engineering shop at a cost of 35s.

A MYRINGOPLAST

Dr. R. FRANCE ROHAN, research fellow, ear, nose, and throat department, Guy's Hospital Medical School, writes: Of recent years a great impetus has been given to research into the management of chronic suppurative otitis media by the excellent results obtained in operative restoration of the perforated drumhead in carefully selected cases. In the clinical assessment of patients who may benefit by plastic otological surgery, it is essential to know the degree of efficiency of the ossicular chain. This can often be done by means of an acoustic probe, which is laborious in application, or by patching of the perforated tympanic membrane with various materials, a simpler procedure for routine use in the out-patient department. Even so, it is a difficult manoeuvre to carry out. I have made a special study of the latter method in the accurate diagnosis and management of chronic otitis media, and have evolved an instrument which could perhaps be called a myringoplast.

It is based on a well-tried principle, and embodies (see diagram): (1) a fixed outer tube, A (11 cm. long), fitted with a notched end-plate, B, which is set at an angle, C, of 110 degrees to the axis of the tube; and (2) a mobile inner wire, D. The latter carries two prongs, E, which can be protruded by a trigger, F, to a distance of 2 mm. beyond the end-plate, in order to pick up a patch prior to application; the prongs subsequently retract by means of a spring fitted inside the hollow handle (see Diagram), and the patch can thus be shed at will by gently releasing the trigger.

The tube and wire are bent to an angle of 130 degrees, G, 9 cm. from the end-plate, and the whole tube is 11 cm. long. This allows one to see the tip of the instrument when a patch is being applied. The inner wire is moved by means of the trigger, which is set above the handle, allowing one to grasp the instrument between the thumb and middle finger, while the index is used to operate the trigger. This ensures accurate control, especially in the final stage of patching, when the trigger is released, the prongs are retracted, and the instrument is moved gently on, thereby applying the patch to the eardrum by means of the end-plate.

The advantages of this instrument are that it does not traumatize the tympanic membrane, and a patch can usually be applied with certainty, under direct vision, and often without anaesthesia, although it is advisable to cocaineize the deep meatus and drumhead beforehand, to avoid hurting the patient. This is particularly true if a tenacious adhesive is used to apply a patch.

It is a pleasure to thank Mr. Philip Reading, who first put me on to the problem of patching the perforated drumhead, and under whose guidance this work was done. Mr. R. J. Cann made some valuable suggestions, and he as well as Mr. L. F. W. Salmon allowed me to treat their patients. I am most grateful to Mr. A. E. Marshall, instrument maker in the works department at Guy's Hospital, for constructing the myringoplast to my design. The drawing is the work of the department of medical illustration of Guy's Hospital Medical School.

Reports of Societies

CHILDREN WITH RECURRENT ABDOMINAL PAIN

[FROM A SPECIAL CORRESPONDENT]

The susceptibility of the nervous child to recurrent attacks of vomiting and abdominal pain was well known to Hector Cameron a generation ago, though Hutchison considered the pain organic and due to unusually active contractions of the intestine. In recent years the importance of psychological causes has been stressed. It is of course possible to reconcile these apparently contradictory views, for we now know that emotion can affect gastrointestinal function, and the increased peristalsis blamed by Hutchison may have been the result of some underlying nervous disorder.

An extensive survey of recurrent abdominal pain in children has been made by Dr. J. Apley, who recently opened a discussion on the subject at the Bristol Medico-Chirurgical Society, and the matter was further discussed at a sectional meeting of the Royal Medico-Psychological Association held in Bristol on May 2.

The Emotional Factor

Dr. GAYNOR LACEY, a child psychiatrist, described a series of 25 children with recurrent abdominal pain and compared them with 25 in-patient controls. Her general finding was that recurrent abdominal pain was more common in the emotionally unstable child or those whose home conditions were unsatisfactory. A peak incidence of abdominal pain at 8 years might be due to the strain of work at school, which often becomes more severe at this age.

Dr. NORA NAISH said she had surveyed 1,000 school-children by attending the normal school medical examinations. Taking as her criterion three attacks of pain sufficiently severe to stop the child from playing, she had found that 10.8% of these children suffered from attacks of recurrent abdominal pain. Again, high incidence of emotional disturbance was evident among the children with pain.

It is not easy to understand why a disturbed mental state should be disclosed by abdominal pain rather than by some other subjective manifestation. One factor is certainly the well-known relationship between the emotions and gastrointestinal function; but Dr. Naish also found a high incidence of organic abdominal disease such as peptic ulcer and appendicitis in the parents of the affected children, and this no doubt is one factor accounting for the location of the pain.

Urinary Tract often to Blame

In the concluding paper Dr. K. SIMPSON, as a paediatrician, emphasized that recurrent abdominal pain could quite well have an organic basis. Nor did the presence of an emotional disturbance in any way exclude serious organic disease. The child with recurrent abdominal pain was no less likely to get appendicitis than his fellow without recurrent pain, but he was much less likely to be diagnosed correctly in the first six hours of the attack. Pain of organic origin, continued Dr. Simpson, was usually more severe in successive attacks and generally situated away from the umbilicus; the umbilicus was the characteristic site of psychosomatic abdominal pain in children. In half the patients with recurrent abdominal pain due to organic disease the lesion was in the urinary tract; it was therefore important always to examine the urine as well as carry out a full physical examination. This aspect of the problem was also emphasized by Professor A. V. NEALE, professor of child health, who in the later discussion called attention to the catastrophic error which could be made if pain was wrongly assumed to be psychogenic when the child had, in fact, some such lesion as an internal hernia or recurrent intussusception.

Recurrent abdominal pain remains a common and difficult problem. It demands care in diagnosis and sympathetic management of both parents and child.

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

Isolation of Measles Virus

SIR,—Workers interested in the isolation of measles virus from patients may like to hear, before the present epidemic closes, of some investigations now in progress. A main object of the work has been to use for culture tissues which are readily available everywhere and thus to obviate the use of human or monkey kidney cultures, which, it may be recalled, were employed by Enders and Peebles¹ in their original investigations on the isolation and cytopathogenicity of measles virus.

In the present investigation cultures of human chorion and human amnion² were inoculated with nose and throat swabs taken from measles patients on the first or second day of the rash. The swabs were inoculated, within 20 minutes of taking them, direct into the nutrient fluid (medium 199+ of 20% ox serum) of the cultures. Fluid changes were made shortly before inoculation, on the day following, and thereafter at 3-4-day intervals. Culture tubes were incubated in the stationary position throughout. Cytopathic changes followed the inoculation in all of five chorion cultures and eight of nine amnion cultures.

In both types of culture the lesions were usually first detectable on the 3rd or 4th day after inoculation. Development of cytopathic changes differed in the two tissues. In the chorion cultures they were diffusely distributed; little necrosis occurred and, on staining, large numbers of nuclei containing eosinophilic inclusions in various stages of development were seen. These were present in many individual cells as well as in the multinucleate syncytia which developed, more particularly, in the marginal areas. In the amnion cultures, on the other hand, the affected areas were discrete, large, and round, and could in fact be seen as "plaques" with the naked eye or hand-lens. They varied in number in individual cultures from one to about twenty. Vacuolation was conspicuous. With continued incubation the lesions increased in size but apparently not in number: the margins of the syncytia became more sharply defined and necrosis developed early. On staining, large eosinophilic inclusions were seen in the nuclei of the multinucleate cells of the affected areas.

The relative merits of the two tissues for serial propagation of virus following isolation in them has not yet been assessed. The widespread invasion of the cultured chorion suggested that this might prove the better tissue, and the few experiments which have as yet been undertaken supported this view. The chorion had an advantage in that it was harder in withstanding any deleterious influences during placental delivery and subsequent collection; it proved a uniformly reliable tissue with which to prepare cultures. On the other hand, an advantage in isolation in amnion lay in the ease with which the discrete plaque-like lesions could be detected in the living unstained cultures; in the chorion the full extent of the cytopathic changes was only revealed by staining. The results suggest that both these tissues, in culture, may find a place in the clinical and epidemiological investigation of measles—for example, in the diagnosis of doubtful cases, in studies of infectivity in the incubation period, and in the prodromal stages of the illness, duration of viraemia, possible faecal excretion of virus. In addition, their use provides a generally available method for the isolation of strains for virus studies.—I am, etc.,

JOYCE WRIGHT.

Notification of Infectious Diseases

SIR,—In the first quarter of 1957 notification of 305,531 cases of infectious diseases in England and Wales alone cost some £38,000. Of this total approximately £36,000 was expended in the notification of four diseases—namely, scarlet fever, whooping-cough, acute pneumonia, and measles, of which the fees for measles alone amount to nearly £30,000.

Can there any longer be justification in notifying these four diseases? In any event those in general practice well know that, owing to pressure of work and oversight, many cases are notified either late or not at all, rendering these statistics open to doubt. These observations do not apply to such diseases as acute poliomyelitis, diphtheria, meningococcal infection, and the enteric dysentery group, the notification of which is of value in public health and research. It is with these facts in mind that we present the following table, for which we are indebted to Dr. W. J. Martin, of the London School of Hygiene and Tropical Medicine.

Year	Total Notifications	Useful Notifications	Total Cost Approx.	Useful Cost Approx.
1952	654,896	21,527	£81,800	£2,700
1953	826,591	25,305	£103,300	£3,160
1954	358,621	36,126	£44,700	£4,500
1955	879,153	45,668	£109,900	£5,700
1956	365,642	54,360	£45,700	£6,700

These figures are for notification fees alone and make no allowance for the considerable expenditure of money and time in the collection and compilation of the statistics. We ourselves can find no justification whatever for the continued notification of the four diseases enumerated, which in the past five years alone have accounted for close on £390,000. By subtracting these four diseases the cost in that five-year period we estimate at £23,000.

The loss in fees would make little difference to the individual practitioner, whereas the global sum saved would be considerable. We tentatively suggest that this money could be better used to further research into the more serious of the infectious diseases.—We are, etc.,

R. M. EMRYS-ROBERTS.

Addison's Disease in a Child

SIR,—The case report by Dr. R. G. Welch of a fatal case of Addison's disease in a 9-year-old girl (*Journal*, April 27, p. 980) is of great interest—and not only because of the rarity of the condition. It illustrates the great difficulty that may be met in treating Addisonian crises, as well as the catastrophic rapidity with which the crisis may occur. On the very day of publication of Dr. Welch's paper, a 9-year-old boy under our care died. The similarity in the terminal pictures seems to us to warrant the following summary being put on record.

A boy of 9 had developed typical clinical features of Addison's disease over two years. The electrolyte findings on admission in March, 1957, were typical except for normal values for blood urea and glucose. His condition did not permit complete investigation then, and he was treated with cortisone. To our surprise he needed 1,200 mg. over six days before he showed a dramatic improvement to good appetite and spirits. After a period of maintenance, cortisone was gradually withdrawn and corticotrophin was given to prove the total absence of adrenal response. His deterioration was slow, but sufficiently great for the test to be abandoned after three days of corticotrophin, and a total of eleven days off cortisone. His blood pressure was 90/50 and his electrolyte values (mEq/litre) had fallen to sodium 117, potassium 5.6, chloride 72. These figures were similar to those on his original admission, but his general state was less grave. Cortisone (100 mg.) was given at noon and repeated at 7 p.m.,

The following week another child about to undergo cardiac catheterization collapsed and became pulseless

shortly after the anaesthetic had started but before the cardiac catheterization had been attempted. Fortunately he responded to stimulation by slapping the chest over the heart. In this case trichlorethylene was not used, the anaesthetic being nitrous oxide, oxygen, and pethidine following induction with thiopentone, and was administered by another anaesthetist.

When glancing through the volume in which Dr. Fleming wrote up his case, I found, shortly after his letter, three letters²⁻⁴ in which the writers state that they had found trichlorethylene to be effective in correcting pre-existing cardiac irregularities. While not denying their value, I feel that these facts and the facts brought out by this and other letters and the facts deduced from the case histories in the article written by Drs. Walter Norris and Peter Stuart (*Journal*, April 13, p. 860) illustrate once more the difficulties and dangers necessarily associated with *post hoc ergo propter hoc* statements. In conclusion, one must always keep in mind the saying, "There are no dangerous anaesthetics; only dangerous anaesthetists."—I am, etc.,

Glasgow.

SIR,—With reference to the article "Cardiac Arrest during Trichlorethylene Anaesthesia" by Dr. Walter Norris and Dr. Peter Stuart (*Journal*, April 13, p. 860), we would agree with Dr. C. Langton Hewer, who in his letter (*Journal*, May 11, p. 1123) states that a sense of proportion should be kept in this matter.

In reviewing the 24,244 anaesthetics given in the Bangour Hospital in the five years ended March 31, 1957, we find that 10,984 of these cases received trichlorethylene. Of these, the only one to suffer cardiac arrest was a man who was found at necropsy to have a cystic phaeochromocytoma of the right adrenal. He was a man of 66 who had had a coronary thrombosis five weeks previously, and who had suffered from angina pectoris for the past seven years. He had been bed-ridden with gangrene of the toes for nine months, and was found to have a blood pressure of 200/105, generalized arteriosclerosis, and auricular fibrillation.

In a personal communication to one of us Dr. Norris states that he is unable to estimate the incidence of cardiac arrest due to trichlorethylene in the region reviewed. We therefore feel that outright condemnation of this agent is unwarranted in the light of our own figures and those of Dr. Langton Hewer.—We are, etc.,

Aortic Stenosis

SIR,—Sir Russell Brock *et al.*¹ have taken us to task for saying that "pressure readings at operation are inaccurate and misleading." What we in fact said² was that "such measurements are likely to be unreliable under the abnormal conditions of the operation." This conclusion was not, as Sir Russell Brock has suggested, made without measurements to support it. It was based on the findings at operation for mitral valvotomy in 37 patients,³ and on a further series of 43 patients at the same operation, in 12 of whom results of a previous cardiac catheterization were available.⁴

We are open to the criticism that our argument was drawn from findings at a different operation. However, Sir Russell Brock himself (*Journal*, May 4, p. 1019) comes to almost identical conclusions for aortic valvotomy, when he says: "It is obvious that the conditions at operation may be different from those existing at other times, and proper allowance can be made for this. Thus the heart's action may be poor, the systemic pressure low, and the gradient correspondingly reduced. Clearly this must be taken into account after the manipulations of aortic valvotomy, when the ventricular pressure might be lower from the insult the heart has received. It is not difficult to recognize this state

and either wait until the condition has improved or just note that the observations are not fully reliable under the conditions pertaining" (our italics). The only point of disagreement seems to be the ease or otherwise with which a "proper allowance" can be made for the numerous variables which control such pressures. Our criticism does not of course apply to pressure measurements made under more physiological conditions.—We are, etc.,

Thrombocytopenic Purpura Following Quinidine

SIR,—The report of a fatal case of thrombocytopenic purpura following the administration of quinidine by Drs. Stanford Bourne and D. J. O'Sullivan (*Journal*, May 4, p. 1046) prompts this communication in which the circumstances were closely similar.

A 53-year-old coal-heaver was admitted to hospital following collapse at his work. The collapse was due to ventricular tachycardia, proved by electrocardiogram, and, with the systolic blood pressure being only 65 mm. Hg, his condition gave rise to concern. It was considered a matter of urgency to restore normal rhythm, and with this in view one gramme of procaine amide was administered intravenously three hours after admission. The tachycardia remained, but the general condition did not deteriorate further and the signs indicative of failure did not become any more manifest. It was decided to keep him under observation until next day, when quinidine was given in five-grain (0.32 g.) doses at two-hourly intervals for 16 hours. Again there was no response, so that on the third day resolute was made again to procaine amide, and before half a gramme had been injected normal rhythm was established. The general condition immediately showed signs of improvement, and although the normal rhythm was interspersed by bursts of tachycardia he remained well. An electrocardiogram revealed that a posterior infarction had been responsible.

On the tenth day following admission it was decided to antagonize the tendency to arrhythmia by giving quinidine in five-grain (0.32 g.) doses thrice daily. This seemed to be only partially successful, but it was continued for 14 days, when the onset of a generalized purpuric rash and epistaxis occurred after a total dosage of 250 grains (16 g.) of quinidine, although it was later discovered that he had been taking five grains (0.32 g.) of quinidine thrice daily for between two and three weeks following an emergency admission to another hospital, which roughly doubles the figure of 250 grains (16 g.). The urine was, at this time, free from red blood cells. The platelet count was then 20,000/c.mm., and the bleeding time exceeded 15 minutes. Quinidine was discontinued and oral procaine amide in 250-mg. doses twice daily substituted. The purpura continued to increase and epistaxis was intermittent, whilst the platelets dropped to 16,000 during the next 48 hours, and one pint of blood was then transfused. The following day the platelets reached 50,000/c.mm. and haemorrhages ceased to appear. His condition changed very little after this until his sudden death four days after the transfusion. Permission for post-mortem examination was not granted. The cause of death appeared to be accelerated by purpura in an individual already in jeopardy following coronary thrombosis.

Is it possible that quinidine is responsible for this serious development more often than reported cases would suggest, and that the dangers of quinidine, though already well known, are even greater by its ability to produce thrombocytopenia?—I am, etc.,

Wallasey, Cheshire.

C. H. STEWART-HESS.

Periodic Fever

SIR,—I have a patient, a man of 62, who, after careful, competent, intensive, and scrupulous investigation at two hospitals, including a London teaching hospital, under one of our most eminent haematologists, has been labelled, albeit reluctantly, periodic fever of Reimann.

In October, 1952, after a year of ill-health with vague symptoms of urinary dysfunction, muzziness, inability to concentrate, and definite symptoms of depression, he saw both a psychiatrist and a surgeon. Involutional depression was diagnosed and a papilloma of the bladder with enlargement of the prostate found. A transurethral operation was performed, the papilloma found to be benign, and the prostatic fragments simple hyperplasia. During his convalescence he began rises of temperature of up to 103.6° F. (39.8° C.) every 7½ days, associated with headaches, faintness, epistaxes, and petechiae of his chest. His depression remained neglected and untreated. He has spent months in hospital; observed to exclude pyrexia artefacta; and no investigation possible omitted. Preceding and during attacks antibiotics, antihistaminics, anticonvulsants, phenicarbazine, ergotamine tartrate, sodium and potassium para-aminobenzoate could not alter the course of the fevers. After three and a half years, in March, 1956, he attempted suicide by coal-gas poisoning, and recovered spontaneously to enter hospital as a voluntary patient. A course of E.C.T. cleared his depression and he experienced only one rise of temperature while an in-patient for four months. Until January, 1957, he had three further rises of temperature, but these were in no way so incapacitating as previously. His depression recurred, he was again suicidal, had E.C.T., and returned home, March, 1957. His pyrexias have returned, but he does not feel so exhausted by them. His general condition has been remarkably good all the time. His mental state is of childish hypochondriasis, full of self-pity, groaning when he can be heard, and given to moods. He had a spell of grunting and belching in the mornings until he made himself sick. On one occasion his wife rebelled against this, shouted at him to stop, and he has not repeated these outbursts.

I was much surprised to read in Dr. Kris Somers's admirable account of his case (*Journal*, May 11, p. 1086) that "no one, however, has been able to entertain a psychogenic cause for this patient's illness." Her periodic fever was preceded by three weeks of diarrhoea and vomiting, undiagnosed, unresponsive to physical treatments. Was this not psychogenic? She had non-classical migraine at the age of 17, which, even by diehards, is acknowledged to be often psychogenic. Her symptoms started at the age of 45, one year after her menopause, and she had severe hot flushes which did not respond to oestrogens and other hormones. Is this not a stress symptom? She received "mild hypnotherapy in the hope that it might enable her to accept her symptoms rationally, but her state remained unchanged." This insinuates an irrational state of mind in the patient. Is mild hypnotherapy carried out by an apologetic hypnotherapist?

As a general practitioner I can see the total misery of my own patient and wish that his depression had found the correct treatment, and his symptoms of dysuria been neglected. Incidentally, his father died in a mental hospital of "prostate trouble and liver abscess."—I am, etc.,

Sidcup, Kent.

L. A. NICHOLS.

Cause of Cancer

SIR,—The problem of the cause and cure of cancer in its various forms still eludes us, although for many years scientists of the first water have concentrated their efforts in this direction. Much has been accomplished by these workers and the boundaries of knowledge have been widely extended, but the fact remains that the cause is still not understood and the cure of many types still uncertain. Many theories as to the cause have been promulgated and an enormous amount of experimental work done in support of these theories.

Whether cancer is due to chronic irritation, chronic inflammation, cell rests, hormonal imbalance, vitamin deficiency, embryological stimulus, chemical action, radioactivity, or virus invasion seems still far from proved. All have their adherents and some support for each may be

postulated. But none of these wholly explains the behaviour and symptoms of malignancy to the satisfaction of the clinician. There seem to be no criteria by which it can be stated that, if a certain set of circumstances in or around a cell is created, then a mutation will always take place in that cell from normality to malignancy. Therefore I think the cause will have to be sought in connexion with something that is universally available to each cell, and yet if this "something" is either deficient or in excess it alters the behaviour of the cell from normality to malignancy and mad growth.

To add yet another theory, may I suggest that perhaps malignant growth is due to, first, irritation of some kind which causes natural reaction and chronic inflammation, which after a varying period settles down to a scarring or fibrosis of the tissue? This fibrosis affects both the nerve supply and the circulation. This dystrophic cell now loses full control of its metabolism with the result that nutrient circulated to its nucleus is wrongly metabolized, so that oxygen is retained in excess in the nucleus, resulting in its increased size and energy (mitosis, etc.) and in the cell giving off a monoxide instead of the normal dioxide. This monoxide, finding its way into the blood stream, combines with the haemoglobin to form carboxyhaemoglobin, thereby gradually producing the symptoms of carbon monoxide poisoning which are so like the clinical picture of malignancy.

This conception of the cause of malignancy requires much further elucidation and experimentation before it can be proved or refuted. Cancer is not just the rapid growth of an innocent tumour, nor does it sap the vitality only by absorbing nourishment intended for its host. It does this, but also it behaves in a toxic manner towards the whole organism.—I am, etc.,

London, W.1.

L. LLEWELIN DAVEY.

Acute Inversion of Uterus

SIR,—The report by Drs. James T. B. Bain and B. K. Ziolkowska (*Journal*, May 11, p. 1102) of spontaneous acute inversion of the uterus brings up again the aetiology of the condition. I believe that the majority are spontaneous, but it should be emphasized that the true origin is the atonic state of the uterus in the third stage of labour or after delivery of the placenta. The flying squads of this country deal predominantly with complications of the third stage of labour, and by far the commonest is atonic post-partum haemorrhage, sometimes with the placenta in the uterus, but more often, in my experience, with the placenta delivered. This atony of the uterus in the third stage of labour can be abolished by the routine use of ergometrine given either with crowning of the head or delivery of the anterior shoulder. A slight rise in the manual removal rate of 1-2% is a small price to pay for the prevention of post-partum haemorrhage and subsequent anaemia in the puerperium with the associated immediate complications of infection, thromboses and pulmonary embolism, and remote morbidity, as the *Journal* (February 12, 1955, p. 405) so truly stated of tiredness in the puerperium due to anaemia. To say that this would require more flying squad calls is obviously false if we could eliminate the calls for the treatment of atonic post-partum haemorrhage. Manual removal of the placenta in the fit patient may well be as safe or safer than blood transfusion and certainly less expensive to the country. I have asked two groups of consultant obstetricians in the south-west and midlands of England if anyone has ever seen inversion of the uterus in association with the routine use of ergometrine as above in the management of the third stage of labour. I would be interested to see a report of such a case, as to date I have not heard of a single instance. In the case reported, ergometrine was not given until the placenta was delivered and followed by a post-partum haemorrhage of three pints (1.7 l.) of blood.—I am, etc.,

London, W.C.1.

W. G. MACGREGOR.

Acute Disseminated Encephalomyelitis

SIR,—I wish to refer to the excellent article by Drs. H. G. Miller, J. B. Stanton, and J. L. Gibbons on acute disseminated encephalomyelitis (*Journal*, March 23, p. 668). Unfortunately, however, it perpetuates an error which has crept into the literature concerning the reports of cases in which the condition of acute haemorrhagic leuco-encephalitis has complicated an infectious exanthem. In 1945 Shallard and Latham¹ reported a case of acute haemorrhagic leuco-encephalitis occurring in a female child whose two younger brothers had developed measles one week before the onset of her first symptom. In 1955, in discussing briefly the possible role of a virus in the aetiology of the condition,² I mentioned, as possible superficial evidence, this presence of measles in the siblings of the female child described by Shallard and Latham. Subsequently, Blackwood³ incorrectly reported that the female child described by Shallard and Latham was herself suffering from measles. This error has now been reiterated by Miller, Stanton, and Gibbons.

While I would agree that the evidence certainly appears to suggest that acute haemorrhagic leuco-encephalitis and acute disseminated encephalomyelitis of a post-exanthematous type are but variants of the one pathological entity,⁴⁻⁶ the fact nevertheless remains, to my knowledge, that in only one human case so far has acute haemorrhagic leuco-encephalitis been reported as complicating an acute infectious disease—that is, varicella.⁴—I am, etc.,

Unusual Twin Pregnancy

SIR,—I was most interested to read of the unusual twin pregnancy reported by Dr. J. H. Taylor (*Journal*, May 11, p. 1103), as I had a similar case which I reported¹ in 1953. This was an unusual twin pregnancy in which the woman had an extrauterine and intrauterine pregnancy occurring together. Despite salpingo-oophorectomy she went on to a full-term pregnancy and was delivered of a normal live child.—I am, etc.,

The H-bomb

SIR,—Your leading article upon strontium-90 (*Journal*, March 30, p. 752) was followed by some interesting letters which emphasized the uncertainties of the situation, but made clear that human life is under risk and that the effects upon bone through atomic radiation are matters which cause anxiety. What I have failed to observe is any serious move by the B.M.A. to take any considerable action in protesting against further nuclear bomb tests. Perhaps there are political questions which make us hesitate to enter the arena of dispute. Yet in our practices, if we discover non-medical circumstances in the environment of our patients which may have a possible effect upon the evolution of disease, we do not hesitate to speak "for the good of their souls" and bodies. As doctors we should all take note of Professor Waddington's letter in *The Times* (May 15). As he says: "Is not the threat of a deterrent in our hands already playing whatever part it can in the preservation of peace? If so, we could offer to postpone the tests." We could also continue to work for an understanding and solution of the fundamental anxieties which are undermining the peace of mind of nations.

Since writing the above the bomb has fallen. Let us try and stop the rest.—I am, etc.,

Exeter.

NORMAN CAPENER.

Obituary

W. H. TYTLER, M.B.

Dr. W. H. Tytler, formerly professor of tuberculosis in the Welsh National School of Medicine, died at Banchory, Kincardineshire, on May 6 at the age of 71.

William Howard Tytler was born on November 2, 1885, and graduated B.A., with first-class honours in natural science, at the University of Toronto in 1906, and M.B. in 1909, obtaining a first silver medal. His interest at that time was in pathology, and he worked in Montreal under Professor J. G. Adami and Dr. Oskar Klotz. Later he held various posts as a pathologist in North America until, in 1911, he became research fellow at the Rockefeller Institute for Medical Research, New York, where, under Dr. Peyton Rous in the department of cancer research, he was engaged on experimental work on filterable tumours. He next became an instructor in pathology at Cornell University Medical College, New York, under Professor James Ewing, adding to his already considerable experience in teaching and research. At the outbreak of the first world war he joined the Canadian Army Medical Corps and came to England with the First Canadian Division. Throughout the war and for some time after it he was attached to laboratories, at first of the British Expeditionary Force and later of Canadian units. During this time he worked on the bacteriology and pathology of enteric fever, on spirochaetosis icterohaemorrhagica, and on the bacteriology of war wounds.

Towards the end of the war he studied influenza in France during the epidemic. It was at this time that he became associated with Professor S. Lyle Cummins, then adviser in pathology to the B.E.F. Tytler was later to work in close association with Cummins in Cardiff. Soon after the war Cummins became David Davies professor of tuberculosis in the Welsh National School of Medicine, and in 1922 Tytler joined him as research bacteriologist to the Welsh National Memorial Association. Between 1918 and 1922 Tytler worked with the Medical Research Council at Oxford and at the National Institute at Hampstead, and also served with the Yellow Fever Commission in West Africa. Cummins retired in 1938, and Tytler, who was his obvious successor, was appointed to the chair and occupied it with distinction until 1949.

In addition to carrying out important research in tuberculosis Tytler instituted a central laboratory service which has flourished ever since. Specimens of suspected tuberculous material from all parts of Wales are still dealt with in this central laboratory. At first Tytler's opportunities for research were restricted, but after a few years he began the study that was to be his chief interest for the next twelve years. This concerned the chemical constituents of the tubercle bacillus and particularly the protein fraction which is responsible for the tuberculin reaction. The growing routine demands of the central laboratory might have put an end to the research of a less energetic worker, but Tytler continued his inevitably restricted investigations with enthusiasm and made interesting observations. Some two years before he was due to retire Tytler was induced to undertake a further responsible and somewhat arduous task in the fight against tuberculosis. He resigned from his chair to become consultant on tuberculosis laboratories to the World Health Organization. This took him to many parts of the world, often where laboratories were primitive or non-existent.

He was rich in his hobbies—gardening, mushroom-growing, beekeeping, fishing, gastronomy—and in his last years in retirement at Banchory he developed a chicken-farm, to which he effectively and enthusiastically applied his ability for scientific planning. An outstanding personality in any company, not only had he extensive knowledge in his own particular scientific field and in practical matters generally, but he was also very well informed in the broad sweep

of world affairs. His surprising memory, shrewd judgment, and well-balanced views more often than not gave him the last word in the spirited arguments of which he was so often the centre. Someone hearing him for the first time, particularly on the telephone, might have been disconcerted by his curt, almost gruff manner, but one did not need to know him long to discover the warmth, kindness, and willing helpfulness of his true nature. He had many sincere friends, and during his last days he had much solace from the letters of those to whom he had said good-bye and who now mourn his passing. He leaves a widow and an adopted daughter.—J. G. and J. M. P.

W. P. YETTS, C.B.E., D.Lit., M.R.C.S.

Dr. W. P. Yetts, emeritus professor of Chinese art and archaeology in the University of London, died at his home at Chesham Bois, Bucks, on May 14, aged 79. He gave up medicine for an academic career in 1930.

Walter Perceval Yetts was born at Reading and educated at Bradfield College and at the universities of Lausanne and London. He became a medical student at St. Bartholomew's Hospital, qualifying M.R.C.S., L.R.C.P. in 1903, and straightway entered the Royal Naval Medical Service, winning the Admiralty gold medal for naval hygiene in 1904. Retiring from the Navy as staff surgeon in 1912, he became acting physician at the British Legation in Peking. During the first world war he served in the R.A.M.C. with the rank of major, and was appointed O.B.E. in 1919 for his wartime service. After working for two years as deputy commissioner of medical services in the Ministry of Pensions, he transferred to the Ministry of Health, working as a medical officer there until 1927.

For many years before this Yetts had been recognized as a leading authority on Chinese art, especially that of the prehistoric period. When in 1930 a lectureship in Chinese art and archaeology was established at London University he was appointed to the post. It was not only his scholarship which qualified him so well for this post, but, being an artist himself, he was able to convey in his writings and lectures his own deep aesthetic appreciation of Chinese art. Bronzes and jades were his special interest. He was a member of the executive committee and chairman of the selection committee of the renowned Exhibition of Chinese Art held at the Royal Academy in 1935. The author of many articles and several books, he wrote three volumes of the catalogue of the Eumorfopoulos Collection. He was promoted C.B.E. in 1944, and appointed to the Order of the Brilliant Star of China in 1948. A year ago Dr. Yetts was awarded the triennial gold medal of the Royal Asiatic Society.

He married Mary Gwendoline Hughes in 1912, and she survives him.

M. A. ARCHDALE, M.B., B.S., D.P.M.

Dr. M. A. Archdale, consulting physician to the psychiatric clinic at Sunderland Royal Infirmary, died on April 12. He was 82 years of age.

Mervyn Alexander Archdale was born at Gateshead on March 1, 1875, the son of Canon T. H. Archdale, and was educated at St. Bees School and at Durham University, where he graduated M.B., B.S. in 1897. He then held house appointments at the Monkwearmouth and Southwick Hospital and at the Royal Southern Hospital, Liverpool. Subsequently, in 1906, he became medical superintendent of the East Riding Mental Hospital, Beverley. During the first world war he served as a major in the R.A.M.C. with the 3rd Northumberland Field Ambulance. In 1918 he was appointed medical superintendent of the Cambridgeshire Mental Hospital, Fulbourn, and four years later he became medical superintendent of the new Sunderland Borough Mental Hospital, where he remained until he retired in 1938. He took the D.P.M. of Cambridge in 1922. Shortly after leaving Sunderland he founded a nursing-home for mentally

ill persons at Middleton Hall in Durham and remained in charge of this until the end of his life. Dr. Archdale, who was a widower, leaves two daughters.

E. O. L. writes: Psychiatry in this country has lost one of its most charming personalities with the death of Dr. Mervyn Alexander Archdale. His career as a doctor had many features of distinction. One was that at the early age of 31 he became medical superintendent of the East Riding Mental Hospital. While Dr. Archdale was at Fulbourn the University of Cambridge established a course of studies in psychological medicine, and granted a diploma in the subject. Dr. Archdale gave the lectures on psychiatry and carried out most of the clinical demonstrations for the course. In this work he was closely associated with such men as Sir Clifford Allbutt, Dr. W. H. R. Rivers, and Dr. C. S. Myers. At the hospitals where he laboured and in the districts these hospitals catered for, new attitudes to mental illness were to be found long before they appeared in the majority of hospitals. His outlook was progressive. For instance, he was the first medical superintendent to persuade his committee to appoint an academic psychologist to the staff of a mental hospital. Archdale was always to be found among the groups on study tours of hospitals in this and other countries. When he thought a new experiment to be sound—and he discriminated wisely in such matters—he would soon be testing the new idea in his own hospital. While he had a sound grasp of the more scientific aspects of psychiatry, his best achievements were a consequence of his attitude to his professional work. He was a man—or more precisely a Christian—dedicated to the service of those who are mentally ill. His natural humility and modesty made it easy for patients to talk to him of their anxieties and difficulties; relatives readily sought his advice and guidance; and the lay members of the hospital and the members of the hospital committee found his humanistic ideas on mental treatment contagious and inspiring. Another example of Archdale's progressiveness was his broadcast of short talks, for about five minutes each morning, from his office to all the wards in the hospital. In this respect he is to be regarded as a pioneer of one form of group psychotherapy. The talks were expressed in simple non-technical terms. They were designed to comfort the depressed, to soothe the excited, to give the deluded some insight, and to penetrate the loneliness of the schizophrenic patient. When I visited him a few months ago he was busy arranging for records to be made of these talks, so that they could be used at other hospitals.

JAMES FISON, M.D.

Dr. James Fison, who died on April 20 at the age of 73, was well known for many years as an ophthalmologist in Harrogate.

After obtaining first-class honours in the natural sciences tripos at Cambridge, James Fison went on to St. Bartholomew's Hospital. There, after graduating B.Chir. in 1912, he became ophthalmic house-surgeon. The first world war broke out soon after he left Bart's, and he served throughout in the Royal Navy, principally as ophthalmic surgeon at Chatham. He obtained the Cambridge M.D. in 1918, and soon after the war settled in practice at Harrogate, and there he remained and worked until his last illness. For the greater part of the time Fison was ophthalmologist to the Harrogate General Hospital and to the Leeds Dispensary. These and other posts brought him a reputation for kindness and thoroughness for which many patients will remember him with gratitude. He was president of the Section of Ophthalmology when the British Medical Association held its Annual Meeting at Harrogate in 1949.

Among other sides of his character which will be equally gratefully remembered by his many friends were a certain old-world courtesy which could disarm criticism and a great faculty for keeping in touch with old comrades. He was blessed with a sense of humour which enabled him to note

with delight the foibles of his colleagues—and others—and to comment on them with a choice of phrase and metaphor which he had made peculiarly his own. With other activities he was a skilful organist, a keen horticulturist, an optimistic golfer, and, it should not be forgotten, some thirty years ago the necessarily intrepid wicket-keeper to the Harrogate doctors' eleven. He was indeed a good companion; and our sympathy is extended to his widow and his three sons, all of whom were also at Bart's.—A. B. P. S.

WILLIAM TAYLOR, M.D., D.P.H.

Dr. William Taylor, for many years county medical officer of health for Shropshire until he retired in 1953, died in the Bridge of Earn Hospital, Perth, on May 1 at the age of 69.

A native of Perthshire, where he was born on February 24, 1888, William Taylor graduated M.B., Ch.B. in 1912 from Glasgow University, and held a number of resident appointments at the Glasgow Royal Infirmary and the Glasgow Maternity Hospital. During the first world war he served first in the R.A.M.C., but later, in 1915, transferred to the Royal Navy. After the war he adopted public health as his career, studying at the university and in the city of Aberdeen, and obtaining the D.P.H. in 1920. In the same year he was appointed a Carnegie research scholar and worked in the Rowett Institute for Nutritional Research and in the Aberdeen public health department, and he published the results of his researches into the physiology of lactation in a number of papers. In 1921 he proceeded to the M.D. with high commendation.

In 1922 Taylor was appointed assistant school and child welfare officer for Shropshire and worked in the Bridgnorth area of the county. He succeeded Dr. James Wheatley as county medical officer of health in 1929. Throughout his years of service with the Salop County Council Dr. Taylor devoted himself wholeheartedly to the duties of his appointment. The years 1947 and 1948, with the planning connected with the new social legislation and the responsibility of giving effect to the reorganized personal health services, imposed a heavy burden on a man whose health was far from robust, but his personality and drive were such that he never spared himself. If any qualities in his work merit special mention it would perhaps be his scrupulous attention to detail, which no doubt owed its origin to his early research work and also to his scholarly command of the written word. The greatest sadness in his life, from which he never fully recovered, was the loss of his only son on active service in Burma in 1943. He is survived by his widow and only daughter.

W. I. WEBSTER, C.I.E., M.C., M.D., D.P.H.
D.T.M.&H.

Lieutenant-Colonel W. J. Webster, formerly senior assistant director of the Central Research Institute of the Government of India at Kasauli, Simla Hills, died in hospital in Aberdeen on May 8, after a prolonged and painful illness. He was in his 64th year.

William Joseph Webster was born at Millmoor, Turriff, Aberdeenshire, on June 27, 1893, and received his early education at Robert Gordon's College, Aberdeen. He studied medicine at the University of Aberdeen, graduating M.B., Ch.B., with honours, in 1915. In the same year he became a lieutenant in the Special Reserve of the R.A.M.C., being promoted to captain seven months later and to acting major in January, 1918. Mentioned in dispatches in 1917 and 1919, he was also awarded the Military Cross and Bar. On leaving the Army in 1919, he returned to the physiology department of Aberdeen University as demonstrator, eventually joining the Indian Medical Service in September, 1920.

Webster spent the greater part of his Indian service in the Medical Research Department, working successively at the Haffkine Institute, Bombay, the King Institute of Preventive

Medicine at Guindy, Madras, and the Central Research Institute at Kasauli. Before assuming the senior assistant directorship at the latter institute he was the last director of the Pasteur Institute at Kasauli before its amalgamation with the Central Research Institute. Webster took the D.T.M.&H. in 1926 and the D.P.H. in 1931, when he also proceeded to the M.D. He became a Fellow of the Royal Society of Tropical Medicine and Hygiene in 1926. Possessing a wide experience of tropical research problems, he published the results of his investigations in numerous papers. It was during the second world war that he had the opportunity of demonstrating his flair for organization and administration, for he was responsible for the production of vast quantities of vaccines and sera for the armed Forces and civilian population of India and other eastern theatres of war. Recognition of his outstanding efforts in this field was the appointment to C.I.E. in 1947, immediately after his retirement from the Indian Medical Service.

His only son, who was an officer in the R.A.F., was killed in 1945. Colonel Webster is survived by his wife and married daughter.—C. L. G.

H. W. M. writes: Lieutenant-Colonel W. J. Webster was for twenty years one of the handful of I.M.S. officers who formed the hard core of the Medical Research Department in India. In addition to research and development work these men were required to accept responsibility for other duties, including public-health laboratory work, clinical pathology, preparation of biological products, teaching, and administration. Only too often did research become a spare-time activity. Although he contributed a number of papers on typhus, rabies, bacteriology, and water analysis, Webster brought to the day-to-day tasks he undertook a wide knowledge and experience as well as that scrupulous conscientiousness which is so essential to their proper performance. He deserves to be remembered not only for his peacetime contribution but for his distinguished service in two world wars. At the outbreak of the second world war Webster occupied a "reserved" post as officer-in-charge of the serum and vaccine section of the Central Research Institute, Kasauli, and he continued to be so employed until he left India on retirement in 1946. The staff of the institute was depleted by the recall of its younger officers for military duty, so that Webster had to meet the ever-increasing demands for biological products with inadequate staff and facilities. Even when the output of vaccines and sera exceeded one million doses a month all demands were met and there was no sacrifice of the very high standards to which all products were required to conform. Webster was a plain, blunt man, but he was greatly respected by all who worked under him. During his last three years of service he was deputy director of the institute at Kasauli during my period as director, and I could not have wished for a more loyal and dependable colleague.

E. T. H. DAVIES, M.D., M.S., F.R.C.S.

Mr. E. T. H. Davies, surgeon to Tredegar Hospital for nearly forty years and formerly medical superintendent of the Tredegar Medical Aid Society, died at his home at Tredegar on May 14. He was 77 years of age.

Edwin Thomas Harries Davies was born at Carmarthen on May 29, 1879. From University College, Cardiff, where he won a natural science scholarship, he went on to St. Mary's Hospital with an open scholarship, and subsequently gained the Meadows Prize in obstetrics at the hospital. In 1906 he took both the London Conjoint diploma and the London degrees of M.B., B.S. After qualification he held the appointments of house-surgeon, house-physician, and obstetric officer at St. Mary's, resident medical officer at Hampstead General Hospital, and surgical registrar at the London Temperance Hospital. During this period he took the F.R.C.S. and the degrees of M.D. and M.S. In 1911 he settled in practice at Tredegar, where he was soon appointed chief surgeon to the hospital and

medical superintendent of the Tredegar Medical Aid Society. Later he became also medical officer of health to the urban district council and medical superintendent of the infectious diseases hospital, posts he held for many years. After his retirement on reaching the age limit in 1949, a ward in the Tredegar Hospital was named after him. Mr. Davies did not give up his professional work entirely, however, for he held a part-time appointment as a surgeon under the Welsh Regional Hospital Board. He is survived by his widow and daughter.

Medical Notes in Parliament

VACCINATION AGAINST POLIOMYELITIS

THE MINISTER OF HEALTH, in a progress report on vaccination against poliomyelitis on May 15, announced the extension of registration to children born in 1955 and 1956, the continuation of vaccination during the summer months this year, and the decision not to import vaccine from America. His statement covered Scotland, as well as England and Wales. He said he had seen suggestions that arrangements should be made to import vaccine from America. When drawing up the scheme they decided on expert advice that the vaccine to be used in this country should have a composition different in certain respects from that of the American vaccine, which was made from strains of virus including the virulent Mahoney strain. That advice still stood, and, while the situation would continue to be kept under close review in all its aspects, they did not consider any departure from this policy was warranted in existing circumstances.

Dr. EDITH SUMMERSKILL (Warrington, Lab.) asked if, in view of the high number of cases of poliomyelitis already notified in the first four months of the year, the Minister could say when there would be enough vaccine available to vaccinate the million children already registered. Mr. VOSPER said he was most anxious not to make forecasts that might prove inaccurate because of production difficulties, but if all went well it should be possible to complete vaccination of those already registered by the end of this summer.

Mr. D. WADE (Huddersfield, West, Lab.) asked if it was correct that the disease common in this country differed somewhat from that in America, and therefore it was desirable to use the vaccine most appropriate here. Mr. VOSPER said he thought that was correct. The composition of the vaccine in this country was different from that in America, and the opposition to using the American vaccine was not so much that it might be unsuitable but that the vaccine used in this country to-day was more suitable for the disease here.

Mr. A. BLENKINSOP (Newcastle upon Tyne, East, Lab.) asked if the Minister was in touch with the United States in the use of the vaccine there, and if he would ensure closer contact with the general practitioners in this country in view of his comments. Mr. VOSPER replied that the present advice would be brought to the notice of all general practitioners that week. There was close contact with the United States, particularly through the Medical Research Council.

Scotland's Anti-tuberculosis Campaign

Mr. W. HANNAN (Glasgow, Maryhill, Lab.) questioned the Secretary of State for Scotland on May 14 about the mass x-ray campaigns against tuberculosis. Mr. J. NIXON BROWNE, the Under Secretary, told him that, in addition to Glasgow, Perth had just completed a magnificently successful campaign. A campaign was under way in West Lothian which had so far exceeded expectations. Eighteen other local authorities proposed to carry out campaigns in the next two years. They had been selected by the Department of Health as being those in whose areas the incidence of tuberculosis was greatest.

Mr. HANNAN asked if he was satisfied that there would be accommodation and nursing staff available to treat those who had been found to be suffering from tuberculosis. Mr. BROWNE assured him that there was.

Medical Care in Prisons

Mr. T. BROWN (Ince, Lab.) asked the Home Secretary on May 13, in order to reassure relatives and others who had been led to think that prisoners were deprived of medical care, what provision existed for the medical care of prisoners, and if he was satisfied that it was adequate for its purpose. Mr. R. A. BUTLER stated that all prisons had medical officers, and where the resources of a prison were insufficient to meet adequately the mental and physical needs of the prisoners arrangements existed for calling in consultant specialists and for sending prisoners to outside hospitals. These arrangements, which in his view were fully adequate, were described in the booklet *Prisons and Borstals*.

Pay for Junior Doctors

Mr. A. BLENKINSOP (Newcastle upon Tyne, East, Lab.) asked the Minister of Health on May 20 what representations he had received on behalf of doctors serving their interim year in hospitals; and whether he had any proposals to make to improve their conditions of service. Mr. J. K. VAUGHAN-MORGAN, the Parliamentary Secretary, told him that the Minister had received no representations on behalf of these doctors. In common with other junior doctors in the hospital service they had had an increase of 10% in their pay as from April 1 last, as an interim measure pending the report of the Royal Commission on doctors' and dentists' remuneration.

Mr. BLENKINSOP asked if the Minister was aware of the great anxiety that had arisen about the hours of work being done by many of these staffs. Was it not due to the restrictions imposed by the Department about the appointment of new senior staff in hospitals? Mr. VAUGHAN-MORGAN replied that living conditions and the organization of work were matters for hospital authorities and the senior medical staff. The other matter was for the appropriate Whitley Council.

Practice in Cyprus.—There are 363 doctors in practice in Cyprus; 312 are Greek Cypriots and 31 Turkish Cypriots.

Registration of Opticians.—Legislation will be introduced as soon as parliamentary time permits, but the Minister cannot say when. He has said that there is no other difficulty except finding parliamentary time in the way of introducing the Bill.

Mental Hospital Patients.—In 1955 the number of voluntary patients admitted to mental hospitals was 75% of the total admissions, and in 1954 it was 71.5%. Final figures for 1956 are not yet available.

Mental Illness Report.—The report of the Royal Commission on Mental Illness and Mental Deficiency is likely to be presented towards the end of May.

Universities and Colleges

UNIVERSITY OF OXFORD

The following degrees were conferred in Congregation on May 2:

D.M.—E. J. L. Lowbury, R. T. Turner Warwick, W. H. Taylor, J. D. L. Reinhold.
B.M.—D. S. Ellis, *J. A. Riley.
*In absence.

UNIVERSITY OF LONDON

Dr. C. F. Harris has been reappointed Deputy Vice-Chancellor for 1957-8.

Professor Esther M. Killick has been reappointed representative of the University on the governing body of Queen Elizabeth College.

Dr. C. F. Harris and Dr. R. S. F. Schilling have been nominated for appointment or reappointment on the governing bodies of the Royal College of Veterinary Surgeons and the Slough Industrial Health Service Ltd. Council of Management respectively.

The following have been recognized as teachers of the University in the subjects indicated in parentheses: *Guy's Hospital*

Medical School, Dr. A. M. Hutton (Anaesthetics); St. Mary's Hospital Medical School, Dr. Derrick Rowley (Bacteriology); London School of Hygiene and Tropical Medicine, Dr. G. R. Wadsworth (Nutrition).

UNIVERSITY OF MANCHESTER

The following candidates have satisfied the examiners at the examinations indicated:

DIPLOMA IN PSYCHOLOGICAL MEDICINE.—Part II: L. Grimshaw, E. Howarth, K. E. Schmidt. Part I: G. Hopkinson, W. P. Walsh.

UNIVERSITY OF BIRMINGHAM

The following representatives have been appointed: Professor Thomas McKeown, at the annual congress of the Royal Society of Health to be held at Folkestone from April 30 to May 3; Professor J. M. Smellie, on the Stafford Local Medical Committee; Dr. R. W. H. Tavenner, on the Central Counties Dental Post-graduate Committee (during the absence of Professor J. Osborne); and the Vice-Chancellor, Dr. R. S. Aitken, on the Foyle Trust.

The title of University Research Fellow has been given to T. Anzai, M.D., British Council Research Fellow in the Department of Chemistry, and P. W. Dykes, M.B., M.R.C.P., M.R.A.C.P., a registrar in the teaching hospital and part-time research worker in the Department of Experimental Pathology, during the tenure of their present awards or appointments in the University.

Dr. N. G. Marr has relinquished his appointment as part-time Lecturer in Occupational Health in the Department of Social Medicine.

In Congregation on December 14, 1956, the following degrees were conferred:

M.D.—R. Astley, B. D. Bower, M. G. Fitzgerald, T. A. Phillips, Rachel E. W. Sillett, G. F. Trobridge.
Ph.D.—In the Faculty of Medicine: R. G. Brown, E. A. Cooper, M.B., B.Chir., D.A., J. W. L. Davies, A. J. Hance, C. E. Rowe, A. Todrick.

M.B., Ch.B.—Margaret J. Aldridge, G. H. Berry, K. G. Branch, D. C. Colwell, J. H. Croft, C. M. David, G. H. Davies, Marion K. Donovan, A. M. Evans, G. S. Farmer, I. M. Fletcher, D. M. Gardiner, N. H. N. Gardner, N. R. Houlston, J. W. E. Johnson, P. W. Lee, Barbara S. M. Marshall, D. H. Targett.

Professor Thomas McKeown has been appointed representative of the University on the governing body of the United Birmingham Hospitals.

The title of University Research Fellow has been given to the following during the tenure of their present awards or appointments in the University: Department of Experimental Pathology, Mrs. Dorothy R. Campbell, F.R.C.S., director of the research department, Birmingham and Midland Eye Hospital, and Dr. R. F. Fletcher, registrar in the metabolic unit, Little Bromwich Hospital; Department of Surgery, H. Sadeghi-Nejan, M.D., a postgraduate student from Iran.

Dr. E. H. L. Harries has been appointed Lecturer in Physiology from February 1, 1957.

UNIVERSITY OF LIVERPOOL

The following candidates have been approved at the examinations indicated:

Ph.D.—In the Faculty of Medicine: J. W. Dundee, M.D., F.F.A. R.C.S. D.M.R.(D.).—Part I: V. Amatyakul, E. H. Burrows, L. R. Levin, T. O'Brien, R. G. Pitman, H. G. Row.
D.M.R.(T.).—Part I: A. K. Bose, G. A. L. G. Glazebrook, N. K. Neogy, R. Spencer.

ROYAL COLLEGE OF PHYSICIANS OF LONDON

At a quarterly comitia of the College held on April 25, with the President, Professor Robert Platt, in the chair, Dr. J. Forest Smith was appointed a representative of the College on the Council of the Imperial Cancer Research Fund.

Licences

Licences to practise were conferred upon the following 165 candidates who have passed the final examination in medicine, surgery, and midwifery of the Conjoint Board, and who have complied with the by-laws of the College:

P. Abraham, L. Adamson, Mary M. Adlington, D. R. Amies, R. St. J. Angel, J. R. Anthony, G. J. L. Ardouin, B. R. Baker, M. A. Barracough, G. Bevan, D. P. Birkett, B. D. Birt, Sybil Birtwistle, J. L. Booth, Anne Bromley, G. Brooke, R. J. A. Brown, J. A. W. Buckley, T. M. Bull, P. G. Burles, J. L. Canter, P. B. Carpenter, Margaret T. Challis, J. A. Chalmers, Zoe D. Chamberlain, T. D. Cochran, Jean R. Colston, Christina M. Comty, Phoebe M. Cotes, D. R. Couchman, J. M. R. Cox, Dorothy Cullen, D. W. Davies, Patricia W. R. Daymond, J. M. Denison, D. M. Dingle, B. C. Dixon-Warren, A. B. Dunderdale, M. J. Dyer, Joan M. Edwards, P. J. Edwards, B. J. Ellam, M. K. El-Din H. El-Rifi, Pauline M. Feavers, J. S. Ferguson, Ann L. M. Field, Elizabeth C. Finn, P. S. Firth, G. N. Flaherty, Evelyn C. Foot, J. A. Fox, G. G. Francis, P. I. Frank,

R. G. G. Gain, Ann F. Gamble, R. D. Gardner, J. C. Garnham, W. H. S. George, J. Goodchild, Pamela J. H. Goodwill, M. S. Gottlieb, J. H. C. Gough, Judith F. Gould, J. N. Graham-Evans, June S. Grant, D. Green-wood, Olive M. Grundy, J. Hajioff, A. Hakki, J. G. Hall, T. J. Hall, J. Hicks, D. L. Hamblen, V. J. Hartfield, Sally Haynes, M. R. Heal, R. C. Hicks, L. M. Hillman, L. J. Hobbs, Margaret B. Howell, P. J. W. Howes, S. W. Hyams, E. E. Inyang, J. D. Jowitt, A. C. Kaeser, J. O. Kesby, M. S. Kessel, K. C. Kewish, D. W. Keys, R. M. Kinsey, J. O. Knowles, M. I. Lander, M. J. Lavine, D. J. Lawson, D. H. Lawton, J. K. Lawton, F. I. Lee, Eva H. Lechner, G. C. Liddle, Helen A. Linn, D. B. Longson, Mary K. Lucas, Gillian B. McCullagh, M. J. McLoughlin, B. C. Mallaband, E. C. Marsh, Nancy E. V. Matthews, P. A. Mead, Katherine M. Moore, R. V. Morris, K. A. A. Mourin, R. C. Mulholland, Elizabeth M. Nicholson, K. F. O'Sullivan, D. W. Owen, R. E. Owen, D. W. Patient, Sylvia J. Pinder, M. A. Pratchell, V. J. Pratt, V. Riddle, E. O. R. Rasaretnam, S. Ravetto, R. L. Raymakers, P. R. Riddle, H. D. Roberts, M. Roburn, Marita R. Rodan, Christine A. Rodgers, H. D. Rogers, J. E. Rogers, Muriel E. Rolfe, K. W. Rowden, D. H. R. Saffer, Marie-Luise B. Seidler, H. G. S. Sergeant, Mary Sibellas, S. H. Simonian, G. B. Smith, J. L. Storey, P. E. Suter, A. R. Taylor, M. F. Terry, C. R. Thomas, Edith H. Thomas, C. D. Thompson, D. F. J. Thompson, I. G. Thomson, Janet E. Timberlake, J. A. D. Walkden, M. P. Walsh, R. R. Watkin, D. M. Wayne, Felice M. Weber, G. T. Whitfield, W. Whitrow, Anne M. Wigley, F. R. Wilkes, R. P. Williams, Wadad Williams, Anne M. Wilson, E. H. Wisely, B. E. M. Wright, Margaret E. G. Wright, G. B. Wyatt.

Diplomas

Diplomas in Physical Medicine, in Ophthalmology, and in Tropical Medicine and Hygiene were granted, jointly with the Royal College of Surgeons of England, to the successful candidates whose names are printed below in the report of the meeting of the Royal College of Surgeons of England held on April 11.

Diplomas in Child Health were granted, jointly with the Royal College of Surgeons of England, to B. K. North and J. N. Rea, and to the other successful candidates whose names are printed below in the report of the meeting of the Royal College of Surgeons of England held on April 11.

Jointly with the Royal College of Surgeons of England a Diploma in Anaesthetics was granted to J. E. S. Relton, and a Diploma in Medical Radiodiagnosis to K. M. Nuttall.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

At a meeting of the Council of the College held on April 11 with the President, Sir Harry Platt, in the chair, the following diplomas were granted, jointly with the Royal College of Physicians of London:

DIPLOMA IN CHILD HEALTH.—I. M. Adamson, B. K. Ahuja, N. J. Al-Chokhachi, Patricia M. Alexander, S. M. Al-Kudcy, Ursula M. Anderson, K. J. Ansari, K. M. M. Ansari, L. P. Balfour-Lynn, P. Bandyopadhyaya, J. F. X. Bastiampillai, Esther B. Bevan, May Blythe, Shirley P. A. Borgkoff, N. L. S. Bourchier, W. H. Brockett, C. W. Brookes, R. J. Buharwalla, Alison G. Carlsie, N. K. Chanda, Aileen P. Cherry, Daphne G. Chesshire, Sau-Lan L. Cheung, T. A. Daly, G. J. Davies, T. C. Dennison, G. S. Dhalliwal, Doreen J. Dicks, K. P. Dikshit, Jean E. Drake, P. G. Drummond-Smith, Ma Tin E, F. P. Frankel, J. D. Frankish, H. J. Fredericks, P. Ganerwala, A. J. Gazder, Grace M. Gee, A. G. Giddins, Marianne A. Gleason, E. Goldblatt, V. K. Gupta, R. D. Haigh, Daphne J. Hall, H. T. Heath, B. E. Heine, Margaret J. Hicks, Siew-Ting Hiew, F. K. M. Hillenbrand, A. Irvine, Hu, M. C. J. Hunt, M. F. Husain, Cecile Ibrahim, Kathleen A. Irvine, J. P. Jayalath, E. E. Jones, J. S. Kalsi, S. Kapur, Pensri Khanjanasthiti, G. S. T. Khoo, Eleanor C. Knox, J. S. Kothiwai, Joan M. Leeming, J. F. Leeton, R. L. Lindon, Barbara Lobo, D. Lonsdale, Kathleen M. Lumb, Jean Y. MacDougall, Agnes M. Maclean, P. N. Mehrotra, Barbara P. P. Melhuish, Inez R. Mendelson, C. J. Morgan, K. Muiranaura, Elizabeth C. Nelson, P. G. Newall-Watson, Pauline A. Nock, Nalinee V. Odak, M. M. Pandit, R. S. Parmar, Margaret P. Patterson, Monica B. Pool, B. R. Pratap, K. R. Purohit, C. R. Ranier-Pope, I. Ramage, P. N. Rastogi, M. J. Ree, Kathleen M. Robb, D. K. Robinson, W. G. Roper, M. A. Sasson, N. S. Satija, W. H. Schutt, Jane M. Semmens, B. C. Sen, R. K. Seth, L. Sinclair, J. J. Slome, Mary N. Smith, Mahalekshmi T. Sushila, R. N. P. Sutton, Sara Syrop, I. G. Taft, O. P. Thaman, Ann Thompson, J. A. R. Tibbles, S. M. Tucker, Naomi Turner, Marian A. Veitch, Lucy A. Warstaff, Allison S. Wallace, I. R. Wallace, R. G. Wari, G. H. Warrick, D. T. Weerawardene, Jean B. Wickins, Joan V. Willcock, A. R. Williamson, R. G. B. Willis, Mary B. Woodfield, Joyce O. Yates.

DIPLOMA IN PHYSICAL MEDICINE.—V. C. De Silva, Charlotte Feldman, S. A. James, B. W. Norington.

DIPLOMA IN OPHTHALMOLOGY.—P. A. Abeyaratne, J. Abraham, J. E. Ball, C. J. Benson, R. D. Billimoria, T. J. A. Casey, I. Cher, N. J. G. Chouler, B. G. Dias, M. El Sayed, R. F. Fisher, D. C. Gibbs, A. G. Ginawi, V. L. Gokhale, A. S. A. Goreish, P. A. Johnson, T. Keldouls, T. H. Kirmani, G. M. Krolman, H. F. Lake, V. J. Marmion, H. H. Massie, M. Maw, F. S. Owen, R. A. Owen, I. Papadopoulos, R. Pararajasegarani, C. S. L. Peiris, M. H. Rizvi, L. Rose, O. P. Sabharwal, B. D. Shrivastava, K. Singh, S. H. Swift, S. V. Thambar, L. J. Topham, P. L. A. Townshend, D. Venkateswarlu, Vera M. Vadden, Olga Voloshin, J. H. Wanla, B. Waters, W. Wilson.

DIPLOMA IN TROPICAL MEDICINE AND HYGIENE.—M. Y. Ali, T. R. Arulambalam, S. N. Basu, G. Battaglia, R. C. Braun, P. Brodie, T. D. Chatterjee, D. Chetty, A. Chopra, R. K. Chopra, J. A. Cooney, G. L. Das, Guha Majumder, A. B. C. Hotobah-During, V. K. Jayaram, Ko Ko, H. S. N. Dutta, M. A. Faghri, P. D. Fario, R. O. J. Fry, P. Grech, M. N. Lal, N. M. P. Mendis, V. R. Mody, A. S. Mohamed, P. R. H. Molesworth, D. A. Narasimhan, Nur-ud-Din, G. G. Prinsell, A. H. Qureshi, Phyllida M. M. Roberts, Y. P. Rudrappa, N. K. Sarker, M. G. Schmiedel, V. B. Setty, M. P. Shaw, M. Sinnappu, K. G. Somers-Dehancy, Tin U. F. Vitanza, Helena T. von Schantz, Wan Yam Mow, D. S. P. S. V. J. Wiesekera, Yao-Tsing Wu.

At a meeting of the Council of the College held on May 9 with the President, Sir Harry Platt, in the chair, the Cecil Joll Prize was presented to Professor P. R. Allison (Oxford); a Jacksonian Prize to Mr. Alan H. Hunt (St. Bartholomew's), and a Certificate

of Honourable Mention to Mr. R. E. Horton (Bristol); and the Begley Prize was awarded to Miss Sybil Birtwistle (Liverpool University).

A Diploma of Membership was granted to J. J. Key and to the other 165 successful candidates whose names were printed in the report of the meeting of the Royal College of Physicians of London held on April 25 (*Journal*, p. 1250).

ROYAL COLLEGE OF PHYSICIANS OF IRELAND

At a meeting of the College held on April 5 the President, Dr. F. J. O'Donnell, admitted to the Licence of Medicine and Midwifery the following candidates who had passed the recent Conjoint Final examinations:

A. S. A. Atchia, Beryl D. Chalkley, S. P. J. Halpin, R. W. Kneafsey, M. B. Labode, G. K. Maghraj, S. V. McAndrew, A. G. McInerney, H. J. O'Brien, C. P. Quinn, A. C. Walsh.

Vital Statistics

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1948-56 are shown thus ----, the figures for 1957 ———. Except for the curves showing notifications in 1957, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

The largest variations in the notifications of infectious diseases in England and Wales during the week ending May 4 were decreases of 3,772 for measles, from 26,960 to 23,188, and 62 for scarlet fever, from 542 to 480, and an increase of 162 for whooping-cough, from 2,237 to 2,399.

The notifications of acute poliomyelitis numbered 60, and these were 9 fewer for paralytic and 6 more for non-paralytic cases than in the preceding week. The largest returns were Essex 19 (Colchester M.B. 10, Brightlingsea U.D. 2), Yorkshire West Riding 9 (Leeds C.B. 5, Thorne R.D. 2), and Sussex 5 (Brighton C.B. 4).

Falls of 100 or more in the number of notifications of measles were reported from 15 counties. The largest falls were 605 in Middlesex, from 1,746 to 1,141, and 498 in Warwickshire, from 2,211 to 1,713. Only small changes were recorded in the local incidence of scarlet fever. The only large fluctuation in the returns of whooping-cough was a rise of 59 in Cornwall, mainly due to increases of 24 in Newquay U.D., from 9 to 33, and 19 in West Renwith R.D., from 4 to 23. Only 1 case of diphtheria was notified, being 6 fewer than in the preceding week.

The notifications of dysentery numbered 574, or 4 more than in the preceding week. The largest centres of infection were Lancashire 113 (Manchester C.B. 23, Liverpool C.B. 18, Ashton under Lyne M.B. 13, Stretford M.B. 11), Yorkshire West Riding 102 (Leeds C.B. 23, Bradford C.B. 15, Worsborough U.D. 15, Rotherham C.B. 14), Cheshire 35 (Hyde M.B. 19), Shropshire 31 (Oswestry M.B. 31), Northumberland 30 (Seaton Valley U.D. 10), London 27 (Southwark 10), and Nottinghamshire 23 (Mansfield M.B. 16).

Week Ending May 11

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 497, whooping-cough 2,362, diphtheria 3, measles 18,265, acute pneumonia 392, acute poliomyelitis 69, dysentery 669, paratyphoid fever 1, and typhoid fever 1.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending May 4 (No. 18) and corresponding week 1956.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES In Countries and London	1957					1956

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenzal pneumonia.
§ Includes puerperal pyrexia.

Medical News

French and British Surgeons at R.C.S.—A joint scientific meeting of the Royal College of Surgeons of England and the Académie de Chirurgie de Paris will be held at the Royal College of Surgeons on May 30 and 31 and June 1. The French surgeons will present papers and films. The remainder of the programme will consist in demonstrations of operative technique, relayed from St. Bartholomew's Hospital on closed-circuit colour television. This is stated to be the first occasion in Britain on which colour television has been used for a medical programme of this sort. Attendance at the sessions on May 30 and 31 is by invitation, but, if seats are available, any member of the medical profession will be welcome on June 1 (10 a.m.-12 noon). On this day two operations will be shown—one for a Dupuytren's contracture by Sir ARCHIBALD MCINDOE, and a cardiac operation under hypothermia by Sir RUSSELL BROCK. Those wishing to attend should write at once to the secretary, Royal College of Surgeons of England, Lincoln's Inn Fields, London, W.C.2.

Radiobiology Unit at Mount Vernon.—The DUKE OF DEVONSHIRE opened the British Empire Cancer Campaign's new radiobiology unit at Mount Vernon Hospital, Northwood, on May 20. The unit, whose director is Dr. L. H. GRAY, Ph.D., will carry out research on the effects of radiation on living cells, particularly during the early stages of damage. Counting the director, there is a permanent staff of three, with a number of visiting workers. A generous gift of £25,000 from an anonymous donor has paid for the unit's laboratories and a 200-kilovolt x-ray machine. In addition the unit is equipped with a "uniquely powerful" electron pulse generator. This machine emits bursts of electrons at such high intensity that cells in the path of the beam, it is stated, "can be exposed to any desired amount of irradiation, up to a limit exceeding anything previously attained, in a single pulse lasting only about two-millionths of a second." The Mount Vernon Hospital itself, which treats some 1,150 cancer patients annually, has an exceptionally well equipped radiotherapy department, fitted with a 4-million-volt x-ray machine and the cobalt-60 theratron unit given to the B.E.C.C. by Mr. MCCONNELL, of Canada. The directors of the other research departments at the hospital are Professor R. W. SCARFF (pathology), Professor J. E. ROBERTS (physics), and Professor B. W. WINDEYER (radiotherapy). Sir STANFORD CADE is engaged on research with the cobalt-60 unit.

Hospital for West Cumberland.—Details of a new 438-bed hospital for West Cumberland were given at a press conference in Carlisle on May 16. The conference was called by the special area committee of the Newcastle regional hospital board, under the chairmanship of Mr. R. S. VENTERS, F.R.C.S. The hospital is to serve an isolated, growing industrial population of 140,000, nearly 40 miles (64 km.) from the nearest alternative hospital centre. The site chosen for the new hospital is just south of Whitehaven. The total cost of the hospital is put at about £2m., and it will be built in four stages. The first stage—a 41-bed unit for tuberculous patients—was completed in January by the conversion of an existing building. Work began on the second stage in March. This provides for about 100 geriatric, psychiatric, and infectious-disease beds, as well as for some staff accommodation, service buildings, and site clearing for the main hospital buildings. Plans for the third stage, comprising the main hospital block with general and specialist departments, wards and out-patient facilities, offices, etc., are now awaiting Ministry approval. The last stage will be a 40-bed maternity and antenatal wing.

Civil Defence in the U.S.A.—The Board of Trustees of the American Medical Association has recently decided to co-operate in research with the Federal Civil Defence Administration in studying the best methods of providing medical care to the surviving population—casualty and non-casualty

—in the event of an enemy attack. The work will be carried out by the American Medical Association's Council on National Defence, and the estimated cost is \$150,000. "The Trustees of the A.M.A. looked with favour on the study because they felt that physicians would carry the primary burden and final responsibility for providing medical care for the American people in the event of a national emergency" (*J. Amer. med. Ass.*, April 20, p. 1542).

Narcotics Commission Warns Against Barbiturates.—The United Nations' Commission on Narcotics, now meeting in New York, has passed a unanimous resolution recommending governments to take measures to prevent the abuse of barbiturates. A "careful watch" on the "tranquillizers" is also advised. The resolution notes that, contrary to the commonly held view, the greatest danger from the barbiturates is not from acute poisonings, and brands their habit-forming propensities a "danger to public health." Governments which have not already done so are advised to take legislative and other measures to prevent abuse of these drugs. The Commission began its session—the twelfth—on April 29, and is expected to adjourn on May 31. The Commission comprises delegates from ten nations elected for an indefinite period (Canada, China, France, India, Peru, Turkey, U.S.S.R., United Kingdom, United States, and Yugoslavia) and delegates from five others elected for three years (Austria, Egypt, Hungary, Iran, and Mexico).

Beit Memorial Fellowships.—Changes in the Trustees, and in the advisory board, of the Beit memorial fellowships for medical research are announced in the Trustees' report for 1956-7. LORD HAILSHAM has been made a trustee in place of LORD SIMONDS. On the advisory board, Professor J. H. GADDUM, F.R.S., has been elected chairman in place of Sir RUDOLPH PETERS, F.R.S., who has resigned from the board after 18 years' membership, and Professor R. H. S. THOMPSON joins the board as a new member. Professor Gaddum is professor of materia medica at Edinburgh, Professor Thompson professor of chemical pathology at Guy's. The following have been elected to Beit memorial fellowships: *Fourth-year Fellowships (£1,000)*—Dr. B. T. DONOVAN, Ph.D., at the Institute of Psychiatry, London; and Dr. D. S. H. W. NICOL, at the Dunn Institute of Biochemistry, Cambridge. *Junior Fellowships (£800 a year)*—Dr. G. A. J. GOODLAD, Ph.D., at the department of biochemistry, Glasgow; Dr. I. OSWALD, at the Institute of Experimental Psychology, Oxford; Dr. I. C. RODDIE, at the department of physiology, Queen's University, Belfast; Dr. S. VARADARAJAN, Ph.D., at the department of radiotherapeutics, Cambridge; and Dr. PAULINE M. MEADOW, Ph.D., at the department of biochemistry, University College, London. Information about Beit fellowships may be obtained from the secretary, Beit Memorial Fellowships, Lister Institute of Preventive Medicine, Chelsea Bridge Road, London, S.W.1.

Chair of Neuropathology.—Dr. P. M. DANIEL, senior lecturer at the Institute of Psychiatry, has been appointed to the London University Chair of Neuropathology tenable at the Institute. The previous occupant of this chair was Professor ALFRED MEYER. Dr. Daniel graduated in medicine in 1942 from Cambridge and the Charing Cross Hospital, where he was T. H. Huxley scholar. He was prosector at the Royal Medical College, Edinburgh, and was awarded the John Hunter medal and triennial prize (1946-8) of the Royal College of Surgeons of England. In 1954 he obtained the M.R.C.P.(London), and in 1955 the D.M.(Oxford). He is honorary consultant neuropathologist at the Maudsley and Bethlem Hospitals and to the Army at home. He edited the section on neurological methods in *Lee's Microtome*'s *Vade-Mecum*.

F.R.C.S.Ed.—At a meeting of the Royal College of Surgeons of Edinburgh on May 10 the following were admitted fellows: B. M. ANDREA, A. C. ARULPRASAM, J. R. BADGER, D. D. BEARD, K. S. BREARLEY, J. J. BREITENBACH, M. R. CHAUDHARY, J. E. CHOO, K. CLARK, J. A. COOMES, K. B. CORNWELL, R. G. DENNIS, J. A. DOIG, G. R. GORDON, S. A. HUSSAINI,

K. JOHNS, R. DE R. JOOSTE, K. A. KALYANAM, I. J. KAPLAN, L. P. B. KIRIELLA, B. LOTZOF, H. L. J. LUSBY, D. C. MACPHAIL, E. MATTHEWS, F. A. MEINTJES, P. R. MYERSCROUGH, J. G. B. MYLES, C. V. PETERSON, W. H. RAYNHAM, A. A. ROUX, J. N. SEGELOV, M. V. SHETTY, T. P. SINGH, M. D. M. STANTON, I. B. TAIT, R. N. TIWARY, C. TOKER, W. K. M. C. WATKINS, H. G. WATTS, D. W. WHITWAY, and G. B. WYLIE.

M.R.C.P.Ed.—At a quarterly meeting of Royal College of Physicians of Edinburgh on May 7 the following were elected members: A. SLESSOR, D. M. DOUGLAS, S. P. V. SHERLOCK, W. G. MACFIE, J. G. OPIE, D. M. PRINSLEY, D. E. ANDERSON, M. M. KUBIK, K. B. YUILL, J. P. ANDERSON, J. C. DAVIDSON, A. E. STUART, B. S. CHINNIAH, T. P. TELFER, K. S. RAI, J. M. WALKER, J. P. LAVENDER, A. J. CAMERON, G. D. FORWELL, E. V. PIERIS, M. I. MEMON, P. T. PIERIS, J. I. FORBES, L. N. SHOURIE, S. P. KHATUA, P. W. A. BOTHA, F. LOTHE, G. P. MCNICOL, J. N. PARK, E. G. WARBURTON, G. ARJUNDAS, C. P. DANCATER, D. SARMA, S. R. ESRACHOWITZ, H. DE V. HOESE, W. J. FESSEL, and W. D. SMITH.

Shortage of Blood Donors.—On May 15 the Minister of Health, Mr. DENNIS VOSPER, appealed for over 100,000 more blood donors. He was speaking at a special showing of a film about the National Blood Transfusion Service called "Blood is Life." He said the Service had over 643,000 civilian donors at the end of March, but with the continually growing demand for blood from hospitals an effective panel of 750,000 donors was needed. Last year the record number of 803,000 blood donations was made, an increase of 44,000 on the previous year.

Doctors' Widows and Orphans.—The annual meeting of the Society for Relief of Widows and Orphans of Medical Men was held in London on May 15, under the chairmanship of the president, Sir ROBERT YOUNG. Last year the Society disbursed £4,130 in grants and presents to members' widows and orphans in financial difficulties. The Society dates from 1788, and membership is open to all male registered medical practitioners living, at the time of election, within 20 miles of Charing Cross. Further details may be obtained from the Society's secretary at 11, Chandos Street, Cavendish Square, London, W.1.

Gilbert Blane Medal.—Surgeon Commander S. MILES, R.N., has been awarded the Sir Gilbert Blane Naval Medal for 1957. This was announced at a council meeting of the Royal College of Surgeons on May 9.

COMING EVENTS

Medical Research Society Lecture for 1957.—Dr. STANLEY BRADLEY (Columbia University) will lecture on May 31 at the London School of Hygiene and Tropical Medicine, at 5.30 p.m. His subject will be "Circulatory Adjustments to Postural Changes." Lecture open to non-members.

Sixth International Congress of Preventive Medicine.—Organized by the International Society for Prophylactic Medicine. June 24-29, at Wassenaar, The Hague, and Scheveningen. Papers in French and German. Details from Dr. E. BERGHOFF, 41, Piaristengasse, Wenen 8, Netherlands.

"Flour and Bread."—Symposium arranged by the Nutrition Society, July 5 and 6, at the Anatomy School, Cambridge. Sir RUDOLPH PETERS, F.R.S., will be the chairman. Details from Miss D. F. HOLLINGSWORTH, c/o Ministry of Agriculture, Horseferry Road, London, S.W.1.

Twentieth International Congress of Psychoanalysis.—Paris, July 28 to August 1. Details from Dr. S. NACHT, 187, rue Saint-Jacques, Paris, 5.

Curare and Curare-like Agents.—International symposium under the auspices of Unesco at Rio de Janeiro, Brazil, August 5-17. Details from Professor D. BOVER, Istituto Superiore di Sanità, 299, Viale Regina Elena, Rome.

NEW ISSUES

Annals of the Rheumatic Diseases.—The new issue (Vol. 16, No. 1) is now available. The contents include:

HEBERDEN ORATION, 1955. Walter Bauer.
HEBERDEN ORATION, 1956. R. E. Tunbridge.
ISOLATED OSTEO-ARTHRITIS OF THE SHOULDER JOINTS. Arthur W. Bagnall.
PLACEROS IN THE TREATMENT OF RHEUMATOID ARTHRITIS AND OTHER RHEUMATIC CONDITIONS. Eugene F. Traut and Edwin W. Passarelli.
INCIDENCE OF RHEUMATIC FEVER IN RELATION TO IMMUNOLOGIC REACTIVITY. V. Rejchle.
RADIOLOGICAL STUDY OF SACRO-ILIAC JOINTS IN ANKYLOSING SPONDYLITIS WITH REFERENCE TO THE EVOLUTION OF THE DISEASE. J. Forestier and P. Desjouis-Paoli.
ENZYMATIC ELUCIDATION OF THE RELATIONSHIP BETWEEN COLLAGEN AND ELASTIN: AN ELECTRON-MICROSCOPIC STUDY. M. K. Keech and R. Reed.
OSTEO-ARTICULAR SITES OF BRUCELLOSIS. J. Rotés-Querol.
DIPHENYLAMINE REACTION IN CHRONIC JOINT DISEASES. Milam Adam.
Jiri Malecek, and Marta Kutyová with Vladimír Maly.
AGGLUTINATION OF SENSITIZED SHEEP ERYTHROCYTES IN DISSEMINATED LUPUS ERYTHEMATOSUS. Nanna Svartz and Karl Schlossman.
SYSTEMIC LUPUS ERYTHEMATOSUS. S. K. Conner.
ADDISON'S DISEASE AND RHEUMATOID ARTHRITIS. C. E. G. Robinson.
PERIPHERAL VASCULAR OBSTRUCTION IN RHEUMATOID ARTHRITIS AND ITS RELATIONSHIP TO OTHER VASCULAR LESIONS. E. G. L. Bywaters.
PLASMA PROTEINS AND CRYOGLOBULINS IN ANARTHRITIC RHEUMATOID DISEASE. L. Bagratuni.
AUGMENTING EFFECT OF RHEUMATOID SERA IN A STREPTOCOCCAL HAEM-AGGLUTINATION TEST. N. R. Link and H. J. Gibson.
PROPOSED DIAGNOSTIC CRITERIA FOR RHEUMATOID ARTHRITIS. Marian W. Ropes, Granville A. Bennett, Sidney Cobb, Ralph Jacob, and Ralph A. Jessar.
AMERICAN RHEUMATISM ASSOCIATION. PROCEEDINGS OF THE THIRD INTERIM SCIENTIFIC SESSION, 1956.
HEBERDEN SOCIETY.
LIGUE INTERNATIONALE CONTRE LE RHUMATISME.
UNIVERSITY OF TEXAS POSTGRADUATE SCHOOL OF MEDICINE.
THIRD ACQUI PRIZE, 1957.
ABSTRACTS.

Issued quarterly; annual subscription £2 2s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

British Journal of Industrial Medicine.—The new issue (Vol. 14, No. 2) is now available. The contents include:

THE HEALTH OF THE WORKER. P. A. B. Raffle.
THE NEUTRALIZATION OF SILICA TOXICITY *in vitro*. J. Marks.
SILICOSIS HAZARDS IN ENAMELLING: A MEDICAL, TECHNICAL, AND EXPERIMENTAL STUDY. Lars Friberg and Harry Ohman.
SOME FACTORS INFLUENCING THE RESPONSE OF INDUSTRIAL WORKERS TO MASS RADIOGRAPHY. G. Z. Breit.
RADIOLOGICAL SURVEYS OF WORKING QUARRYMEN AND QUARRYING COMMUNITIES IN CAERNARVONSHIRE. T. Francis Jarman, J. Glyn Jones, J. H. Phillips, and H. E. Sciorry.
AN OUTBREAK OF WEAVER'S COUGH ASSOCIATED WITH TAMARIND SEED POWDER. Robert Murray, I. Dingwall-Fordyce, and Ronald E. Lane.
AN OUTBREAK OF TRI-ORTHO-CRESYL PHOSPHATE (T.O.C.P.) POISONING IN DURBAN. Mervyn Susser and Zena Stein.
INTERNAL DERANGEMENT OF THE KNEE JOINT IN MINERS. J. B. Atkins.
THE RESPONSIBILITIES OF THE MEDICAL PROFESSION IN THE USE OF X RAYS AND OTHER IONIZING RADIATIONS. United Nations Scientific Committee on the Effects of Atomic Radiation.
MISCELLANEA:
OCCUPATIONAL MORTALITY IN SCOTLAND. S. L. Morrison.
WORK, CONFLICT, AND COMMUNITY. D. H. Allcorn.
A DISCUSSION OF TECHNIQUE AND AN ANALYSIS OF ERRORS IN TAKING INDUSTRIAL HISTORIES IN COAL-MINERS. G. Jonathan, F. Moore, and L. Roberts.
A NEW KIT FOR SODIUM NITRIDE-THIOSULPHATE THERAPY IN THE TREATMENT OF ACUTE CYANIDE POISONING. N. Langdon Lloyd.

Issued quarterly; annual subscription £2 2s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, May 27

INSTITUTE OF CARDIOLOGY.—9.30 a.m., Sir John Parkinson: Cardiovascular Syphilis.

INSTITUTE OF PSYCHIATRY.—5.30 p.m., public lecture by Professor H. G. K. Westenberg (Utrecht): Some Investigations Concerning Vitamin B₁₂ with Special Reference to Brain.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Institute, 5 p.m., Dr. S. Udenfriend (U.S.A.): Clinical Studies Relating to Tryptophan Metabolism.

Tuesday, May 28

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Professor C. A. Keele: Cutaneous Pain and Itch.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., Mitchell Lecture by Dr. F. P. Lee Lander: Rest and Pulmonary Tuberculosis.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Professor R. T. Turner-Warwick: Lymphatics of the Breast in Relation to the Spread of Carcinoma and its Treatment.

ROYAL STATISTICAL SOCIETY.—At Keene Lecture Theatre, 2nd Floor, Westminster Medical School, 5.30 p.m., annual general meeting. Dr. J. H. Edwards: Some Aspects of Cigarette Poisoning.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Institute, 5 p.m., Altmouth Wright Lecture by Dr. J. F. Loutit: Immune Response following X-irradiation.

UNIVERSITY COLLEGE LONDON: DEPARTMENT OF PHARMACOLOGY.—At Physiology Theatre, Gower Street, W.C., 5.15 p.m., public lecture by Professor P. Bálint (Budapest): Nervous Regulation of Renal Function.

Wednesday, May 29

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. W. Riddell: Differential Diagnosis of Fungous Infections of the Skin.

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. P. D'Arcy Hart: Place of B.C.G. Vaccination in an Established Tuberculosis Service.

INSTITUTE OF NEUROLOGY.—5.30 p.m., Professor G. Schaltenbrand (Würzburg, Germany): Myographic Analysis of Spasticity and Rigidity.

●INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—4 p.m., Mr. A. L. Gunn: Kielland's Forceps and Their Use.

LONDON AMATEUR BOXING ASSOCIATION.—At Great Northern Hotel, King's Cross, N., 8 p.m., Dr. J. H. Taylor: Psychiatric Aspects of Head Injuries.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Dr. Joan Taylor: Recent Developments on the Role of Enterobacteriaceae in Gastro-enteritis.

Thursday, May 30

●Guy's HOSPITAL MEDICAL SCHOOL.—5 p.m., Carbutt Memorial Lecture by Dr. William Evans: Conditions That Mimic Heart Disease.

HONYMAN GILLESPIE LECTURE.—At Anatomy Theatre, University New Buildings, Edinburgh, 5 p.m., Dr. J. A. C. Fleming: Some Radiation Injuries in Clinical Practice.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. H. J. Wallace: Skin Diseases of the Vulva.

ROYAL NORTHERN HOSPITAL.—2.45 p.m., Dr. Martin Hynes: Urine. ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Institute, 5 p.m., Dr. S. Udenfriend (U.S.A.): Metabolism of Phenylalanine, Tyrosine, and Adrenaline.

Friday, May 31

●Guy's HOSPITAL MEDICAL SCHOOL.—5 p.m., Fison Memorial Lecture by Sir John Cockcroft, F.R.S.: Atomic Energy and its Biological Implications.

●INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. G. B. Dowling: clinical demonstration.

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. F. H. Young: clinical demonstration.

●INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—3 p.m., Mr. A. J. Wrigley: Deficiencies in the Present Obstetric Service.

MEDICAL RESEARCH SOCIETY.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. Stanley F. Bradley (Columbia): Circulatory Adjustments to Postural Changes.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—10 a.m., Professor F. A. R. Stammers: Mechanical Factors in Post-gastroctomy Complications and Syndromes.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Institute Theatre, 5 p.m., Professor W. J. Hamilton: The Early Ovum.

Saturday, June 1

LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.—At Royal National Orthopaedic Hospital, Stanmore, Middlesex, 3 p.m., clinical meeting.

SOUTH-EAST METROPOLITAN REGIONAL TUBERCULOSIS SOCIETY.—At Royal Sea-Bathing Hospital, Margate, 10 for 10.30 a.m., meeting. Scientific papers and film.

WEST MIDLANDS PHYSICIANS ASSOCIATION.—At Holme Lacy Hospital, Hereford, 11 a.m., spring meeting.

Sunday, June 2

PADDINGTON GENERAL HOSPITAL.—11 a.m., clinical meeting for general practitioners.

UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL.—10.15 a.m., clinical demonstration for general practitioners. The Rt. Hon. Lord Amulree: Some Medical Problems of Old Age.

APPOINTMENTS

DAWKINS, JOAN M. St. V., M.B., B.S., D.P.H., D.C.H., Assistant County Medical Officer of Health and District Medical Officer of Health for Daventry Borough and Brixworth and Daventry Rural Districts.

EAST ANGLIAN REGIONAL HOSPITAL BOARD.—S. S. A. Jaffery, M.B., B.S., Anaesthetic Registrar, West Norfolk and King's Lynn General Hospital; I. N. S. Heald, M.B., Ch.B., Registrar in Psychiatry, Hellesdon Hospital; C. E. Cook, M.B., B.Ch., Registrar in Psychiatry, St. Andrew's Hospital, Thorpe, Norwich; E. G. Oram, M.B., Ch.B., Registrar in Psychiatry, Fulbourn and Addenbrooke's Hospitals; A. B. Shearer, M.B., B.S., Medical Registrar, Ipswich and East Suffolk Hospital; S. K. Sen, M.B., D.G.O., Registrar in Obstetrics and Gynaecology, West Norfolk and King's Lynn General Hospital.

HOSPITALS FOR DISEASES OF THE CHEST, London.—Ronald G. Grainger, M.D., F.F.R., M.R.C.P., D.M.R.D., and Basil Strickland, M.B., B.S., F.R.C., M.R.C.P., D.C.H., D.M.R.T., D.M.R.D., Part-time Consultant Radiologists.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Martin.—On May 8, 1957, at Birmingham Maternity Hospital, to Winifred (formerly Attenborough), wife of Dr. Robert F. Martin, a son—Nigel Paul.

Mulhern.—On May 11, 1957, at Queen Elizabeth Hospital, Birmingham, to Ruth (formerly Heller), wife of Dr. P. H. Mulhern, a daughter.

Searle.—On April 3, 1957, at Poole General Hospital, to Gwenllif (formerly Edwards), M.R.C.S., L.R.C.P., D.O., wife of J. S. T. Searle, M.B., B.S., D.R.C.O.G., a daughter—Anne.

DEATHS

Grant.—On April 10, 1957, Robert Grant, M.B., Ch.B., of Mackay, Queensland, Australia, formerly of Edinburgh.

Stuart.—On April 18, 1957, at 4, Clifton Terrace, Southsea, Hants, Alan Roy Douglas Stuart, M.R.C.S., L.R.C.P., aged 41.

Taylor.—On May 1, 1957, at Bridge of Earn Hospital, William Taylor, M.D., D.P.H., of Downfield, Stanley, Perthshire, formerly of Shrewsbury, Salop.

Wilson.—On April 30, 1957, at Queen Mary's Hospital, Roehampton, London, S.W., William Fothergill Wilson, M.C., M.B., B.Ch., Wing Commander, R.A.F. (retired).

Wylie.—On May 4, 1957, at his home, Woodlands, Doncaster, Yorks, John Wylie, M.C., M.B., Ch.B., aged 66.

Zanker.—On April 30, 1957, at his home, 35, Elmhurst Court, St. Peter's Road, Croydon, Surrey, Arthur Zanker, M.D.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Mental Disability and Testamentary Capacity

Q.—If a will is contested on the grounds that the testator was not of sufficiently sound understanding at the material time to realize fully what he was doing, what degree of mental disability must be proved to satisfy a court that this was so? I have in mind the case of an elderly person whose mental powers underwent a gradual deterioration during his last few years of life.

A.—First a caution is necessary. Within the scope of a reply to an "Any Question?" it is impossible to provide an answer that will necessarily apply to the facts of every case. It is possible to indicate guiding principles only.

Testamentary capacity is interpreted in a very wide sense. Provided a will is made voluntarily and without interference in an attempt either to remedy any mental defect or weakness of mind which may be present, or to influence the testator unduly in some particular direction, especially if the will is a sensible document—the courts will be loth to set it aside.

It is essential that the testator should understand the nature and effects of his acts and the extent of his property; be able to appreciate the claims that should be taken into account and their strength; that his memory should be good enough to remember all persons who might reasonably have a claim on him; and that no disorder or senility of mind should pervert his sense of right or influence him in the disposal of his property. A testator may, however, indulge his caprice or even malice, if he wishes, leaving nothing to his family, provided such caprice is not brought about by an insane state, senile suspicion, or undue influence. To upset a will in the case of a senile testator, the onus would normally be on those contesting the will to show that the testator had not complied with the above requirements.

Aetiology of Twinning

Q.—(1) What are the aetiological factors in twinning in man? How do they differ in the case of monozygous and dizygous twins? (2) What is the risk of twins in a couple where one of them is a twin? Is the risk the same for a parent who is a monozygous twin as for a dizygous twin, and does this affect the type of twin that may be born? (3) One of my patients, a monozygous twin, is marrying a man who is himself a monozygous twin. What are their chances of having twins, and do they incur an increased risk of having monozygous twins? What are the comparable risks in the marriage of a monozygous twin with a dizygous twin, and of two dizygous twins?

A.—(1) Monozygous twins are derived from the early splitting of a single cell and so are formed from a single sperm and a single ovum. Dizygous twins are derived from two ova which happen to have been released at the same time and two sperms. The results of genetic research on twinning have been conflicting, in part probably because the distinction between monozygous and dizygous twin pairs was not accurate. Recent work suggests that the two forms are aetiologically distinct, and that there is no tendency for the two types to occur together in the same family with more than random frequency. The frequency of monozygous twinning varies little if at all with the mother's age, and is much the same, 3 to 4 per 1,000, in widely different parts of the world. There is no convincing evidence that the tendency to monozygous twinning is in any way inherited. Dizygous twinning

is almost certainly more frequent in certain families than others; it is also more frequent in certain races than others—for example, the incidence is 9 to 10 per 1,000 in some European countries, but only about 2 per 1,000 in Japan. The frequency of dizygous twinning in European countries increases as the mother ages, from about 3 per 1,000 at age 20 to a maximum of 13 per 1,000 at about 35 years, after which it falls again.

(2) Where one of a couple is a monozygous twin there is probably no significant increase in the risk of the couple having twins themselves. Where the father is one of a dizygous pair there is also probably no increased risk of twinning. Where the mother is one of dizygous twins there is an increased risk that the couple will have twins, but this increase is only for dizygous twins.

(3) Monozygous twinning in either or both parents, or the father being one of a dizygous pair, probably has, as indicated above, no effect on the risk of the children being twins. If, however, the mother is one of a dizygous pair, the risk of her having dizygous twins is increased from the random risk of about 1% to a figure of the order of 10%. In one survey¹ 60 mothers with a twin brother, and therefore one of a dizygous pair, had 11 twins in 122 births.

Colostrum Test for Pregnancy

Q.—What is known of a pregnancy test in which colostrum is injected into the superficial layers of the skin of the forearm? It is said to be accurate within two or three weeks of conception.

A.—The colostrum test was described by Falls, Freda, and Cohen.¹ It was claimed that the intradermal injection of 0.02 ml. of a solution consisting of equal parts of human colostrum and physiological saline produced no reaction in pregnant women, but a typical allergic response (flare and weal) within half an hour in non-pregnant women. In the original publication there were 98% correct answers in 265 pregnant women and 96% correct answers in 113 non-pregnant women. Few subsequent reports have confirmed these findings, and most—for example, those of Pulver and Posner² and Allen and Donaldson³—indicate the test to be quite unreliable. There do not seem to have been any reports since 1945, and it may therefore be concluded that no further interest in the test remains.

Pulmonary Eosinophilia

Q.—What criteria are necessary to establish a diagnosis of "pulmonary eosinophilia of unknown cause"? Have there been any recent advances in the treatment of this condition, and in particular is steroid therapy of any value?

A.—The criteria necessary to establish a diagnosis of "pulmonary eosinophilia of unknown cause" are x-ray finding of pulmonary infiltration and a blood eosinophilia of over 6% in a case where either full investigation has failed to uncover a primary cause or the picture conforms to a known syndrome of unknown aetiology.

Crofton *et al.* in a paper from the Brompton Hospital (based on a personal experience of 16 cases and a review of some 450 others) pointed out that eosinophilia in the blood is an incidental finding in certain well-defined pulmonary conditions—the resolving stage of pneumonia, hydatid disease of the lung, Hodgkin's disease, and sarcoidosis. They defined pulmonary eosinophilia as a condition in which pulmonary infiltration on the radiograph is accompanied by blood eosinophilia (6% or over) but in which all of the four diseases listed above can be excluded. They considered that all cases of pulmonary eosinophilia form a

continuum, but suggested the following classification, which provides a very helpful clinical approach to these difficult cases: (1) Simple pulmonary eosinophilia or Loeffler's syndrome: transient infiltrations (less than one month), usually due to infestation with *Ascaris lumbricoides*. (2) Prolonged pulmonary eosinophilia: prolonged (over one month) or recurrent infiltrations without asthma (usual duration two to six months). (3) Pulmonary eosinophilia with asthma: infiltration with asthma (duration less than one month in just under a third of cases, one to three months in one third, and over three months in just over a third). (4) Tropical pulmonary eosinophilia: usually with arthritic symptoms. (5) Polyarteritis nodosa. The article should be read in order to assess any case of "pulmonary eosinophilia of unknown cause."

Steroid therapy is often an effective symptomatic therapy in pulmonary eosinophilia. A suitable dose of cortisone would be 300 mg. in divided doses on the first day, 200 mg. on the second, and 100 mg. on the third day, followed by 100 mg. for a period depending on the progress of the patient, with reduction to 75 mg. and then 50 mg. a day to tail off the treatment or for more continuous therapy. Continuous therapy should be on the smallest effective dose. Prednisone or prednisolone could be used at approximately one-fifth or one-quarter the above dosage. No case should be put on steroid therapy until the usual contraindications have been excluded, i.e., peptic ulceration, tuberculosis, an unstable nervous background, hypertension, or cardiac failure.

Barbiturate Addiction

Q.—What ill effects result from regular nightly doses of barbiturates?

A.—Forgetfulness, lassitude, impairment of mental concentration, mild depression, and prolongation of reaction-time are common results of a nightly dose of barbiturate, especially of the long-acting and widely prescribed phenobarbitone. The more pronounced effects of barbiturate addiction are described in such works as *The Pharmacological Basis of Therapeutics*¹ and *Narcotics and Narcotic Addiction*.² Heavy dosage with barbiturates also affects glucose metabolism, producing abnormal glucose-tolerance curves.³

Artificial Respiration after Electrocutation

Q.—It is alleged by first-aid men that Eve's method is best for asphyxia caused by electric shock, owing to the fact that it keeps the blood circulating even if the heart has stopped, and that the heart may subsequently restart. Is this true?

A.—Ventricular fibrillation will not of course be countered by Eve's rocking method of artificial respiration, but it is just possible that in cases of severe circulatory collapse this method might force some blood into the thorax and thus improve cardiac output. The method is not therefore likely to help if the heart has really stopped, but might help if the heart is beating faintly though imperceptibly. In practice, the method of artificial respiration of choice should usually be the method which can be provided most quickly, as every second counts.

NOTES AND COMMENTS

Infra-red Apparatus.—Dr. G. C. Soeters (Philips Medical Information Service, N.V. Philips' Gloeilampenfabrieken, Eindhoven, Holland) writes: "I agree with the view that a source of radiation having a high output is necessary where the whole body or a large part of it is to be irradiated [*"Any Questions?"* March 23, p. 718]. Indeed, I consider an output of 500 watts rather low for that purpose, even if a good parabolic reflector is used. To my mind, however, it is neither necessary nor—for practical reasons—advisable to use sets of such high power for treating local affections (local inflammation, haematoma, circumscribed pain). The usual practice when localized treatment is given is to make the intensity of the radiation per unit area of the irradiated surface as high as possible. The limit is formed by the capacity of the skin to withstand burning and painful sensation. For a good (50-watt set with its source properly fitted in a good reflector the irradiation distance is between 12 and 16 in. (30–40 cm.). Raising the output of such sets would necessitate increasing the irradiation distance. This would merely mean higher current consumption without any compensatory advantage. The statement that domestic gas and electric fires would be an effective substitute for radiation sets designed for medical purposes seems to be open to discussion. Even should recent investigations inspire doubt as to the tenability of the view that short-wave (0.7–1.4 μ) infra-red radiation induces a higher temperature in the deeper skin layers and subcutaneous tissue than does the same quantity of radiant energy of longer wavelength (over 1.4 μ)—even then it will be well to recall the advice of Stafford L. Osborne, professor emeritus and chairman, department of physical medicine, Northwestern University Medical School. He writes: "First the evidence shows that when the skin-source distance and the energy output are identical more effective heating is secured with the far infra-red source. It does not prove that this band of radiation is absorbed at a greater depth. . . . From the evidence of Gersten and co-workers,² it would seem to indicate then, that, at a maximum skin tolerance for both sources, the inner band of infra-red would be more effective." With this I am in full agreement, and conclude that the most reasonable course for the time being is to use short-wave infra-red radiation for medical purposes. This, in accordance with the Wien displacement law, means radiation from sources operating at high temperature. Domestic gas and electric fires, and other sources of radiation giving infra-red of wavelengths almost exclusively above 3.4 μ , cannot be included in this category.

² Gersten, J. W., Waxman, K. G., Herrick, J. F., and Krzycki, F. H., *ibid.*, 1949, 30, 601.

Dr. W. SUMMER, D.Sc. (Director, Barker Medico-Electronic Laboratories, Ltd., Birmingham), writes: "I would like to draw your attention to the fact that certain points have not been mentioned in the reply [*"Any Questions?"* March 23, p. 718], though they are of fundamental importance, namely: (1) that it is the power-area ratio (intensity) obtaining on the irradiated skin, and not the power of the source, which is a criterion; (2) that the absorption spectrum of the skin tissues requires the emitted infra-red radiation to centre at between 10,000 and 11,000 Å; (3) the fact of an optimum of skin transparency occurring within a well-defined spectral region also accounts for the view that neither gas nor electric space-heating appliances are quite the equipment to be used in physical therapy, even if the wavelengths of the radiations emitted by the fire should, by sheer accident, fall within the therapeutically optimal range.

Books of "Any Questions?" and Refresher Course Articles.—The following books are available through booksellers or from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1. TELEPHONE: EUSTON 4499. TELEGRAMS: *Atiology, Western, London*. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad. ADVERTISEMENTS should be addressed to the Advertisement Director, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 4499. WILLIAM HARVEY, 1578-1657

TERCENTENARY OF HIS DEATH

With the kind permission of the University of Glasgow we reproduce overleaf the portrait of William Harvey at the age of about 78, now in the University's Hunterian Collection.

Sir Geoffrey Keynes, in his Linacre lecture, 1949, on "The Personality of William Harvey," says this of the portrait:

"It was acquired very early in the eighteenth century by the famous Dr. Mead, who knew all the famous men of his time, including some that must have known Harvey. At the sale of Mead's collection in 1754 it was bought for Hunter, and in his collection it has remained ever since. It is a much less formal, more intimate, picture of Harvey than the ceremonial portrait at the College of Physicians. He does not look a very happy or satisfied man, as we have reason to know that he was not. The characteristic eyebrow is there, and the complexion in the picture itself entirely agrees with Aubrey's description as olivaster, the colour of wainstot. The patches on the cheeks are due to high colour, agreeing with Aubrey's description of his hot-headedness, and our knowledge that his blood-pressure was certainly raised in his last years. Notice also the faithful rendering of the distended temporal vein. But you may ask, why does he finger the leaves of a book with a Vesalian engraving of a skull, and why a background representing a view of Rome? The book is the *Works of Spigelius*, 1645. It happens to contain a reprint of Harvey's *De Motu Cordis*, but in fact it serves also to remind us that Harvey was a general anatomist, not merely the demonstrator of the circulation of the blood. The background shows the Church of S. Maria de Loreto and Trajan's Column; for Harvey had visited Rome in 1636, and the library he had built for the College of Physicians was inspired by an admiration for Roman architecture. . . . The Hunterian portrait is, then, almost, if not quite, the most interesting representation of Harvey in his old age that we possess, and there are a number of other portraits derived from it, including the well-known engraving by Houbraken."

BRITISH MEDICAL JOURNAL

LONDON SATURDAY JUNE 1 1957

TERCENTENARY OF THE DEATH OF WILLIAM HARVEY

To commemorate the death of William Harvey, Fellow of the Royal College of Physicians, we reprint from the pages of this journal two Harveian Orations (abridged) delivered at the Royal College of Physicians of London by two of its most distinguished Fellows: Sir William Osler and Sir Thomas Barlow

1. THE GROWTH OF TRUTH:

AS ILLUSTRATED IN THE DISCOVERY OF THE CIRCULATION OF THE BLOOD

Being the Harveian Oration delivered at the Royal College of Physicians, London, October 18, 1906

BY

WILLIAM OSLER, M.D., F.R.S.

[b. 12 July, 1849. d. 29 Dec., 1919]

I

After an introduction in which he discoursed on scientific truth the Orator continued: By no single event in the history of science is the growth of truth, through the slow stages of acquisition, the briefer period of latent possession, and the for us glorious period of conscious possession, better shown than in the discovery of the circulation of the blood. You will all agree with me that a Fellow of this College must take his courage in both hands who would, in this place and before this audience, attempt to discuss any aspect of this problem. After nearly three centuries of orations the very pictures and books in this hall might be expected to cry out upon him. But I have so taken my courage, confident that in using it to illustrate certain aspects of the growth of truth I am but obeying the command of Plato, who insists that principles such as these cannot be too often or too strongly enforced. There is a younger generation, too, the members of which are never the worse for the repetition of a good story, stale though it may be in all its aspects to their elders; and then there is that larger audience to be considered to which the season is never inappropriate to speak a word.

II

The sixteenth century, drawing to a close, had been a period of acquisition unequalled in history. Brooding over the face of the waters of mediaevalism, the spirit of the Renaissance brought forth a science of the world and of man which practically created a new heaven and a new earth, and the truths announced by Copernicus and Galileo far transcended

the searching schoolmen's view

And half had staggered that stout Stagyrte.

Among other things, it had given to medicine a new spirit, a new anatomy, and a new chemistry. In the latter part of the fifteenth century Hippocrates and Galen came to their own again. A wave of enthusiasm for the fathers in medicine swept over the profession; and for at least two generations the best energies of its best minds were devoted to the study of their writings.

How numerous and important is that remarkable group of men, the medical humanists of the Renaissance, we may judge by a glance at Bayle's *Biographie Médicale*, in which the lives are arranged in chronological order. From Garbo of Bologna, surnamed the expositor, to Rabelais, more than 150 biographies and bibliographies are given, and at least one-half of these men had either translated or edited works of the Greek physicians. Of our founder, one of the most distinguished of the group, and of his influence in reviving the study of Galen and so indirectly of his influence upon Harvey, Dr. Payne's story still lingers in our memories. Leonicens, Linacre, Gonthier, Monti, Koch, Camerarius, Caius, Fuchs, Zerbi, Cornarus, and men of their stamp not only swept away Arabian impurities from the medicine of the day, but they revived Greek ideals and introduced scientific methods.

The great practical acquisition of the century was a new anatomy. Vesalius and his followers gave for the first time an accurate account of the structure of the human body, and while thus enlarging and correcting the work of Galen, contributed to weaken the almost divine authority with which he dominated the schools. Nearly another century passed before chemistry, in the hands of Boyle and others, reached its modern phase, but the work of Paracelsus, based on that of the "pious Spagyrist," Basil Valentine, by showing its possibilities, had directed men's minds strongly to the new science. Of the three, the new spirit alone was essential, since it established the intellectual and moral freedom by which the fetters of dogma, authority, and scholasticism were for ever loosened from the minds of men.

Into this world, we may say, stepped a young Folkestone lad, when, on the last day of May, 1593, he matriculated at Cambridge. Harvey's education may be traced without difficulty, because the influences which shaped his studies were those which had for a century prevailed in the profession of this country. We do not know the reason for selection of Caius College, which, so far as I can gather, had no special connexion with the Canterbury school. Perhaps it was chosen because of the advice of the family physician, or of a friend, or of

WILLIAM HARVEY, 1578-1657

his rector; or else his father may have known Caius; or the foundation may already have become famous as a resort for those about to "enter on the physic line." Or, quite as likely, as we so often find in our experience, some trivial incident may have turned his thoughts towards medicine. When he came up in 1593, there were those of middle age who could tell racy stories of Caius, the co-founder of the college, against whose iron rule they had rebelled. "Charged not only with a show of a perverse stomach to the professors of the Gospel, but with Atheism," the last days of Caius's noble life were embittered by strife and misunderstanding. Doubtless the generous souls among them had long since learned to realize the greatness of his character, and were content to leave "the heat of his faith to God's sole judgement, and the light of his good works to men's imitation," with which words, half a century later, the inimitable Fuller concludes a short sketch of his life. I like to think that, perhaps, one of these very rebels, noting the studious and inquisitive nature of Harvey, had put into the lad's hand the little tractate, *De libris propriis*, from which to glean a knowledge of the life and works of their great benefactor.

The contemplation of such a career as that of Caius could not but inspire with enthusiasm any young man. No one in the profession in England had before that time reached a position which I may describe as European. An enthusiastic student and the friend of all the great scholars of the day; a learned commentator on the works of the Fathers; the first English student in clinical medicine; a successful teacher and practitioner; a keen naturalist; a liberal patron of learning and letters; a tender and sympathetic friend—Johannes Caius is one of the great figures in our history. Nor need I dwell, before this audience, on his devotion to our interests, other than to say that the memory of no Fellow on our roll should be more precious to us. Four years hence, on October 6th, will occur the quarter-centenary of his birth. As well in love as in gratitude, we could celebrate it in no more appropriate manner, and in none that would touch his spirit more closely, than by the issue of a fine edition of his principal works (including the MS. annals of the College). For the preparation of this there are those among us well fitted, not less by veneration for his memory than by the possession of that critical scholarship which he valued so highly.

When Harvey set out on the grand tour, Italy was still the *mater gloriosa studiorum*; to which one hundred years earlier, so tradition says, Linacre on leaving had erected an altar. The glamour of the ideals of the Renaissance had faded somewhat since the days when John Free, an Oxford man, had made the ancient learning his own; and had so far bettered the instruction of his masters that he was welcomed as a teacher in Padua, Ferrara, and Florence. In a measure, too, the national glory had departed, dimmed amid the strife and warfare which had cost the old republics their independence. Many years earlier Fracastorius, one of our medical poets, had sung of her decadence:

To what estate, O wretched Italy,
Has civil strife reduc'd and moulder'd Thee!
Where now are all thy ancient glories hurl'd?
Where is thy boasted Empire of the world?
What nook in Thee from barbarous Rage is freed
And has not seen thy captive children bleed?

And matters had not improved but had grown worse. In the sixteenth century Italian influence had sunk deeply into the social, professional, and commercial life of England, more deeply, indeed, than we appreciate; and it was not for

a generation or two later that the candlesticks were removed from the Cisalpine towns to Montpellier, Paris, and Leyden. In 1593 a well-to-do young Englishman who wished to study medicine thoroughly went to North Italy, and most naturally to Padua—"fair Padua, nursery of the arts"—whose close affiliations with us may be gathered from the fact that, of universities next to Oxford and Cambridge, she has given us more Presidents than any other. In the years that had passed since Vesalius had retired in disgust, the fame of its anatomical school had been well maintained by Fallopius, Columbus, and Fabricius, worthy successors of the great master. Of each may be said what Douglas says of the first named: "*In docendo maxime methodicus, in medendo felicissimus, in secundo expertissimus.*" While the story of Harvey's student life can never be told as we could wish, we know enough to enable us to understand the influences which moulded his career. In Fabricius he found a man to make his life-model. To the enthusiastic teacher and investigator were added those other qualities so attractive to the youthful mind, generous sympathies and a keen sense of the wider responsibilities of his position, as shown in building, at his own expense, a new anatomical theatre for the University. Wide as was the range of his master's studies, embracing not alone anatomy but medicine and surgery, the contributions by which he is most distinguished are upon subjects in which Harvey himself subsequently made an undying reputation. The activity of his literary life did not begin until he had been teaching nearly forty years, and it is a fact of the highest significance that, corresponding to the very period of Harvey's stay in Padua, Fabricius must have been deep in the study of embryology and of the anatomy of the vascular system. His great work on generation was the model on which Harvey based his own, in some ways, more accurate studies—studies in which, as my colleague Professor Brooks of the Johns Hopkins University has pointed out, he has forestalled Wolf and von Baer.

The work of Fabricius which really concerns us here is the *De Venarum Ostiis*. Others before him had seen and described the valves of the veins, Carolus one of the great Stephani, Sylvius and Paul Sarpi. But an abler hand in this work has dealt with the subject, and has left us a monograph which for completeness and for accuracy and beauty of illustration has scarcely its equal in anatomical literature. Compare Plate VII, for example, with the illustrations of the same structures in the Bidloo or the Cowper *Anatomy*, published nearly one hundred years later; and we can appreciate the advantages which Harvey must have enjoyed in working with such a master. Indeed, it is not too far-fetched to imagine him, scalpel in hand, making some of the very dissections from which these wonderful drawings were taken. But here comes in the mystery. How Fabricius, a man who did such work—how a teacher of such wide learning and such remarkable powers of observation, could have been so blinded as to overlook the truth which was tumbling out, so to speak, at his feet, is to us incomprehensible. But his eyes were sealed, and to him, as to his greater predecessors in the chair, clear vision was denied. The dead hand of the great Pergamite lay heavy on all thought, and Descartes had not yet changed the beginning of philosophy from wonder to doubt. Not without a feeling of pity do we read of the hopeless struggle of these great men to escape from slavish submission to authority. But it is not for us in these light days to gauge the depth of the sacred veneration with which they regarded the Fathers. Their mental attitude is expressed in a well-known poem of Browning's:

those divine men of old time
Have reached, thou sayest well, each at one point
The outside verge that rounds our faculty,
And where they reached who can do more than reach?

Willing to correct observations or to extend anatomy by careful dissection, it was too much to expect from them either a new interpretation of the old facts or a knowledge of the new method by which those facts could be correctly interpreted.

The ingenious explanation which Fabricius gave of the use of the valves of the veins—to serve as dams or checks to the flow of the blood, so that it would not irrigate too rapidly and overflow the peripheral vessels to the deprivation of the upper parts of the limbs—shows how the old physiology dominated the most distinguished teacher of the time in the most distinguished school of Europe. This may have been the very suggestion to his pupil of the more excellent way. Was it while listening to this ingenious explanation of his master that, in a moment of abstraction—dimly dreaming, perhaps, of an English home far away and long forsaken—there came to Harvey a heaven-sent moment, a sudden inspiration, a passing doubt nursed for long in silence, which ultimately grew into the great truth of 1616?

The works of Vesalius, of Fallopius, and of Fabricius effected a revolution in anatomy, but there was not at the close of the sixteenth century a new physiology. Though he had lost an anatomical throne, Galen ruled absolutely in all conceptions of the functions of the body, and in no department more serenely than in that relating to the heart, the blood and its movements. Upon his views I need not dwell further than to remind you that he regarded the liver as the source of the blood, of which there were two kinds, the one in the veins, the other in the arteries, both kinds in ceaseless ebb and flow, the only communication between these closed systems being through pores in the ventricular septum. He knew the lesser circulation, but thought it only for the nutrition of the lungs. The heart was a lamp which was furnished with oil by the blood and with air from the lungs. Practically until the middle of the seventeenth century Galen's physiology ruled the schools, and yet for years the profession had been in latent possession of a knowledge of the circulation. Indeed, a good case has been made out for Hippocrates, in whose works occur some remarkably suggestive sentences. In the sixteenth century the lesser circulation was described with admirable fullness by Servetus and by Columbus, and both Sarpi and Caesalpinus had Hippocratic glimmerings of the greater circulation. These men, with others doubtless, were in latent possession of the truth. But every one of them saw darkly through Galenic glasses, and theirs was the hard but the common lot never to reach such conscious possession as everywhere to make men acquiesce. One must have the disinterestedness of the dead to deal with a problem about which controversy has raged, and in which national issues have been allowed to blur the brightness of an image which would be clear as day to those with eyes to see. Nor would I refer to a matter long since settled by those best competent to judge, had not the well-known work of Luciani, the distinguished Professor of Physiology at Rome, appeared recently in German dress, edited by Professor Verworn, and spread broadcast views to which, with a chauvinism unworthy of their history, our Italian brethren still adhere. It has been well said "that he alone discovers who proves," and in the matter of the circulation of the blood, this was reserved for the pupil of Fabricius. Skipping many arduous years we next meet him as Lumleian Lecturer to the College.

III

The really notable years in the annals of medicine are not very numerous. We have a calendar filled with glorious names, but among the saints of science, if we know an era it is as much as can be expected—perhaps because such men are less identified with achievements than representative of the times in which they lived. With many of our greatest names we cannot associate any fixed dates. The Grecians who made Hippocrates possible, live in memory with some theory, or a small point in anatomy, or in regard to the place of their birth; while the "floruit" cannot always be fixed with accuracy.

Hippocrates himself, Erasistratus, Galen, and Aretaeus have no days in our calendar. We keep no festival in their honour as the churches do those of St. Jerome and

St. Chrysostom. It is not until after the Renaissance that certain years (*anni mirabiles*) stand out in bold relief as connected with memorable discoveries, or with the publication of revolutionary works. Nevertheless, only a few in each century; even the sixteenth, so rich in discoveries, has not more than five or six such years, and not one of them is connected with work done in this country. As to the seventeenth century, it is hard to name four made memorable by the announcement of great discoveries or the publication of famous works; in the eighteenth century not three, while in the century just completed, though it is replete with extraordinary discoveries, one is hard pressed to name half a dozen years which flash into memory as made ever memorable by great achievements. Of the three most important, anaesthesia, sanitation, and antiseptic surgery, only of the first can the date be fixed, 1846, and that for its practical application. For the other two discoveries, who will settle upon the year in which the greatest advance was made, or one which could be selected for an anniversary in our calendar?

There is one *dies mirabilis* in the history of the College—in the history, indeed, of the medical profession of this country, and the circumstances which made it memorable are well known to us. At ten o'clock on a bright spring morning, April 17th, 1616, an unusually large company was attracted to the New Anatomical Theatre of the Physicians' College, Amen Street. The second Lumleian Lecture of the annual course, given that year by a new man, had drawn a larger gathering than usual, due in part to the brilliancy of the demonstration on the previous day, but also it may be because rumours had spread abroad about strange views to be propounded by the lecturer. I do not know if at the College the same stringent rules as to compulsory attendance prevailed as at the Barber Surgeons' Hall. Doubtless not; but the President, and Censors, and Fellows would be there in due array; and with the help of the picture of "The Anatomy Lecture" by Bannister, which is in the Hunterian collection, Glasgow, and a photograph of which Dr. Payne has recently put in our library, we can bring to mind this memorable occasion. We see the "Anatomy," one of the six annually handed over to the College, on the table, the prosector standing by the skeleton near at hand, and very probably on the wall the very *Tabulae* of dissection of the arteries, veins, and nerves that hang above us to-day. But the centre of attention is the lecturer—a small dark man, wand in hand, with black piercing eyes, a quick vivacious manner, and with an ease and grace in demonstrating which bespeaks the mastery of a subject studied for twenty years with a devotion that we can describe as Hunterian. A Fellow of nine years' standing, there was still the salt of youth in William Harvey when, not as we may suppose, without some trepidation, he faced his auditors on this second day—a not uncritical audience, including many men well versed in the knowledge of the time and many who had heard all the best lecturers of Europe.

The President, Henry Atkins, after whose name in our Register stands the mysterious word "Corb," had already had his full share of official lectures, less burdensome three hundred years ago than now. Let us hope the lecture of the previous day had whetted his somewhat jaded appetite. The Censors of the year formed an interesting group; John Argent, a Cambridge man, a "great prop of the college," and often President, of whom but little seems known; Richard Palmer, also of Cambridge, and remembered now only for his connexion with Prince Henry's typhoid fever, as Dr. Norman Moore has told us; Mathew Gwinne of Oxford, first Professor of Physic at Gresham College and a playwright of some note in his day; and Theodore Goulston of Merton College, one of our great benefactors, and for 267 years past and gone purveyor-in-chief of reputation to the younger Fellows of the College. Mayerne would be there, not yet a Fellow, but happy in his escape from the Paris Faculty; still dusty with conflict, he would scent the battle afar in the revolutionary statements which he heard. Meverell, fresh from incorporation at Cambridge, also not

is made by the veins, as its going forward is performed only by the arteries."

Sir William Temple well expresses the attitude of mind of the intellectual Philistine of the time, who looked for immediate results. Speaking of the work of Harvey and of Copernicus he says: "Whether either of these be modern discoveries or derived from old foundations is disputed; nay, it is so too, whether they are true or no; for though reason may seem to favour them more than the contrary opinions, yet sense can hardly allow them, and to satisfy mankind both these must concur. But if they are true, yet these two great discoveries have made no change in the conclusions of Astronomy nor in the practice of Physic, and so have been but little use to the world, though, perhaps, of much honour to the authors." It is pleasant to notice that our old friend, Sir Thomas Browne, with his love of paradox, declared that he preferred the circulation of the blood to the discovery of America.

Of the reception of Harvey's views in Holland and Germany there is nothing to add to the admirable account given by Willis. The early and strenuous advocacy of Descartes, must have influenced the Dutch physicians; but in this, as in so many other things, the infection of his early years proved too powerful, and he could not get rid of the "ancient spirits." Of the discovery of the circulation he says it is "la plus belle et la plus utile que l'on pût faire en médecine." "Tout à fait contraire au sien touchant le mouvement du cœur," which he held to be due to an ebullition of the spirits—a sort of ferment (*espèce de levain*) existing in it. Much more actively discussed in Holland than elsewhere, the writings of Drake, Walaëus, Regius, Plempius, Sylvius, de Bach, Conringius, T. Bartholini (the Dane), and others threshed out the whole question very thoroughly, and their views, with those of Hoffman, Slegel, and others, are referred to by Willis and given in greater detail by Riolan.

In the oft-quoted statement that Harvey, "conquering envy, hath established a new doctrine in his lifetime," Hobbes was right so far as England and Holland are concerned. But it was far otherwise in France, where it met with a bitter and protracted hostility. The Medical School of the University of Paris, at the time one of the best-organized and most important in Europe, declined to accept the circulation of the blood during his lifetime and for some years after his death. The history of the period is pictured for us in vivid colours in that *journal intime* which Gui Patin kept up with his friends, Spohn and Falkconet of Lyons and the Belins (*père et fils*). With all his faults, particularly his scandalous lack of charity, one cannot but feel the keenest sympathy with this dear old man. Devoted to his saints, Hippocrates and Galen, Fernel and Duret, and to his teachers, Piètre and Riolan, to him the circulation of the blood was never more than an ingenious paradox. To such a lover of books and of good literature everything can be forgiven, and in his letters we follow with deepest interest his vigorous campaign against his dear enemies, the *Cuisiniers Arabesques*, who had enslaved people and physicians alike, the haemophobes, the chemists, the astrologers and the *stibiate*, or as he calls it, the *Stygiate* group. To him the Koran was less dangerous than the works of Paracelsus, the appearance of the new Geneva edition of which he deeply deplores. Reverence for Galen and friendship with Riolan, rather than any deep interest in the question, inspired his opposition. To him the new doctrine was ridiculous, and it was he who called the partisans of it *circulateurs* in allusion to the Latin word, *circulator*, meaning charlatan. In 1652 he writes to Spohn that the question is still open whether the blood passes through the septum of the heart or through the lungs. In 1659 he promises to send him a work of Vineau against the circulation. More extraordinary still is the fact that as late as 1670, twelve years after Harvey's death, the thesis of one Cordelle, a bachelor of medicine, publicly discussed the circulation of the blood, and Gui Patin, who presided, decided in the negative. The fiction of an ingenious narrator, *le doux songe*

of Harvey, are the terms in which he speaks of it. The whole passage is worth quoting as possibly the last public denouncement of what seemed a rank heresy to the old Galenists: "Supposer que le sang se meut toujours circulairement, que de la veine cava ascendante il tombe dans l'oreillette droit du cœur, que de là il aille traverser toute la substance du poumon pour retomber de là dans l'oreillette gauche en passant par la veine pulmonaire, et qu'enfin de là il soit projeté dans l'aorte et toutes les artères qui le feront passer dans les veines, et dans le cœur, lui faisant par ce moyen suivre un circuit, voilà le doux songe de Harvey, la fiction d'un narrateur ingénieux, mais nullement prouvée par l'évidence. La circulation du sang, son transport circulaire par les vaisseaux, c'est l'enfantement d'un esprit oisif, un vrai nuage qu'embrassent les Ixions pour procréer les Centaures et les monstres."

As I said, we can forgive a great deal to the man who has left us such a picture of seventeenth-century life, drawn, all unconsciously, with a master hand; and through the mists of prejudice and hate we can recognize the good sense which had the courage to protest against the *forfanterie Arabesque et héraodesque* in much of the therapeutics of the day.

Though a professor in the Paris Faculty and a brilliant lecturer, Patin at that time did not occupy such a distinguished position, nor was his opposition of such importance as that of Riolan—"John Riolan, the Son, the most experienced Physician in the Université de Paris, the Prince of Dissection of Bodies, and the King's professor, and Dean of Anatomie and of the knowledge of simples, chief physician to the queen-mother of Louis XIII"—as he is quaintly, but very truly, described by Harvey. Brought up by his father to regard Hippocrates and Galen as the sources of all wisdom, the intensity of his zeal increased with his years until at last "to see the physic of Galen kept in good repair" became the passion of his life. The deep pity of it all is that such mental blindness should have stricken a really great man, for he was a brilliant anatomist and teacher, the author of the best anatomical textbook of its day, a man of affairs, profoundly versed in literature, a successful practitioner, and for years the head of the profession in France.

The opposition of such a man was serious, and naturally had a profound influence. Not content with the comparatively brief statement in the *Encheiridion*, 1648, Riolan published in England the following year his *Opuscula Anatomica nova*, one very large section of which is taken up with the problem of circulation. It was this probably as much as a present of the *Encheiridion* that induced Harvey to break his long silence and to reply. After a report of a discussion upon a thesis in 1645 and a statement of objections, a most interesting discussion follows the literature, in which the opinions of various writers are examined, particularly those of Cartesius, Conringius, Wallaeus, and Plempius.

It is quite possible that the second *Disquisition* of Harvey to Riolan, published with the first in duodecimo form at Cambridge in 1649, was brought out by Riolan's latter publication, though it is not directly referred to. Little did Harvey appreciate that his old friend was both blind and deaf—incapable of seeing obvious facts. It was not a question of being conversant with anatomy or of having had experience, on both of which points Harvey dwells at length. Riolan knew his anatomy as well as, or better than, any man of his generation. It was not that he would not—but that he could not—see the truth which was staring him in the face. As Raynaud mentions, an occasional thesis (Fagon, 1663; Mattol, 1665) supporting the circulation did slip through the Faculty; but the official recognition in France did not come until 1673, when Louis XIV founded a special Chair of Anatomy at the Jardin des Plantes for the propagation of the new discoveries.

The satire of Molière and the *Arrêt Burlesque* of Boileau completed the discomfiture of the "anticirculateurs," but it had taken nearly half a century to overcome the opposition of those who saw in the new doctrines the complete destruction of the ancient system of medicine.

IV

Even when full grown in the conscious stage Truth may remain sterile without influence or progress upon any aspects of human activity. One of the most remarkable of phenomena in mental biography is the failure of the Greeks to succeed after giving the world such a glorious start. They had every essential for permanent success: scientific imagination, keen powers of observation; and if in the days of Hippocrates the mathematical method of interrogating Nature prevailed rather than the experimental, Galen carried the latter to a degree of perfection never again reached until the time of Harvey. Only when placed in its true position in relation to Greek religion and philosophy, as has been done so skilfully by Gomperz,* do we realize the immensity of the debt we owe to those "our young light-hearted masters." And Gomperz makes clear the nature of the debt of Greek thought to the practical sense of the physicians. But alas! upon the fires they kindled were poured the dust and ashes of contending philosophies, and neither the men of the Alexandrian school nor the brilliant labours of the most encyclopaedic mind that has ever been given to medicine sufficed to replenish them. Fortunately, here and there amid the embers of the Middle Ages glowed the coals from which we have lighted the fires of modern progress. The special distinction which divides modern from ancient science is its fruitful application to human needs—not that this was unknown to the Greeks; but the practical recognition of the laws of life and matter has in the past century remade the world. In making knowledge effective we have succeeded where our masters failed. But this last and final stage, always of slow and painful consummation, is evolved directly from truths which cannot be translated into terms intelligible to ordinary minds. Newton's great work influenced neither the morals nor the manners of his age, nor was there any immediate tangible benefit that could be explained to the edification or appreciation of the "ordinary man" of his day; yet it set forward at a bound the human mind, as did such truths as were proclaimed by Copernicus, by Kepler, by Darwin, and others. In a less conspicuous manner Harvey's triumph was on the same high plane. There was nothing in it which could be converted immediately into practical benefit, nothing that even the Sydenhams of his day could take hold of and use. Not so much really in the demonstration of the fact of the circulation as in the demonstration of the method—the *inventum mirabile* sought for by Descartes, the *Novum Organum* of Bacon—lies the true merit of Harvey's work. While Bacon was thinking, Harvey was acting; and before Descartes had left his happy school at le Flèche Harvey was using *le nouvelle méthode*; and it is in this way that the *De Motu Cordis* marks the break of the modern spirit with the old traditions. No longer were men to rest content with careful observation and with accurate description; no longer were men to be content with finely spun theories and dreams, which "serve as a common subterfuge of ignorance"; but here for the first time a great physiological problem was approached from the experimental side by a man with a modern scientific mind, who could weigh evidence and not go beyond it, and who had the sense to let the conclusions emerge naturally but firmly from the observations. To the age of the hearer, in which men had heard, and heard only, had succeeded the age of the eye, in which men had seen and had been content only to see. But at last came the age of the hand—the thinking, devising, planning hand; the hand as an instrument of the mind, now reintroduced into the world in a modest little monograph of seventy-two pages, from which we may date the beginning of experimental medicine.

No great discovery in science is ever without a corresponding influence on medical thought, not always evident

*The three volumes of his *Greek Thinkers*, now in English dress, should be studied by every young man who wishes to get at the foundations of philosophy. The picturesque style of Professor Gomperz and his strong sympathy with science add greatly to the interest of the work.

at first, and apt to be characterized by the usual vagaries associated with human effort. Very marked in each generation has been the change wrought in the conceptions of disease and in its treatment by epoch-making discoveries as to the functions of the body. We ourselves are deeply involved to-day in toxins and antitoxins, in opsonins, tulases, and extracts, as a direct result of the researches in bacteriology and in internal secretion. There were sanguine souls in Harvey's day who lamented with Floyer that the discovery had not brought great and general innovations into the whole practice of physic. But had the old Lichfield physician lived he would have seen the rise of a school based directly upon the studies of Harvey and Santorini, the brilliant reasonings of Descartes, and the works of Bellini and Borelli. The mechanical school rose in its pride on solid foundations which appealed to practical men with singular force. Very soon that "beautiful epitome of creation," man, was "marked out like a spot of earth or a piece of timber with rules and compasses," and the medical terminology of the day became unintelligible to the older practitioners who could make nothing of the "wheels and pulley, wedges, levers, screws, cords, canals and cisterns, sieves and strainers," and they cracked their jokes on "angles, cylinders, celerity, percussion, resistance, and such-like terms which they said had no more to do with physic or the human body than a carpenter has in making Venice treacle or curing a fever." Once accepted, men had a feeling that so important a discovery must change all the usual conceptions of disease. As has been said before, Harvey tells that he had in preparation a *Practice of Medicine conformable to his Thesis of the Circulation of the Blood*, and it soon became customary to put in the title pages of works some reference to the new doctrine. Even Riolan's *Opuscula Anatomica* makes an allusion to it. Walaëus, a keen defender of Harvey, published in 1660 a little compendium of practice *ad circulationem sanguinis adornata*, but there is nothing in it to suggest any radical change in treatment. Rolfinck's *Dissertationes Anatomicae*, 1650, embracing the older and more recent views in medicine, are *ad circulationem accommodatae*, and even as late as 1690 the well-known anatomy of Dionis was *suivant la circulation*. With the loss of his work on the *Practice of Medicine* it is impossible to say whether Harvey's own practice was modified in any way. To part from the spirits and humours must have left his attitude of mind very sceptical, and that his "therapeutic way" was not admired (as Aubrey tells us) speaks for a change which may have set many against him. More important than any influence upon treatment was the irresistible change in the conceptions of disease caused by destruction of the doctrine of spirits and humours, which had prevailed from the days of Hippocrates. While Harvey, as he says, had in places to use the language of physiology, that is, the language of the day, he makes it very clear, particularly in the second letter to Riolan, that he will have none of the old doctrine to which the *De Motu Cordis* dealt the death blow.

[The Orator concluded with some general reflections on the College and its Fellows.]

"I remember he kept a pretty young wench to wayte on him, which I guesse he made use of for warmeth-sake as king David did . . .

"He was, as all the rest of the brothers, very cholerique; and in his young days wore a dagger (as the fashion then was) . . .

"He was not tall; but of the lowest stature, round faced, olivaster complexion; little eie, round, very black, full of spirit; his haire was black as a raven, but quite white 20 yeares before he dyed . . .

"He was much and often troubled with the gowte . . .

"He was hote-headed and his thoughts working would many times keepe him from sleepe; he told me that then his way was to rise out of his bed and walke about his chamber in his shirt till he was pretty coole . . .

"William Harvey." *Aubrey's "Brief Lives."* Oxford, 1898.

2. HARVEY, THE MAN AND THE PHYSICIAN

The Harveian Oration delivered before the Royal College of Physicians of London on St. Luke's Day, 1916

BY

Sir THOMAS BARLOW, Bt., K.C.V.O., M.D., F.R.S

[b. 4 Sept., 1845. d. 12 Jan., 1945]

After his introductory remarks the Orator said: We know that the young Harvey was a pupil at the King's School, Canterbury, from the age of 10 to 15, where we may well assume that he gained the foundations of that classical knowledge which stood him in such good stead throughout his life. It was there probably that he made his first acquaintance with Virgil, whose poetry fascinated him in his later life; is it possible that he may even have begun to read Aristotle, whose influence over him was probably greater than that of any other writer, ancient or modern?

But were there no other studies than the classics which laid hold of young Harvey in his schoolboy days?

Dr. Venn, the learned President of Caius College, Cambridge, has drawn my attention to the regulations of the scholarship which Harvey obtained and which enabled him to go from King's School, Canterbury, to Caius College for six years. It was founded in 1571 by Matthew Parker, Archbishop of Canterbury, who was an intimate friend of Dr. Caius, and it is not unlikely that Caius influenced Parker in framing the conditions under which it was given. The most interesting of these is the enactment that at the university the scholar shall be educated first in subjects that pertain to or are serviceable to medicine and then in subjects which actually constitute medicine itself. Such a regulation for a medical scholarship is very remarkable and Dr. Venn considers unique at that time.

Let us consider for a moment its bearing upon Harvey and his predilections. It is not unreasonable to assume that he had already determined to become a doctor. Are we justified in any further speculations?

We know that throughout his later life Harvey was not only devoted to comparative anatomy, but that he was a keen naturalist. Dr. Norman Moore points out that in Harvey's *Prelectiones* there are references to the anatomy of no less than eighty animals. His book on generation is a mine of observations on natural history. In his Continental travel with the Duke of Lennox he complains bitterly that there was scarcely a dog, crow, kite, raven, or any bird or anything to anatomize; and when he was travelling with Lord Arundel in Germany, on the testimony of Hollar the artist, he made frequent excursions in the woods, making observations on strange trees, plants, earths, and naturals, and caused some anxiety to Lord Arundel lest he should be waylaid or murdered.

This intense lifelong devotion to natural history is usually an inborn quality, and it is by no means unlikely that in Harvey's schoolboy days it was this strong predilection that justified the authorities in nominating him to what was practically a medical scholarship. Harvey's first term at Cambridge began in May, 1593, when we are told he was admitted to the scholars' table at Caius College. Dr. Caius had been gathered to his fathers twenty years before. Dr. Legge, whom he had appointed as his successor, was of Caius' way of thinking in his Roman proclivities, and there was a stormy time in the college for a while. There is no indication that Harvey

was drawn into this conflict, and it may have quieted down when he entered the college.

His tutor and surety was George Estey, who seems to have been a worthy parson and was appointed Hebrew lecturer the year after Harvey's entrance; but Harvey never refers to him.

Although Caius College had a medical reputation we find rather meagre evidence of systematic instruction in medical subjects, and this in spite of Dr. Caius having laid down certain definite plans for its maintenance. He had obtained a licence for the dissection of two bodies annually in the winter and for their decent burial. The church registers give evidence that bodies, chiefly of prisoners, were dissected. Demonstrations were given.

Dr. Venn, by reference to the *Exiit Book* and the *Computus Book* of the college, which give detailed entries respectively of the students' absences and the charges for their commons, has been so good as to furnish me with some interesting and suggestive information about Harvey's time at Cambridge. As these entries have an important bearing on the question of when Harvey left Cambridge and when he entered Padua I bespeak consideration of them. It is commonly stated that Harvey took his B.A. degree in 1597 and that he left Cambridge in 1598 and entered Padua in that same year. I think you will see that this is incorrect. He entered Padua in 1600.

The *Exiit Book*, which was made up half-yearly, shows that during the first three years there were no absences. This may mean that Harvey did not leave the college at all during this period or for such brief intervals as did not involve any deduction from the stipend of his scholarship. We have to remember that one month's absence for holiday was allowed by statute, and that could be taken at any time. The *Computus* or *Account Book* is consistent, for it shows that Harvey's stipend from his scholarship was very nearly sufficient to pay the cost of his commons.

But from 1596 to 1599 the *Exiit Book* shows repeated absences. It is clear from the dates that Harvey was away from college not less than sixteen months. Some of his absences were of two months' duration or more, and some of them a few days up to a fortnight, and from his own letter in Michaelmas, 1599, he evidently required at times a long period of convalescence. The accounts show that he only received a stipend for one quarter between Michaelmas, 1599, and Lady Day, 1600—so that his scholarship lapsed at Christmas, 1599.

We know that, like Sydenham, Harvey suffered at various times severely from gout. He complained very little of his ailments, and somewhere speaks of the help which his pathological and anatomical investigations gave him by rousing keen interest and making him forget his pains. I suggest that the absences during the last half of Harvey's time at Cambridge were probably due to attacks of gout.

Harvey took his Arts degree in 1597, but there are no details obtainable concerning it, nor about his work at

Cambridge after he had taken his degree. It is significant that there are no references in Harvey's works to his Cambridge life. His poor health and the limited facilities for anatomical study may have left this period as one which he would gladly pass by. There is a categorical statement in Aubrey's *Memoirs* that Harvey bequeathed the house in which he was born in Folkestone to Caius College, Cambridge, in spite of the protest of his brother Eliab. This has been quoted again and again, but, like many of Aubrey's statements, it is untrue. Harvey bequeathed nothing to Caius College.

We may take it, then, that following in the footsteps of Linacre and Caius and of other fellows of this college, Harvey went, in the year 1600, to Padua, and not in 1598. Now it is interesting to mention that an examination of the archives of Padua, made by the university authorities at Mr. D'Arcy Power's request, has failed to reveal any mention of Harvey before 1600. To quote from Mr. Power's admirable life of Harvey, there are entries which show that at the usual time of election—that is to say, on August 1st in the years 1600, 1601, and 1602—he was elected a member of the Council of the English nation in the Jurist University of Padua. This I take to have been a sort of Students' Association.

Those of you who have been to Padua will remember, in the university courtyard, the host of memorial tablets giving the arms and name and the nationality of centuries of alumni. Two in the lower cloister are alleged to pertain to Harvey. One of them is decayed and the inscription to Harvey. The other is well preserved, is undoubted, and gives 1600 as the date. This agrees with the data which I have given already.

The two most interesting things at the University of Padua are the great cathedra or wooden pulpit from which Galileo addressed his class in Harvey's time, and the anatomical theatre where Fabricius demonstrated his dissections to Harvey and his fellow students. They are not far apart.

There is a capital picture of the anatomical theatre in the charming book on Harvey written by Dr. Curtis of Columbia University and published last year. Dr. Curtis points out that the tiers are really standing places with rails in front to lean upon, which rise at a very steep angle from the central pit. The arrangement now in vogue, in fact, more resembles that in our hospitals, in which students stand and look down at the operations or at *post-mortem* demonstrations, than an ordinary anatomical lecture theatre. Dr. Curtis makes the suggestive remark that "the place looks fit to have been a nursery of object teachers, for it is too small to hold a pompous cathedra, and the veteran to whose Latin the young Englishman listened must have stood directly beside the dead body."

Before we follow Harvey's further career, let us pause for a moment to consider the intellectual atmosphere of Europe when he began his course at Padua.

There had been the great revival of classical learning, followed not only by the Reformation and the consolidation of the Protestant states, but by the Counter-reformation in the old Catholic countries. And there was a great ferment of free inquiry on philosophy, on the principles of government, on the polity of nations, the rights of the humbler folk, and the conduct of life. The creation and the dissemination also of our greatest literature was then in progress in our own country.

England, in spite of its insularity, always, I believe, the most tolerant and open-minded of European countries, welcomed to permanent posts many learned men from other lands. Continental travel attracted many of our countrymen, and English scholars sought illumination in those days far more in Italy than in Germany or even in France.

It concerns us most of all to ask what branch of natural science chiefly attracted educated men. I have already

referred to our president, William Gilbert, the inspirer of Galileo. Galileo had been lecturing six years at Padua before Harvey went there. But we must bear in mind that, though he had many ardent disciples both in Padua and Florence, yet he had to encounter formidable opposition as well as persecution, and both his discoveries and his doctrines were a long time in gaining acceptance. Harvey himself seems always somewhat timid about the findings of astronomy, and regards them as unprovable. Astrology was still widely accepted.

Robert Boyle was not born till 1627, and the work of Torricelli and of Pascal was yet to come. The Royal Society held a few informal meetings in 1645, but did not receive its charter till 1662.

Thus, although at the end of Harvey's life physics had made great advances, at the time of which we now speak—namely, 1600—it was by no means a popular science. The chemistry of that time was dominated by unverifiable hypotheses, and it is quite what we should have expected that Harvey, according to Aubrey's statement, undervalued its exponents, and spoke against it. It was much too vague and nebulous to suit Harvey.

We have, then, to turn from the physical to the biological sciences. The subject which not only engaged the energies of some of the greatest men of that generation, but also attracted the interest of educated people, was human anatomy. Italy was the Mecca of anatomical students. At Padua itself there was a great tradition, for Vesalius, Fallopius, and Fabricius formed a brilliant succession of teachers. Dr. Caius, as we know, had not only studied with Vesalius, but had lived in the same house with him.

But with regard to human anatomy as a subject of interest amongst educated people, let me quote a sentence or two from Evelyn's *Diary*, though they relate to a time a little later than this particular date. During the troublous years immediately preceding the Commonwealth, Evelyn travelled on the Continent. Whilst at Padua he took out a short course of anatomy and physics. During a month he tells us that he saw a man, a woman, and a child dissected by Veslingius, the anatomical professor, with all the manual operations of the surgeon on the human body. He also purchased from Veslingius's assistant some rare tables of veins and nerves, and gave orders for a third to be prepared of the lungs, liver, and nervi sexti par, and the gastric veins, which he sent to England and ultimately presented to the Royal Society. But before that presentation was actually made we find that Sir Charles Scarborough, who succeeded Harvey as Lumleian lecturer, induced Evelyn to lend them for a time to our College for his own lectures. Scarborough had been unable to induce Evelyn to present them to our College. They were given by the Royal Society to the British Museum and by the British Museum to the Hunterian Collection, and are now in the Royal College of Surgeons Museum. These tables are similar to those six preparations which were given to this College in 1823 by the Earl of Winchelsea. They were said to have been inherited from Harvey, and to have been used by Harvey at his lectures. That, I think, is more than doubtful.*

Thomas Hobbes, the philosopher, dissected many brains, and with his friend the many-sided physician William Petty, and at a later period Robert Boyle also dissected in Ireland under the same friendly guidance.

Descartes studied human anatomy, dissected many brains, and repeated Harvey's experiments on the circulation for himself. The Port Royalists, following Descartes's lead, repeated many vivisection experiments on the circulation.

*I suggest for consideration whether these tables may have come into the Winchelsea family not through Harvey, but possibly through Sir John Finch (the son of Sir Heneage Finch) who was M.D. of Padua, and not only English Consul there, but was a fellow of our College in 1660, and seems to have had for an anatomical pupil one Marchetti, who made "tables of veins, nerves, and arteries, five times more exact than are described in any author." Vide Dr. Edward Browne's letter to Sir Thomas Browne. *Sir Thomas Browne's Works*, vol. i, p. 91.

Fra Paolo Sarpi, the ecclesiastical statesman and adviser of the Venetian Republic, seems to have found time and opportunity to study anatomy to considerable purpose and even to make observations on the valves in veins. He was probably in touch with Fabricius, and we know that Padua partly depended on Venice for some of its anatomical material.

Charles I took the greatest interest in anatomy and in the numerous demonstrations, not only on the circulation of the blood but on embryology, which Harvey gave him from time to time.

But it is important to note that although the great Italian anatomists had made enormous strides in the study of structure their knowledge of function was lamentably small—in other words, physiology had not kept pace with anatomy. It has indeed been affirmed that physiology had not advanced since the time of Galen, and doubtless its inadequate progress was partly the consequence of the prevailing ignorance of physics and chemistry. But in the evolution of knowledge and of method the disproportionate study of human anatomy on its structural side must be credited with the development of observation, and so far it was a big step in the long and bitter struggle against the trammels of authority.

That was the beginning of a momentous epoch in the history of human knowledge when, on St. Luke's Day, 1600, a young Englishman, aged 22 years, rather under the average height, with raven hair, dark piercing eyes, rather sallow complexion, and with a keen restless demeanour and rapid speech, enrolled himself amongst the pupils of the learned, laborious, and generous Fabricius. What was Harvey's exact attainment at this time in the details of anatomy and the technique of dissection we have no means of knowing. But we have reason to believe that even then he was by no means ill equipped with ancient learning; we know that he was a keen and accurate observer and an enthusiastic naturalist, and that he had a mind reflective as to the causes and relations of things, fertile in recognizing resemblances, and, above all, ready in making working hypotheses and in devising experiments which would more or less verify those hypotheses. It was in these latter qualities that Harvey's supremacy over his teachers and predecessors ultimately became so manifest. The addition of experiment to observation was vital and far reaching. The exact relationship between teacher and pupil we do not know, but it must have been very intimate, as proved by all Harvey's references to Fabricius, not only in respect to the organs of circulation but also in respect to his observations and speculations on generation. These references are not merely respectful but reverent.

From the time when Vesalius described the valves of the heart the Italian anatomists had been keenly exercised on the valves in various parts of the vascular system, and Fabricius's discovery of the valves of the veins was as far back as 1574. But the scientific use of the imagination seems to have been dormant with these clever observers, and they were singularly inept in explaining the mechanism of the valves. Sir William Osler suggests that it was reflection on the mechanism of the valves of the veins which at this early period of his career set Harvey on the right track in his great discovery, and there is a remark of Harvey's friend Robert Boyle which is not inconsistent with that suggestion. Boyle says that Harvey's observations on "contrivances similar to the valves used in hydraulic engines for preventing counter currents led to his discovery of the circulation of the blood." Whether Boyle's remark refers to the period of study at Padua or not, it is certain from the terms of his diploma in our possession that Harvey enormously impressed his teachers and examiners with his knowledge and ability.

Harvey returned home in 1602, and after his incorporation as Doctor of Medicine at Cambridge he came to our College and submitted himself to examination as a "can-

didate," which title in those days I take to have been equivalent to our present designation of member.

Dr. Norman Moore has found, by consulting the *Annals*, that Harvey was examined no less than four separate times between May, 1603, and August 4th, 1604, although he satisfied his examiners on each occasion. Moreover, of his contemporary candidates he was the last to be elected to the fellowship—namely, on May 16th, 1607, he being then 29. Whether in that early period of his connexion with this College he had any opponents we have no other means of ascertaining, but he seems to have had the support of the president, Dr. Atkins, when he applied for the post equivalent to what we should now call assistant physician at St. Bartholomew's Hospital, and especially that of Dr. Wilkinson, whom he assisted and after his death succeeded.

In the literature about Harvey there is nothing more interesting than Sir James Paget's records, drawn from the *Annals* of St. Bartholomew's Hospital. The relations between the governors and Harvey are altogether honourable and creditable to both sides. I will only refer to the revised hospital regulations submitted by Harvey in 1633 and adopted. These rules show that in general medical policy Harvey was a strong conservative, and that he stoutly maintained the then existing supremacy of physicians over surgeons. The surgeon was not only obliged to consult the physician in all difficult cases, and whenever inward physic was required, but he was not to be allowed to perform any major operation without the approbation and the direction of the physician. The surgeon was not only forbidden to give inward physic, but was required to declare to the physician what external remedies he applied in any given case. The surgeon had to attend the physician in his weekly consultations in the great hall to which the patients were brought, and where both matron and apothecary attended. In those days the surgeons had to visit their patients in the wards, and the physician as a rule only went to the wards when his patients could not be brought to the hall where most of the medical work was done.

During the thirty-six years, with certain intervals, that Harvey was connected with St. Bartholomew's Hospital he must have seen a great deal of disease amongst the London poor. But his post of Court physician, first to James I and subsequently to Charles I, led to his having a considerable clientele amongst the well-to-do. We know that some of the most eminent men of the time were his patients. Aubrey disparages his "therapeutic way," and maintains that although he was a great anatomist he was not much of a physician, and that after his great discovery was fully announced his practice waned. Aubrey is a very inaccurate person, but this statement may have some truth in it. It is interesting to realize that the philistine is the same in every generation in his estimates of the merits of medical practitioners as in other estimates. If a doctor proves his greatness by some purely scientific discovery which has no immediate practical application, if he distinguishes himself in literature or art, the philistine shrugs his shoulders and says that is all very well, but that such a man should be a good practitioner is impossible. Let us, then, consider some of the evidences derived from Harvey's writings bearing on the subject of his clinical experience.

In his first disquisition to Riolanus, Harvey refers to his unpublished MS. on medical anatomy or anatomy in its relation to medicine. This MS., then in Harvey's possession, has alas! been lost, but it may yet be found. But his own references to this MS. are very relevant to our inquiry. In alluding to its contents Harvey says he "desires to relate from the many dissections of the bodies of persons diseased, worn out by serious and strange affections, how and in what way the internal organs were changed in their situation, size, structure, figure, consistency, and other sensible qualities from their natural forms and appearances, and in what various and remarkable ways they were affected." I quote this long sentence because it

embodies Harvey's ideal of the morbid anatomist and shows that he belonged to the truth faith—namely, that the best physicians are first of all good morbid anatomists. In this letter his illustrations are, as might be expected, chiefly drawn from the diseases of the circulatory system; he gives interesting references to aneurysms, apoplexies, and calcified arteries. In more than one place he refers to the small radial pulse on the distal side of an aneurysm of the neck. He recognized that empyema might ulcerate into the lung and discharge through the bronchi.

In his work on generation, which contains many clinical illustrations, there is a careful analytical description of the case of Lord Montgomery's son, who had an exposed heart, left bare after a severe suppurating injury to the chest, and his report of the *post-mortem* examination of Thomas Parr is a sample of the thorough way in which he made his autopsies.

In his second letter to Riolanus he shows how wide was his acquaintance with local disturbances of circulation, which he had discussed at length in the lost Medical Observations. There was one disease common in his contemporaries, and of which he had abundant experience in his own person—namely, gout. Whether he was permanently crippled is, I think, doubtful, but that he suffered severe pain, especially in his lower limbs, is quite certain. Heberden sneers at the methods which Harvey adopted to relieve what we may probably regard as attacks of localized gouty hyperaemia. But Harvey's plan of plunging his feet into a pail of cold water seems to have been justified by the results, and Heberden has the candour to admit that he lived till he was over 80 and does not appear to have died from gout, but from old age. This mode of treatment shows not only Harvey's courage, but his independence of conventional dogmas. In our own times we have learnt that the local application of cold in febrile and hyperaemic states is not the dangerous thing it was once supposed to be.

In Harvey's *Praelectiones* there are many clinical observations introduced by way of illustration. In his valuable introduction Dr. Norman Moore points out that Harvey was "familiar with scarlatinal desquamation; he had noted the enlarged liver in those who died after long suppuration, and the shrunken liver in cirrhosis." "The varying appearances of gall stones and the common shape of large renal calculi were well known to him, and he describes pericarditis and its symptoms from his own observation." It is quite true that Harvey says very little about drugs in any of his memoirs. That is not exceptional in physicians who are distinguished as morbid anatomists. One would like to believe that when the apothecaries of that time disparaged his "bills" (as prescriptions were then called), they may have been too short and too simple to please the apothecaries. There is a report on the case of Prince Maurice when Harvey was with the King at Oxford, in which it is stated about Harvey and his colleague, Edmund Smith, that the "doctors do resolve to give very little physic, only a regular dyett and cordyall antidotes." It is significantly added that Prince Maurice did well.

But I think I have noticed occasionally that when a morbid anatomist ventures into the realm of therapeutics he may show an immense confidence in some particular preparation, and it is not altogether an exceptional incident that in a letter to his friend Hamey, which we possess, concerning the ailment of a poor woman in whom they were both interested, Harvey extolled the therapeutic value of the heel bone of the deer. Perhaps he had found it a useful way of administering phosphate of lime. But whether he gave many drugs or few, Harvey had confidence in the relief or removal of pain by "the detraction of blood, the application of cupping glasses, or the compression of an artery which leads to a part." He also used cupping glasses for the relief of asthma.

In his work on generation Harvey shows practical acquaintance with both midwifery and gynaecology. He recognized the dangers of retained secretions in the body of the uterus and showed courage and decision in dilating the cervix, and

in some cases in the employment of intrauterine injections. He had carefully studied cancer of the uterus, and I commend to my gynaecological brethren a remark which shows Harvey's shrewdness. Speaking of certain uterine troubles he says: "Women are peculiarly liable to these accidents, especially those among them who lead a luxurious life or whose health is naturally weak and who easily fall into disorders. Countrywomen and those accustomed to a life of labour do not become dangerously ill on such small grounds."

But Harvey was not unacquainted with the surgery of his day. In this same mine of clinical experience—the work on generation—will be found reference to cases of large sarcoceles, the treatment of which he had initiated by tying the afferent artery so as to limit the blood supply. He subsequently removed the tumour by extirpation with the knife or the searing iron.

Perhaps Harvey's conservatism as regards the relative status in his time of physicians and surgeons and his daring to have an independent opinion on surgical cases and even performing some operations (for in his will he left his surgical instruments to his friend Scarborough) may have roused the antipathy of the Barbers' and Surgeons' Company. At all events, they endeavoured to convict him of ill practice in the case of an alleged fracture of the skull. There was no allegation of operation on his part, but only of erroneous opinion. But I do not gather that the Barbers' and Surgeons' Company supported their condemnation by any *post-mortem* evidence. I think we may rest content that our Harvey, who was universally admitted to be a great anatomist and naturalist, was also an experienced pathologist, a learned physician, and that he had the qualifications of a good all-round practitioner.

Harvey's Court duties were by no means strictly limited to medicine. As physician to the Court he was instructed to take two long and important Continental journeys. The first of these was in 1630, when he accompanied the young Duke of Lennox on a rather prolonged tour in which he was obliged to dodge the plague on several occasions and was greatly impressed with the impoverishment of the countries through which they travelled. The second Continental journey made at the Royal command was in 1636 when Harvey accompanied Thomas Earl of Arundel, the Lord High Marshal, on an embassy to Vienna and Ratisbon which was mainly concerned with efforts to secure the restoration of the King's nephew, the young Prince Palatine, to his proper status. About three years ago I had the good fortune to secure for this College eleven of Harvey's letters referring to a painful episode of this particular journey. Harvey's writing is very hard to read. It is the writing of a man of terse expression and who had no time to waste. The contractions are appalling. These letters are not quite so difficult as the few others which are extant, and they show that when he took pains he could make a tolerable script as well as express himself forcibly. They were written to Harvey's friend, Basil Lord Feilding, the eldest son of Lord Denbigh. Feilding was English Ambassador at Venice, and, it would appear, had invited Harvey to visit him. Harvey looked forward to this visit with great delight. There exist in the Clarendon State Papers fairly complete reports of this embassy on the official side, forwarded by Lord Arundel and his staff. It may interest you to follow Harvey's steps on this journey. Lord Arundel's reports are addressed to Sir Francis Windebank, one of the Secretaries of State for Foreign Affairs. The first is from Utrecht, in which Arundel informs Windebank that he has left his son at Leyden suffering from a stomach attack, but under the care of Dr. Harvey. They soon rejoined the party, and we next hear from Arundel at Cologne, where he says he has been this evening "at the Jesuits' fair new church and college where they used me with all civility. I found in the college little Dr. Harvey who means to convert them."

I think it is more than likely that this polemic related, not to theology, but to Harvey's doctrine on the circulation, for at the next stage, Nuremberg, Harvey writes a very

courteous letter to Dr. Hoffmann, in which he tries to disabuse his mind of certain misconceptions, and offers to give him a demonstration of the circulation. This letter is included in Harvey's published works, and shows that along with his scrupulous courtesy he could usefully blend a little elegant sarcasm, for he begs Hoffmann, if he will not come to a demonstration or investigate by his own dissection, that he will not vilipend the industry of others nor charge it to them as a crime; "do not derogate," he says, "from the faith of an honest man not altogether foolish nor insane who has had experience in such matters for a long series of years."

The first and second of Harvey's letters to Lord Feilding relating to this journey were written from Lintz, to which the ambassador's party had gone on leaving Nuremberg. Here the first meeting with the Emperor Ferdinand took place. Harvey says he accompanied the Emperor on some hunting excursions. He speaks of him as a pious, good man, desirous of all love, quietness, peace, and justice! He refers to the impoverishment of the country by the thirty years' war and to the licence and oppression and anarchy which prevailed in Germany. Nevertheless they had joined in a feast given by the Count of Milan, "the chief Major Domo of his Majesty where they drunk hard and had many expressions and many good wishes." There are ominous references to the plague and the fear of it.

The next move is to Vienna, where Harvey sees the Queen of Hungary and praises her two fine little babies. Then they go to Ratisbon, where they have to await the assemblage of the Diet of the German Empire, which somewhat shadowy and dilatory body will have to discuss the questions respecting the young Prince Palatine's claims. From the Clarendon State papers we learn that everybody in Lord Arundel's mission was excessively tired by the long delay. Harvey seems to have been terribly bored, and to have besought Lord Arundel to let him go to Italy during the vacancy, as he styles the waiting time. In one of the Clarendon dispatches there is a reference to "honest little Harvey, whom the Earl is sending to Italy about some pictures for His Majesty." This opens up a very interesting little bypath upon which other correspondence of Lord Feilding's throws additional light. Lord Arundel, as we know, was one of the great English virtuosos of that day, and was the first to collect objects of art from Italy and elsewhere. His name is chiefly associated with the collection of Greek and Roman marbles which was ultimately secured for the University of Oxford by the mediatory efforts of John Evelyn. But he was a collector of pictures also. In some of the Feilding letters there are references to the pictures which at various times Feilding acquired for the King's collection, and the Marquis of Hamilton writes to Feilding on the same subject, in which he delicately hints that Lord Arundel might take the opportunity of feathering his own nest, and that he might even forestall Feilding in some of his bargains.

At all events, the invitation to Harvey to visit Lord Feilding at Venice may well have led to the extemporized mission which was entrusted to Harvey by Lord Arundel. But poor Harvey little dreamed of what was in store for him. He doubtless left Ratisbon in high spirits at his escape from the weary diplomatic tedium so trying to his active spirit. He was armed with visé to his passport and commendatory letters, but when, having crossed the boundary of the Venetian territory, he arrived at Treviso, he writes to Lord Feilding that he was unjustly affronted, being stayed and commanded by the podestà to go into the lazaretto without any cause or suspicion alleged. It is clear that they were terribly and perhaps unreasonably afraid of the plague. Harvey produced his visé passport and recommendations from the King of Great Britain, from the Emperor, and from Lord Arundel, but the podestà would not look at them. Harvey refused to go to the lazaretto for fear of the infected persons who had been sent there before, and elected to stay in the open fields. He scribbles his letter on the grass in the field,

and begs Lord Feilding to procure his release with all expedition. He seems to have subsequently arranged to sleep in a poor open garden house and to lie upon straw, but was by force and threatening of muskets compelled to go into the lazaretto, into a very nasty room, where the vetturin and his two servants and saddles lay!

The podestà, probably as the result of Lord Feilding's complaint, in three days' time sent a coach offering to take Harvey back to the poor garden house (where he had been before). Harvey did not conceal his irritation, and indignantly refused to accept anything whatever from the town authorities, least of all a bed which he believed would have been an infected one, so he elects to sleep on straw. Subsequently the Senate of Venice sent him a message that he must stay where he was till further orders, without specifying the time. Meanwhile poor Harvey, having bad food and great exposure, had contracted sciatica. He seems to have been kept between a fortnight and three weeks, but we do not know the exact date or method of his release. He sent on his letters to Lord Feilding, and though he did not stay long in Venice he seems to have had a good time there, and then he went to Florence, where he enjoyed the hospitality of the Grand Duke, who lavished everything upon him that heart could wish.

Harvey's last letter to Lord Feilding was to announce his return to Ratisbon in November so as to be ready to accompany Lord Arundel on his return to England, his mission having turned out rather a fiasco. It has hitherto escaped notice, but I find in the Clarendon Papers a letter from Sir John Borough in which it is stated that they were aware at Ratisbon that Dr. Harvey had been kept in quarantine at Treviso, "being not as yet, for aught we hear, released." His return to Ratisbon may have been somewhat surprising. A perusal of Harvey's letters and of the State Papers gives us a poor opinion of the estimation in which Englishmen were held in Charles I's time in foreign lands, and we may be sure that Cromwell would not have brooked such scant consideration to any English subject during his rule.

Between the time of Harvey's leaving Florence and going back to Ratisbon we must, I think, intercalate his visit to Rome, where, under the hospitable roof of the English College, he dined with one who became a very staunch friend. This was Dr. Ent, who, in the evening of Harvey's life, secured for publication his work on generation. The alleged visit to Rome with Dr. Ent which Aubrey mentions has been shown by Dr. Munk to be one of his many inaccuracies. The joint visit was the one just mentioned; it was in October, 1636. Harvey was back in London at the end of the year. He doubtless made other visits to Italy, and probably to Padua.

As Court physician, Harvey accompanied the King for his Scottish coronation. It is eminently characteristic that the chief interest for Harvey was not the ceremony, nor the theological disputes, but his own visit to the Bass Rock in order to find out some points with regard to the solan goose, which then, as now, congregated on that island in great numbers. He probably also accompanied the King in his abortive warlike journey to Berwick in 1639, and perhaps again in 1640, but there do not appear to have been any important questions of natural history to be solved in those journeys, and I find no reference to them in Harvey's papers. The clouds were gathering for the Civil War, and Harvey's official association with the king rendered him persona ingrata not only to the Parliamentarians in the House of Commons, who tried to oust him from St. Bartholomew's Hospital, but to a mob who sacked and plundered his official lodgings in Whitehall. It is somewhat piquant and characteristic that Harvey, referring to this outrage, says the cause of his sorrow is that certain rapacious hands "stripped not only my house of its furniture, but what is subject of far greater regret with me my enemies abstracted from my museum the fruits of many years of toil, . . . whence it has come to pass that many observations, particularly on the generation of insects, have perished, with detriment, I venture to say,

to the republic of letters." It has been assumed that Harvey's "Medical Observations" as well as some other papers were destroyed by this mob. But Sir George Paget has drawn attention to the fact that Harvey himself speaks of these same Medical Observations being in his possession at the time when he writes, many years afterwards, his first letter to Riolanus.

In regard to the historic incident of Harvey looking after the two young princes at the fringe of the battlefield of Edgehill, it is interesting to remember that his friend Lord Feilding had been removed from his ambassador's post at Venice and was fighting on the Parliamentary side, whilst the Earl of Denbigh (Lord Feilding's father) was fighting for the King. There must have been many of Harvey's friends on both sides of the great struggle, but it is noteworthy that throughout the four years, from 1642 to 1646, that Harvey was with the King at Oxford there is no evidence that he took any part in political affairs, and there is no report of any utterance of greater resentment than is expressed in the one just quoted concerning his natural history collection.

Nothing daunted by the limitations of his surroundings at Oxford he goes to visit his friend Bathurst at Trinity College and conducts with him daily observations on the development of the hen's egg. He was incorporated a Doctor of Medicine of Oxford, and during the last year was appointed Warden of Merton College. His brief opening address to the fellows, appealing to them to cultivate harmonious friendship amongst themselves and pledging himself for the development of the welfare of the College, is quite in harmony with Harvey's subsequent utterances at the College of Physicians. One interesting experience at Merton was his welcome to Scarborough, who had been expelled from his fellowship at Harvey's old college in Cambridge on account of his Royalist principles. Scarborough seems to have been not unnaturally interested in the lively military expeditions around Oxford of Prince Rupert and his fellow officers. Harvey said to him, "Prithee leave off thy gunning and stay here and I will bring thee to practice." He probably recognized Scarborough's mathematical abilities and foresaw a great future for him, and Scarborough is said to have helped Harvey in some of his investigations.

In Clarendon's *History of the Rebellion* some of the most attractive pages are the character sketches of the chief men on both sides, and it is significant that Harvey finds no place. Indeed there is not a single mention of him in the whole of the work. Clarendon seems not to have concerned himself, in writing his history, with a single person who took no active political or military part in the great struggle. It seems remarkable in view of Harvey's long personal devotion to Charles I, in prosperous as well as in adverse days, that when the surrender came he left him, and it is doubtful if he ever saw him again. But in fairness we must remember that after the surrender Charles's movements up and down the country were not under his own control, and very shortly the access of particular adherents and attendants was regulated and Harvey may not have been permitted to join him even if it were desired. At all events, he retired a saddened man of 68 to the quiet and rest provided him by his relatives in London and its neighbourhood, and his rich and influential merchant brothers may well have secured him protection in his retirement.

It is probable that from 1602 onwards Harvey was working at his subject, and from 1609, when he was formally elected physician to St. Bartholomew's Hospital, he must have gradually acquired a reputation as an anatomist as well as a physician. In 1615, being then 37, he was appointed Lumleian lecturer to this College, a post which he held, with certain inevitable absences, until 1656, the year before he died. The *Preelectiones*, which bear the date of 1616, are really the lecture notes for the first anatomical course which he delivered. His introduction, with its detailed categories of anatomical study, is interesting as a logical academic statement, but the practical instructions which Harvey laid down for his own guidance in method

seem to me the last word as to the proper objects and limits of oral teaching and demonstration, and are a model to be utilized by every medical teacher of our own time. The special value of this MS., which deals chiefly with the viscera, is that we have here Harvey's first account of the circulation of the blood, the full exposition of which he gave in his printed book in 1628. For these twelve years Harvey had expounded his doctrines to our predecessors, and it is significant that from within this College there was no criticism or opposition to the full acceptance of those doctrines, with the solitary exception of one licentiate, a certain Dr. Primrose, who was rather an abject pupil and follower of Riolanus, the anatomical professor at Paris. Harvey demolished the master Riolanus in the two disquisitions addressed to him, and the pupil needs no further consideration.

I need not dwell on Harvey's masterpiece, so brief, so terse, and so convincing, a model for all time of inductive reasoning. Let us never forget the two supreme doctrines which he established, and which neither his predecessors nor his contemporaries had understood: (1) The circulation of blood from heart through arteries and back through the veins to the heart again. The pulmonary circulation, it is true, had been more or less apprehended, but it was reserved to Harvey to establish the true nature of the systemic circulation and to give the *coup de grâce* to the ebb and flow movement of the blood current now this way, now that, which was the accepted explanation up to his time. (2) The muscular contraction of the ventricles, the real motive force of the circulation, which had been conspicuously ignored and misinterpreted previously.

It is quite true that Harvey's view of the respiratory function was inadequate. For him it was summed up in cooling and ventilation; he never thoroughly faced the difference between arterial and venous blood, and it is doubtful if the meaning of oxidation had taken any definite shape in his scheme of life. But the day of chemistry was not yet, though it was not far off, and it was impossible for him without the help of the microscope to bridge over the space between the arteries and the veins. How he would have leapt for joy if Malpighi had only demonstrated the existence of the capillaries within Harvey's lifetime!

What was Harvey's method? It is certain that he had a wide and thorough acquaintance with the work of his predecessors, but he differs from them all in the courage and independence with which he really begins his work by ascertaining by his own senses what are the anatomical facts untrammelled by the statements of authority. He follows up his human anatomy by comparative studies of the circulatory organs of every animal that he can obtain. Then he reflects on the simplest explanation of the anatomical mechanism before him. Finally he devises experiments, vivisectional and otherwise, to test and verify his hypotheses.

The question has been asked again and again, What was the relation between Bacon and Harvey? Bacon, in his *Novum Organum*, which was published in 1620, makes no reference to Harvey's discovery. Harvey's book appeared in 1628, and Bacon died in 1626, but one would have supposed that Bacon might have heard the account of Harvey's discovery during the four years which had elapsed since he first expounded it in the College. On the other hand, Sir Samuel Wilks is not, I think, correct when he says that Harvey had not read Bacon's works, and owed nothing to Bacon. In the twenty-fifth exercise of Harvey's book on generation there is a sentence in which he proposes to review and analyse some of his previous results, and he says: "Wherefore I think it advisable here to state what fruits may follow our industry, and, in the words of the learned Lord Verulam, to enter upon our second vintage." If Aubrey is to be credited, Harvey, "esteemed Bacon for his wit and style, but would not allow him to be a great philosopher." He writes philosophy like a Lord Chancellor. Harvey says, 'but I have cured him.' I think probably, in spite of Bacon's many-

sided enlightenment, Harvey looked upon him as an academic *littérateur* who had had no claims to eminence in practical investigation, and it may well be that Bacon's deep-rooted antagonism to Aristotle, which dated from the time when he was a student at the university, may have roused Harvey's distrust. "A man of genius lights his own fire," said John Foster, and in spite of all that has been said about every man's work being more or less dependent upon his environment and the heritage of the past, I do not think we are wrong in claiming that Harvey was a creative genius.

The work on generation has been spoken of as Harvey's aftermath, but in many ways it is more interesting than his *magnum opus* on the circulation, and I do not think it has received adequate appreciation from my distinguished predecessors. It tells us a great deal incidentally about the world experiences of a long and chequered career, and it shows Harvey to us on the speculative and contemplative side. The anatomical observations are of course circumscribed by the absence of microscopical methods, though it must be admitted that Harvey used such magnifying lenses as he possessed to some purpose. There are some erroneous conclusions, but not bad ones.

The introductions on the manner and order of acquiring knowledge and on the method of study are, I submit, masterpieces of lucid exposition. This work is interesting as showing Harvey's own estimate of his teachers. "Foremost of all among the ancients," he says, "I follow Aristotle; among the moderns Fabricius of Aquapendente, the former as my leader, the latter as my informant of the way. . . . For even as they who discover new lands and first set foot on foreign shores are wont to give them new names which mostly descend to posterity, so also do the discoverers of things, and with perfect propriety, give names to their discoveries. . . . And now I seem to hear Galen admonishing us that we should best agree about the things, and not dispute greatly the words."

But with all Harvey's reverence for Aristotle's philosophy, I believe he respected him most of all as a great naturalist and observer, and it is noteworthy that for him as well as for Fabricius and for Galen, his reverence never prevented Harvey from pointing out their blunders in anatomical observation as well as in the deductions drawn therefrom. For example, in his fourteenth exercise, Harvey goes so far as to suggest that in one point Aristotle had not himself seen things he described but received them secondhand from another observer, and that the periods were not given rightly.

As I have already indicated, from 1646 to 1657, his Court duties ended, his private practice relinquished, Harvey lived henceforward in retirement, first with one of his merchant brothers then with another in London or in the country near by. His brothers were substantial and influential people. In earlier years, when their father had left Kent and had come to live in London, Fuller tells us that "as the sons got great estates they made their father treasurer thereof, who, being as skilful to purchase land as they to gain money, kept employed and improved their gainings to their great advantage; so that he survived to be the meanest of them of far greater Estate than himself." In later years his brother Eliab looked after Harvey's money affairs, and he had no anxieties.

We know little of Harvey's married life, but I think it must have been a happy one. His wife was the daughter of a cultivated and eminent physician, Dr. Launcelot Browne. They were married at the very outset of Harvey's professional career, and the wife died probably during the time Harvey was with the King at Oxford. The references in Harvey's will to his dear deceased loving wife show his solicitude to perpetuate her wishes and his gracious desire that certain of his benefactions should be regarded as from her, though she had long since passed away, manifest his tender affection for her. It is clear that his sisters-in-law and all their respective households were unceasing in their care and solicitude, and the detailed and thoughtful remembrance in his will of all his relatives and their servants, and of many poor folk,

is very touching. He was childless, but his care for his nephews and nieces was very marked.

This College was the chief interest of his old age. Besides being Lumleian lecturer he had been at different periods censor, treasurer-elect, and finally, when he graciously declined the proffered presidency, councillor of the College.

It is interesting to think of the devotion and long duration of his friendships. In old days he had nominated Dr. Edmund Smith as his substitute at St. Bartholomew's. Edmund Smith was with Harvey at Oxford, and now when Harvey was building at his own expense the costly and beautiful addition to the College edifice it was Edmund Smith who really superintended the whole business for him and whose name at Harvey's desire, along with that of Dr. Prujean, the president, appeared on the commemorative inscription. I have referred to the brotherly attachment of Harvey, Ent, and Scarborough. Harvey's discoveries were at length warmly accepted by foreign universities and by foreign anatomists and scholars, notably by Siegel, Bartholin, and Descartes. Some of these foreign anatomists stoutly defended Harvey's doctrines against the few remaining obscurantists who were still in opposition. His friend Thomas Hobbes said that Harvey was the only man whom he knew that had lived to see his own doctrine established in his lifetime. Abraham Cowley's poetry is seldom read in these days, but his two poems on Harvey, based on intimate knowledge of the man and of his work, are full of genuine feeling and devotion. But the recognition most precious to him was the homage of his College. Fuller says of him he was not only Doctor Medicinæ but Doctor Medicorum. The homage of the College was shown during his lifetime by the erection of his statue. It was further shown by the large gathering of fellows who followed his remains beyond the city walls in the first part of his funeral. How many of them gathered round his tomb at Hempstead in Essex we do not know. The homage of his successors in this College was shown in 1883 by the reverent removal of his remains from the damaged outer vault where they lay, to a sarcophagus in the chapel above.

Whilst we of this generation render our homage to our great benefactor let us in a few words picture to ourselves the outstanding features of his work and character.

First observe his pursuit of truth for its own sake, even though a complete solution were not forthcoming and quite independently of any ulterior benefit that might ensue. His discovery was one of those which, in Bacon's phrase, might fairly be called "light bearing" rather than "fruit yielding."

Amongst the objections which Harvey had again and again to combat in his work on the circulation was the ever-recurring question, *Cui bono?* Listen to his reply:

I own I am of opinion that our first duty is to enquire whether the thing be or not, before asking wherefore it is. . . . Meantime I would only ask how many things we admit in physiology, pathology and therapeutics the causes of which are unknown to us? Whoever therefore sets himself in opposition to the circulation because if it be acknowledged he cannot account for a variety of medical opinions, nor in the treatment of diseases, give satisfactory reasons for the phenomena that appear or who regards it as in some sort criminal to call in question doctrines that have descended through a long succession of ages; to all of these I reply that the facts cognisable by the senses wait upon no opinions, and that the works of nature bow to no antiquity for indeed there is nothing either more ancient or of higher authority than nature.

With what labour (he says) do we attain to the hidden things of truth when we take the averments of our senses as the guide which God has given us for attaining to a knowledge of his works, avoiding that specious path on which the eyesight is dazzled with the brilliancy of mere reasoning, and so many are led to wrong conclusions to probabilities only and too frequently to sophistical conclusions on things.

The doctrine of "spirits" dominated the physics and the physiology of that time. Harvey says:

As it is still a question what they are, how extant in the body, of what consistency, whether separate and distinct from the blood and solids or mingled with these—upon each and all of

these points there are so many and such conflicting opinions that it is not wonderful that "the spirits" whose nature is thus left so wholly ambiguous should serve as the common subterfuge of ignorance.

Persons of limited information when they are at a loss to assign a cause for anything, commonly reply that it is done by the spirits, and so they bring the "spirits" into play upon all occasions even as indifferent poets are always thrusting the gods upon the stage as a means of unravelling the plot and bringing about the catastrophe.

Harvey's demolition of the doctrine of "spirits" marks an epoch in the history of science.

Long sentences were the fashion of the time, but Harvey makes his meaning plain. He was keenly alive to the bondage of names and phrases. He was anxious to get the *knowledge of things* and not greatly concerned about names. He maintains that our business is not so much to inquire what a word properly signifies as how it is commonly understood. His writings are lit up by quaint and homely similes, but they are free from the pedantry of his time. Sir Clifford Allbutt thinks he was lacking in imagination. Perhaps that is so, and I think the result is that although some of his conclusions are incomplete and inadequate they contain remarkably little that is erroneous.

And about his character: There is in the opening sentences of his will a humble and definite statement of his Christian faith, and in his book on generation he expresses his conviction of the immanence of God. "He takes," Harvey says, "the right and pious view of the matter who derives all generation from the same eternal and omnipotent Deity at whose nod the universe itself depends."

THE ASSESSMENT OF THE BRITISH VACCINE AGAINST POLIOMYELITIS

A REPORT TO THE MEDICAL RESEARCH COUNCIL BY ITS POLIOMYELITIS VACCINES COMMITTEE*

In April, 1955, the report of a large-scale controlled trial, carried out in the United States in 1954, showed that the attack rate of paralytic poliomyelitis in about 200,000 children given formalized virus vaccine was significantly reduced compared with that in an equal number of children given placebo injections (Poliomyelitis Vaccine Evaluation Center, 1955). The allocation of children to the two groups had been made at random and the observations had been conducted without the observers having any knowledge of the group to which a particular child belonged. In these children, aged mainly 6-9 years, the rate of paralytic disease in the vaccinated was only 28% of that in the placebo group—that is, the vaccine conferred an apparent protection of 72%. With the numbers involved it is unlikely— $P=0.05$ —that the real level was less than 61% protection. No significant protection was conferred against non-paralytic illness.

At the time this report was published manufacture of vaccine by similar methods, and incorporating the same three strains of virus, had already begun in this country. A small quantity of this vaccine had been used in tests of antigenicity in adult volunteers when reports were received of the occurrence of cases of poliomyelitis in the United States associated with some commercial batches of vaccine. Further use of formalized vaccine was therefore abandoned for the time in Great Britain. Subsequently the Medical Research Council's Com-

*The members of the committee are: Professor C. H. Stuart-Harris (chairman), Dr. T. Anderson, Dr. W. C. Cockburn, Dr. W. H. Bradley, Professor G. W. A. Dick, Dr. J. A. Dudgeon, Professor A. Bradford Hill, Dr. F. O. MacCallum, Dr. C. Metcalfe Brown, Dr. W. L. M. Perry, Dr. W. Ritchie Russell, Mr. H. J. Seddon, Professor E. T. C. Spooner, Dr. I. N. Sutherland, Dr. G. S. Wilson, and Dr. J. Knowelden (secretary).

Aubrey says that Harvey, like his brothers, was choleric. You may say that the Treviso letters support that assertion, but remember he had great provocation, and he was a gouty subject. At all events, his choleric temper did not interfere with his courtesy and modesty in controversy, nor with generous appreciation of the work of his contemporaries. Harvey's power of concentration and detachment in biological observation in adverse surroundings was amazing. He was patient and laborious in his investigations, and reluctant to make any premature announcement of his conclusions. He was content to wait the judgment of time and enlightenment. He grew more and more fond of contemplation and even of solitude at times, because it gave him greater opportunity for contemplation. His love of family and of friends has been already noted, and to this may fitly be added his unfailing kindness to young men and readiness to advise them as to travel and books, and his willingness to take trouble on their behalf.

The concluding parts of his last letters are very touching. The nearer he approaches the great divide the more he craves for the abiding remembrance and the affection of his correspondents. It is not only the old man eloquent, but the old man mellowed and gentle.

And now in these severe and strenuous days, when we trust that "the winter of our discontent" is soon to pass away, we recall once again the last exhortation of our great master. He bids us "ever to search out and study the secrets of Nature by way of experiment, and for the honour of our profession to continue mutual love and affection amongst ourselves."

mittee on Safety Tests of Poliomyelitis Vaccine recommended that vaccine distributed in this country should not contain the virulent type I Mahoney strain used in American vaccine and adopted up to that time elsewhere. By the winter of 1955-6 further batches of vaccine were in preparation by Glaxo Laboratories, using the less virulent Brunenders strain as the type I component, but the same type II (MEF-1) and type III (Saukett) strains incorporated in earlier batches here and in America.

The Poliomyelitis Vaccines Committee of the Medical Research Council, which had been reviewing the situation, considered that two questions regarding such vaccine needed answering urgently. It was important to know first of all whether the substitution of the Brunenders for the Mahoney strain had reduced the capacity of the vaccine to protect against type I infection. Secondly, the American field trials had given evidence of protection in children 6, 7, 8, and 9 years of age only, with a slight suggestion of less protection in the youngest of this group. It was therefore also important to know whether formalized vaccine would protect younger pre-school children, who have the highest rates of paralytic poliomyelitis in this country and are, possibly, subject to a different epidemiological background from that of American children. Consequently, when the Minister of Health and Secretary of State for Scotland announced in January, 1956, that a poliomyelitis vaccination programme was to be started in England, Wales, and Scotland, the Medical Research Council's Statistical Research Unit, acting on behalf of the Poliomyelitis Vaccines Committee, was invited to plan for an assessment of the protective effect of the vaccine that

was to be issued later in the year. Antigenicity tests of the vaccine in the laboratory and in children were an essential part of this assessment. These were carried out by other departments and have been reported elsewhere (Committee on Laboratory Investigations of Poliomyelitis of the Medical Research Council, 1957). This report describes the investigation to determine the protective effect against clinical poliomyelitis in children.

Plan of Investigation

The plan of this study was influenced by two factors. It was estimated that sufficient vaccine might be available to give 400,000 children two doses of 1 ml. spaced at an interval of at least three weeks before the end of June. After this vaccination would stop in view of the possible risk of provoking paralytic illness by intramuscular injections given in an epidemic period—or of appearing to do so at a time when many cases would naturally be occurring. To be reasonably certain of a clear answer to the assessment it was necessary to have at least 250,000 vaccinated children under observation, and an equal number of unvaccinated children, if the paralytic attack rate in the unvaccinated group was 20 per 100,000. Such a rate had been reached in most years since 1947, but occasionally a lower rate had occurred and might be repeated in the 1956 epidemic during which observations were to be made. It followed that the assessment had to cover the whole country, as the available vaccine, by the terms of the Health Departments' announcement, was to be offered to all local health authorities, and that the administrative procedure had to be simple and of general applicability. It was organized through the generous help of the Ministry of Health and Department of Health for Scotland. The second factor, arising from the distribution of vaccine to the whole country and from the scale of the investigation, was that it was impossible to adopt the ideal of a controlled trial in which children were randomized to two groups, one to receive vaccine and the other placebo injections. It was, however, anticipated that the demand for vaccine would be in excess of the supply. If this were so it was intended to compare the incidence of poliomyelitis in those who received vaccine with the incidence in those who wanted it but for whom none was then available. As a form of random allocation the selection of children to be vaccinated was to be made according to the month of birth.

The Numbers Vaccinated

All but two of the local health authorities in England, Wales, and Scotland took part in the scheme. In January, February, and March, 1956, parents of children born in the years 1947 to 1954 were invited to register them for vaccination on the understanding that if there was insufficient vaccine for all before the summer they would be the first to be vaccinated when further supplies became available. Local health authorities sent returns to the Statistical Research Unit by mid-April of the numbers of children registered, dividing them by their year and the month of birth and by sex. Altogether, 1,910,093 children were registered, about 30% of the estimated total of 6,266,000 in this age group, roughly 1-9 years. The proportion of available children registered was greater in the school than in the pre-school years. After taking into account likely supplies of vaccine, then estimated to be about 400 litres, the months of birth selected for children who were to be vaccinated were November for those born in 1947-50 and March and November for those born in 1951-4. This allocation gave 95,723 children aged 5½ to 9½ and 98,687 children aged 1½ to 5½ eligible for vaccination. As a reserve for any excess vaccine that could not be used in these children, August was nominated for all years of birth. It had been anticipated that one or two other months of birth would also be selected for vaccination, but the limited supplies of vaccine available made this impossible.

Vaccination was carried out by local authorities in their clinics from early May to the end of June. Returns of the numbers given one and two injections were then furnished by local health authorities to the Statistical Research Unit. In total, 178,161 children were given two injections and 32,379 received one only.

Local Reactions to Vaccination

A total of 2,291 children in the counties of Buckinghamshire and London, and the county boroughs of Manchester and Sheffield, were visited the day after receiving their injections to determine the degree of any immediate reaction to vaccination. Taking children of all ages and of both sexes together, the proportions showing some degree of local reaction to the first injection were as follows: Buckinghamshire 7%, London 15%, Manchester 4%, and Sheffield 9%. In each area the corresponding proportions after the second injection were less, being 2, 13, 1, and 7% respectively. Most of these reactions were redness at the site of injection of less than ½ in. (1.3 cm.) diameter without swelling, and it is understandable that there should be considerable variability from area to area in the frequency of recording such minor conditions. First injections were accompanied by some degree of malaise, usually of minor degree, in about 2-3% of children, these proportions being fairly constant from area to area. After second injections those with malaise were less than 2% of those visited in each area.

The local reactions thus recorded seem to have been mild.

Examination of the Urine from Vaccinated Children

Arrangements were made for the examination of urine from a sample of vaccinated children in Sheffield, Glasgow, and Dundee.

Sheffield.—Thirty-seven children, some of whom had polio antibodies before inoculation, were included in this special investigation. During the first 15 days after the first inoculation 239 specimens of urine were examined from these children. During the 15 days after the second injection 176 specimens of urine were tested from 30 of them. In general, the urine tests were carried out at intervals of two days during the period following each inoculation.

In no instance was any albuminuria or haematuria encountered. A few hyaline casts appeared in the occasional specimen, and also leucocytes. In no case were these considered to be in excess of the normal. No attempt was made to carry out Addis counts.

Glasgow.—Fourteen children submitted 63 specimens of urine before and after the first or second inoculation of polio vaccine. Apart from one child with a symptomless urinary infection (discovered in the first specimen) no abnormality was found.

Dundee.—Seven children submitted 98 specimens after the first inoculation. One showed a very few red cells on the 10th day; one showed occasional leucocytes (3/4 per high-power field from the 6th to the 14th day). There was no other abnormality. Six of these same children submitted 84 specimens after the second inoculation, and all were normal.

Illnesses in Vaccinated Children, Possibly Related to the Injections

In letters sent in April, 1956, to medical officers of health and hospital clinicians in England, Wales, and Scotland outlining the scheme of investigation a request was made that they should report any illness in a vaccinated child which, in their opinion, might be related to the inoculation. As a result reports were received of six children who developed illnesses shortly after vaccination. These are described below:

1. A boy aged 4 years developed meningism and fever two days after his first injection. The C.S.F. findings were normal,

but culture of a throat swab grew β -haemolytic streptococci. Recovery was complete.

2 and 3. From one area two boys were reported to have had fever, one up to 104° F. (40° C.), following their first doses of vaccine. No other abnormalities were detected and they recovered completely.

4. A boy aged 3 years developed convulsions and meningism 10 days after his first injection. *Salm. typhimurium*, but no virus, was isolated from the stools.

5. A boy aged 18 months developed convulsions and hyperpyrexia 24 hours after vaccination. The C.S.F. was normal and no virus was isolated from the stools. The child made a gradual recovery, but was left with a left-sided hemiplegia. Six months later he was walking and had very little residual weakness. The clinician concerned regarded the incident as coincidental and in no way connected with the vaccination.

6. A boy aged 18 months developed nephrosis four days after his second injection. In the opinion of the paediatrician the illness was merely coincidental. Diuresis and complete recovery followed treatment with prednisolone.

In none of the six children could the illness be related definitely to the preceding injections on clinical or laboratory grounds. When such a large number of children, over 200,000, are being given intramuscular injections it is inevitable that some will develop coincidental illnesses within a short period of inoculation. It is obvious, too, that the reporting of such illnesses can come from the vaccinated group only. It is impossible, therefore, to determine whether there was an excess of such illness in vaccinated children. It is quite possible that all, or at least some, of the illnesses reported here had nothing to do with vaccination. At the worst, if all were related to vaccination, one child only of those involved in the episodes appeared to have any residual disability, and this was very mild.

The Case Reports

From the beginning of May local health authorities sent case reports to the Statistical Research Unit for all children under 10 years of age suspected to be suffering from poliomyelitis. Besides the name, address, and date of birth, each report indicated whether the child had been vaccinated, registered but not vaccinated, or not registered for vaccination. It also gave the hospital to which the patient was admitted or the name of the family doctor if treated at home. For vaccinated children the details of each injection were given. Nearly 2,000 of these reports were received by the Unit up to the end of January, 1957. A check was then made with each authority to ensure that complete reports had been made and that the details were correct. In many instances, for example, the original diagnosis of poliomyelitis was not confirmed.

On receipt of a case report on a child who had been vaccinated or registered but not vaccinated a request was sent to the clinician in charge of the patient for a clinical report. The form provided for this purpose asked for details of the history of the illness, extent and severity of paralysis if present, cerebrospinal fluid examinations, and final diagnosis. The section on paralysis included a chart distinguishing 56 separate muscle groups, to be completed at the 21st day of the illness. In addition to this initial clinical report, a follow-up report, to be completed three to five months from onset, was sent to the appropriate clinicians for patients who had exhibited some paralysis at the 21st day of illness. This form included a muscle chart like that in the earlier record. Through the co-operation of the M.R.C. Committee on Laboratory Investigations of Poliomyelitis and the Public Health Laboratory Service, arrangements were made for stools and sera taken from patients to be examined in the virus laboratories of the Universities of Aberdeen, Edinburgh, Glasgow, Manchester, and Sheffield, and in the public health laboratories at London (County Hall), London (Colindale), Cambridge, Leeds, Nottingham, Sheffield, Stafford, and Cardiff. In letters to hospital clinicians and pathologists outlining in advance the

scheme of investigation a request had been made that, when possible, two stool and two serum specimens, one early in the illness and the other about 10 days later, should be taken from each patient. These specimens were taken and examined in the majority of the patients for whom clinical reports were requested.

From the beginning of May, 1956, to the end of January, 1957, case reports were received from local authorities regarding 512 children who had been vaccinated or registered for vaccination. Clinical reports were completed for all except three of them. All these three were registered but not vaccinated and were treated at home by general practitioners. They have been excluded from the analysis. Follow-up reports in the paralytic cases must necessarily come some time after the original illness and are not yet complete for all the relevant children. The following analysis, therefore, is based on the initial reports only.

The clinical reports have been classified as follows:

Paralytic Poliomyelitis.—All patients with muscle weakness at any time during their illness, subdivided according to whether any paralysis recorded on the muscle chart for the 21st day of illness was of cranial, spinal, or mixed spinal and cranial distribution. A further subdivision of this group included all the children with a transient paresis, of whatever distribution, which had fully recovered by the 21st day.

Non-paralytic Poliomyelitis.—All patients with aseptic meningitis, as indicated clinically or by C.S.F. changes or by both. Patients with no signs of meningism, whether or not polio virus was isolated, were excluded from this group.

This classification of the clinical reports was made independently of the results of virus isolation from stools. Sera collected from patients have not yet been fully examined and the findings are not included in this analysis.

Cases Excluded from Analysis

Table I shows the number of patients reported as suspected poliomyelitis but excluded from the analysis on clinical grounds. In 10 children there were no signs of

TABLE I.—Patients Whose Illnesses were Reported as Suspected Poliomyelitis With Onset from May 1, 1956, to January 31, 1957, but Who Were Subsequently Excluded From the Analysis

Year and Month of Birth	No. of Children	Patients Excluded	
		* "Abortive Poliomyelitis"	Not Poliomyelitis

Total	1,910,093	10	37

* "Abortive poliomyelitis" includes healthy carriers and patients for whom no signs of meningism or paresis were recorded at any stage of their illness.

meningism, and in some of these hardly any illness at all (one child who was found to be excreting type 1 virus was perfectly well, but had been admitted to hospital solely because both parents were patients with paralytic illnesses). In 37 children the clinicians rejected the diagnosis of poliomyelitis altogether. From the records of children born in November and March there were 6 exclusions, and 5 would be expected at the rates observed for all other months. For the reserve month, August, there are 6 exclusions, and between 3 and 4 would be expected. There is therefore no indication from these exclusions that a diagnosis of poliomyelitis was being reported excessively in children who were registered and were in the selected months of birth for vaccination.

Table II shows the cases of poliomyelitis in registered and in vaccinated children in which the onset was in May

TABLE II.—Cases of Poliomyelitis with Onset from May 1 to June 30, 1956

or June, 1956. During this period vaccination was in progress, and, although it was known whether an individual patient was vaccinated or not, the population at risk could not be determined. This table therefore groups patients according to their month of birth irrespective of vaccination history, but shows the selected months separately. There is no evidence of any significant or consistent difference in attack rates between the selected and unselected months of birth. In children born in November and March, 3 paralytic and 2 non-paralytic attacks were recorded. At the rates observed in the unvaccinated children born in all other months the expected numbers (to the nearest unit) are 3 and 3. For children born in August the observed numbers are 2 and 4 and the expected numbers 2 and 3. Though the numbers are small they suggest a similarity between the groups during the period.

Cases Occurring Within 30 Days of Vaccination

The reports on paralytic poliomyelitis provoked by injections of diphtheria and pertussis prophylactics suggest that the risk is limited to the period of 30 days following inoculation, and that in such provoked cases there is an association between the site of inoculation and sites of paralysis. In the report on the surveillance of poliomyelitis in the United States in 1955 Langmuir, Nathanson, and Hall (1956) show that the site of first paralysis in the cases associated with Cutter vaccine was commonly the inoculated limb, and that the interval from vaccination to onset was usually between 4 and 11 days. Special importance, therefore, attaches to cases of poliomyelitis occurring within 30 days after vaccination. Six children developed poliomyelitis within 30 days of vaccination, and in all the onset was in May or June. As was general throughout the programme, they had been given their injections intramuscularly in the left arm. Other details of their vaccination and illnesses are listed below.

Case 1.—Girl, born in August, 1951. First injection given May 30, 1956. Onset of illness on June 3—that is, four days later—with complete paralysis of muscle groups of right shoulder girdle and right arm, with minimal finger movements only. Type I virus isolated from the stools.

Case 2.—Boy, born in November, 1954. First injection May 11, 1956; second injection June 8. Onset of illness on June 12, four days after the second and 32 days after the first injection. Paresis of moderate severity affected the muscles controlling the left hip and knee; there was good recovery (M.R.C. grade 4) by December, 1956. Type I virus was isolated from the stools.

Case 3.—Boy, born in March, 1953. First injection May 9, 1956, second injection June 6. Onset of illness on June 27, 21 days after the second and 49 days after the first injection. He was not confined to bed completely, but appeared to have slight weakness of the right leg following a feverish cold with headache. The paresis disappeared rapidly. No virus was isolated from the stools.

Case 4.—Boy, born in November, 1950. First injection May 25, 1956, no second injection. Onset of illness May 30, five days later, with meningism, raised protein, and lymphocytic response in the C.S.F. No paresis was seen at any time. No virus was isolated from the stools.

Case 5.—Boy, born in August, 1950. First injection May 24, 1956, no second injection. Onset of illness on June 1, eight days later, with meningism, raised protein, and marked lymphocytic response in the C.S.F. No paresis was seen at any time. No response in the C.S.F. No paresis was seen at any time. In view of the finding of virus was isolated from the stools. In view of the finding of high titres to a single mumps complement fixation test on the 19th day, this illness may have been due to the mumps virus.

Case 6.—Boy, born in March, 1951. First injection May 31, 1956; no second injection. Onset of illness on June 24, 24 days later with meningism, raised protein and lymphocytic response in the C.S.F. No paresis was seen at any time. No virus was isolated from the stools.

These six cases gave no evidence of being associated with vaccination. In the three paralytic cases there was no involvement of the injected limb, which was a feature of those associated with the Cutter vaccine in the United States.

Defaulters from Vaccination

In the seven months following the completion of vaccination, from July 1, 1956, to January 31, 1957, the populations of children vaccinated and of children registered but not vaccinated were known from the returns supplied by local health authorities. The assessment of the protective effect of vaccine is based, therefore, on the cases occurring in this period. Although vaccination did not start again till mid-March, 1957, the few cases occurring since January 31, 1957, have not been included, as their records are not yet complete. About three-quarters of the eligible children born in the primary selected months, March and November, received two injections of vaccine, whereas only about 20% of those in the reserve month, August, received two injections. As there was no universal method by which children born in August were chosen for vaccination, each authority adopting its own appropriate system, it is not certain what factors governed this selection and how they may have influenced the result in these children. Consequently the children in this month of birth have been excluded from the further analysis.

In the months of November for those born in 1947-50, and of March and November for those born in 1951-4, all registered children were eligible for vaccination, but a proportion, referred to as defaulters, for one reason or another did not receive any vaccine. Table III compares the inci-

TABLE III.—Attack Rates in Unvaccinated Children (1) Born in November and March, the Months Selected for Vaccination, and (2) Born in Other Months of Birth (Excluding August)—Cases With Onset July 1, 1956, to January 31, 1957

Year and Month of Birth	No. of Children	No. of Cases *		Rate per 100,000	
		Paralytic	Non-paralytic	Paralytic	Non-paralytic
1947-50:					
All unselected months	1,116,359	91	25	8.2	2.2
November	15,271	0 (1.2)	0 (0.3)	—	—
1951-4:					
All unselected months	446,857	90	15	20.1	3.4
March	10,736	3 (2.2)	0 (0.4)	27.9	—
November	7,057	6 (1.4)	1 (0.2)	85.0	14.2

* = Aseptic meningitis with isolation of typed polio virus from stools.
 — = Aseptic meningitis without isolation of typed polio virus from stools.
 * The italicized figures in parentheses indicate the number of cases that would have been expected at the attack rates in the months not selected for vaccination.

dence of poliomyelitis in eligible children born in November and March who received no vaccine with that in children born in the months not selected for vaccination (vaccination was carried out in a few children born in these months, but the number was only 0.5% of the total). The older children in the unselected months, those born in 1947-50, show a paralytic attack rate of 8.2 per 100,000 based on 91 cases. No cases were seen in the 15,271 November-born defaulters, whereas 1.2 cases would have been expected at the rate for other months. For the younger children in the unselected months, those born in 1951-4, the paralytic attack rate was

20.1 per 100,000 based on 90 cases. In the 10,736 March-born defaulters the rate was 27.9 based on 3 cases, whereas 2.2 cases would have been expected at the rate for the other months. In the 7,057 November-born defaulters the rate was 85.0 based on 6 cases, whereas only 1.4 cases would have been expected at the rate for unselected months. This finding of a high incidence in the younger defaulters born in November might suggest that in some way the children who failed to be vaccinated were a selected group specially at risk, and that the children who were vaccinated were in consequence a biased sample liable to less risk even without vaccination. If such a bias were operating, however, there seems no reason why it should be limited to this month of birth in the younger ages alone. The defaulters of the same years of birth born in March and the 1947-50 November defaulters showed no excess of paralytic illness over the unvaccinated children in other months. Totalling the three groups of absentees gives 9 observed paralytic cases; at the corresponding rates for all other months the expected number is 4.8, a difference which is not formally significant. It is concluded, therefore, that the high attack rate of paralytic poliomyelitis in the young November-born defaulters is a chance finding and does not indicate a bias in the group receiving vaccination.

The Assessment of the Vaccine

(a) Paralytic Disease

The further analysis is a comparison between the attack rates in vaccinated children given two injections with those in the unvaccinated children in the remaining months (excluding August). Table IV shows the number of paralytic

TABLE IV.—Attack Rates of Paralytic Poliomyelitis—Cases with Onset from July 1, 1956, to January 31, 1957—in Vaccinated Children in Selected Months of Birth Given Two Injections and in Registered, Unvaccinated Children of all Other Months of Birth (Excluding August)

* Transient = Cranial or spinal paresis, not remaining at the 21st day of illness.

cases in the four categories, spinal, cranial, mixed spinal and cranial, and transient paresis. In the older group, born 1947-50, the rate in vaccinated children of both sexes, 1.3 per 100,000, was only 16% of that in the unvaccinated, 8.2 per 100,000. At the unvaccinated rate 6.1 cases would have been expected compared with the 1 case observed. This reduction is significant: $P=0.019$ (single tail test). Although there is an apparent protection of 84%, this estimate, based on very small numbers, could vary widely from the true value. It is possible (95% confidence limits) that the degree of protection could have been as little as 6% or as much as 99%. Taking the two sexes separately there is apparent protection in each, but the difference in rates is not significant.

In the younger children, born 1951-4, the rate in vaccinated children of both sexes, 4.1 per 100,000, is only 20% of that in the unvaccinated, 20.1 per 100,000. At the unvaccinated rate 14.9 cases would have been expected compared with the 3 observed. This reduction is highly significant, $P=0.0005$ (single tail test). There is an apparent protection of 80%, and it is possible (95% confidence limits) that the degree of protection could have been somewhere between 39 and 96%.*

(b) Non-paralytic Disease

Table V presents the number of non-paralytic cases in the two categories—aseptic meningitis with and without isolation of polio virus. In the older group, born 1947-50, the rates in boys from whom polio virus was isolated were the

TABLE V.—Attack Rates of Non-paralytic Poliomyelitis—Cases with Onset from July 1, 1956, to January 31, 1957—in Vaccinated Children in Selected Months of Birth Given Two Injections and in Registered Unvaccinated Children of all Other Months of Birth (Excluding August)

+ = Aseptic meningitis with isolation of typed polio virus from stools.
 — = Aseptic meningitis without isolation of typed polio virus from stools.

same for vaccinated and unvaccinated, 2.6 per 100,000. The absence of any such cases in vaccinated girls was of no significance, as only 0.7 case would have been expected at the unvaccinated rate. There were no cases from whom virus was isolated in vaccinated boys and girls born in 1951-4, but the numbers expected at the corresponding unvaccinated rates were only 1.5 and 1.0 respectively. In the unvaccinated children the cases without virus isolation were over twice as common in boys as in girls. In neither age group was there any significant difference between the rates in the vaccinated and unvaccinated children.

It thus appears that two injections of vaccine conferred significant protection against paralytic disease in children of both school and pre-school age, but did not modify the incidence of illnesses reported as non-paralytic poliomyelitis consistently or significantly.

The Question of Bias

As it might be argued that the vaccinated children were a biased sample of those eligible in their month of birth, a comparison free from bias could be made between all those

* A girl born in March, 1952, received two injections of vaccine in May and June, 1956. While on holiday in August she was unwell but not feverish, and developed an "unusual" gait. She was not seen by a doctor until her return home, when no abnormal signs were detected and an injury was suspected. Some months later she was referred to an orthopaedic department and was found to have 4-in. (0.6 cm.) wasting of the left calf, slight tightness of the Achilles tendon, but no muscle weakness. The patient was then reported as a possible case of poliomyelitis. Lack of information about the early illness makes it impossible to classify her. If at the worst she is regarded as having had paralytic poliomyelitis, her inclusion in Table IV would increase the attack rate of the vaccinated group to 5.4, which is still significantly below the rate of 20.1 in the unvaccinated group.

registered in the selected months, including both vaccinated and defaulters, and those registered in other months. Because of the inclusion of unvaccinated children and those given only one injection in the selected months, such a comparison should underestimate the true effectiveness of vaccine. In those born in 1947-50 the apparent protection against paralytic disease is increased—1 case observed to 7.8 expected—and becomes more significant because the November-born group has been increased in size without any addition to the cases observed. On the other hand, in those born in 1951-4 the apparent protection is less than in the earlier comparison—12 cases observed to 19.9 expected—and is no longer significant. This change has occurred principally because of the inclusion in the November group of the unvaccinated defaulters with their high incidence, a feature which has already been discussed. For non-paralytic illnesses the pattern remains one of no significant protection against aseptic meningitis either with or without virus isolation.

Results of Virus Isolation

Table VI shows the results of virus isolation from the stools of all registered and vaccinated patients whose records were included in the assessment of the vaccine (Tables IV and V). Stool specimens were obtained from 64 of the 92

paralytic cases born in 1947-50. Polio virus was isolated from 44 of these—36 type I, 4 type II, and 4 type III. In the children born in 1951-4, 67 specimens were obtained from 93 children and polio virus was isolated from 48—39 type I, 6 type II, and 3 type III. In both groups, therefore, specimens were obtained from just under three-quarters, and virus, predominantly type I, was isolated from about 70% of the specimens examined.

In the non-paralytic group, 89 specimens were obtained from 123 children born in 1947-50, but virus was isolated in only 26—20 type I, 3 type II, and 3 type III. From the 48 children born in 1951-4, 33 specimens were obtained and virus was isolated in 15—11 type I, 3 type II, and 1 type III. Apart from the less frequent isolation of virus compared with paralytic cases, the same pattern of predominantly type I infection emerges.

It might be inferred, therefore, that as the vaccine appears to have protected against paralytic illness it must have been effective against those due to type I infection. This is supported by Table VII, which, like Table IV, is a comparison of paralytic attack rates in vaccinated children in the selected months of birth and unvaccinated children in other months, but includes only those patients from whom type I virus was isolated. In both age groups there is a reduction in the attack rate in vaccinated children; in the older group the difference is not statistically significant, and in the younger group it is just significant ($P=0.018$, single tail test).

Children Given One Injection Only

Table VIII shows the number of children given one injection only and the attack rates in this group. Some of these children were in the selected months of birth, November and

TABLE VIII.—Attack Rates in Children Given One Injection Only—Cases with Onset from July 1, 1956, to January 31, 1957

Year of Birth and Sex	No. of Children	No. of Cases		Rate per 100,000	
		Paralytic	Non-paralytic	Paralytic	Non-paralytic
1947-50:					
Boys	9,151	0	1	—	10.9
Girls	8,991	0	0	—	11.1
Both sexes	18,142	0	1	—	5.5
1951-4:					
Boys	7,390	0	0	—	13.5
Girls	6,847	0	0	—	—
Both sexes	14,237	0	0	—	7.0

— = Aseptic meningitis without isolation of typed polio virus from stools.

March, but failed to complete both injections largely because there was insufficient time before the end of June or because they defaulted. A large proportion of this group were born in August and received their injection late in the vaccination period. The group is therefore heterogeneous and by no means randomly selected. Although no cases of paralytic poliomyelitis occurred among them, only 1.5 would have been expected in those born in 1947-50 and 3.0 in those born in 1951-4 at the corresponding rates of the unvaccinated children. This apparent reduction in attack rate is not statistically significant, and because of this and the nature of the group it is impossible to draw any conclusions regarding the effectiveness of one injection.

Summary and Conclusions

1. In the autumn of 1955 a British formolized vaccine containing the Brunenders type I, MEF-1 type II, and Saukett type III strains was put into production, and early in 1956 the Ministry of Health and Department of Health for Scotland announced a vaccination programme for children born in the years 1947-54. Through the

local health authorities parents of these children were invited to register them for vaccination.

2. It was anticipated that the demand would greatly exceed the supplies of vaccine that could be produced in the limited time available before the onset of the 1956 epidemic season. The efficacy of vaccines incorporating the Brunenders strain and the protection conferred by vaccinating children of pre-school age had not been previously measured. In these circumstances of scarcity, therefore, the opportunity was taken of issuing the vaccine in such a way as to allow its protective value to be scientifically assessed.

3. All but two of the local health authorities in England, Wales, and Scotland took part in the scheme and nearly two million children were registered for vaccination—almost one-third of the total number who were eligible.

4. To secure two large and comparable groups of children, equivalent except in respect of vaccination, it was essential that the vaccine should be distributed without bias on a uniform and simple basis throughout the country. For this purpose the allocation was based upon the month of the year in which a child had been born. It was offered to the 95,723 registered children born in any November of the years 1947-50 and to the 98,687 registered children born in any November or March of the years 1951-4. For various reasons, 33,064 of these eligible children did not receive any injections. The defaulters born in November, 1951-4, were subsequently found to have a higher attack rate of paralytic poliomyelitis than unvaccinated children who were not eligible for vaccination. The remainder of the defaulters, those born in November, 1947-50, and in March, 1951-4, showed no such excess. It was considered, therefore, that this excess limited to one group was due to chance and had not biased the assessment of the vaccine.

5. Vaccination was carried out by local authorities in their clinics from early May to the end of June, 1956. Of the registered children born in March and November 148,684 received the required two injections, with not less than three weeks between them. School and pre-school children each provided some 74,000. For comparison there remained over 1½ million registered children born in other months and for whom vaccine was not then available (children born in August were excluded from the comparison, since any supplies of vaccine surplus to the demands of March and November were distributed to them on any system that the medical officer of health found convenient).

6. From the beginning of vaccination until January, 1957, special returns were supplied by the local health authorities for every notification of poliomyelitis relating to a child under 10 years of age. Of these reports, 512 related to registered children, vaccinated or unvaccinated. Further details were then sought from general practitioners, hospital clinicians, and pathologists regarding each of these.

7. Nearly 400,000 injections were given and there was no evidence that they had been accompanied by any risk. Of six cases of notified poliomyelitis that occurred within thirty days of an injection only three were paralytic and in none of them was the injected limb involved. Local reactions to vaccination were mild. No albumination or obvious excess of cells or casts was

detected in an examination of specimens of urine from a small sample of children subsequent to vaccination.

8. In the 74,660 vaccinated children born in 1947-50 and aged, roughly, 5½ to 9½ years who received two injections of vaccine, one case of paralytic poliomyelitis occurred, giving an attack rate of 1.3 per 100,000. The attack rate in the corresponding unvaccinated children was 8.2 per 100,000. At this latter rate 6 cases would have occurred in the vaccinated group in place of the 1 actually observed.

In the 74,024 children born in 1951-4, and aged, roughly, 1½ to 5½ years who received two injections of vaccine, three cases of paralytic poliomyelitis occurred, giving an attack rate of 4.1 per 100,000. The attack rate in the corresponding unvaccinated children was 20.1 per 100,000. At this latter rate 15 cases would have occurred in the vaccinated group in place of the 3 actually observed.

In both age groups, therefore, the observed incidence of paralytic disease in the vaccinated children was only about one-fifth of the incidence in the unvaccinated.

9. The incidence of illnesses reported as non-paralytic poliomyelitis appeared to be uninfluenced by vaccination.

10. Although the number of observations is small there appears to be no doubt that the Brunenders strain incorporated in the vaccine conferred protection against type I infections prevailing in the community.

11. There was insufficient evidence on which to judge the effect of one injection only.

12. Owing to the shortage of vaccine and the very short time (6 weeks) in which to utilize supplies that were available the numbers of children who completed the course of two injections of vaccine (148,684) fell far short of the numbers originally hoped for. As a result it is not possible to assess with any real precision the degree of protection which was conferred by the vaccine. Since some cases of paralytic disease were observed in the vaccinated children, in the form in which it was given the vaccine did not offer complete protection. On the other hand it did confer some protection, which was probably quite substantial over the ages 1½ to 9½ years. If the small numbers available are taken at their face value the apparent protection conferred was very similar to that observed in the 1954 trial in the United States.

Acknowledgments

The assessment of poliomyelitis vaccine would have been impossible without the co-operation of a large number of people. The Committee wishes to express its appreciation of the generous help given to it by the medical officers of health of local health authorities in England, Wales, and Scotland, who provided records of the numbers of children registered and vaccinated in their areas and reports on children who were notified as cases of poliomyelitis, and who in Buckinghamshire, London, Manchester and Sheffield organized special visits to a sample of the vaccinated children. The Committee are grateful to the many general practitioners and hospital clinicians who willingly provided clinical reports on their patients, and to the pathologists in hospital and university laboratories and in laboratories of the Public Health Laboratory Services who examined specimens from these children. A study of this nature involves considerable administrative and clerical routine in the collection and analysis of the records. The Committee wishes to acknowledge its debt to Dr. A. H. Bottomley, Mrs. D. King, and Mrs. L. Clargo, of the Statistical Research Unit, for their invaluable contribution to this task.

Atrial septal defect is one of the commoner congenital heart lesions. Wood (1956) found it in 18% of 900 cases of congenital heart disease that he studied. A large proportion of patients with this defect remain symptom-free for many years, but the average age of those seen by Wood was 23 years, and 84.5% were under 40, which suggests that these individuals tend to die young. Therefore it is not surprising that methods for surgical closure of the defect have now been developed, and, although the operative risks are being reduced, the physician is faced with the problem of weighing the prognosis of the natural course of the disease against the hazards of surgical correction at the present time. However, the risks and inconveniences to the patient suspected of having an atrial septal defect often begin long before surgery is even contemplated; for clinical diagnosis from physical signs, electrocardiography, and chest x-ray examination are not absolutely reliable, and more or less elaborate and potentially hazardous investigations involving cardiac catheterization and angiography are required before an accurate anatomical diagnosis can be made. These procedures are justified in patients with symptoms, but it would be a great convenience if a simple test were available that enabled the clinician to arrive at a firm diagnosis in the symptomless patient with atrial septal defect.

The present paper describes such a test, which depends upon being able to alter the pressures within each atrium separately. This produces changes in pressure differential between the two chambers, which consequently result in alterations of blood flow across any defect that may exist in the septum. As a result, alterations occur in oxygen saturation of the blood leaving the left atrium, and these can be detected by an oxymeter placed on the patient's ear.

Methods

Thirty-two patients have been studied. An oxymeter earpiece (Wood, 1950) was placed on the right ear and connected to a chopper amplifier similar to that described by Stott (1953), enabling percentage arterial oxygen saturation to be recorded continuously. The intrathoracic pressure was measured via a water-filled catheter placed in the oesophagus, connected to a Hansen capacitance manometer (Dornhorst and Leathart, 1952), while the brachial artery pressure was recorded by a second Hansen manometer (Hansen, 1949) connected via a "polythene" catheter to a fine needle inserted in the brachial artery after the overlying skin had been anaesthetized with 2% lignocaine hydrochloride.

The patient usually sat in a chair, or sat propped up on a couch or bed. A period of 10 minutes was allowed for him to become used to his surroundings; continuous recordings of arterial oxygen saturation, intra-oesophageal (intrathoracic) pressure, and brachial artery pressure were obtained. The patient was then asked to perform Valsalva's manoeuvre; this consisted in blowing a mercury column to a height of 50 mm. for 10–15 seconds. The mercury column

consisted of a standard blood-pressure machine, with a mouthpiece provided in place of the arm cuff and bellows. Following this procedure, the patient repeated the manoeuvre after exercising against two car foot-pumps. Patients who showed negative responses to the Valsalva tests were then asked to perform the reversed procedure, or Müller's manoeuvre. This consisted in inspiring against a fixed resistance to produce a negative intrathoracic pressure of 40–50 mm. Hg for 10–15 seconds. Most individuals found this a much more difficult task to perform. Lastly, the patient's legs were lifted whilst a continuous oxymeter recording was made. In three patients the test was also performed during diagnostic cardiac catheterization and the oxymeter record obtained simultaneously with the oesophageal and net intracardiac pressures, using a differential manometer system (Lee, Matthews, and Sharpey-Schafer, 1954).

Results and Discussion

A previous study of the pressures within the right atrium and "pulmonary capillary" (Lee *et al.*, 1954) has been used as the basis for the design of the present test. Right atrial and "pulmonary capillary" pressures minus the intrathoracic pressure were obtained, using a differential manometer system, and are referred to as net pressures. At rest, the net right atrial pressure was found to be 2–4 mm. Hg below the net pulmonary capillary pressure in the normal individual. Epps and Adler (1953) have shown that the pulmonary capillary pressure is almost identical with the left atrial pressure in man, so that this slight difference in pressure level is also representative of the pressure difference between the right and left atrium. Recently, Dexter (1956) has confirmed that the same pressure differences exist between the two atria in those individuals who have small atrial septal defects, but that in patients with larger atrial septal defects pressures tend to become uniform throughout both atria.

Valsalva's manoeuvre produces characteristic pressure changes in both the right atrium and pulmonary capillary (Fig. 1). Prior to the manoeuvre, the patient usually breathes in deeply. This lowers the intrathoracic pressure, which has the effect of sucking blood from the systemic venous system into the thorax, so that the net right atrial pressure rises (Fig. 1, A). During Valsalva's manoeuvre the intrathoracic pressure is raised, which impairs venous return to the heart, and the net right atrial pressure falls towards zero (Fig. 1, B).

FIG. 1.—Comparison of effect of Valsalva's manoeuvre on net right atrial pressure (above) and net pulmonary capillary pressure (below). Time in seconds. BA=brachial artery pressure. dRA=net right atrial pressure. dPC=net pulmonary capillary pressure. OES=intra-oesophageal pressure. A, B, and C=before, during, and after Valsalva's manoeuvre, respectively.

The deflection below zero seen on the atrial pressure record is due to an artifact produced by a contraction wave passing down the oesophagus affecting the differential manometer system. After Valsalva's manoeuvre the intrathoracic pressure returns to normal, and the previously impaired venous return from the now engorged systemic veins is suddenly resumed. The net right atrial pressure therefore

rises well above its resting level, and this becomes particularly marked during each phase of inspiration (Fig. 1, C). A similar series of events occurs in the pulmonary capillary, but some three to five seconds after events in the right atrium because of the circulation time through the right ventricle and lung vessels. There is not the same degree of modification by respiration as in the right atrium.

If an atrial septal defect exists, then a right-to-left shunt of desaturated blood should occur across the defect during the first few seconds after the end of the Valsalva manoeuvre, because the sudden rise in net right atrial pressure will cause a right-to-left pressure gradient across the defect. This has been found to be the case.

Fig. 2 shows a typical tracing obtained from a 24-year-old man with an atrial septal defect and moderate pulmonary hypertension. His resting arterial oxygen saturation was 89% (Fig. 2, A). Swan and his colleagues (1954) have shown by dye-injection studies in patients with atrial septal defect that, although the predominant shunt is from left to right, small right-to-left shunts also take place at the same time, due to streaming effects from the two venae cavae across the right atrium. We found that minor degrees of systemic arterial oxygen desaturation were common, and the oxymeter test confirmed that they were due to small right-to-left shunts at the atrial level. This was shown by the oxymeter response during the Valsalva manoeuvre (Fig. 2, B). At this time, when the intrathoracic pressure was raised and the net right atrial pressure was falling because of the decreased venous return to the heart, the systemic arterial oxygen saturation rose towards normal (97%). This was due to the disappearance of the small right-to-left shunt previously present. When Valsalva's manoeuvre was concluded and right atrial filling suddenly resumed (Fig. 2, C), the net right atrial pressure rose rapidly and a temporary pressure gradient was created from right to left across the atrial defect, with the result that desaturated blood entered the left atrium and the oxymeter record showed a fall in oxygen saturation below the initial resting level (81%). It will be noted that events in the oxymeter record occurred two to three seconds after the changes in intrathoracic pressure. This lag was accounted for by the circulation time from the atrial defect to the ear.

The Valsalva test was positive in all 12 patients where the diagnosis of atrial septal defect had already been proved, either by an exploring cardiac catheter entering the left atrium or by subsequent thoracotomy to close the defect. In one of these patients the test was negative at rest but positive following exercise. For this reason we made it a rule to exercise all patients in whom a negative response was obtained at rest. The patient mentioned was a boy of 7, who was referred to Dr. Raymond Daley for a cardiological opinion because of a soft systolic murmur at the base of the heart and complete heart-block. He did not complain of symptoms. Cardiac catheterization revealed a small atrial septal defect with an insignificant left-to-right shunt. The catheter tip entered the left atrium. It would seem, therefore, that if the defect is small the build-up of pressure gradient from right to left atrium is not great enough to produce a detectable right-to-left shunt following Valsalva's manoeuvre at rest. This is shown in Fig. 3, A.

The oxymeter record showed no characteristic dip in saturation following Valsalva's manoeuvre, and the record was indistinguishable from that of a normal subject. The slight dip in the tracing is thickness artifact due to congestion of the ear as the patient strains during Valsalva's manoeuvre. This was shown by an equal and opposite deflection when the oxymeter was switched to record changes in haemoglobin content only (Fig. 3, B). It is important to calibrate each record for thickness artifact in this way to avoid errors in interpretation. However, when the cardiac output is increased by exercising, then right atrial filling becomes much more rapid and a sufficient pressure gradient is created to produce a small right-to-left shunt following Valsalva's manoeuvre, with a consequent transient dip in the oxymeter tracing (Fig. 3, C).

A further 14 patients with evidence of a left-to-right shunt at the atrial level, but in whom the cardiac catheter could

not be manoeuvred into the left atrium, gave positive Valsalva tests, indicating the presence of an atrial septal defect. In three of these patients, anomalous pulmonary veins were entered by the exploring catheter. Two children with systolic heart murmurs and x-ray evidence of prominent pulmonary vessels have also shown positive Valsalva's tests after exercise. They are symptom-free and we have felt confident enough in the test to avoid submitting them to cardiac catheterization.

The Valsalva test was negative in only two cases of atrial septal defect. Both these patients had large atrial septal defects, and both had congestive cardiac failure at the time of the test. The explanation for the test's failure is shown in Fig. 4. Fig. 4, A shows the brachial artery pressure and oesophageal pressure obtained from a normal subject during Valsalva's manoeuvre. At the beginning of the strain period the brachial artery pressure is raised by approximately the same amount as the rise in intrathoracic pressure. This is due to the increased intrathoracic pressure squeezing the thoracic aorta. However, as already shown (Fig. 1), right atrial filling is impaired at the same time, so that the stroke volume soon falls, with the result that the brachial artery mean and pulse pressures also fall. By inference, therefore, a fall in brachial artery pulse pressure during Valsalva's manoeuvre indicates that right atrial filling has been impaired effectively, and that when the Valsalva is concluded it will

FIG. 5.—Effect of leg-raising on arterial oxygen saturation of patient with atrial septal defect and congestive cardiac failure. Abbreviations as Fig. 1. Top line: arterial oxygen saturation (oxymeter).

FIG. 6.—Changes in systemic arterial oxygen saturation in patient with atrial septal defect, coarctation of aorta, and congestive cardiac failure. Top line: arterial oxygen saturation. Abbreviations as Fig. 1. A=During Valsalva's manoeuvre. B=During Müller's manoeuvre.

FIG. 7.—Effect of Valsalva's manoeuvre on systemic arterial oxygen saturation in patient with pulmonary hypertension and patent foramen ovale. Top line: arterial oxygen saturation. Abbreviations as Fig. 1.

be followed by a sharp rise in right atrial filling pressure, so that the necessary gradient across an atrial defect will be produced.

However, in very large atrial septal defects, and also in heart failure, no fall in brachial artery pulse pressure occurs during Valsalva's manoeuvre (Fig. 4, B), and the imposed squeeze on the thoracic aorta by the rise in intrathoracic pressure produces a sustained rise in brachial artery pressure, or square wave response. Under these circumstances, it appears that Valsalva's manoeuvre either produces insufficient change in right atrial filling pressure to alter the gradient across the atrial defect, so that no reversal of shunt occurs, or the defect is so large that the two atria behave as a common chamber (Dexter, 1956), and again no alteration of shunt is produced. However, if the right atrium is suddenly overfilled by elevating the patient's legs, then a reversal of shunt will occur across the defect and the systemic arterial oxygen saturation will fall. Fig. 5 shows this; it was obtained from a man aged 20 with congestive cardiac failure. The brachial artery pressure showed variations due to multiple extrasystoles. He died four days later with ventricular tachycardia, and at post-mortem examination a large fenestrated septum primum defect was found.

An alternative method of suddenly raising the right atrial pressure in such patients is by means of Müller's manoeuvre. Fig. 6 shows the oxymeter record from a 27-year-old man who had severe congestive cardiac failure, auricular fibrillation, coarctation of the aorta, and bacterial endocarditis. A systolic and diastolic murmur was audible in the pulmonary region. Valsalva's manoeuvre (Fig. 6, A) produced little alteration in brachial artery pressure, and the oxymeter recording showed no consistent change in arterial oxygen saturation. However, when the patient performed Müller's manoeuvre (Fig. 6, B) the systemic arterial oxygen saturation fell, indicating that a temporary right-to-left shunt had been produced. The patient died one month later, and post-mortem examination revealed an atrial septal defect 2 cm. in diameter, in addition to coarctation of the aorta, a bicuspid aortic valve, and bacterial endocarditis.

The oxymeter test has been negative in the small number of patients that we have studied with left-to-right shunts from causes other than interatrial communication. In these patients no significant alteration in arterial oxygen saturation occurred following Valsalva's manoeuvre, Müller's manoeuvre, or leg raising. One patient had a ventricular septal defect. The right ventricular pressure at rest was 63/3 mm. Hg, and at no time during the tests did the right ventricular pressure rise to systemic arterial levels. Two patients had evidence of a left-to-right shunt at the atrial level; both had moderately raised pulmonary artery pressures; in one, an exploring catheter passed into an anomalous right superior pulmonary vein entering the right atrium; in the other case, neither anomalous veins nor the left atrium were entered. From the negative oxymeter study, partial anomalous pulmonary venous drainage without an associated atrial septal defect was diagnosed. The diagnosis was confirmed in the first patient at post-mortem examination when she died from congestive cardiac failure a year later. Thoracotomy was performed in the second patient, as atrial septal defect was still suspect clinically and its repair was to be undertaken. Three anomalous pulmonary veins opening into the right atrium were found. No atrial septal defect was present. Mr. Charles Bailey, of Philadelphia, who undertook the operation, successfully corrected the anomaly surgically.

Occasionally data obtained from cardiac catheterization are still insufficient to allow an anatomical diagnosis to be made. Fig. 7 shows the oxymeter record and net right atrial pressure from such a patient in whom the Valsalva test was positive and aided the diagnosis. The patient was a 34-year-old woman who had a resting arterial oxygen saturation of 92% but who became deeply cyanosed on exertion. The cardiac catheter failed to enter the left atrium, to cross a ventricular septal defect, or to enter the aorta. Pulmonary hypertension was found. On the basis of the

positive Valsalva test, a patent foramen ovale was suspected. She died later from congestive cardiac failure, and post-mortem examination revealed a moderate-sized patent foramen ovale in addition to changes associated with pure pulmonary hypertension.

We have little experience in the use of the oxymeter tests in patients with cyanotic congenital heart disease, but preliminary work suggests that Fallot's tetralogy may be associated with a characteristic pattern of changing arterial oxygen saturation during Valsalva's manoeuvre. One possible source of confusion in interpreting results from such patients may occur from individuals with cyanosis due to lung disease. We have found that patients with cor pulmonale and central cyanosis who perform Valsalva's manoeuvre alter their arterial oxygen saturation considerably. During Valsalva's manoeuvre the breath-holding that is entailed is associated with a fall in arterial oxygen saturation. Following the manoeuvre the arterial oxygen saturation rises again, and often exceeds the resting value temporarily. This is probably due to hyperventilation that occurs as soon as the test is completed.

Conclusion

The oxymeter tests described appear to be both simple and reliable for demonstrating the presence of an atrial septal defect or patent foramen ovale. Having established the conditions under which the tests can be relied upon, we feel that it is not strictly necessary to record either the oesophageal pressure or brachial artery pressure provided that one is careful to follow a routine to eliminate false-negative results. We therefore record the arterial oxygen saturation with the ear oxymeter during Valsalva's manoeuvre at rest. If the test is negative it is repeated after exercise; if a negative response is still obtained, then the Müller procedure, followed by elevation of the patient's legs, is carried out. In this way what appears to be an extremely reliable test is available for use in the clinic, with symptom-free patients of any age suspected of having an interatrial communication. The youngest child we have studied was 3½ years old.

We have so far not encountered an incorrect response to the tests in any patient in whom the diagnosis was proved by alternative means. In addition, an atrial septal defect was demonstrated by the tests in three patients in whom catheter data were equivocal, and confirmed the absence of an atrial septal defect in two patients with anomalous pulmonary venous drainage, where atrial defects could not be definitely excluded from catheter data. Provided that balanced pressures between the right and left ventricles do not exist, the tests appear to be negative with ventricular septal defects; and the response pattern also appears to be different in the few cases of Fallot's tetralogy so far studied. We are also studying a group of normal subjects after exercise to discover whether it is possible to recognize those who have a persistent foramen ovale.

Finally, we would like to express our gratitude to Dr. Raymond Daley and Mr. Kent Harrison, who allowed us to study patients in whom they had established an anatomical diagnosis by cardiac catheterization or at subsequent thoracotomy. This information formed the main evidence that the oxymeter test was a reliable procedure for diagnosis of inter-atrial communication.

Summary

Thirty-two patients suspected clinically of having atrial septal defects have been studied by means of the ear oxymeter during the performance of Valsalva's manoeuvre.

Twelve of these patients in whom the diagnosis was proved by cardiac catheterization or thoracotomy had characteristic and reproducible changes in arterial oxygen saturation during and following Valsalva's manoeuvre.

If the defect was small, exercise prior to Valsalva's manoeuvre was required in order to obtain a positive oxymeter response.

Fourteen further patients gave positive oxymeter responses to the Valsalva test. These patients had catheter evidence of a left-to-right shunt at the atrial level but definite anatomical proof of an atrial septal defect was lacking. One patient with pulmonary hypertension, who became cyanosed on exertion and in whom cardiac catheterization was unhelpful in locating the site of the shunt, gave a positive response to the Valsalva test. Subsequent post-mortem examination revealed a patent foramen ovale.

Five patients gave a negative response to the Valsalva test. Two of these were subsequently found to have partial anomalous pulmonary venous drainage but no atrial septal defect. One patient had a ventricular septal defect; and two patients had congestive cardiac failure associated with atrial septal defects.

In the patients with atrial septal defect and cardiac failure, Müller's manoeuvre or elevation of the legs caused a fall in systemic arterial oxygen saturation, enabling the correct diagnosis to be made.

GONADAL DYSGENESIS IN NORMAL-LOOKING FEMALES

A GENETIC THEORY TO EXPLAIN VARIABILITY OF THE SYNDROME

BY

R. HOFFENBERG, M.B., M.R.C.P.

AND

W. P. U. JACKSON, M.D., M.R.C.P., D.C.H.

From Endocrine Group, Department of Medicine, Groote Schuur Hospital and University of Capetown

Swyer (1955) described two cases with an unusual clinical picture under the heading of "Male Pseudohermaphroditism: A Hitherto Undescribed Form." Briefly, these patients showed normal height with eunuchoidal proportions, female appearance, and female genitalia. They did not develop secondary sexual characters nor did they menstruate. Their nuclear pattern was male. They had no congenital anomalies of the Bonneville-Ullrich-Turner type. Attempts to place these two patients into one of the recognized categories of intersex appear to have failed. In the *Year Book of Endocrinology, 1955-1956*, a précis of Swyer's paper is followed by an editorial comment which confirms this dilemma.

It is our contention that these patients suffer from a variant of the syndrome of gonadal dysgenesis. We present the case report of a patient showing a similar clinical picture but with female "genetic sex" in whom the presence of dysgenetic gonads was demonstrated at laparotomy.

Case Report

An attractive female school-teacher aged 22 presented with primary amenorrhoea. Her height was 66½ in. (169 cm.) and span 69 in. (175 cm.), and, apart from complete lack of breast development and eunuchoid proportions, she appeared a perfectly normal female (see illustration). Axillary and pubic hair were moderately profuse. The

Note eunuchoid proportions and lack of breast development.

vagina was small, the clitoris not enlarged, and the uterus infantile on palpation; adnexae could not be felt.

The family history was not contributory. There was no history of mumps or of other significant illness. The patient had not experienced hot flushes. The psychological orientation was completely female following a normal female upbringing and education.

The urinary gonadotrophin (F.S.H.) excretion was strongly positive at 6 mouse uterine units, but negative at 96 mouse units. A skin biopsy showed a normal female nuclear pattern.

At laparotomy typical primitive gonadal ridges were disclosed. Histology showed ovarian stroma, no follicles, but aggregates of cells resembling ovarian hilar cells (Dr. C. J. Uys).

Cyclical oestrogen therapy (1 mg. of stilboestrol daily) was instituted after the operation. Six months later the patient was extremely pleased with the results: her breasts had grown considerably; monthly bleeding had ensued; the vagina had increased in size; general feminization of the contours had occurred; and she was engaged to be married.

Vagaries of Gonadal Dysgenesis

Several major advances over the past few years have widened the original concept of "ovarian agenesis." It has been recognized that patients may lack many of the classical features which have been associated with the syndrome. There are numerous reports of tall patients and even of attractive ones (Wilkins and Fleischmann, 1944; Lissner *et al.*, 1947; del Castillo *et al.*, 1947; Kerkhof and Stolte, 1956; Greenblatt *et al.*, 1956; Hoffenberg and Jackson, 1957), axillary and pubic hair are often normal in amount or even luxuriant (Hoffenberg and Jackson, 1957). The congenital anomalies of Turner's syndrome need not be present (del Castillo *et al.*, 1947; Grumbach *et al.*, 1955; Greenblatt *et al.*, 1956) and good breast development has been reported (Varney *et al.*, 1942; Wilkins and Fleischmann, 1944; Lissner *et al.*, 1947; Hertz *et al.*, 1950; Hoffenberg and Jackson, 1957). The urinary gonadotrophin, while generally high, may be normal or low (Dorff *et al.*, 1947; Hertz *et al.*, 1950; Sternlieb *et al.*, 1954; Carpentier *et al.*, 1956; Hoffenberg and Jackson, 1957); cases have been described with androgenic manifestations (Gordan *et al.*, 1955; Greenblatt *et al.*, 1956), and one proved case showed pseudohermaphroditic external genitals (Grumbach *et al.*, 1955); finally, we have encountered two patients who claimed to have menstruated for five and six years respectively (Hoffenberg *et al.*, 1957). The skin sex pattern in gonadal dysgenesis may be male or female.

Our patient showed no recognizable congenital anomalies; she appeared, in fact, to be a normal thin female with

poor breast development. Her F.S.H. excretion was not raised and her skin sex pattern was female. Yet, at laparotomy, typical dysgenetic gonads were found.

Sun and Rakoff (1956) include in a series of 15 patients with gonadal dysgenesis one who was 64 in. (162.5 cm.) tall and had normal skeletal proportions. She, however, had a high urinary F.S.H. excretion, and the diagnosis was confirmed at laparotomy.

Greenblatt *et al.* (1956) refer to another tall patient without the anomalies of Turner's syndrome, but with poor breasts, primary amenorrhoea, and otherwise normal female appearance, except for enlargement of the clitoris; her urine F.S.H. excretion was normal and skin sex was female. The diagnosis of gonadal dysgenesis was proved in this patient at laparotomy. Our patient displayed an almost identical picture. There was, however, no clitoral enlargement.

Reconsideration of Swyer's Cases

The two patients described by Swyer were apparent females with primary amenorrhoea; they had poor mammary development, eunuchoid proportions, and normal axillary and pubic hair. The external genitalia were normal, except for clitoral enlargement in one. Each displayed a rudimentary uterus, a normal, non-oestrinized vagina, normal cervix, and apparently normal oestrogen levels. F.S.H. excretion was normal in one, low in the other. Blood smears showed a male pattern in both. Laparotomy was not performed.

Swyer considers gonadal dysgenesis in the differential diagnosis. He dismisses the condition on the grounds of numerous distinctions between his patients and those with the hitherto-accepted classical syndrome. However, in the light of the cases reported above, including our own, it is apparent that his cases differ in no specific manner from the less common variants of gonadal dysgenesis. The Table summarizes the salient features of "classical" gonadal dysgenesis, atypical gonadal dysgenesis, Swyer's "new" syndrome, and "classical" male pseudohermaphroditism. From a perusal of this Table it becomes apparent that Swyer's cases are, in fact, variants of the syndrome of gonadal dysgenesis. The difficulty in classification has arisen because his cases showed a number of atypical features, all of which have been described separately in other patients.

Genetic Considerations

These atypical cases of gonadal dysgenesis require some aetiological explanation. It has been suggested that the general Bonnevie-Ullrich-Turner syndrome might be produced by a primary intrauterine disturbance during early foetal life (Grumbach *et al.*, 1955). On the other hand, the type, multiplicity, and comparative constancy of the clinical features suggest that a genetic aberration is more likely. Thus this kaleidoscopic syndrome would resemble such states as mongolism, the Laurence-Moon-Biedl syndrome, and osteogenesis imperfecta, all of which show combinations of genetically determined anomalies. If the syndrome were caused by a mutation of dominant type occurring in one gene or in several closely related genes of a parental germ cell, no hereditary tendency could be observed because of the essential infertility of the sufferers.

This conception is supported by Rossi and Caffisch (1951), who demonstrate beyond all doubt the hereditary nature of the various skeletal anomalies of the pterygium and Bonnevie-Ullrich syndromes, which are variably embodied in Turner's syndrome. Indeed, in some of the families they describe, cases of infantilism—that is, gonadal dysgenesis—actually appear together with non-infantilistic siblings who have, for instance, webbed neck, but who are capable of reproduction. The authors adduce evidence of direct parent-child transmission of anomalies, and claim, apparently on excellent grounds, that the hereditary trait concerned is dominant, of high penetrance, and of variable expressivity. Further confirmation of the hereditary nature

Varieties of Gonadal Dysgenesis and Classical Male Pseudohermaphroditism Compared

	Stature	Congenital Anomalies	Breasts	Sex Hair	Vagina	Cervix	Chromosomal Sex	Gonadotrophins	Oestrogen	Gonads
"Classical" gonadal dysgenesis	Short	Usual	Undeveloped	Usually scanty	Infantile	Infantile	Male or female	High	Low	Primitive streaks
Atypical gonadal dysgenesis	May be tall or normal height	Often absent	Usually undeveloped	May be normal	Small or normal	Infantile or normal	Male or female	High, normal, or low	Normal or low	May show some development
Swyer's "new" syndrome	Tall or normal	Absent	Undeveloped	Within normal limits	Normal	Normal	Male	Normal	Apparently normal	?
Classical male pseudohermaphroditism	Normal or tall	"	Variable	Absent or scanty	Short; may be oestrogenized	Minute or absent	"	"	Low	Developed testes

of this syndrome is provided by the report of its occurrence in sisters (Davidson and Smith, 1956) and in twins (Solis and Schwartz, 1951).

It would seem possible to explain the varieties of this syndrome by postulating three closely connected genes situated on the same chromosome: one gene for infantilism—that is, intrauterine hypogonadism—called "I"; one gene for shortness of stature, "S"; and one gene or gene-complex for the various anomalies of musculo-skeletal, cardiac, cutaneous, renal, ocular, and other systems, "A." It is evident that the genetic factor A is very variable in its expressivity, since several different anomalies usually occur together, but never all in the same person. Now, if we imagine either that these three factors are not invariably inherited together or, alternatively, that they always occur together, but that the penetrance of each is not 100%, we can account for the complete syndrome and for the various partial ones. We thus have:

I+S+A (in genetic male or female)=Full Turner's syndrome.

S+A=Pterygium and other developmental syndromes, with short stature and normal sexual differentiation (Rossi and Caffisch, 1951).

A alone=Pterygium and other syndromes, with normal stature (Rossi and Caffisch, 1951).

I+S="Normal-looking" Turner's syndrome; with shortness of stature, infantilism, but no anomalies (Grumbach *et al.*, 1955; Hoffenberg and Jackson, 1957).

I alone=Apparent females of normal height with amenorrhoea and no anomalies (Swyer, 1955; Greenblatt *et al.*, 1956; Sun and Rakoff, 1956; and our case reported above). Nuclear sex may be male or female.

Grumbach *et al.* (1955) apply the experimental results of Jost and other workers to the problem of human intersex. The infantilism in gonadal dysgenesis results from very early failure of the developing gonad (our factor "I"), with consequent feminization of genital tract and body form. If gonadal failure occurs at a slightly later stage of male embryonic development, partial differentiation along masculine lines will already have taken place. Further development of the genital tract will be of female type, and so "male pseudohermaphroditism" will result. This is equivalent to our factor "I" coming into operation at a slightly later stage. Thus:

I alone (slightly later in genetic male)=Male pseudohermaphroditism.

I (slightly later in genetic male)+S+A=Male pseudohermaphroditism with short stature and anomalies (Grumbach *et al.*, 1955).

Stature in Gonadal Dysgenesis

The shortness of stature which is seen in most cases of gonadal dysgenesis conflicts with the tall eunuchoid proportions generally associated with prepubertal gonadal failure. It is best regarded as a distinct genetic anomaly. To test the validity of this hypothesis we have reviewed the reported cases of gonadal dysgenesis without shortness of stature.

Varney *et al.* (1942) describe the case of a patient 6 ft. (183 cm.) tall, with "eunuchoid elongation of the extremi-

ties." They also refer to patients reported by Pela in 1935 and Humphrey—the former 5 ft. 10 in. (178 cm.) tall with "long extremities," the latter 5 ft. 6½ in. (169.5 cm.) with "eunuchoid skeletal proportions." Wilkins and Fleischmann (1944) refer to a patient (reported by Kaliga) who was 5 ft. 9 in. (175 cm.) tall with "eunuchoid proportions." Del Castillo *et al.* (1947) cite a patient, 5 ft. 5½ in. (166 cm.) tall with the same arm-span. Greenblatt *et al.* (1956) state that their 5 ft. 10 in. (178 cm.) tall patient "resembles the tall eunuchoid male in appearance."

Of Swyer's two cases, the first is stated to have "definitely eunuchoid proportions," the second to have the general appearance of "a tall eunuchoid female." Our patient, referred to above, displays the same eunuchoid habitus.

Thus the majority of tall patients with gonadal dysgenesis show eunuchoid proportions. This supports the view that the typical shortness of stature seen in gonadal dysgenesis is genetic in origin (our factor "S"). If this particular genetic aberration does not occur, patients show the body-build which is expected in individuals who are deprived of gonadal function before puberty.

Conclusion

From a consideration of our own case and a review of reported instances of gonadal dysgenesis, we conclude that the two patients described by Swyer are, in fact, suffering from a variant of this syndrome. His patients may be re-appraised in the light of several other similar protocols. Consideration of the variable clinical picture in the syndrome of gonadal dysgenesis leads to the conclusion that this syndrome results from a genetic disturbance rather than a primary intrauterine disorder.

As the heterogeneous nature of gonadal dysgenesis becomes more widely recognized, we believe that this disorder will be found responsible for most cases of primary amenorrhoea—whatever the appearance of the patient.

Summary

A case of gonadal dysgenesis is reported in a patient who was tall and eunuchoid, had no congenital anomalies, and had a female nuclear pattern. This and two other cases are compared with two cases reported by Swyer under the title of "Male Pseudohermaphroditism: A Hitherto Undescribed Form." Reconsideration of Swyer's cases suggests that they, too, suffer from a variant of the syndrome of gonadal dysgenesis.

The genetic aberration responsible for gonadal dysgenesis and its variants is discussed and a hypothesis is submitted to account for the whole syndrome and its less complete forms.

A reconsideration of reported tall patients with gonadal dysgenesis lends support to the view that the shortness of stature is genetic in origin.

We are grateful to Professor F. Forman for his constant interest and advice; to Professor James T. Louw, under whose care the patient was admitted; to Dr. W. H. Muller, who performed the laparotomy; to Dr. C. J. Uys for the histological reports; to

Professor H. Zwarenstein and Mr. D. G. Duncan for the gonadotrophin (F.S.H.) estimation; and to Mr. B. Todt for the photograph.

HUMAN INFECTION WITH SALMONELLA CHOLERAESUIS

BY

A. M. LAYLEE, M.B., Ch.B.

Late Senior House Officer, Sefton General Hospital,
Liverpool

Salmonella choleraesuis differs from other salmonellae by the frequency with which it invades the blood stream, causing a generalized infection, and by its high mortality. Infection may manifest itself in three ways: as a gastro-enteritis, a typhoid-like illness, or a septicaemia. The septicaemia may localize in the lungs, bones, joints, or meninges. Reports of sporadic cases of the generalized type of infection have been published by Harvey (1937). He reviewed the literature, finding 50 cases, and added a further 21 cases. Goulder, Kingsland, and Janeway (1942) reported 11 cases, and Jager and Lamb (1943) six cases. Saphra and Wassermann (1954) analysed 329 cultures of *Salm. choleraesuis* from human sources submitted for identification to the New York Salmonella Center between 1940 and 1954. The organism had been isolated from the blood in 247 instances, and in only 26 from the faeces alone.

In this country only 12 cases of the generalized type of infection have been recorded. Nabarro, White, Dyke, and Scott (1929) and Schwabacher, Taylor, and White (1943) reported two cases each, and single cases were described by Boycott and McNee (1936), Herring and Nicholson (1939), and Guthrie (1941). Five cases of unusual manifestations of *Salm. choleraesuis* were reported in the *Monthly Bulletin of the Ministry of Health* (1950a, 1950b, 1951). These comprise two cases of septicaemia, a septic arthritis, and a cold abscess of the scalp, and in one case the organism was isolated from the urine. No clinical details were given.

During 1923-53 *Salm. choleraesuis* was isolated from 66 food-poisoning incidents in England and Wales out of a total of 14,847 due to salmonella organisms.

The following two cases are put on record because they present features not previously reported in this country.

Case 1

A personnel manager in a bakery firm, aged 53, was admitted to Sefton General Hospital on December 16, 1954, with a history of an influenza-like illness and backache one month earlier, followed by swelling of his ankles. There

was no history of gastro-enteritis, but three months previously, in the course of his work, he had been in contact with the contents of a large tin of ham which was obviously decomposed and was in fact condemned, although no record of a bacteriological examination is available.

On admission his temperature was normal. Oedema of the ankles and sacrum was present, but no cause for this could be found. Three days after admission he had a temperature of 100-104° F. (37.8-40° C.). Four blood cultures were taken over a period of 24 hours, and an organism of the salmonella group was isolated from three. These were identified by Dr. Joan Taylor at the Salmonella Reference Laboratory as *Salm. choleraesuis* var. *kunzendorf*.

The patient was transferred to Fazakerley Hospital on December 24. He was treated with chloramphenicol, 500 mg. six-hourly for seven days. His temperature settled. On January 8, 1955, he complained of pain in the right loin and dysuria. *Salm. choleraesuis* was cultured from the urine. On January 14 he was again pyrexial, and on January 26 a further course of chloramphenicol, 500 mg. six-hourly for seven days, was started. His temperature settled. An intravenous pyelogram showed normal excretion of the dye.

On February 19 he complained of pain in both loins and was found to be tender over the lower dorsal vertebrae. X-ray examination of the spine showed diminution of the disk space between D9 and 10 with erosion of the adjacent vertebral margin and a paravertebral abscess, presumably due to *Salm. choleraesuis*.

Stools cultured 23 times between December 25, 1954, and March 3, 1956, failed to grow *Salm. choleraesuis*. The urine was frequently cultured, and was found to be sterile except on January 8.

The patient was eventually discharged from hospital on November 16, 1955, wearing a spinal support. The stools of relatives were examined but no carrier was found.

An x-ray film taken on August 21, 1956, showed the destructive lesion between the ninth and tenth dorsal vertebrae to be healed. There was very little destruction in these two vertebrae, but the intervertebral disk had been destroyed. The paravertebral abscess had almost disappeared. He was still wearing a surgical support.

Case 2

A woman confectioner aged 23, suffering from idiopathic thrombocytopenic purpura, was admitted to Sefton General Hospital for splenectomy on February 1, 1955. There had been no history of gastro-enteritis, and a chest x-ray examination showed the lung fields to be clear.

Splenectomy was performed on February 11, using a trans-thoracic approach through the bed of the tenth rib, and the chest was closed without drainage.

On the second post-operative day the patient became febrile. A chest x-ray film showed a left basal opacity. She was treated with penicillin, 500,000 units six-hourly by intramuscular injection, and her temperature settled slowly. On February 22 she again became pyrexial. On clinical examination there was an impaired percussion note at the left base and air entry was diminished. Chest x-ray examination showed consolidation of the left lower lobe. Penicillin was stopped and chlortetracycline, 250 mg. six-hourly, was given. Chest aspiration carried out three days later produced 3 fl. oz. (85 ml.) of dark straw-coloured fluid. Microscopical examination showed an excess of leucocytes, but the fluid on culture was sterile.

The patient remained pyrexial and exploration of the chest was carried out on March 17. A posterior loculated empyema was found and a drain inserted. An organism of the salmonella group was isolated from the pus. This was identified by Dr. Joan Taylor as *Salm. choleraesuis* var. *kunzendorf*. Treatment was begun on March 19 with chloramphenicol, 0.5 g. four-hourly for eight days. Her temperature settled after six days. An organism of the salmonella group was isolated from the pus draining from the chest on April 4 and 6.

Culture of numerous specimens of faeces failed to grow the organism. Blood cultures taken after the chest exploration also failed to grow the organism.

The drain continued to discharge pus until April 26, when it was gradually shortened. The wound closed at the end of May.

Stools of relatives were examined but no carrier was found.

Discussion

The commonest site for the infection to localize is the lungs, where it may produce a bronchopneumonia, lobar pneumonia, pleurisy with effusion, or an empyema. The organism has been isolated from the sputum and the pleural fluid. Pulmonary involvement occurred in one-third of Harvey's cases and in 32 of Saphra and Wassermann's, and in this country the organism was isolated from the lungs at necropsy in one of the cases of Schwabacher *et al.*

Harvey noted several cases of infection due to *Salm. choleraesuis* occurring post-operatively. It followed such procedures as laparotomy, cystoscopy, antral operation, and drainage of an ischio-rectal abscess. One patient developed bronchopneumonia after laparotomy for myomas of the uterus. The organism in this case was cultured from the blood but not from the sputum.

Localization in bone and joints occurred in 15 of Harvey's cases and in 19 of Saphra and Wassermann's. Two cases have previously been reported in this country; arthritis of the shoulder-joint in an infant 8 months old (Nabarro *et al.*, 1929), and arthritis of the shoulder-joint in an infant 7 months old (Guthrie, 1941).

The mortality is high. In Harvey's series it was 38%. In Saphra and Wassermann's series it was 21%, and they compared the mortality rate with 300 consecutive infections of *Salm. oranienburg* and *Salm. typhimurium*; here it was 4.7% and 4% respectively. There have been five deaths in the seven cases reported in this country.

The organism in both the above cases was sensitive *in vitro* to chloramphenicol, yet sterilization was not achieved by courses of this drug. In Case 1 the blood stream may have repeatedly been reinfected from the osteomyelitis of the spine which possibly was present for some time, although evidence of this was lacking.

American workers have shown that the hog is the main carrier of *Salm. choleraesuis*. Infection is probably acquired through careless handling of contaminated pork or eating it insufficiently cooked. The carrier rate is low compared with other salmonellae. Scott (1940), in this country, isolated 38 strains of *Salmonella* from mesenteric lymph nodes of 1,000 healthy pigs, 10 of these were of the species *Salm. choleraesuis*. A more recent investigation by the Salmonella Subcommittee of the Public Health Laboratory Service (1955) failed to isolate the organism from a large number of samples of bile, liver, mesenteric lymph nodes, and faeces of healthy pigs. It was suggested, however, that the medium used, selenite-F, may not have been the best medium for isolating this organism. The source of the organism in these two cases is not known for certain, but in Case 1 it is reasonable to suppose that infection was acquired by contact with diseased ham.

From the wider aspect it can be seen that in view of the patients' occupations the infections presented a major risk to the public health. It is surprising that no further infections by this organism were notified in Liverpool at this time.

Summary

Two cases of the generalized type of infection with *Salmonella choleraesuis* are reported: one case with septicaemia and osteomyelitis of the spine, and the other with empyema following splenectomy. The high mortality is noted. The source of infection in these two cases is not known.

I thank Dr. C. M. Miller for permission to report these two cases and for his helpful advice; Dr. A. B. Christie and Mr. J. P.

Heron for further details of Case 1, which was under their care at Fazakerley and Aintree Hospitals; and Dr. J. Carr Brundret.

UNUSUAL HAEMOGLOBIN VARIANT IN A GUJERATI INDIAN

BY

ALAN B. RAPER, M.D., B.Sc., M.R.C.P.
D.T.M.&H.

From the Medical Laboratory, Kampala, Uganda

During a survey for haemoglobin D an example of an unusual haemoglobin was discovered. This haemoglobin, which was accompanied by normal adult haemoglobin, moved faster than the latter at pH 8.6 on paper electrophoresis, and its characters are described below.

The subjects surveyed were 326 Indians living in and near Kampala, Uganda, and nearly all were first-, second-, or third-generation immigrants from the Bombay region of India. A few Sikhs and Punjabis were included. Two unrelated subjects were found to exhibit both haemoglobins A and D. It may be mentioned here that this series, added to the 174 persons examined by Jacob *et al.* (1956), brings the total of Uganda Indians examined to 500; and among these the number of examples of haemoglobin D found now becomes four.

The Haemoglobin

One woman (Mrs. L. M.), however, showed the abnormal haemoglobin here described, and it was demonstrated in her blood on two subsequent occasions. Both she and her husband came from Gujerat, north of Bombay. Unfortunately the family is scattered in India, Tanganyika, and Kenya, and it was not possible to examine her husband, parents, brother, or sister. Three children, aged 16, 14, and 13, were examined, and showed normal adult haemoglobin only.

A haemolysate of the washed erythrocytes of Mrs. L. M., prepared without freezing, resolved into two components when subjected to electrophoresis on paper in 0.05 M barbitone buffer at pH 8.6. One of these components, representing 20-25% of the whole, moved more quickly than haemoglobin A, its separation being slightly less than that

Paper electrophoretic pattern, at pH 8.6 in barbitone buffer, of the new haemoglobin and haemoglobins A and S.

between haemoglobins A and S (see Fig.). In phosphate buffer at pH 7.8 two components were still discernible, the abnormal haemoglobin having the greater mobility, but complete separation did not occur. At pH 6.5 in phosphate buffer, however, the abnormal haemoglobin was not separable from haemoglobin A, but trailed behind it.

The solubility of Mrs. L. M.'s haemoglobin was 1.57 g. per litre in 2.58 M phosphate buffer, by the method of Itano (1953). After ten weeks' storage at about -25° C. no precipitate was formed in a haemolysate that contained 8 g. per 100 ml., and no change was observed in the proportion of the abnormal haemoglobin after this period of freezing.

Haematological Findings

The relevant findings in Mrs. L. M. and three of her children are given in the Table. None of these subjects showed sickling, malaria was absent in all, reticulocytes did not exceed 0.2% in any subject, the serum bilirubin was normal in all, and alkali-resistant haemoglobin was absent in every case—less than 2% by the method of Singer *et al.* (1951). No changes were observed in wet preparations in saline, dithionite, and cresyl blue.

Haematological Findings in the M. Family

	Mrs. L. M., Mother	T. M. (16), Daughter	P. M. (14), Son	N. M. (13), Son
Haemoglobin (g./100 ml.)	15.06	12.57	14.9	14.67
Erythrocytes (mil. c.mm.)	6.15	5.91	5.5	5.55
M.C.V. (cubic microns)	77.2	66.8	76.4	79.0
M.C.H.C. (%)	31.8	31.8	35.4	33.7
Plasma Fe (µg./100 ml.)	73	235	—	—
Osmotic Limits	0.42-0.3	0.34-0.24	0.42-0.3	0.42-0.3
fragility 50%	0.37	0.29	0.36	0.35

The stained blood film of Mrs. L. M. showed no abnormality except that a very occasional oval erythrocyte could be found. The films of the two younger children were quite normal, and, though the M.C.V. recorded in these three members was rather low, this did not appear to represent any abnormality. The daughter (T. M.), however, displayed definite abnormalities, her erythrocytes showed considerable variation in size and shape, there were many elliptocytes, target cells were numerous, but no polychromatic staining was seen. These findings accord with the lowered cell volume (66.8 cubic microns) and the increased resistance to hypotonic saline, and are suggestive of thalassaemia minor. The plasma iron of this girl was high (method of Ramsay, 1953), which is in favour of the same diagnosis. Presumably the inheritance was through T. M.'s father, who unfortunately was not available for examination. The presence of the thalassaemia gene in this family must be a coincidence, but it is not a surprising one, for thalassaemia is by no means rare in the Indian immigrants in Uganda.

Discussion

Several human haemoglobins having greater mobility than haemoglobin A at pH 8.6 have been described.

The present haemoglobin differs from haemoglobin H (Rigas *et al.*, 1956) in its cathodal mobility at pH 6.5, its stability when frozen, and the absence of any associated disease. It differs from haemoglobin I (Rucknagel *et al.*, 1955) and from the haemoglobin described by Cabannes *et al.* (1955), in that it appears to be less mobile at pH 8.6.

Haemoglobins J and K are less mobile than H and I. Exactly which haemoglobin should be designated K has been the subject of some confusion. The letter was originally reserved by Itano (1955) for a component reported by Battle and Lewis (1954), but subsequently he could not confirm that this was a distinct variant (Itano *et al.*, 1956). At the sixth International Congress of Haematology it was suggested that K might describe another haemoglobin reported from Algeria by Cabannes *et al.* (1956), and one of the new variants (Liberia II) found by Robinson *et al.* (1956) in Liberia.

Fortunately haemoglobin J is a clearly defined entity. Described by Thorup *et al.* (1956) in a negro, it had a mobility

similar to the present example, and was not associated with disease. Robinson *et al.* (1956) found a haemoglobin in Liberia (Liberia I) that is identical with haemoglobin J, and in both these descriptions the abnormal fraction in A-J individuals accounted for about 60% of the total haemoglobin. Huisman *et al.* (1957) reported the finding of haemoglobin J in an Indonesian, in whom it formed only 35% of the haemoglobin.

Through the kindness of Dr. H. Lehmann and Dr. T. H. J. Huisman the present haemoglobin has been compared with haemoglobins H, I, J, K, and found to correspond with haemoglobin J in its mobility at pH 8.6. Thus the presence of the gene for haemoglobin J in the Indian mainland is established, and this gene (like that for haemoglobin S) appears to have a rather wide variability of expression in heterozygotes, producing in different individuals from about 20% to 60% of the total haemoglobin.

Summary

A haemoglobin variant, with greater mobility than haemoglobin A at pH 8.6, was discovered in an Indian woman in Uganda. It was unassociated with any abnormality in the blood. Its properties are recorded, and correspond with those of haemoglobin J.

Medical Memorandum

Acute Myeloblastic Leukaemia following Chloramphenicol Treatment

Various blood dyscrasias, ranging from slight granulocytopenia to agranulocytosis and aplastic anaemia, following administration of chloramphenicol have been reported during the last few years, but no case of acute leukaemia has yet been published. A case has recently been seen where acute myeloblastic leukaemia was discovered following agranulocytosis and hypoplasia of bone marrow after a single course of chloramphenicol.

CASE REPORT

A man aged 63 was first seen in September, 1953, with a history of sudden attacks of amnesia over the last year. No very definite abnormality was found on physical examination; a peripheral blood film showed a normal picture with haemoglobin 94%. Wassermann reaction negative. He had no symptoms when seen in January, 1954, but was admitted to this hospital in August, 1954, with further attacks of amnesia, frontal headaches, and momentary aphasia. Examination revealed slight nominal dysphasia, right homonymous hemianopia, slight papilloedema of right disk, and accentuated right-sided tendon jerks. A skull radiograph was normal, but the cerebrospinal fluid was xanthochromic, under enhanced pressure, and contained increased protein and excess globulin. Blood count on August 27: Hb 74%; R.B.C. 4,060,000 per c.mm.; C.I. 0.92; W.B.C. 6,800 per c.mm.; polymorphs 62%; lymphocytes 37%; monocytes 1%. A left carotid angiogram

showed a moderate-sized angiomatous malformation in the temporo-parietal region with pineal shift to the right.

He was admitted to the Manchester Royal Infirmary in October, 1954, for removal of the angioma. On October 14 his haemoglobin was 72%. Operation was on October 22, and the same evening a post-operative clot was removed and blood loss was replaced with 6 pints (3.4 litres) of blood. Chloramphenicol, 500 mg. six-hourly, was started by mouth. Four days later the haemoglobin was 48%. Blood examination on the 29th showed W.B.C. 1,110 per c.mm. (polymorphs 38%, lymphocytes 52%), and on this day chloramphenicol was stopped. A few pints of packed cells was transfused, and on his discharge on November 28 the haemoglobin was 72%.

He was readmitted on February 14, 1955, as he was becoming increasingly pale and listless. There was no enlargement of liver, spleen, or lymph nodes. A soft systolic murmur was present at the apex. Blood pressure 160/90 mm. Hg. Blood count: Hb 40%; R.B.C. 2,600,000 per c.mm.; C.I. 0.98; W.B.C. 850 per c.mm. (polymorphs 17%, monocytes 1%, lymphocytes 81%); platelets 147,000 per c.mm.

He was given a transfusion of 4 pints (2.3 litres) of packed cells on admission, followed by a course of treatment with penicillin, sodium pentose nucleotides, and pyrimidine hydrochloride. Blood examination after transfusion showed: Hb 54%; R.B.C. 2,630,000 per c.mm.; C.I. 1.02; W.B.C. 1,100 per c.mm. (polymorphs 18%, lymphocytes 82%). A further 4 pints (2.3 litres) of packed cells was transfused four days later, and 500 mg. of iron given intravenously; but on February 28 the leucocyte count fell to 600 per c.mm., with 28% polymorphs; sternal marrow puncture showed markedly decreased cellularity and very scanty precursor cells, the appearances being of severe hypoplasia of bone marrow. Packed cells, again 4 pints (2.3 litres), were transfused on March 1, and the blood picture on the 7th was: Hb 85%; R.B.C. 4,060,000 per c.mm.; C.I. 1.04; W.B.C. 1,800 per c.mm. (polymorphs 55%, lymphocytes 45%); platelets 199,000 per c.mm. On March 9 he suddenly became comatose and lumbar puncture revealed blood-stained fluid. After remaining in coma for a few days he gradually improved, C.S.F. on April 1 being clear with normal cells and chemistry. The blood picture during the rest of March remained steady with Hb 75% and W.B.C. 1,500 per c.mm. (polymorphs 42%).

He was fairly well, getting up and about, and cheerful though often irrational, till April 2, when an abscess developed in the right gluteal region and streptomycin treatment was added; the abscess opened spontaneously and discharged for a few days before healing. The blood count on April 4 was: Hb 68%; R.B.C. 2,910,000 per c.mm.; W.B.C. 1,700 per c.mm. (polymorphs 34%, lymphocytes 65%, monocytes 1%); but as the leucocyte count fell to 600 per c.mm. on the 19th 2 pints (1.1 litres) of packed cells was transfused. Average blood count during the following month was: Hb 45%; R.B.C. 2,100,000 per c.mm.; W.B.C. 2,000 per c.mm. (polymorphs 20%, lymphocytes 78%). He complained of abdominal pain, but examination of urine and by barium meal showed no abnormality, and liver function tests gave normal results.

Two pints (1.1 litres) of blood was transfused on May 10. Another abscess developed in the right buttock a week later; a further course of streptomycin and penicillin was given without effect, and the abscess was incised with removal of a small amount of thick pus containing a moderate number of leucocytes and numerous Gram-positive cocci in clusters, and from which coagulase-positive *Staphylococcus aureus* was grown. It gradually healed.

On May 26 raised circular pinkish nodules developed on the chest and back. Liver and spleen were not palpable and there were no enlarged lymph nodes. Peripheral blood count: Hb 41%; R.B.C. 1,840,000 per c.mm.; C.I. 1.12; W.B.C. 13,000 per c.mm. (immature cells, type not definitely identified, 33%; monocytes 41%, lymphocytes 11%, polymorphs 5%, polymorphs 10%). Sternal marrow puncture showed predominance of primitive blast cells with occasional premyelocytes, myelocytes, metamyelocytes, and

polymorphs. Erythrocyte reaction was normoblastic and cells were poorly presented, only an occasional proerythroblast and intermediate and late normoblast being seen. The picture was one of acute myeloblastic leukaemia; this was confirmed by Dr. J. F. Wilkinson, and 3 pints (1.7 litres) of packed-cell blood transfused. On June 1 a few areas of haemorrhages developed under the skin. For the first time both liver and spleen were palpable, but no lymph nodes. The pinkish skin nodules were more prominent. The patient was slightly febrile and occasionally irrational.

On June 11 he was given 6-mercaptopurine, 50 mg. six-hourly, and this was continued up to the 26th, 3 pints (1.7 litres) of packed cells having been given on the 18th. Blood counts remained as follows: on June 2—Hb 36%, W.B.C. 9,900 per c.mm. (blast cells 81%, unidentified cells 4%); and on June 15—Hb 39%, W.B.C. 12,300 per c.mm., with 81% blast cells. On June 23, following transfusion, the Hb was 56%, but the W.B.C. had fallen to 2,700 per c.mm., probably due to the 6-mercaptopurine; it further fell to 1,200 per c.mm. four days later.

On June 29 the patient suddenly became comatose, starting with a right-sided convulsion, and died two hours later. Permission for necropsy was withheld.

COMMENT

Since 1950 innumerable cases of blood dyscrasia following chloramphenicol administration have been reported in the world literature; these range from transient depression of the bone marrow causing minor granulocytopenia to fatal aplastic anaemia involving erythrocytes, granulocytes, and platelets. Usually they occur after prolonged administration of large doses, but cases are on record in which aplastic anaemia has developed after a single course or after a small precipitating dose at an interval of weeks or months after a sensitizing course. In the present case only one course of chloramphenicol to a total of 12 g. was given, and it seems certain that the patient had not had the drug previously.

No case has hitherto been described of acute leukaemia developing after chloramphenicol treatment. Recently Wilkinson (1955) has drawn attention to the occurrence of acute leukaemia as a sequel to agranulocytosis caused by sulphonamides, and he cited nine cases of acute leukaemia developing after sulphonamide therapy. If acute leukaemia can follow agranulocytosis due to sulphonamides there is no reason why it cannot similarly develop after treatment with chloramphenicol. The hypoplastic bone marrow, in an effort to produce cells, may suddenly pour primitive blast cells into the circulation, giving a picture of leukaemia.

In the present case leukaemia was found after an abscess had developed. Sometimes a leukaemoid reaction of the marrow is seen after an acute fulminating infection, but in the present case the findings in the peripheral blood and marrow, correlated with the clinical findings, left no doubt as to the diagnosis of leukaemia—severe anaemia, thrombocytopenia, granulocytopenia, and a high percentage of blast cells in the peripheral blood and marrow are not seen in any other condition. A sternal marrow biopsy was not carried out before the operation or immediately after it, and the possibility that the process was present before the administration of chloramphenicol cannot be ruled out. The patient died in spite of treatment with the new cytotoxic drug 6-mercaptopurine and repeated blood transfusions. Cortisone was not tried.

I am grateful to Dr. R. M. Maher for continuous encouragement and for permission to publish this case; to Dr. J. F. Wilkinson, Director of the Department of Haematology, Manchester Royal Infirmary, for seeing the case and for helpful criticism of this paper; to Mr. R. T. Johnson, Neurosurgeon, Manchester Royal Infirmary, who carried out the operation; and to Drs. R. A. Daly and S. Szutowicz, of the Department of Pathology, Birch Hill Hospital, for help with the haematological work.

P. S. MUKHERJI, M.B., B.S., D.C.H.,
Late Medical Registrar, Birch Hill Hospital, Rochdale, Lancs.

Reviews

HARVEY'S LIFE AND WORKS

William Harvey: His Life and Times: His Discoveries: His Methods. By Louis Chauvois. Foreword by Sir Zachary Cope. (Pp. 271. 25s.) London: Hutchinson Medical Publications. 1957.

This new biography of William Harvey by an eminent French physician and classical scholar appears appropriately in this tercentenary year of Harvey's death. As Sir Zachary Cope observes in the foreword: "To Harvey's countrymen it should be regarded as a sincere and great compliment that such an enthusiastic biography should now be forthcoming from France." The biography published in Paris in French appears simultaneously with this English version. A word of praise is due to the anonymous English translator and the editor of the book, who seem to have performed their task with competence and wisdom. Only a few misprints have been noted; for instance, "Magendi" for Magendie and "Wilmott" for Sir Wilmot Herringham (footnote on page 177 and index).

Dr. Chauvois has spared no pains in this study. Not only has he carefully read the Latin text of Harvey's works and previous biographies, but he has sought aid from the College of Physicians and from English authorities on Harvey, especially Lady Moran and Sir Geoffrey Keynes. In addition he has made several visits to England to see the scenes of Harvey's labours—Cambridge, St. Bartholomew's Hospital, Oxford—and has stood beside Harvey's last resting-place in the Harvey Chapel at Hempstead parish church in Essex. The main facts of Harvey's life are well known and are ably set forth here. But Dr. Chauvois is a poet as well as a historian, and from time to time he enlivens the book by speculations as to what Harvey may have thought and done. Chapter I tells of "A Day with William Harvey, London, 1627"; in Chapter IV is given a charming but purely imaginative account of an Italian country ramble by Harvey after taking his doctor's degree at Padua; and in Chapter V it is suggested that Harvey met Shakespeare somewhere in London, although there are no documents of the time to prove that the two men were acquainted. These excursions into the realm of "what might have been" are unusual in a scientific biography. Dr. Chauvois is in error in surmising (on page 180) that the Harvey family has become extinct. Several members of the family, including some of Eliab Harvey's descendants, are with us at the present day and take a keen interest in their illustrious forebear.

The author's brilliant and learned commentary on *De Motu Cordis* adds to our knowledge of the magnitude of Harvey's discovery. He gives due credit to Servetus, Colombo, and Caesalpinus, but shows that their works on the circulation of the blood in no way detract from Harvey's fame as the discoverer. It will be remembered that Harvey, shortly before his death, told Robert Boyle that it was the existence and position of the valves in the veins that led him to think of the circulation of the blood. Re-examination of the Latin texts impels Dr. Chauvois to suggest that some current interpretations of Harvey's teaching on the circulation, especially as to the heart being its initiator, are seriously at fault. In this connexion he considers that too little attention has been paid to Harvey's two letters of 1649 to Jean Riolan, which represent Harvey's matured judgment on his discovery. Chapter IX gives an illuminating account of the contemporary reception of Harvey's discovery in France. Descartes was one of the first to accept this with some reservation. It is of interest that Louis XIV, having been advised by his surgeon, Dionis, that the Faculty of Medicine had ostracized the new doctrine of the circulation of the blood, decided in 1673 that Dionis should occupy an independent chair of anatomy in the royal *Jardin du Roy* where the teaching of Harvey should be imparted. This led

to mention and praise of Harvey's discovery by Molière, Boileau, and La Fontaine.

Only a short space is given in this book to an account of Harvey's *De Generatione*. Here the author's evaluation is based on the scholarly papers of H. P. Bayon. But *De Generatione* deserves greater appreciation than it has hitherto received. It reveals Harvey as a pioneer in embryology, a forerunner of Wallace and Darwin, the founder of scientific midwifery, an epidemiologist, one who first showed that contagious and infectious disease spread through the blood, and whose prophetic vision saw even to the threshold of bacteriology. The pillage of Harvey's papers, "the fruits of many years of toil," by the soldiers of the Parliament, and the destruction of his books and manuscripts in the burning of the College of Physicians in the Great Fire of London, have deprived medical science of much further knowledge obtained by Harvey in his busy and industrious life.

In the epilogue to this delightful book Dr. Chauvois pays homage to Harvey in a graceful French poem, which is worthy to rank beside the lyrical tributes penned by Cowley, Dryden, and John Collop on Harvey and his discovery.

ARTHUR S. MACNALT.

TONSILLAR TUMOURS

Les Tumeurs de l'Amygdale et de la Région Vélopalatine. By A. Ennuyer and J.-P. Bataini. (Pp. 536+vi; illustrated. 5,000 frs.) Paris: Masson et Cie. 1956.

This volume—one of a series dealing with cancer of small areas in the upper respiratory tract—confines itself to growths of the tonsil, soft palate, and parapharyngeal spaces in so far as they impinge on the tonsil. In their preface the authors point out that they are radiologists, so that ray treatment takes first place and surgery is but briefly discussed. Certainly it would be difficult to conceive a more comprehensive, painstaking, and detailed account of the varieties of ray treatments—radium needles, telradium, deep x-rays, cobalt bomb, and linear accelerators, alone or in combination—and their results; statistics from many sources are set out in tables. Through Dr. Fautrel the figures from the Curie Foundation over 30 years are made available, 534 cases of growths of the tonsil and palate having been followed up. A list of 1,500 references stresses the enormous extent of the authors' research in the literature. The treatise is divided into eight parts, of which the first, on epithelioma of the tonsil, occupies almost a third of the book; somewhat unusually pathology and treatment are dealt with first. The second part is concerned with the soft palate and the third with sarcoma. All treatments are described in great detail, and the results shown in many tables from diverse sources.

Surgical removal of the tonsil used to give very poor results, not to mention post-operative mortality, but in 1954 Dargent introduced transmandibular pharyngectomy with immediate plastic flaps, and there are several very clear pictures of the stages of this operation which greatly improved the results. Cures (survival for five or more years) among the 534 cases dealt with occurred in an average of 29%, though this figure was not reached in several of the sources quoted. Necrosis of the mandible occurred in 29 cases as a result of x-ray treatment of the tonsil, but never after telradium. For epithelioma of the soft palate diathermy excision is advised if the growth is localized; endobuccal x rays are applied through a metal tube (a *localisateur*) provided with a hinged flap which is adjusted behind the soft palate, so protecting the surrounding structures. There follows a discussion on symptoms and diagnosis of the early cases, since not unnaturally the prognosis is so much better when treatment is started during the first month and before cervical lymph nodes are palpable. All other types of growth—innocent, plasmocytic, and Hodgkin's disease—are dealt with, also treatment with radioisotopes and A.C.T.H. Finally there is an interesting list of 47 cures, each with a diagram showing the position of the original growth accompanied by details of treatment.

Throat surgeons will not find much new in this encyclopaedic work, but reference to it will assist them in choosing appropriate radiotherapy in individual cases. Radiologists should find the book of interest and a matter for admiration.

W. M. MOLLISON.

THERAPEUTICS

A Course in Practical Therapeutics. By Martin Emil Rehfsuss, M.D., F.A.C.P., LL.D.(Hon.), and Alison Howe Price, A.B., M.D. Third edition. (Pp. 972+xvii; illustrated. £6.) London: Baillière, Tindall and Cox Ltd. 1956.

The numerous textbooks on therapeutics which are published in America—mostly very large and expensive and nearly all of which run into several editions—are a testimony to the widespread interest in the subject which exists on that continent. They are nearly all composite works, written by groups of men whose investigations and teaching experience in certain aspects of internal medicine qualify them to make authoritative statements. From a British point of view their only drawbacks—apart from their price—are the unfamiliar nature of some of the proprietary drugs mentioned and the dreadful crimes which are often committed in them on our common heritage, the English language—though it must be confessed that such crimes are by no means the prerogative of Americans. The great majority of these textbooks are very good, and this one—the product of the staff of the Jefferson Medical College of Philadelphia—is among the best of them. It is the third edition since 1948, superbly bound, beautifully printed on excellent paper, and splendidly illustrated; it weighs over 6 lb. and sells in this country at £1 a pound. The extraordinarily rapid evolution of therapeutics which quickly renders large parts of such books out of date makes it doubtful whether it is wise to produce a volume of such evanescent value on such a sumptuous scale. This is the only serious criticism of the work, though it is inevitable that occasionally there should be a therapeutic recommendation in it with which the reviewer disagrees. The book, which is remarkably comprehensive, is produced in four sections: Section 1 deals with general therapeutic principles—prescription writing, dietetics, nursing problems, and the contents of the physician's bag; Section 2 is concerned with symptomatic treatment—backache, constipation, cyanosis, fever, etc.; Section 3—much the largest—with the treatment of specific disorders; and Section 4 with special treatment—antibiotics, psychotherapy, isotopes, rehabilitation, and so forth. The standard is everywhere worthy of the distinguished authors.

D. M. DUNLOP.

BLOOD TRANSFUSION

Physiologie und Klinik der Bluttransfusion. By Horst Möller. (Pp. 222+x; illustrated. D.M. 16.) Jena: Veb Gustav Fischer Verlag. 1956.

This book on the physiological and clinical aspects of blood transfusion contains a good deal of useful information, but it also contains rather a lot that is useless and even misleading. This arises from the fact that all opinions which can be supported by a reference to the literature are treated with equal respect. For example, four methods of collecting placental blood are described, two "open" and two "closed," but the author does not say which he prefers. The reader might conclude that allowing the cord to drip into a funnel is just as satisfactory as collecting the blood by puncture of the umbilical vein with a needle attached to a standard "taking" set. The book contains many statements which are out of harmony with modern views. Thus it is not nowadays believed that transfusion stimulates the marrow (p. 63), or that diathermy of the kidney is beneficial in anuria (p. 144), or that a compound with a molecular weight of about 13,000 would stay in the circulation for one or two days (p. 135), or that the transfusion of fresh blood is indicated in the treatment of cardiac infarction (p. 191), or that fresh blood is of any special value in the treatment of leucopenia (p. 96). Although quite a lot is said about the preservation of red cells the book contains no quantitative data about their post-transfusion survival. The information

about blood groups is behind the times. Thus the Kell, Lewis, Lutheran, Duffy, and Kidd groups are dismissed in a few lines as being rare blood factors to be dealt with only in special laboratories. It would be wrong to give the impression that this book is of no value at all; there are many interesting sections, such as those on the history of transfusion and on transfusion techniques. The weakness of the book lies in the fact that the author has too often been unable to call upon his own experience and has been uncritical in selecting the opinions of others.

P. L. MOLLISON.

PULMONARY EMPHYSEMA

Pulmonary Emphysema. Edited by Alvan L. Barach, M.D., and Hylan A. Bickerman, M.D. (Pp. 545+x; illustrated. 80s.) London: Baillière, Tindall and Cox. 1956.

Pulmonary emphysema is one of the common diseases which constantly challenge modern therapeutics. Much investigation has been carried out during the last decade into the aetiology, treatment, and laboratory tests of disturbed respiratory function in this disease. A book embracing the up-to-date views on these diverse aspects and presenting them lucidly to the general reader would indeed be welcome. *Pulmonary Emphysema*, a symposium written by 18 American authors and edited by A. L. Barach and H. A. Bickerman, is an attempt to supply this need. The book is written by experts; it contains a galaxy of facts; it is admirably produced and the bibliography is excellent. The current views on treatment are described in detail and treatment is logically related to the mechanical defects and impaired ventilation which occur in emphysema. The use and dangers of oxygen, the technique of physiotherapy, and the pharmacological approach to treatment are fully and dogmatically outlined. Yet, as a book, it fails because it appears to have been written without considering for whom it has been written. The physician, for example, approaching with relish the chapter on the use of corticotrophin and corticosteroids in emphysema, will find it irksome to read 25 pages devoted almost entirely to the well-established facts about these preparations in general medicine. The chest physician will find much of the material commonplace, whereas the chapter on respiratory function tests will give him a confused account of technique and terminology without supplying a guide to the practical application of the tests described. The general reader will find it cumbersome as a reference book. It is a pity that such excellent material drawn from such wide experience could not have been more clearly presented. It is hoped that future editions of the work will be written more concisely and with more regard and sympathy for the intended reader.

T. PARKINSON.

PHASE-CONTRAST MICROSCOPY OF THE BLOOD

Das Phasenkontrastverfahren in der Haematologie. By H. G. Hansen and Alexander Rominger. (Pp. 126; illustrated. D.M. 16.) Hamburg: Materia Medica Nordmark. 1956.

This book on phase-contrast microscopy in haematology consists of several hundred photographs of cells, each shortly described and linked by a more discursive text. The authors seem to be especially interested to assign cells seen by phase-contrast to categories devised for stained cells. The short sections on physical and cytological fundamentals are quite inadequate, and the book depends for its interest mainly on the pictures. These are of very unequal value. Most of them show less detail than can be attained in comparable material, and, though much of this is due to imperfect reproduction, some appear to be due to technical imperfection. There are, however, some excellent pictures of malaria, toxoplasma, trypanosomes, and leishmania, of unusual leukaemias, and capillaries and sinusoids of bone marrow. One can only learn phase-contrast cytology by using a phase-contrast microscope, and this book will be of very little help to beginners or to anyone else.

GEORGE DISCOMBE.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY JUNE 1 1957

THE OLD AND THE NEW

William Harvey died three hundred years ago—on June 3, 1657—and medical men and women from all over the world will commemorate the event at the Harvey Tercentenary Congress in London next week and in Folkestone, Harvey's birthplace, during the following week-end. The Congress will be under the presidency of Mr. A. Dickson Wright, and many professional and learned bodies, including the Royal Society and the Royal Colleges of Physicians and of Surgeons, have helped to draw up the programme, details of which are given elsewhere (p. 1296). The meetings will be held mainly in the commodious premises of the Royal College of Surgeons of England in Lincoln's Inn Fields. The place would have been even more appropriate had it developed as a joint centre of all the medical colleges, for there is no department of the healing art, whether surgery, internal medicine, obstetrics, or general practice, and no specialty from otology to psychiatry that is not deeply affected by advances in knowledge of the physical, chemical, and biological aspects of the circulation. May this occasion be an omen for the reunion of the fragmented body of medicine that would be as welcome to Harvey as to his great predecessors Hippocrates and Galen.

Apart from the many remarkable advances in the diagnosis and treatment of diseases of the vascular system, some may perhaps ask whether there is really anything new to be said about the work of such a historical figure as Harvey and about the man himself—the object of hundreds of "Orations," two of which we have chosen to reproduce in the opening pages of this issue. The true answer is surely in the affirmative. As F. N. L. Poynter remarks in his informative article (see p. 1297), Harvey's place in the history of scientific thought cannot be immutably fixed, but is subject to a continuing process of reassessment. First as regards the man himself. He is represented, or alleged to be represented, by a very large number of portraits. All were thought to be of Harvey well advanced in life. A few years ago Sir Geoffrey Keynes found at Rolls Park in Essex a portrait of him near the date of his discovery (reproduced in the middle of this issue). This is specially to be

cherished, for it represents him in the vigour of his forties. We know that he was then busied with the dissection and examination of every kind of animal, and this portrait is that of a man that we can well think of as so occupied. Sir Geoffrey has reproduced and described it in his admirable Vicary lecture *The Portraiture of William Harvey* (1949). In that volume he also discusses the portrait in the Hunterian Collection at Glasgow of about 1655, which is represented in the frontispiece to this number of the *Journal*, and the sculptured bust of about 1656 at Hempstead Church. This Sir Geoffrey believes to have been taken rather from a life-mask than a death-mask and is therefore in a sense the most authentic. It is of Harvey in the late seventies and renders very carefully the wrinkles, creases, and prominent temporal veins of old age. We would here draw attention also to the clear, concise, and interesting account of Harvey and his sojourns and travels by Mr. H. R. Trevor-Roper and others in the interesting handbook issued by the Congress itself. Above all there will be available at the Congress the new translation of Harvey's great book by Professor Kenneth J. Franklin, F.R.S., of the Medical School of St. Bartholomew's, Harvey's own hospital. Professor Franklin combines devotion to scholarship with practice in experimental physiology to a degree which must be unique. Harvey's book is difficult both in language and in structure, and it was high time for a new translation with all the apparatus of modern scholarship and modern scientific knowledge. Some further comment on this work will be found at p. 1293.

So much for *vetera*, of which we have pointed to a few highlights. Were we to attempt to treat in the same way the *nova* of even the last two or three decades neither this article nor even this number would suffice. We can but indicate a very few matters which must come under discussion at the Congress itself. Apart from the clinical aspects, which can hardly be discussed here, there is, in the region of naked-eye anatomy, the question of the astounding change at birth of the circulatory system of the foetus to that of the air-breathing child. This matter, though often discussed, was not treated adequately on an experimental basis until about twenty years ago with the work of Joseph Barcroft. It was hardly made clear until twelve years ago, with the remarkable book on *The Foetal Circulation* by Drs. Alfred Barclay, Kenneth Franklin, and Marjory Prichard. This showed that the modifications of foetal anatomy and physiology preparatory to the great event of birth had begun very early in foetal life and had already been in part functional long before birth. Nevertheless the oxygen saturation of the arterial blood of the

newborn—in the sheep at least—does not equal that of the adult for an hour or two after birth. It is worth recalling that nearly 1,800 years ago Galen saw the *via sinistra* (foramen ovale) and the ductus arteriosus and found their closure even more wonderful than their original creation.

In Harvey's time the microscope had not yet become an instrument of research. Thus he did not so much describe the circulation as demonstrate its inevitability, and left open the question of how the blood passes from the arteries to the veins. The capillaries, first of the lungs and then of the tissues, were described in his own century but after his death. Throughout the eighteenth and nineteenth centuries the vessels of the blood were described mostly from the point of view of their anatomy and mechanism, both of which were explored in detail. The seventeenth, eighteenth, and nineteenth centuries saw also a similar development in the knowledge of the lacteals and of the lymphatics, which were also treated as closed systems. It was always obvious that since the blood brought nourishment to the tissues there must be some stage at which it, or some part of it, issued from the apparently closed system and came in contact with the minute elements of those tissues themselves. Migrations of white blood corpuscles from the capillaries were described by Lister, Metchnikoff, and others during the nineteenth century, but it was upon the drama of the mechanics and physics of the theoretically closed vascular system that attention was almost entirely riveted. Only during the last sixty years has this emphasis changed. The rise of the sciences of biochemistry and biophysics has brought about this change. We can now at least gain a glimpse of how vast is the area of which we are ignorant. The extravascular fluid, dimly appreciated by Galen and Harvey, has now come into its own. It will in itself provide ample opportunity for observation and thought for generations to come of both clinicians and experimenters. *Quis separabit?* Who will or should sunder them? The time is coming for a reunion of medicine into one body as Harvey would have wished.

BRITISH POLIOMYELITIS VACCINE

The field trial carried out by the Medical Research Council last year on the British poliomyelitis vaccine is reported in the *Journal* this week at p. 1271. This vaccine differs from the American and Canadian vaccines in that its type I strain, called Brunenders, is considerably less virulent than the dangerous Mahoney strain, which caused trouble in America in 1955. The object of this change was to make as cer-

tain as possible that no paralytic cases of the disease could follow injection of vaccine containing active virus. The British vaccine is made from strains of such relatively low virulence that the infective dose for a child would be many thousands of times greater than the occasional "live" virus particle which might, most improbably, elude the very stringent tests by tissue culture and inoculation of monkeys.¹ At the same time antibody studies on monkeys and on children with no previous antibody to poliomyelitis have shown that the Brunenders strain is a good antigen.² It is important to know whether it can also prevent paralytic poliomyelitis, because the predominant type of virus causing the disease in this country is type I. Further, the highest attack rate of paralytic poliomyelitis in Great Britain is in children under 6 years of age. The American 1954 trial³ was only on children aged 6–9, and the results suggested that vaccination might be less efficacious at the youngest age. During the past year the Medical Research Council's Poliomyelitis Vaccines Committee has therefore endeavoured to answer two main questions: Can vaccine containing the Brunenders strain prevent paralysis, and will vaccination protect the younger children? The Committee's careful assessment answers both of these questions in the affirmative and tells how the answers were obtained.

The British vaccine available early in 1956 was administered to children born in the years 1947 to 1954 whose parents registered their wish for vaccination. Because there was enough vaccine for only about 200,000 of the nearly 1,900,000 who registered, it was possible, by giving vaccine only to children born in certain designated months, to accept those who registered but received no vaccine as strictly comparable controls, and to compare their experience of poliomyelitis through the ensuing poliomyelitis season with that of the vaccinated children. In the American 1954 trial the control group received injections of an inert substance; in the different circumstances of the British trial this, even if regarded as desirable, was impracticable. Nearly 400,000 injections of vaccine were given during May and June, 1956, with no ill effects; the only reactions attributable to the injections were trivial. Disregarding 32,379 children who received one injection only, the Committee considers the rest, who were all given two injections with about three weeks between them, in two groups, the older born in the years 1947 to 1950 and the younger in the years 1951 to 1954. In the older group only one case

⁵ Salk, J. E., *J. Amer. med. Ass.*, 1955, 158, 1239.

of paralysis occurred among the vaccinated children, corresponding to an attack rate of 1.3 per 100,000. Had the attack rate been the same as in the unvaccinated controls of this group (8.2 per 100,000), 6 cases would have been expected. The younger vaccinated children produced 3 cases (4.1 per 100,000), whereas 15 would have been expected on the rate observed among the younger controls (20.1 per 100,000). In both groups, therefore, the apparent protection was about 80%, though with such small numbers of cases this figure must be accepted with great reserve.

In the significant part of the American trial of 1954 (the so-called placebo control study) the numbers of children in both vaccinated and control groups were about 200,000. Though the number vaccinated was therefore about the same as in the British trial, the incidence of poliomyelitis was higher in both control and vaccinated groups, giving attack rates respectively of 16 and 57 per 100,000 and an apparent protection of about 72%. On this showing, the admittedly slender experience of Great Britain in 1956 gives no reason for thinking that the performance of the British vaccine, in spite of its greater margin of safety, was inferior to that of the American. The evidence on the effect of vaccination on non-paralytic poliomyelitis is hard to assess because of the inevitable difficulty of diagnosis, but it seems possible that vaccination may produce some reduction in non-paralytic cases yielding virus in the stools.

The ultimate value of the vaccine remains uncertain. Both American and British trials relate only to the months immediately after vaccination, when levels of antibody and probably protection are at their highest. In the American trial three doses of vaccine were given at intervals of a week and a month. Probably the spacing was too close and the effect much the same as that of two doses three weeks apart, as in the British trial. Salk's antibody studies⁵ suggest that a third dose given considerably later may produce a higher antibody level, which stays high for much longer. Does this higher antibody level imply better protection? In short, is a third dose necessary? There are theoretical dangers and practical disadvantages in giving many repeated doses. Will protection last without them? The younger the age at which children are given their poliomyelitis vaccine, the more important do these questions become. It is to be hoped that no opportunity to gain more information in later years will be missed.

In a remarkably short time a difficult and dangerous new manufacturing process has been brought to a high and consistent level of performance. Each batch of vaccine issued has been double-checked for

its safety and antigenic potency; and we now have the best assurance we can expect to get that the product is effective in preventing paralysis in children down to the age of 2 years. Great credit is due to the firm which has made the British vaccine, and to those who have put it through its laboratory tests, administered it, and learned from it what has so far been learned; and also to those who have directed the programme against a background of publicity not always helpful. Throughout, American colleagues have given all the help they could. Without their pioneer research and that of the Connaught Laboratories, there would be no vaccine. The development and testing of the British vaccine is a smaller but valuable contribution to the story which began hardly five years ago, and which will not be completely told for many more years.

NEW TRANSLATION OF "DE MOTU CORDIS"

There have been several English translations of *De Motu Cordis*. The first one, by an unknown translator, was issued in 1653.¹ On the occasion of the tercentenary of *De Motu Cordis* in 1928 this first English text was newly edited by Sir Geoffrey Keynes and printed at the Enschedé Press in Holland for the Nonesuch Press. In *The London Medical and Surgical Journal* for 1832 Dr. M. Ryan published a translation of *De Motu Cordis*, which ran through several numbers, and a biographical sketch. In 1847 *The Works of William Harvey* were translated from the Latin with a life of the author for the Sydenham Society by Dr. Robert Willis, librarian to the Royal College of Surgeons from 1828 to 1845. His translation of *De Motu Cordis*, hitherto, has been in general use. A revised edition, edited by Alexander Bowie, was published in 1889. Willis's translation, with an introduction by E. A. Parkyn, was included in Everyman's Library in 1907.

For a long time medical historians have desired a retranslation of Harvey's first great work, for the earlier versions were not sufficiently accurate for those doing either historical or experimental research upon the circulation. Dr. Chauvois, whose *William Harvey* is reviewed in this issue of the *Journal* (p. 1288), has emphasized that it is necessary to read Harvey's original Latin text in order to get the full meaning of *De Motu Cordis*. This need for retranslation was voiced a year or two ago by Professor John F. Fulton, and was shared by Sir Russell Brain, then President of the Royal College of Physicians. It was clear that the translator must not only be a Latin scholar but also a physiologist and medical historian. These gifts are united in Professor

Kenneth J. Franklin, who occupies the chair of physiology at St. Bartholomew's Hospital Medical College, and at the official invitation of the President of the Royal College of Physicians he undertook the task in time for the new version to be ready by the tercentenary of Harvey's death. This new volume² contains Professor Franklin's elegant translation, Harvey's Latin text (standard 1766 edition), and, as frontispiece, a reproduction in colour of the contemporary portrait of Harvey by Cornelis Janssen in the Royal College of Physicians. It should increase understanding of Harvey's contribution to knowledge, on which modern scientific medicine is based, and will be valued especially by all physiologists and medical historians. We should have welcomed some notes on Harvey's text and the new interpretations which Professor Franklin has discovered. Some of this information will be found in his recent paper.³

It is no small tribute that Professor Franklin has rendered to the *manes* of William Harvey in this tercentenary year of his death. May we express the hope that at some future date he will translate the two *Anatomical Disquisitions* which Harvey addressed to Jean Riolan in 1649? These letters throw further light on Harvey's discovery and represent his mature judgment on the subject. There is need also for a retranslation of *De Generatione Animalium*. Professor Franklin has been so successful in his aims with this scholarly translation that like *Oliver Twist* we are impelled to ask for more.

GOITRE CAUSED BY COBALT

Since cobalt is a constituent of the vitamin-B₁₂ molecule, it may be regarded as essential for erythropoiesis. Moreover, there have been several reports that, in certain cases of anaemia failing to improve with vitamin B₁₂ alone, the addition of cobaltous chloride has led to favourable responses. Such responses have been observed in anaemias associated with chronic infection,^{4,5} chronic renal disease,⁶ prematurity,⁷ pregnancy,⁸ and sickle-cell disease.⁹ But unfavourable as well as favourable reports have appeared, and in particular many cases of cobalt toxicity have been recorded. Rashes, anorexia, nausea, vomiting, tinnitus, and nerve deafness have been encountered, and in addition there is now evidence that cobalt may in certain circumstances interfere with thyroid function.

D. Gairdner, J. Marks, and J. D. Roscoe have described the development of a goitre in an infant during treatment of anaemia with cobalt,¹⁰ while J. P. Kriss, W. H. Carnes, and R. T. Gross¹¹ observed a

goitrogenic effect while treating four children and one adult suffering from sickle-cell disease. Goitres appeared after as little as 6-9 weeks of treatment and evidence of depression of ¹³¹I uptake was obtained. In one of the patients obvious clinical myxoedema was present after three months of treatment, and the plasma protein-bound iodine was down to 1 µg. per 100 ml. Complete remission occurred within a month of withdrawal of the cobalt. In a case reported by H. Breidahl and Russell Fraser¹² a man aged 21 with microcytic anaemia was treated with cobaltous chloride 50 mg. three times a day because of failure to maintain an adequate level of haemoglobin with the usual haematinics alone. Within three months he developed a large, hard, painful goitre. Four days after stopping the cobalt there was rapid uptake of ¹³¹I and conversion to protein-bound ¹³¹I. The low basal metabolic rate (-19%) indicated that the thyroid gland, now active and avid, had previously been under-secreting as a result of the anti-thyroid action of the cobalt the patient had received. Breidahl and Fraser agree with Kriss and colleagues that the goitrogenic effect of cobalt is probably due to its action as a heavy metal in inhibiting an enzyme system, and indeed S. Kirkwood and D. Fawcett¹³ have shown that, in a cell-free suspension of thyroid tissue *in vitro*, cobalt inhibits the activity of tyrosine iodinase.

Though several other reports¹⁴⁻¹⁶ confirm the goitrogenic action of cobalt, it is clear that not everyone is susceptible to this action. Thus, of a series of 15 children receiving cobaltous chloride in a daily dose of 1 to 6 mg. per kg. of body weight for ten weeks, no clinical or laboratory evidence of thyroid dysfunction appeared in 13, though in 2 who received the higher dose significant depression of ¹³¹I uptake was noted.¹⁷ No thyroid dysfunction was observed in a group of 78 pregnant women (or in their offspring) when treated with 60 to 100 mg. per day of cobalt for at least three months.⁸ Nor was any goitrogenic effect observed in two other groups of adults and children treated for periods of up to several months, though thyroid function was not specifically studied.^{18,19} It therefore seems that only a small proportion of patients are susceptible to the goitrogenic effects of cobalt, but it is far from clear what determines this susceptibility. Though the risk is not great, and thyroid function becomes normal when administration of cobalt is stopped, it would nevertheless seem wise to reserve cobalt for the treatment of conditions other than anaemias simply due to pregnancy or to deficiency of iron.

THE SQUINTING CHILD

The advent of orthoptic treatment some thirty years ago revolutionized the attitude of the ophthalmic surgeon to the management of the squinting child. Until that time a squint was regarded largely as a cosmetic defect amenable to surgical correction during adolescence, and little attention was paid to the restoration of binocular function. As the study of orthoptics developed the treatment

of squint became directed along certain well-defined lines—the re-establishment of a harmonious relationship between the accommodation and convergence reflexes by the correction of any refractive error; the restoration of adequate vision in the squinting amblyopic eye by occlusion of the non-squinting eye; and, finally, the restoration of binocular single vision by orthoptic treatment, supplemented if necessary by surgical operation. This new approach represented a great advance over earlier methods, but there was a tendency to overstress the role of orthoptic treatment by applying it indiscriminately to all types of cases, sometimes for prolonged periods, with little regard to the ultimate value of such treatment. This danger was appreciated by F. B. Chavasse,¹ who showed that the presence of good vision in each eye is not enough for the re-establishment of binocular vision, and that the earlier the age of onset of the squint and the longer the interval of time before corrective treatment is carried out, no matter how intensive this treatment may be, the less likely is the restoration of binocular function.

A recent critical analysis of a large series of unselected cases of all types of squint by T. Keith Lyle and Jill Foley² puts into true perspective the part played by orthoptics in the treatment of squint. In some types of squint (for example, non-paralytic accommodative convergent strabismus) treatment by glasses and by operation will usually give binocular vision without recourse to orthoptic treatment. But in other types of squint (for example, non-paralytic non-accommodative convergent strabismus) full binocular vision is obtained in only a small number of cases despite the most energetic orthoptic treatment, although a few children may reach the stage of possessing a subnormal form of binocular vision. The likelihood of attaining binocular single vision may be determined accurately at an early stage in the investigation of a squint, because the age and mode of onset of the squint, the family history, and a simple clinical examination (quite apart from examination on a major amblyoscope) will give valuable information on which the ultimate progress of the case can be predicted. In this way it should be possible to avoid the tedious repetition of orthoptic procedures when the child will not obtain binocular single vision, and thus to enable the orthoptist to concentrate on the more promising cases. Consequently the orthoptic department must be essentially diagnostic before it can hope to be therapeutic.

CENTRAL HEALTH SERVICES COUNCIL

The annual report¹ of the Central Health Services Council, published last week, records the decisions of the council and of its advisory committees on a number of matters. The standing joint committee on the classification of proprietary preparations continued its work during the year, classifying about 400 new products. Of the 5,000 proprietary preparations classified by the committee and now on the market, 70 are in category 1 (new drugs of proved value not yet standard), 4,100 in cate-

¹ Report of the Central Health Services Council for the year ended December 31st, 1956, preceded by a statement made by the Minister of Health, 1957, H.M.S.O., London.

gories 2, 3, and 4 (not regarded as therapeutically superior to standard preparations), and the remainder in categories 5 and 6 (preparations of unproved therapeutic value). The standing medical advisory committee has been inquiring into the incidence and treatment of bronchitis and come to the conclusion that patients with this disorder should be admitted for treatment to hospitals in the country or to air-conditioned wards in urban hospitals. A majority of a subcommittee appointed to look into the present need for welfare food supplements decided that children between 2 and 5 received enough vitamin C from a mixed diet and that the issue of orange juice should be restricted to children under 2. This subcommittee also recommended that the content of vitamin D in national dried milk, welfare cod-liver oil, and infants' cereals should be reduced so as to minimize the risk of inducing hypercalcaemia.

A large part of the report is devoted to the work of the standing mental health advisory committee, which has been reviewing the functions of the various authorities concerned with the treatment and care of the mentally ill, including those who are mentally infirm because of old age. The primary purpose of this review was to see whether the pressure on mental hospitals could be relieved by devising alternative forms of care. After "exhaustive consideration" the committee, like others before it, found that many faults in the present system could be attributed to lack of co-ordination. Closer co-operation between the staff of mental hospitals and clinics, local health and welfare authorities, general hospitals, and general practitioners should do much to improve matters. A properly co-ordinated scheme—of the type which has been working well in Oldham and Nottingham—enables new patients to be admitted according to need to a mental or chronic-sick hospital or to a welfare home, or to be given help in their own homes, with possible attendance at a day hospital. The unsatisfactory nature of present arrangements can be judged from the fact that the committee finds it necessary to stress that "the general practitioner should be furnished with a report on his patients on discharge or as soon after as possible, and that it should state the diagnosis, the treatment given, the stage of recovery reached, and any suggestion for subsequent treatment or care. He should also be notified of the death in hospital of any of his patients." A useful suggestion is that housing authorities might help younger tenants to look after their elderly and infirm relatives by providing suitable accommodation for them either in the family home or in separate buildings near-by. In all this work the report emphasizes the continuing need for the help of voluntary organizations.

MECONIUM

Meconium is a viscid, semifluid mass which consists mainly of mucus. With it are mixed epithelial debris, keratin squames, and bilirubin, which imparts the dark green colour. It also contains a variable number of small, firm, yellow particles, meconium bodies, the origin of which is uncertain. The keratin squames are derived from the foetal skin, and are swallowed with liquor amnii. Their presence in meconium smears is used

ROYAL SOCIETY CONVERSAZIONE

Some years ago an astronomer remarked that he had more than once been asked, after lecturing to a lay audience, "You say the spectra showed you what the stars be made of, but how did you get at their names?"¹ We may be more sophisticated nowadays, but a visit to the Royal Society's annual conversazione is enough to stir the same feelings of amazement at man's ingenuity. The display this year on May 23, at which Sir Cyril Hinshelwood, P.R.S., received the guests, contained many striking exhibits, some illustrating new research in medicine and physiology.

Rotation of the eyeball to compensate for rotation of the head was the subject of a demonstration by Dr. P. A. Merton and his colleagues, of the neurological research unit, National Hospital for Nervous Diseases. Compensation by horizontal and vertical movements so as to keep the image on the retina steady is a matter of common observation, but the eye can also be seen to rotate as the subject's head is swung through a small arc. The conjunctiva, not being so mobile, slides over the eyeball. Glasgow University and the Western Regional Hospital Board were showing an artificial respirator for newborn babies. The infant's feeble efforts to take breath activate the machine to supply air in the volume he needs instead of in proportion to his weak muscular movements. Experience has already shown this device to be of great value in practice. Mr. J. A. Armstrong and Dr. Janet S. F. Niven, of the National Institute for Medical Research, showed some beautiful histological specimens in a fluorescence microscope, as well as colour transparencies obtained with this instrument. The sections are treated with fluorescent compounds and then illuminated with violet or ultraviolet light. This induces differential fluorescence, so that structures containing ribonucleic acid show red, while those containing deoxyribonucleic acid show yellow. An exhibit by Dr. A. C. Allison and Mrs. W. ap Rees, of Oxford University, illustrated the inheritance of the haptoglobins. These are serum proteins; four have been identified and their mode of inheritance analysed. Rarely, they are absent from the serum, and the patient then suffers from haemoglobinuria, since one of their functions is to prevent the renal excretion of haemoglobin. An exhibit of uncommon interest and beauty was put on by Professor H. G. Callan and Mrs. L. Lloyd, of St. Andrews University, showing giant chromosomes from the eggs of newts. The structure of the chromosomes, under moderate magnification, notably resembled the strings of beads to which they and their genes are sometimes colloquially likened. Elsewhere, the spirit that animates small boys to rush from case to case in the Natural History Museum on a Sunday afternoon in Kensington was found to be by no means absent from their seniors, and there was quite an ugly rush of Fellows and guests to see this Museum's exhibit of dinosaur eggs. Fragments over 100 million years old, and casts of actual specimens which included one showing baby dinosaurs hatching, stirred conflicting thoughts on the brevity of human existence.

in Farber's test to prove the patency of the alimentary tract. At the distal end of the mass of meconium, in the anus and rectum, is a cap of pale mucus, firmer than the meconium, and presumably derived from the colon and rectum.

The foetus does not normally pass meconium before birth, because the expulsive action of the rectum and anus is absent, though the small intestine has some peristaltic activity. At full-time birth the distal colon and rectum are loaded with it. The first meconium stool should be passed within twenty-four hours of birth. Passage of meconium before delivery is evidence of foetal distress, and is ominous because it indicates severe foetal anoxia and also because it creates the risk that the foetus will aspirate meconium into the lungs. If the baby is then born alive its respiration may be so impeded that it suffocates; or the meconium may cause death from obstructive emphysema and pneumothorax.

Impaction of meconium as a cause of intestinal obstruction in the foetus and newborn is familiar in association with fibrocystic disease of the pancreas. A feature of that disease is an abnormally viscid secretion from all mucous glands. Because of this and the absence of pancreatic enzymes, the viscosity of the meconium is greatly increased and causes it to be impacted in the distal ileum, where it is inspissated to clay-like consistency. Hirschsprung's disease with a long aganglionic segment causes similar impaction, but the fault is in the innervation of the bowel, not in the meconium, which therefore does not have such an extremely hard consistence. Two recent papers by J. L. Emery¹ and R. B. Zachary² draw attention to a less familiar and less serious cause of obstruction due to impacted meconium—the presence of meconium plugs. These are most often in the anus and rectum, and are formed from the cap of pale mucus, which is unusually hard, probably because of delay in passing it rather than because the meconium is abnormal. Removal of the plug by rectal examination or wash-out relieves the obstruction. Emery also describes plugs of tenacious meconium causing obstruction in the small intestine. He found that the water content of the plugs was much below that of the normal meconium, and ascribed them to a disturbance of water balance in the affected segment.

Inspissation and impaction of meconium may cause ulceration of the intestinal mucosa even before birth. Organization of inspissated meconium in the bowel at the site of ulceration is responsible for some examples of congenital intestinal atresia. When an ulcer perforates before birth, meconium escaping into the peritoneal sac causes an aseptic inflammation, with adhesions, among which particles of meconium become calcified. In newborn infants perforation of similar ulcers may cause death from septic peritonitis. Emery and Zachary describe several cases in which perforated ulcers were related to hard faecal masses, and suggest that the cause may be excessive absorption of water from the faeces, or possibly an anomaly or immaturity of the intrinsic innervation which eludes histological recognition.

HARVEY TERCENTENARY CONGRESS

On Monday the Harvey Tercentenary Congress opens at the Royal College of Surgeons. William Harvey was born at Folkestone in 1578 and died on June 3, 1657, in the eightieth year of his life. The Congress will commemorate, in the words of Mr. A. DICKSON WRIGHT, its president, "the passing of the great discoverer of the circulation of the blood."

The Congress is as much concerned with the present as the past. The theme for the five-day scientific meeting at the Royal College of Surgeons is "Our Present Knowledge of the Circulation." Here, distinguished speakers from the United States, Canada, Belgium, France, Germany, Sweden, and Switzerland will join British workers in reviewing our knowledge of the circulation of the blood. Their contributions will cover the role of the heart, haemodynamics, the coronary and pulmonary circulation, cardiac surgery, and the cerebral, splanchnic, and peripheral circulation. This contemporary conspectus will be preceded by an opening session on the knowledge of the circulation from the seventeenth century onwards. But the main historical commemoration will be during the two-day meeting at the week-end, under Sir GEOFFREY KEYNES'S chairmanship, at Folkestone. Harvey's birthplace, Harvey at Cambridge and Padua, Harvey's influence on French medicine, and Harvey the scientist will be the subjects of discourses.

The idea of the Congress originated with the Harveian Society of London two years ago. Since then other learned bodies have joined with the Society to make the Congress possible. The Congress president is this year's president of the Harveian Society.

Special Features

Accompanying the Congress will be memorial services in St. Paul's Cathedral (Royal College of Physicians) and at Canterbury Cathedral; banquets in London and Folkestone; Harveian exhibitions at the Wellcome Historical Medical Museum, the Royal College of Physicians, and the Royal College of Surgeons; a special meeting of the British Cardiac Society; a civic procession in Folkestone to Harvey's statue; films; and a number of receptions for the delegates.

Certain events, however, are of more than ordinary interest. During the scientific meeting at the Royal College of Surgeons the transatlantic radio-telephone will be used to allow American doctors attending the American Medical Association's annual meeting in New York to participate in the discussion on cardiac surgery. A programme of closed-circuit colour television, sponsored by Messrs. Smith, Kline and French Laboratories Ltd., has also been arranged. This is only the second time that colour television has been used at a medical meeting in Britain: the first was at the joint meeting of French and British surgeons at the R.C.S. this week, and next month there will be further demonstrations at the Royal College of Surgeons of Edinburgh and at the B.M.A. Annual Meeting in Newcastle upon Tyne. At the Harveian Congress delegates will see on television, among other "live" demonstrations, Melrose's heart-lung machine and the mass spectrometer described by Fowler and Hugh-Jones in our last issue (p. 1205). The Royal College of Physicians has sponsored a new translation of Harvey's *De Motu Cordis*, with Professor K. J. Franklin, F.R.S., as the translator, and also a new edition of the film on Harvey. The film will be shown at the Royal College of Physicians at 5 and 5.45 p.m. on June 3, 5, 6, and 7, admission to it being free to Fellows, Members, and licentiates of the College as well as to the Congress delegates. Finally, the banquet at Folkestone, which the civic authorities and Messrs. Pfizer Ltd. are arranging, will be Elizabethan in both setting and menu, and the banqueters will be regaled with madrigals.

Congress Handbook

As frontispiece to the official Congress Handbook are reproduced the Royal College of Physicians' portrait, show-

ing Harvey in his old age, and a specimen of his signature—"Will. Harvey"—taken from a document in the archives of St. Bartholomew's Hospital. The Handbook also provides some historical background. Mr. H. R. Trevor Roper writes on "Harvey: The Man and His Times," Professor F. J. W. Roughton, F.R.S., on "Harvey and Cambridge," Professor A. Dalla Volta on "Harvey and Padua," and Sir Charles Dods, F.R.S., on "The Royal College of Physicians and Harvey." There are also unsigned contributions on "Harvey and Folkestone" and "William Harvey at St. Bartholomew's Hospital." Lastly there is an account of the Royal College of Surgeons "and its surroundings," and an essay by Dr. M. C. W. Long, last year's president, on the Harveian Society of London. The Society began on September 15, 1831, as the Western London Medical Society, but only eleven days later changed its name to the Harveian Society, "in token of a resolution strictly to adhere to the course of observation and induction so successfully pursued by the illustrious discoverer of the circulation of the blood."

The Wellcome Exhibition

On June 3 (at 6 p.m.) Sir RUSSELL BRAIN will open a special tercentenary exhibition at the Wellcome Historical Medical Museum, Euston Road. It is designed to illustrate Harvey's life and the development of the ideas which led up to his discovery. The exhibition will then remain open to the public, from 10 a.m. to 5 p.m. daily, for about a month. Besides displaying the Wellcome Library's unrivalled collection of Harvey's books, beginning with the first edition of the short treatise in Latin in which in 1628 Harvey announced his discovery to the world, there will also be on view various personal documents such as the original probate copy of his will.

ROLLS PARK PORTRAIT OF HARVEY

The portrait, reproduced opposite, is the only known authentic likeness of William Harvey in his prime. It was identified by Sir Geoffrey Keynes at Rolls Park, near Chigwell, the estate acquired early in the seventeenth century by Eliab Harvey, William Harvey's brother. The portrait was one of seven uniform heads-and-shoulders of Thomas Harvey's sons surrounding a large panel depicting their father. In an addendum to his Thomas Vicary Lecture, 1948, on "The Portraiture of William Harvey" Sir Geoffrey Keynes describes the portrait as follows:

"William Harvey is shown as a man of about 45, with dark hair, a heavy moustache, and a small peaked beard. He is wearing a doublet. The background is inscribed, *Doctor William Harvey*. There is no date, but it is plain that we see here an image of Harvey as he was about 1620-1625, not long before he published his immortal treatise, *De Motu Cordis*. The picture adds authenticity, if any were needed, to the later images . . . since it was possible to recognize Harvey's face almost in the dark from knowledge of his appearance in old age, and demolishes more completely than ever the claims of pictures such as the forgery . . . dated 1628. It is a satisfaction," states Sir Geoffrey Keynes in conclusion, "to be able to round off this iconography of Harvey by the addition of a virtually unknown image painted 30 years earlier than any hitherto described."

The Rolls Park portrait is at present on loan to the Royal College of Physicians, where it may be seen in the entrance hall. We are indebted to Mr. Andrew Lloyd, the owner of the portrait, for permission to reproduce it.

CURRENT THOUGHT ON HARVEY

BY

F. N. L. POYNTER, Ph.D., B.A.

Prospect as well as retrospect marks the character of this week's Harvey Tercentenary Congress at the Royal College of Surgeons, and it is good that it should be so. There is no sharp dividing line which marks off past from present, history from current research. In pointing out those strands of the past which are woven into current thought the historian forces us to examine more closely and more objectively much of what is accepted as fact. When the historian is engaged in tracing the development of ideas in science and medicine his work is an essential complement to research, for it helps to maintain conditions favourable to critical inquiry and the emergence of new ideas, without which the most elaborate experimentation in the most splendidly equipped research laboratories becomes dull routine.

Nowhere is the emergence of a new fundamental truth from a critical examination of past beliefs more beautifully demonstrated than in Harvey's own *De Motu Cordis*. For generations medical historians have argued the significance of Harvey's debt to the past and some have questioned the originality of his ideas, so that eminent physicians paying tribute to Harvey's genius have felt it safer to emphasize the revolutionary nature of his work purely as a demonstration of scientific method. But the ideas and opinions of historians themselves have to be submitted to the same kind of scrutiny, and the reassessment of Harvey's place in the history of scientific thought has been proceeding steadily since 1928, when the tercentenary of the publication of the *De Motu Cordis* was celebrated. Some important aspects of this new assessment are to be found in the current issue of the *Journal of the History of Medicine* (1957, 12, No. 2) which is a commemorative number devoted entirely to Harvey. The editor of the journal, Dr. John Fulton, professor of the history of medicine at Yale University, has invited contributions from a

number of countries, and, of the 21 papers included, nine come from Britain, four from the United States, and one each from Canada, Denmark, East Germany, France, Israel, Italy, Spain, and Sweden, a collection which can truly be described as an international tribute to Harvey's memory.

Harvey's Debt to the Past

In an attempt to place this in its proper perspective no fewer than nine of these papers are concerned with the body of knowledge which was available to Harvey when he began to formulate his new doctrine. In a brief note on Harvey's use of Galen, Mr. Kilgour, of Yale, reminds us that in the *De Motu Cordis* alone Harvey quoted Galen a score of times, and with the greatest respect, in support of his new findings. Galen was, like Harvey himself, one of the greatest of experimental biologists, and Professor Lain Entralgo (Madrid), who published in 1948 a Spanish translation of Harvey's works, here provides us with an admirable summary of the scientific thought and method of both Galen and Harvey. Scattered quotations cannot do justice to this closely reasoned and penetrating analysis, but a few points should be noted. Harvey's inductive method was not that of Bacon but of Aristotle—and Padua, it will be recalled, was the stronghold of Aristotelianism. "To Galen his experiments were a paean of nature; Harvey's experiments are an ingenious trap to force nature into admitting the truth. . . . In Harvey's very simple calculations the expression of reality in terms of formal mathematical laws is still minimal. . . . [He] is still far from thinking, like Galileo and Descartes, . . . that the book of nature is written in mathematical language, and still farther from believing that only that which is measurable is true."

If Entralgo portrays Harvey as a Janus-like figure facing both past and future he does so in no spirit of denigration, and even suggests that this dual character has advantages over the narrow philosophy of some moderns. But the process of revealing Harvey's debt to the past has sometimes been employed to serve chauvinistic ends rather than the interests of historical accuracy. It is refreshing to see the "allusions, anticipations, and counter-claims," familiar to all who have studied the history of the discovery, so thoroughly examined and so decisively dismissed as they are in the long study by Walter Pagel. This shows how the idea of "circular motion" in the body is linked with circular

William Harvey, circa 1622
Formerly at Rolls Park, Essex

motion in the universe in order to satisfy the age-old analogy of microcosm and macrocosm. It is in this context that the "allusions" in Plato, Thomas Aquinas, Cecco d'Ascoli, and others (all quoted in translation) should be understood. They have little or nothing to do with physiology. The passages which are often employed to support claims for Cesalpino are quoted and examined at length, with the conclusion that "a reconciliation of his 'correct' and his 'incorrect' statements hardly supports the extreme claims made on his behalf in the history of the discovery of closed blood circulation. Cesalpino did not discover it."

Felix Boenheim, the present Director of the Institute of the History of Medicine at Leipzig founded by Karl Sudhoff, studies eastern parallels to the western ideas examined by Pagel, and particularly the claim first made by the Jesuit Father du Halde in 1770 that "the Chinese had known about the circulation of the blood for at least 2,000 years," with the conclusion that "it is evident that the Chinese did not know anything about the circulation of the blood in the Harveian meaning. Their doctrine is mystic, not biological."

Pagel's judgment on Cesalpino is strongly reinforced by Louis Chauvois, of Paris, whose new biography of Harvey has just been published in simultaneous French and English versions. Professor Pazzini, of Rome, writes of Padua as the nursery rather than the progenitor of Harvey's genius, and stresses the value of the training in the techniques of experimental biology offered there by Fabricius. Lord Cohen of Birkenhead rates the influence of Padua as highly as does Pazzini, but suspects "that a chance (though inaccurate) observation led Harvey to postulate a continuity of arteries and veins . . . [i.e.] 'that the arteries contain the same blood as the veins and nothing but the same blood.'" This may be true, for a discoverer does not always recall accurately what first put him on the track. Harvey told Boyle that his first clue was the valves in the veins, and Professor Leibowitz (Jerusalem), who discusses here early accounts of their discovery, credits Amatus Lusitanus with the first published account (1551) of the valves (in the azygos vein), but concludes, "It is clear that Amatus did not understand [their] physiological significance . . . any more than did all the other authors before Harvey, including Fabricius."

The early history of the discovery of the pulmonary circulation has also been the subject of much study since Meyerhof, in 1933, drew attention to the clear and convincing description in the surviving manuscripts of the thirteenth-century Arab, Ibn-an-Nafis, of Damascus. Recent research indicates the probability of some link (possibly by way of Andrea Alpago) between this early description and its "rediscovery" by Servetus and Colombo (cited by Harvey) in the sixteenth century. Professor O'Malley (Stanford University) offers some further suggestions towards a clarification of this problem.*

It should be noted that there are now no outstanding claims, from East or West, for priority in the discovery of the general circulation, and after this very thorough exposition of the climate of ideas in which Harvey began his great work those who come to praise Harvey may give him due credit for originality of thought as well as of method.

The Reception of Harvey's Discovery

How Harvey's little book impressed his younger contemporaries is vividly illustrated in a letter quoted by Professor Gottfredsen, of Copenhagen, writing of the reception of Harvey's doctrine in Denmark. This letter was written at Leyden on July 13, 1631, by a Danish student, Jacob Svabe, to his former teacher in Copenhagen, Oluff Worm, and in it he says, "This doctrine so greatly impressed my mind that, for a full week, I was quite heartsick owing to these profound thoughts." The young man consults his middle-aged professors (Conring, van Heurne, van Valkenburg) and is put off with platitudes: "in changing old

theories and approving of new ones we must rather be timid and hesitating than audacious and temerarious."

In spite of Worm's opposition, it was another of his protégés, Thomas Bartholin, who contributed most to the establishment of the doctrine in Denmark. Aided and abetted by his master at Leyden, Joannes Walaëus, Bartholin was also responsible for its first appearance in an anatomical textbook which was used widely throughout Europe. In neighbouring Sweden, Olaus Rudbeck chose the circulation as the theme of an academic dissertation which he defended at Uppsala in May, 1652. Dr. Sten Lindroth discusses this thesis at length, and traces the influence of Descartes as well as Harvey; for Rudbeck's teacher, Olaus Stenius, was Uppsala's first Cartesian and may even have met the philosopher at the court of Queen Christina. The Scots, as Douglas Guthrie shows in his survey of the Harveian tradition in Scotland, were strangely unenterprising in this cause. Archibald Pitcairne in 1701, when the circulation was already generally accepted, was the first Scot to write in its favour. As a guide to the reception of Harvey's doctrine in various countries, Dr. Ernst Weil has compiled a useful bibliographical table of Harvey references and allusions, both favourable and adverse, published in Harvey's lifetime.

Other Aspects of Harvey's Work

The *De Motu Cordis* has made us familiar with the range and character of Harvey's biological experiments, but the value of his work in this field is underlined by the very informative paper by Dr. F. J. Cole entitled "Harvey's Animals." From a study of Harvey's published work, as well as his lecture notes, Dr. Cole has collected references to "128 types of animal life which fall into the following categories: Zoophyta, Worms (3), Crustacea (4), Insecta (12), Arachnida, Mollusca (6), Fishes (18), Amphibia (3), Reptilia (4), Birds (33), Mammals (43)." The species are named and Harvey's work with them is briefly discussed, and the author believes that the evidence admits "of no conclusion but that he was the pioneer of the experimental method in biology."

Although this claim seems reasonable, it will surprise many to find the formidable array of evidence which Richard Hunter and Ida Macalpine have succeeded in amassing to support the claim which they make for Harvey as neurologist and psychiatrist. Why this evidence has so far been neglected is that it lies in scattered observations in his own notes and in the writings of others. "Modern neurology," state the authors, "developed from two fundamental discoveries—to each Harvey contributed: firstly, the distinction between motor and sensory nerves and, secondly, the differentiation of irritability from sensibility and contractility." Among the conditions recognized as of "nervous" origin by Harvey are syringomyelia, hydrocephalus, epilepsy, apoplexy, paralysis, loss of sensation, blindness due to cerebral disease, delirium, phrenitis, and coma. He also gave one of the earliest clinical descriptions of *folie à deux*, and "clearly recognized the signs and symptoms of the condition familiarized as 'la grande hystérie' by Charcot at the Salpêtrière more than two hundred years later." The authors also draw attention to the notes which Harvey wrote in a volume of Galen's tracts, now in the British Museum Library, which illustrate "how much thought he gave to mental illness."

The remaining contributions to this outstanding special number are of a biographical or bibliographical nature. Professor K. J. Franklin, whose new translation of the *De Motu Cordis* is published this week for the Royal College of Physicians, discusses the various attempts which have been made to produce an English translation which conveys Harvey's thought and style and gives some details of the various translators. Dr. Krumbhaar, of Philadelphia, thinks that the time is ripe for a bibliography supplementary to that of Sir Geoffrey Keynes in which all the literature that has been written about Harvey and his work would be brought together and classified. Dr. W. B. McDaniel, also of Philadelphia, describes the collection of Harveiana in the

library of the College of Physicians in that city, built up chiefly through the efforts of Weir Mitchell.

Dr. W. W. Francis, of the Osler Library at McGill University, gives an English translation of the untimely verses on the death of Harvey which Nikolas van Assendelft prefixed to his Dutch translation of the *De Motu Cordis* in 1650. The present writer contributes a note on the official probate copy of Harvey's will with the grant of administration made to Eliab Harvey in May, 1659, now in the Wellcome Library; and another note drawing attention to a hitherto unnoticed English version of the *De Motu Cordis* published in London in 1714.

Most interesting, however, for the fresh light which it throws on Harvey's personality, is the manuscript of a Harveian oration, almost certainly the missing oration of 1662 delivered by Sir Charles Scarborough, which has been discovered in the Bodleian Library and is described here by Mr. L. M. Payne, Assistant Librarian at the Royal College of Physicians. Scarborough was Harvey's own pupil and anything he has to tell us of his master must be enormously interesting. Some kinder and gentler touches are added to Aubrey's portrait, for we are told of "his candour of mind, charm of manner, and an affability which made it easy for all to meet the old man and ply him unceasingly with questions. One returned from his presence not only wiser—this was always so—but often more cheerful. The sharpness of his intellect continued unimpaired and a certain youthful disposition persisted to the end, as if this keen mind could not be weakened by age." Even better is Harvey's own reply to his friends, who urged him to reply to his detractors: "It is of no great importance that I for my own gratification should molest for a second time the republic of letters. I will not be the author or sponsor of any new controversial doctrine. Let my thoughts perish if they are worthless, my experiments if they are erroneous, or if I have not properly understood them. I am satisfied with my industry. It is not in my nature to upset the established order. . . ."

What better phrase could be chosen for closing this notice? For there speaks the very voice of the man who calls himself on the title-page of his epoch-making book, "William Harvey, Englishman," uttering the greatest understatement in the history of science.

FROM BOTH SIDES OF THE IRON CURTAIN

[FROM SPECIAL CORRESPONDENTS]

Below we print two dispatches from correspondents who attended congresses abroad last month, one on either side of the Iron Curtain. The first records a visitor's impression of what is said to have been the first international medical congress in Rumania; the other picks out some of the more challenging papers read at the May meetings of the American Society for Clinical Investigation and the Association of American Physicians, both held at Atlantic City.

RUMANIAN MEDICAL CONGRESS

The first international congress of medicine to be held in Rumania took place in Bucharest from May 3 to 11. It was the National Congress of Medical Sciences, and had been arranged by the Academy of the Rumanian Republic. This Congress, held in a communist country, differed somewhat from similar congresses over here. It was organized at national level, with active support from the Treasury as well as of all the various departments concerned with the medical and scientific life of the country. Delegates were drawn from twenty-three countries, including Great Britain, and hospitality was on an unusually lavish scale. The meetings were followed by excursions, including a three-day steamer journey down the Danube, around the delta, and back.

The delegates from Britain were officially invited through medical bodies, such as the Royal Society of Medicine, who nominated them, and their stay in Rumania was made particularly agreeable. An interpreter-guide was appointed to each delegate, and from arrival to departure everything was organized most efficiently. In a country such as ours it is difficult to appreciate how smooth such arrangements can be, once the essential authority has been granted, and we envied our hosts' ability to jump the economic hurdles which surround any similar undertaking here. At the same time, although the munificence of the State was so apparent, it was equally clear that individual physicians, surgeons, and physiologists had worked long and hard to achieve success in what was for them a unique enterprise. The personal friendship extended to delegates was impressive, and the opportunity for individual discussion in the lobbies of the Congress hall was as great as over here. Apart from this, the organization was a rigid one, with the efficient guides shepherding their charges to the hospitals and institutions chosen for visits and demonstrations.

Scientific Contributions

The Congress mainly concerned itself with four fields of medicine: physiology, the rheumatic diseases—particularly rheumatic fever—neurology, and virology. These four sections met simultaneously, and there were joint meetings of welcome and farewell. The latter were remarkable for the many lengthy speeches of a general kind. The sectional meetings lasted with breaks from 8.30 a.m. to 7 p.m., and consisted of a long succession of 15-minute papers, read from typescript.

In the physiological section the weight of interest was upon the endocrine system, particularly the adrenal glands, the electrophysiology of the nervous system, and the application of Pavlovian theory to the study of behaviour. In the "rheumatic" diseases focal infection was still the main subject of study. As yet there is not the interest in the associated biochemical upsets which hold our attention in this country and the United States. In the field of neurology, led by Academician PARHON and Academician KREINDLER, interest centred particularly on the physiology of epilepsy and the basis of the neuroses where the application of Pavlov's doctrines is dominant. In neurology, too, the chief preoccupation was with the effects of endocrine activity upon the vegetative nervous system and with the study of neuronal activity resulting from experimental changes in adrenal function. In bacteriology and virology the approach was very similar to that here, under the leadership of Academician NICOLAU.

Prestige of the Academic Worker

Naturally, we were as much interested in the delegates attending the Congress as by their work. We were impressed by the intensity of their listening and by the enthusiasm of the speakers. As everywhere, the social and economic background colours the pattern of work. Whereas in Britain so many of us engage in academic activities against a background of routine medical practice, in Rumania the academic worker is highly specialized, more highly paid than the clinician, and he may enjoy an increase in his income because of the quality or the quantity of his scientific output. He receives much publicity, and throughout the Congress arc lights, movie cameras, and photo flashes were much in evidence. An important foreign delegate would give his paper with six arc lights a few feet away and two cinematograph photographers and several press men at very close quarters. The photographers even attended all the hospital visits. The pictures were used for the Congress newspaper, for the national journals, and for record purposes. We saw articles and photographs dealing with a similar congress in Hungary, and no doubt they appeared in the papers of other countries too. Though we were rather disconcerted with such publicity, our hosts seemed to accept it as usual and desirable. By contrast the evening meals, excursions, and entertainments

*This paper should be read in conjunction with another on the same subject by Edward D. Coppola in the current issue of the *Bulletin of the History of Medicine*, 1957, 31, 44-77.

were quiet, very friendly, and without any pomp or publicity. The lasting impression which the Congress left with us was one of a level of communal and personal hospitality which transcended criticism.

ATLANTIC CITY MEETINGS

The American Society for Clinical Investigation held its 49th annual meeting at Atlantic City on May 6. A series of short papers were presented.

Growth hormone from the pituitaries of slaughterhouse animals has generally proved ineffective in man, so considerable interest attached to a report from Dr. M. S. RABEN (Boston, Mass.) on its preparation from human pituitaries. Human pituitaries, removed *post mortem*, were stored in acetone for weeks or months, and from these growth hormone was extracted and purified. The yield was two to three times that obtained from the equivalent weight of pig pituitaries, and the effective dose (0.1 mg. per kg.) appears small enough to make human necropsy material a practical source of growth hormone. A team of workers from Bethesda and Chicago discussed congenital defects in bilirubin metabolism. It has recently been found that bilirubin is excreted in the bile as a glucuronide (direct-reacting bilirubin). A study was made of three patients with congenital non-haemolytic jaundice (Gilbert's disease), and it was found that all the bilirubin (20-35 mg. per 100 ml.) was of the unconjugated type. This suggested a defect in the transfer of glucuronic acid to bilirubin in this disease. *In vitro* studies with liver enzyme confirmed this. But, as was pointed out in the discussion, the importance of these findings depends on how much this is a general rather than an isolated phenomenon.

"Buffy Coat" and Transfusion Reactions

Drs. T. E. BRITTINGHAM and H. CHAPLIN, jun. (St. Louis), discussed "non-specific" transfusion reactions. Patients had been observed to develop leucoagglutinins coincident with the onset of recurrent transfusion reactions, and it was postulated that this mechanism was responsible for the severe, febrile non-specific reactions often observed, particularly in those repeatedly transfused. In five such patients removal of the "buffy coat" from the donor bottle before transfusion prevented these reactions. Dr. E. BEUTLER (Chicago) spoke on iron enzymes in iron deficiency. It had been thought, he said, that the iron-containing intracellular enzymes were not affected by iron deficiency. A study was made of the tissue content of the iron-containing enzyme cytochrome C in induced iron-deficiency anaemia in rats. A spectacular decrease was observed in the concentration of cytochrome C in the liver and kidney, greatly exceeding the decrease in haemoglobin. He suggested that some of the symptoms in iron-deficiency anaemia, which are often out of proportion to the degree of anaemia, might be due to some such cause. He was careful to point out, however, that these might not necessarily be related to cytochrome C, as this enzyme had been chosen only as a model for the study. Dr. L. O. JACOBSON and his colleagues from Chicago reported increased haemopoietic activity in patients with certain blood diseases. The demonstration of plasma-erythropoietic activity has been facilitated by the finding that in the hypophysectomized rat an increased uptake of radioactive iron into the erythrocytes follows injection of human plasma. Normal plasma did not show any activity unless it was concentrated 30 times. Increased erythropoietic activity was found, however, in the plasma of patients suffering from hypoplastic anaemia, pernicious anaemia, anaemia following haemorrhage, and acute leukaemias. It was not found in plasma from anaemic patients with uraemia or advanced neoplasms.

Natural and Acquired Immunity to Polio

The meeting of the Association of American Physicians occupied the next two days, May 7 and 8.

On the first day workers from New Haven, Connecticut, reported a comparison of the responses of vaccinated and naturally immune children to the ingestion of live, attenuated poliovirus. In a residential children's institute a study was made of the effect of administering an attenuated type I oral poliomyelitis vaccine. The children with natural immunity were identified by antibodies studies, and the remainder then given a Salk-type vaccine. After oral administration of the attenuated virus it was found that those with natural immunity excreted less of the live virus, and for shorter periods, than those who had been vaccinated. It was concluded that there was a difference between the natural immunity and the acquired immunity. No absolute reversion to pathogenicity occurred in the excreted attenuated virus, but some change in behaviour was noted in two of nine recovered viruses by testing in the monkey and in three out of twenty tested *in vitro*.

Among the other papers on the first day two were on the action of bacterial endotoxins. Dr. L. THOMAS and his colleagues from New York said that rabbits injected subcutaneously with 200 µg. of adrenaline developed petechiae, progressing to confluent ecchymoses, at the site of injection if they had previously received an intravenous injection of endotoxin. In the absence of endotoxin no lesions occurred at this dose. They suggested that release of serotonin following the administration of endotoxin might be responsible, as similar lesions were produced by a combination of histamine and adrenaline but not by a combination of histamine and adrenaline. Dr. I. L. BENNETT, jun., of Baltimore, and his colleagues discussed the evidence for believing that the pyrogenic effect of endotoxins may be due to a direct cerebral action. Bacterial endotoxins are potent pyrogens. This effect, which is mediated through the central nervous system, has been thought to result from release of "endogenous pyrogen" from the leucocytes following the administration of the endotoxin. Endotoxin was therefore injected directly into the subarachnoid space, and it was shown that a pyrexial response occurred. These experiments were held to indicate that endotoxin exerted a direct effect in causing pyrexia. Careful control experiments with other substances did not cause pyrexia.

Hyperthyroidism and Infertility

Drs. S. P. ASPER, jun., and E. HUNTER WILSON, jun., on the second day, raised the question of whether testicular deficiency in hyperthyroidism could be due to the latter condition and not just coincidental. They reported six patients with hyperthyroidism in whom there was a coexisting testicular disease, as judged by azoospermia and testicular biopsy. Four of these cases also had gynaecomastia. They had also noticed a high incidence of infertility in the marriages of male thyrotoxic patients. Isolated cases of this combination of disorders have previously been described by other workers, but this series suggests that there may be some direct association.

Drs. J. A. LUETSCHER, jun., and A. H. LIEBERMAN (San Francisco) described 15 women with idiopathic oedema. All showed emotional lability, obesity, and fluctuating oedema. Low-salt diets and diuretics had been effective treatment for short periods of time. The blood pressure, liver function, and serum electrolytes were all normal. Urinary aldosterone excretion, however, was high, and some cases showed a marked impairment of sodium excretion. An interesting discussion followed in which it was agreed that these were probably further examples of secondary aldosteronism. Dr. CONN (Ann Arbor) described one patient in whom partial adrenalectomy had been carried out; aldosterone excretion fell but later returned to previous levels. Dr. THORN (Boston) described a case that had shown improvement on "amphenone" on three occasions, although adrenalectomy was carried out later. Dr. PERERA (New York) had seen five patients in one of whom spontaneous remission occurred after marriage. This speaker warned against adrenalectomy in view of the possibility of spontaneous remission, and there was general agreement on this point.

Periodic Paralysis

Dr. J. W. CONN and his colleagues from Ann Arbor presented their findings in two cases of periodic paralysis. In these subjects the attacks were preceded by increased urinary aldosterone output and retention of sodium. On a low-sodium diet no attacks occurred; biopsy studies showed a great increase in sodium content during an attack. It was postulated that these changes rather than the classical potassium changes were the primary cause of the paralysis. In the discussion that followed it was emphasized that these cases were sporadic cases of periodic paralysis, and that no such studies had yet been made on a familial case.

Dr. E. B. ASTWOOD (Boston, Mass.) reported a remarkable series of 15 patients with an extremely high protein-bound iodine serum level. The normal serum protein-bound iodine is 4 to 8 µg. per 100 ml., but these patients had values up to 4,000 µg. Isolation of the iodine compound from their sera made it clear that it had not been synthesized by the thyroid: it represented the persistence of a previously administered gall-bladder dye ("teridax"). The serum half-life of this compound was approximately 2½ years, and it would therefore be 33 years before it ceased to interfere with the protein-bound iodine determination.

WHO SHOULD BE SENT TO A MENTAL HOSPITAL?

[FROM A SPECIAL CORRESPONDENT]

The Birmingham Medical Institute has just moved to a new and pleasant building, and on May 22 its psychiatric section inaugurated the new hall with discussion of a question which, the section president, Dr. W. MAYER-GROSS, indicated, is now critical: What are mental hospitals for? Some of the differences of opinion about this were illustrated by the three principal speakers, who viewed the question from their own work as general practitioner, prison medical officer, and hospital superintendent respectively.

From General Practice

Dr. C. A. H. WATTS, a general practitioner from Leicester, sent people to mental hospital only if they required active treatment which they could not get as out-patients. Only a fraction of the mentally sick actually went to hospital, and the rest managed at home. He illustrated this with an analysis of his own practice in a part-rural, part-industrial area, with a static population. With two partners he serves 8,000 people, and in the decade 1946 through 1955 they saw 100 people with psychosis, some for more than one attack in that time; they saw about 14 attacks a year, therefore. Mostly these were attacks of endogenous depression, some mild, some severe. In the latter category were a number who would have benefited from in-patient hospital treatment but who refused to go voluntarily and whom he was loath or unable to certify. 32 out of a total of 84 stayed at home, but the recovery rate there (56%) was less good than in hospital (70%). However, even with the best modern treatment this meant that 30% of his endogenous depressives ended badly—in a chronic state or in death. He regarded the risk of suicide or depression with agitation as the only indications for immediate admission to hospital. Otherwise he preferred to befriend the patient, get a good rapport, and if the depression continued longer than three months he recommended hospital admission, and the patient was then very likely to trust his advice.

Apart from impending suicide, mania was the only other emergency, but it was rare. So were alcoholic psychoses (4) and acute confusional states (5)—in old people with bronchopneumonia treated with antibiotics—and both could be treated at home with sedatives and vitamins, since they mostly

resolved in a few days. Schizophrenics (about 20) went to hospital for treatment, but became an important responsibility of the G.P. when they were discharged home. Nearly half of them so far had been able to resume home life and employment. He made every effort to keep mental defectives, epileptics, and senile patients out of hospital. They got more individual attention and love at home, and the only role he saw for the mental hospital in such cases was that of a kind of holiday home—to give the relatives a fortnight's or a month's rest from their burden of care. Patients with hysteria or anxiety states should never be sent to mental hospitals, and indeed he wanted to see more psychiatric out-patient clinics and more in-patient psychiatric facilities in general hospitals, so that the mental hospital would remain for the intractable chronic case only. This would encourage depressive patients to enter hospital for treatment, and be less traumatic for the patient and his relatives than admission to mental hospital direct from home.

Finally he described a severe psychosis which subsided at home, a man with organized delusions about his wife's fidelity who frightened her with threats which had to be taken seriously. However, he remained a very good worker, and therefore, instead of sending him to hospital, which might well have confirmed him in his paranoid ideas, a legal separation from his wife was arranged. Two years later the couple were able to come together again, and the wife reported that, although a trace of his former delusions persisted, they had now all but vanished and were of no practical consequence.

Social Misfits

Dr. G. A. WRAY, as a prison medical officer, was averse to committing people to institutions of any kind unless it was really going to help them. He saw 300 or 400 people a year on remand to assess whether they needed mental hospital treatment, and some of these people were unusual, eccentric, certainly not average citizens, but in previous centuries would have been allowed to go their own way. They were caught up in the legal machine for vagrancy, sleeping out, minor delinquencies, or for unusual acts like trying to row across the Channel. Under the Welfare State we were always sending people into homes or hostels or Borstals or hospitals, trying to tidy them up instead of tolerating their peculiarities. In modern social work the answer too often seemed to be an institution.

He also raised the question of the meaning of the word "treatment" in psychiatry. Many prisoners might stand in need of re-education; few needed E.C.T. or courses of injections or drugs, which, when it came to the point, was what mental hospitals mostly offered. He did not feel, therefore, that many of the people he saw should be sent to mental hospital even though there was sometimes strong pressure to advise this in place of prison. He believed that the so-called psychopaths later either became frank psychotics or spontaneously grew out of their antisocial behaviour and therefore should not be sent to hospital.

Mental Hospitals To-day

Dr. A. M. SPENCER, superintendent of Powick Hospital, near Worcester, said mental hospitals were unfit for modern human habitation, and quite inadequately staffed—indeed, because the admission rates had risen and the number of staff if anything had declined, standards of care were going down. There was still a pauper outlook; there was no privacy, no culture; people became dehumanized in the vast mid-Victorian wards. The ordinary mental hospital was forced to mix psychotics with mental defectives (because of shortage of beds in mental deficiency institutions), and the many ordinary mentally ill people had their liberties restricted because the hospital had to house a few dangerous patients. At Powick 90 men were locked up in the only closed ward of the hospital because twelve of them at the most might escape and cause trouble. Mental hospitals ought to be much smaller—about 200 beds each, perhaps—the dangerous people segregated in a special hospital, mental

defectives excluded, and then we could begin to invite those who needed mental hospital treatment to come in.

But the mental hospital existed for more than active treatment. It ought to accept the chronic patient who made his relatives' lives intolerable to them, and it ought to take in the baby with the mother suffering from a puerperal psychosis. He thought Dr. Wray was too pessimistic about court cases, and believed lysergic acid diethylamide (L.S.D.) could help psychopaths. There were also what he called the "inadequate biological variants," people who could not cope emotionally with the complex responsibilities of modern life and craved an asylum. On the other hand, he feared that children at home were greatly upset, perhaps permanently harmed, by the admission of their parents to a mental hospital.

Discussion

Several speakers in the general discussion emphasized the importance of family difficulties. Dr. R. A. SANDISON said that the housewife with young children could not have out-patient E.C.T. because her home responsibilities conflicted with her treatment. The burden of nursing a chronic patient at home often fell on one person, the housewife, said Dr. MAY PEARCE, while Dr. MAYER-GROSS thought families who kept a chronic patient at home might sacrifice the other normal members of the family to do it. Dr. MYRE SIM suggested that a duly authorized officer—the man who in daily practice often decides who shall go to mental hospital—should have been asked for his views. Dr. J. R. MATHERS took up a theme of Dr. Spencer's, that the mental hospital is a community within the community, and emphasized that it was often the nature of the wider community which determined admission. Some communities were sick, and produced mental illness, because they were intolerant of eccentricities or slow to accept the lonely isolated individual. It was the psychiatrist's duty to educate the public into healthy ways of life by talking to small groups in churches and clubs. Mental hospitals in the past had worked too much in isolation from the community they served.

Preparations and Appliances

MODIFIED RYALL'S DIRECTORS

Mr. W. B. GABRIEL, surgeon, Royal Northern Hospital, writes: For many years Ryall's curved director has been a useful instrument in rectal surgery, particularly when dealing with anal fistulae secondary to infected crypts or fissures, when an internal opening in the anal canal has to be searched for and a probe passed from within outwards. Lately this

instrument has been unobtainable and seems to be no longer listed; I have therefore taken the opportunity of modifying the design in order to provide curved ends of different sizes, as follows: the No. 1 instrument has ends of $\frac{3}{8}$ and $\frac{1}{2}$ in. (16 and 19 mm.) diameter; the No. 2 size has curved ends of $\frac{3}{8}$ in. and 1 in. (22 and 25 mm.). In each case the narrower end is on the left side of the instrument. When the anal canal is inspected through a bivalve proctoscope or a proctoscope such as Fansler's, the surgeon can select one of these four sizes to suit any particular case, and it has proved useful in defining the main tract of a high-level fistula.

The directors have been made by A. L. Hawkins and Co. Ltd., 15, New Cavendish Street, London, W.1.

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

Ganglion-blocking Effect of Noradrenaline

SIR,—I gained the impression, while recently lecturing in the United States, that many anaesthetists and others were unaware of an important side-effect of noradrenaline. In common with adrenaline, noradrenaline has a blocking action on sympathetic ganglia.¹⁻³ When administered, as it is commonly, by intravenous drip in suitable dilution, its effect on the blood pressure by peripheral vasoconstriction is dominant—an effect desired by those treating the patient. However, when the drip is ultimately stopped, a sharp fall in blood pressure generally follows, and great difficulty is frequently encountered in "weaning" the patient from the noradrenaline. The ganglionic blockade now becomes apparent, and a patient originally suffering from hypotension due to, say, traumatic shock is transformed into one with hypotension due to ganglionic blockade.

This action should be borne in mind when embarking on noradrenaline therapy. The use of this substance, other than as an emergency treatment for a comparatively short time, should be most carefully considered in the light of this known effect on the ganglia. One cannot help wondering in how many cases recovery after prolonged administration of large doses of noradrenaline was in spite of, rather than due to, this form of treatment.—I am, etc.,

Cardiff.

Pregnancy in Addison's Disease

SIR,—Dr. M. M. Singh (*Journal*, March 2, p. 503) reported the successful outcome of pregnancy in a patient suffering from Addison's disease treated with cortisone. In his review of the literature he found that only seven similar cases had been reported. We should like to describe a further case in which pregnancy was uneventful on cortisone maintenance therapy.

A nulliparous woman, aged 22 years, was admitted to the Royal Free Hospital in November, 1953, with an acute onset of diarrhoea, vomiting, and right lower abdominal colicky pain preceded by some weight loss, tiredness, and anorexia. Menses were regular. On admission she was underweight. Temperature was normal, but there was a tachycardia of 120 per minute. Blood pressure was 85/60. There was pigmentation of the tongue, lips, and skin, especially of the areolae and exposed pressure areas. There was slight tenderness in the right hypochondrium. A clinical diagnosis of Addison's disease was made and confirmed by the laboratory investigations: blood urea 70 mg. per 100 ml.; serum chlorides 82 mEq/litre; serum sodium 125.5 mEq/litre; serum potassium 6.56 mEq/litre; blood sugar 84 mg. per 100 ml.; haemoglobin 14.0 g. per 100 ml.; E.S.R. 17 mm. in one hour. Chest x-ray was normal. She was treated by a continuous intravenous glucose saline drip and oral cortisone 25 mg. six-hourly. Her condition steadily improved, the blood chemistry reverted to normal, and the haemoglobin fell to 11.2 g. per 100 ml. The blood pressure rose, but only to 100/60, the same figure as had been recorded on several routine medical examinations before this illness. The dose of cortisone was reduced so that on her discharge, two months later, she was taking 25 mg. daily, together with 6 g. sodium chloride. Subsequently this dose had to be increased at times of minor infections.

A year later she married. She was advised to take 25 mg. twice daily during her honeymoon in Switzerland; on this dose she was able to take violent exercise, such as ski-ing, without untoward effects. In February, 1955, she became pregnant and soon complained of morning nausea, which was treated beneficially by promethazine-8-chlorotheophyllinate ("avomine") 25 mg. each morning. During the first trimester the patient, who had some medical knowledge, was able to keep herself symptom-free by varying the dosage of cortisone, taking usually from 50 to

75 mg. daily but for three weeks 100 mg. In spite of these comparatively big doses, in May, 1955, her blood pressure was only 95/70. Therefore she was given in addition deoxycortone acetate 6 mg. sublingually daily and continued on this together with 50 mg. of cortisone until nearly the end of pregnancy. The blood pressure rose and she was well. Two weeks before delivery evidence of overdosage with cortisone was noticed: "mooning" of the face, mild hirsuties, slight evening oedema of the lower legs, and disproportionate weight gain. Her blood pressure, 120/90, was slightly raised. Cortisone was then reduced to 37.5 mg. daily and then deoxycortone acetate was discontinued. On November 5, 1955, she was admitted in labour; 100 mg. of cortisone was given immediately, intramuscularly. After an easy labour lasting six hours she was delivered of a 7 lb. 11 oz. healthy girl. Trichlorethylene, gas, and oxygen were given for repair of an episiotomy. The puerperium was uneventful and she was able to breast-feed the baby. Although well, her biochemical tests a fortnight after delivery suggested underdosage: serum chloride 94 mEq/litre; serum sodium 136 mEq/litre; serum potassium 6.4 mEq/litre; blood urea 50 mg. per 100 ml. She was discharged on the following day with instructions to take 100 mg. cortisone orally in divided doses. By the following week the blood chemistry had returned to normal so that the cortisone was reduced to 87.5 mg. and later to 75 mg. daily. Lactation proceeded normally for two months and then gradually diminished. The dose of cortisone was concurrently reduced to 50 mg. daily. Mother and child are both doing well.

We would like to stress the following points in our case: the ease of management, the patient adjusting the dose of cortisone herself with medical guidance; the signs of overdosage late in pregnancy, probably the effect of the additional steroids produced by the foetal adrenals; the single dose of cortisone at the onset of labour, which proved to be uneventful; the lactation lasting for two months and the absence of hypoglycaemic symptoms throughout. Gurling and his colleagues¹ have recorded another case of Addison's disease in which a successful outcome of pregnancy occurred, despite the complications of diabetes, uterine inertia, severe haemorrhage, and ruptured uterus. Although only ten cases have been reported, cortisone appears to have made pregnancy more likely and safer for the woman suffering from Addison's disease. However, careful medical supervision is still essential.

We would like to thank Dr. Una Ledingham and Miss Jocelyn Moore for their permission to publish this case.—We are, etc.,

A. GORDON BECKETT.

Oral Treatment of Trichomonas Vaginitis

SIR,—It may be of interest to your readers in comment on a recent article by Miss Josephine Barnes and her colleagues (*Journal*, May 18, p. 1160) to report the following investigation.

A series of 41 partners in whom the woman had trichomoniasis were treated as out-patients of Paddington General Hospital and St. Mary Abbots Hospital by oral administration of 100 mg. of enteric-coated tablets of 2-acetylamin-5-nitro-thiazole ("trichorad") kindly supplied by Ward Blenkinsop and Co. Ltd. The tablets were taken thrice daily after food for fourteen days and no treatment of the vagina was carried out, and it was demonstrated that cure did occur, but infrequently. Trichomonads had been found in the case of each of the women in a suspension made by rotating a swab dipped in the vaginal discharge from the posterior fornix in 1-2 ml. saline. The men had not been examined. In two women of the 41 partners who had been given the tablets the parasite ceased to be demonstrated in the vaginal discharge with relief of symptoms after one course. Two women who were not cured by one course were free from trichomonads in the vaginal discharge when examined after a second course of treatment. The parasite temporarily disappeared with temporary relief of symptoms after two women and their partners had been given three or four courses each of fourteen days' duration. Recurrence occurred in these two in less than four weeks. Only one

patient showed any adverse effects of the oral administration and she developed severe vomiting after ten days' treatment. On cessation of the drug the vomiting ceased but the trichomoniasis continued.

Our figures of four successes and two partial successes in the treatment of 41 partners are not dissimilar to those of six cures out of 37 women treated. They are slightly less disappointing than the series of 44 partners reported by Gardner and Dukes,¹ but the incidence of failure suggests that the effectiveness of the drug is dependent on some rare factor as yet unknown.—We are, etc.,

KENNETH J. R. CUTHBERT.
VALENTINE M. HUSBAND.

Acute Amphetamine Poisoning

SIR,—I read with interest Dr. M. S. Pathy's letter (*Journal*, April 20, p. 946) concerning acute amphetamine poisoning, in which he suggested that "the absence of severe symptoms was partly due to the form in which the drug was taken"—that is, "spanules."

An even better and more reliable method of delaying absorption from the gastro-intestinal tract, and one which is much more economical—an important advantage in view of the increasing cost of the N.H.S.—is one that bonds the drug to an appropriate physiologically inert resin and makes use of the "ion-exchange" principle. The drug is then released at an even rate from the resin complex over a period of 10 to 12 hours, and this is, moreover, entirely independent of the physiological factors that often affect the release of drugs from enteric-coated preparations. If the drug is taken in such a form the effects of a toxic dose would be greatly reduced by giving the patient a large dose—say 1 oz. (28 g.)—of the pure ion-exchange resin which would further considerably delay absorption. As the resin is entirely non-toxic this treatment would provide the margin of time necessary to apply other methods of detoxification, such as stomach wash-out, purging, etc.

My own clinical experience with amphetamine resinate suggests that the risk of poisoning is much reduced by this form of medication, owing to (1) the smooth and evenly spread action of the drug, and (2) the remarkably small incidence of side-effects. Some of my own cases sensitive to amphetamine itself were able to tolerate it when administered in the form of a resinate. The particular preparations which I now use are "dexten" and "barbidex," the latter containing also an amount of phenobarbitone.—I am, etc.,

GEORGE NEWBOLD.

London, E.18.

Rheumatoid Arthritis and Reiter's Syndrome

SIR,—As a result of my clinical investigations since 1942 into Reiter's syndrome, I suggested some six years ago to a member of the M.R.C. staff that research into this condition with a view to establishing its aetiology would be of the utmost importance towards the solution of rheumatoid disease in general, and it was pleasing to learn from the paper by Drs. G. W. Csonka and J. K. Oates (*Journal*, April 13, p. 866) that such a project has now at last been sponsored.

This paper and that of Dr. J. Sharp (*Journal*, April 27, p. 975), although of great interest, are, in my opinion, marred by an approach which on present knowledge is unwarranted, in spite of its general acceptance. At line 31 in the discussion, Drs. Csonka and Oates state that "arthritis following genital infection and classical rheumatoid arthritis are dissimilar in many respects," while Dr. Sharp, after beautifully illustrating the interrelationships among all the various groups, concludes that ankylosing spondylitis is also of a different genre. May I, as one whose interest in rheumatoid disease arose originally from cases associated with urethritis, put forward the following clinical findings as indicative, in conjunction with what is already known, of a

unitarian aetiology, and so open up a hopeful line of research so sadly lacking to-day?

(1) The systemic triad of "arthritis (rheumatoid distribution), eye and skin lesions" traditionally believed to result from gonorrhoeal infection has no foundation in fact. These manifestations are due to infection by the organism responsible for a type of urethritis that is clinically distinctive in itself and has nothing whatever to do with Neisserian infection. Incidentally, Case 4 in Drs. Csonka and Oates's cases should be excluded, as it is primarily a bladder condition not of viral origin, and not associated with Reiter's disease.^{1,2} (2) Reiter's syndrome may arise (a) following sexual intercourse, and (b) intestinal disorders of various types. (3) In the case of 2 (a) "sexual" must not be taken as synonymous with "venereal," and in 2 (b) all the available evidence indicates that the agent responsible for the bowel disorder is not itself the cause of the systemic complications, but by altering the mucosal barrier allows an unknown specific organism to pass the barrier and enter the circulation. (4) Reiter's syndrome, although originally described as consisting of urethritis, arthritis, and eye and skin lesions, may appear in many guises and *formes frustes*. Not only may all the signs, either singly or in any combination, occur, but other rheumatic facets—for example, sciatica, spondylitis, lumbago, etc.—may be so pronounced that the real condition may go unsuspected and tell-tale signs of minimal activity in other tissues are unobserved. (5) *Psoriasis and keratoderma blennorrhagica*.—These terms appear to describe identical skin manifestations. In a case of Reiter's syndrome under my care at present, nail changes, typical of psoriasis, are the only skin lesions present. (6) *Urethritis*.—Absence of discharge or a history of one must not be taken as absence of a urethral lesion. A two-glass test is essential, and it is surprising the clinical knowledge that may be gleaned from this simple test. Threads are often found in the first glass in cases where infection of the urethra has never been suspected. (7) *Rheumatoid arthritis in women*.—This subject is too vast to be discussed in a short letter, but two points may be recorded. The female may infect the male with non-specific urethritis, but she herself presents no obvious signs of genital disease, and, secondly, it is to be remembered that bowel disorder in the female is associated with classical rheumatoid arthritis.

Many more points could be raised, but I hope enough has been said above, which, if read in conjunction with Dr. Sharp's paper, presents a unitarian concept which suggests that an unknown organism (or group) whose habitat is the bowel is responsible for all rheumatoid disorders, be they affections of the joints, skin, or eyes. However, owing to the inert type of tissue involved—i.e., collagen—it appears that in order to penetrate this substance the organism needs the simultaneous presence of a spreading factor. Thus the traditional belief in streptococcal or various types of focal infection is afforded a reasonable explanation. It only remains to wish Dr. Csonka and Dr. Oates every success in their difficult task to discover the organism causing non-specific urethritis, since, in spite of various beliefs in viruses or organisms of the pleuro-pneumonia type, success in this direction has not as yet been achieved.—I am, etc.,

Dermatitis Medicamentosa Due to Tetracycline

SIR,—At present the application of tetracycline to the skin seldom causes a sensitization dermatitis, and I have been unable to find a record of an eruption due to oral administration. The following case report, therefore, may be of interest.

The patient was a woman aged 56 who was grossly obese and had mild diabetes, controlled by diet alone. She had been subject to winter bronchitis for many years, and on December 14, 1956, she was given phenoxymethylpenicillin 250 mg. six-hourly for six days for an exacerbation of this. As there was no clinical improvement, on December 22 tetracycline was given, 250 mg. six-hourly for four days. On December 27 she developed an itching eruption which somewhat resembled urticaria. On December 29 she was found to have a widespread eruption on the trunk, upper limbs, and thighs. The lesions were pink, raised, slightly oedematous, and relatively sparse. Some were discoid from 1 to

4 cm. in diameter, while others were annular and much larger. The skin inside the rings was either normal or of a faint mauve tinge. The individual lesions, once they had appeared, persisted and grew steadily larger, unlike the usual course of urticaria in which individual lesions tend to disappear after 12 to 48 hours and are replaced by fresh lesions.

A tentative diagnosis of dermatitis medicamentosa was made, but, as the itching and constitutional disturbance were severe and it was thought the eruption might possibly be the prodromal stage of bullous pemphigoid, she was admitted to hospital on December 30, 1956.

No other abnormal physical signs were found, and skiagrams of the chest, blood count, plasma proteins, and blood sugar were all normal. The temperature was raised to 100°–101° F. (37.8°–38.3° C.) on admission, but gradually subsided in the next five days without treatment.

The skin lesions steadily enlarged peripherally, some of the discoid lesions becoming annular. The central mauve colour became more obvious, but faded about the same time as the pink margin. The largest lesion on the back eventually measured about 25 cm. No bullae developed. The rash and all symptoms had completely gone on January 5. The probability of future attacks of bronchitis requiring antibiotic treatment was thought to justify giving her test doses, at 24-hour intervals beginning on January 9, of crystalline penicillin intramuscularly 100 units, then 1,000 units, then "penicillin pulvule" 125 mg. orally, which caused no reactions, and finally tetracycline 250 mg. A few hours after the last test dose on January 12 she developed severe generalized itching and uniform erythema, which had subsided 24 hours later without treatment.

The morphology of the original eruption was somewhat like the fixed drug eruptions caused by phenolphthalein, phenacetin, and occasionally other drugs, such as the sulphonamides and streptomycin, but the character of the reaction to the test dose of tetracycline, widespread and uniform erythema instead of a reproduction of the original lesions, makes it impossible to place it within that group.

I should like to express my thanks to Dr. Keith Lockhart for referring the case and for details of the clinical history.—I am, etc.,

Exeter.

J. R. SIMPSON.

Range of Movement of Testicle

SIR,—Mr. Denis Browne's memorandum on the range of movement of the testicle (*Journal*, May 18, p. 1165) reminds me that, when I was medical officer to the Mahratta Training Battalion in India, I noticed the sepoys were accustomed to make use of the pouch to which Mr. Browne draws attention. I asked the sub-assistant surgeon (*jemadar tewari*), who worked with me, about this, and he told me that all Mahrattas tucked their testicles up before taking part in games, physical training, horse exercise, and long parades. To the British officers this was a well-known habit and regarded as a very sensible one. There must be many members of the B.M.A. from India who could say whether or not this method of protection is practised in India by other Jats.—I am, etc.,

Edmonton, Canada.

J. SHEGOG RUDELL.

SIR,—In his article (*Journal*, May 18, p. 1165) Mr. Denis Browne refers to his description in the *British Medical Journal* of the "upward prolongation of the scrotal cavity as the 'superficial inguinal pouch'" and wonders "how long will it take for this piece of knowledge to get into the anatomy books." Surely figure 368 in Cunningham's *Textbook of Anatomy*,¹ 1937 edition (figure 398 in 1951 edition), showing better than verbal description the continuity of the membranous layer of the superficial fascia (Scarpa's fascia) of the abdominal wall and perineum, illustrates his point?—I am, etc.,

Aberdeen.

R. D. LOCKHART.

Operations for Varicose Veins

SIR,—I am distressed to see that once again the subcutaneous or percutaneous ligation of varices is being recommended by your correspondent, Mr. C. A. F. Uhma (*Journal*, May 11, p. 1122), especially since he gives this treatment without "the conventional high ligation." Davat found this treatment 120 years ago to be of little value, and it was not until Schede revived it in 1877 that it was reintroduced in a modified form again. Since that time there have been spasmodic attempts to reinstate that which has proved to be a most unsatisfactory pseudo-surgical procedure.

There is no way of guaranteeing a permanent success with any surgical method, but bloodless removal of varices by the stripping method after a careful high resection at the sapheno-femoral junction has been proved by many of us to offer the patient the most permanent results of any treatment so far evolved. Blocking a river spreads the waters into the surrounding fields, and ligation of veins similarly spreads the varices into the surrounding areas. This makes efficient stripping difficult or impossible at a later date. I do hope your readers will give this matter serious thought before considering local sub- or percutaneous ligations.—I am, etc.,

London, W.1.

R. ROWDEN FOOTE.

Mental Deficiency

SIR,—I am sure that all physician superintendents of mental deficiency hospitals will agree with the letter written by Dr. W. Alan Heaton-Ward (*Journal*, May 11, p. 1120) concerning the treatment of mentally defective patients. In fact in my letter to the *Journal* of June 23, 1956 (p. 1487) I mentioned most of the points that he has made in his more recent letter; and I made various suggestions concerning the solution to this problem.

I have found that a partial answer to this problem, within the framework of the present Acts, is to admit all high-grade cases to a hostel either directly or at least within a very short time of admission to the parent hospital. I look forward to the day when such hostels will be run jointly by the hospitals and by the local authority. Such a scheme would allow the early discharge of stabilized patients who have no home, and would also prevent the unnecessary certification of homeless patients in the community.—I am, etc.,

Driffield, E. Yorks.

J. NEWCOMBE.

Acute Immediate Reactions to Penicillin

SIR,—Dr. G. W. Lewis in his interesting article on the above subject (*Journal*, May 18, p. 1153) gives a detailed description of 12 of these incidents. There must be many hundreds of thousands of patients to whom these injections are given each year. It is at least probable that many of them are penicillin-sensitive but do not show signs of shock reaction when given injections.

It is generally agreed that the risk of precipitating a reaction is much increased if the injection passes directly into a vessel. The site of injection is therefore of considerable importance. The buttocks have been sanctified (if that is the right word to use) as the appropriate place for intramuscular injections ever since intramuscular therapy was introduced. A sillier place could hardly have been chosen. The skin of the buttocks has a particularly rich nerve supply (most of the older generation of public school boys would readily agree with this), and injections there can be very painful both immediately and for some time afterwards. Beneath the gluteus maximus a perfectly appalling concentration of nerves and large vessels is present; even the so-called "safe" quadrant has a very free vascular supply, and moreover it is unlikely that the area is invariably carefully delimited when injections are made. I have seen the whole of a child's buttock resembling an area of nodular leprosy after repeated injections of bismuth compounds; obviously no great attention had been paid to restricting the injections

to the "safe" area. The deltoid is often used, but the circumflex vessels and nerve form an intricate plexus just beneath the part of the muscle likely to be chosen, and under the triceps is the profunda brachii with quite large accompanying veins.

Of all regions, probably the safest in avoiding the risk of intravascular injection is the middle third of the outer aspect of the thigh into the substance of the vastus lateralis. No large venous plexuses are present and the relatively poor cutaneous nerve supply favours an injection with minimal pain. The usual precaution of a preliminary withdrawal of the plunger is of course necessary, but in this region proceedings are much less likely to be delayed by the appearance of blood in the syringe.—I am, etc.,

Carshalton, Surrey.

C. E. THORNTON.

SIR,—May I once again, having read Dr. G. W. Lewis's article (*Journal*, May 18, p. 1153) on acute immediate reactions to penicillin, repeat that for the past eight years, after consulting the late Sir Alexander Fleming, I have given all penicillin, when injected, subcutaneously, using only crystalline penicillin. I have never seen any reaction: there is no need to use any but a small hypodermic needle, even when injecting 500,000 units, which are easily dissolved in 1.5 ml. of water. The penicillin given by this route is probably more slowly absorbed. The pain is negligible—a very important thing in children.—I am, etc.,

Broadstairs, Kent.

MARTIN O. RAVEN.

SIR,—Following the publication of the original cases of an unusual reaction to procaine penicillin in aqueous suspension,¹ my patients continued to experience these reactions with about the same frequency until early in 1955. Injections of from 2 to 3 ml. were given intramuscularly into the buttock with the utmost care with the patient in the recumbent position. Some were given deeply and some superficially, but still the reactions occurred. The anxiety caused among the patients in the waiting-rooms by the noise as well as by hearsay made it imperative that the injections of aqueous suspensions be discontinued. A return was made to the supposedly outdated procaine penicillin in oil. For two and a half years till now all the patients under my care suffering from syphilis have received procaine penicillin in oil, and no patient has suffered an acute reaction. This undoubtedly is the solution to the problem which Dr. G. W. Lewis discusses (*Journal*, May 18, p. 1153).—I am, etc.,

Norwich.

Sign of Rain

SIR,—The delightful poem on the signs of rain quoted by Dr. F. Parkes Weber in his letter (*Journal*, May 18, p. 1181) can be read in full in *Weather Lore*, by Richard Inwards.¹ However, the author is given there as Dr. Erasmus Darwin, and not Dr. Edward Jenner. Perhaps others of your readers could help to establish which of the two really did write it.—I am, etc.,

Dartford, Kent.

Buthalitone Sodium for Electropexy

SIR,—Having noted favourable reports on the use of buthalitone sodium as an intravenous anaesthetic for electropexy it was decided to initiate a trial at this unit. So far we have used this drug on 500 occasions, and we have found the use of buthalitone sodium followed by succinylcholine, 50 mg., most satisfactory. We have been able to judge patients' responses more easily, with minimal doses of

buthalitone. Induction and recovery have been, in our experience, smoother and more rapid using buthalitone than with any other agents we have used. There has been consequent economy in staff time; this, we feel, is important, with the large number of cases treated daily. Although side-effects with buthalitone, such as headaches, generalized clonus, and trismus and hypotension, have been reported, we have not experienced any of these reactions. As the favourable results we have had agree with other trials, we feel it deserves wide attention.—We are, etc.,

Wakefield, Yorks.

MARSHALL FRIEZE,
IDA MATHER.

Herpes Zoster and Chicken-pox

SIR,—The report of two interesting cases by Dr. S. W. Vivian Davies (*Journal*, May 11, p. 1119) prompts me to mention a case which is at present under my care.

A male child, aged 2 years 9 months, was seen on May 8. Supra-orbital zoster of a severe type with conjunctival involvement was diagnosed (two days' duration). Slight headaches had been complained of for ten days previously, but the parents were adamant that he had no acute pain either before or after the appearance of the rash. The child was not unduly upset apart from the eye irritation; this was surprising, considering the severity of the lesion. The history of this case was rather interesting. When he was three months old he had a bad attack of chicken-pox, and three weeks before he developed zoster had been in contact again with the disease. Checking my records, I find that one or two points concerning herpes zoster may be of interest to fellow practitioners: (1) Ten cases out of the last 35 occurred in patients under 25 years of age, four of these being under 11. (2) The supra-orbital type (8 cases) is almost as prevalent as the more familiar thoracic one (11). (3) The lay public idea of "shingles" being a disease of middle and old age only is a fallacy.—I am, etc.,

Leicester.

ERIC LODGE.

Women's Footwear

SIR,—Mr. Reginald Payne points out (*Journal*, May 18, p. 1180) the appalling exploitation of the frailty of human nature by commerce, exemplified by fads and fancies in female footwear. In this respect, even the Government became an ally of commerce during the war, insisting on men's shoes of one pattern which compressed the forefoot. Doubtless austerity justified national care of production, but was not a harmful uniformity misgovernment? In happier times the failure is equal when a government ignores the deplorable fact of an unthoughtful populace expending its wealth injuriously.

Mr. Payne is right. Craftsmen may yield to the necessity of earning wages, but they regret debased work. Many are uneasy and many are demoralized when a social conscience is dumb. We all admire the fleet and enduring feet, often bare, of those peoples living closer to nature. Our hard paths, roads, and floors call for foot cover, but civilization can modestly choose shoes shaped to natural outlines of the foot, broadest at the front, and with a low heel that does not drive the toes against the shoe front. Will the Government please have the courage to reply to Mr. Payne's appeal by a national publicity campaign on healthy footwear? Fifty per cent. of foot troubles are due to improper shoes.—I am, etc.,

Bristol, 8.

A. WILFRID ADAMS.

SIR,—Although there is much truth in Mr. R. T. Payne's letter on women's footwear (*Journal*, May 18, p. 1180) the case against the boot trade as a whole is very much overstated. The third paragraph states distinctly that women "have tried shop after shop without success," and again another lady is quoted as having "recently spent a whole

day in London shoe-shops in a completely vain endeavour to get reasonable shoes." My wife has found no trouble in getting a thoroughly comfortable, well-balanced, and neat shoe with arch supports and moderate practical heels, and certainly did not spend more than a few minutes studying the windows for something of her choice. If women would only leave alone the absurd and even potentially deforming type of shoe displayed, the makers would not put them out. There are, to my personal knowledge, enough of the good type, provided the price can be met.—I am, etc.,

London, S.W.19.

B. J. BOUCHÉ.

Premedication in Children

SIR,—The paper by Dr. R. Goulding *et al.* on the sedation of children as out-patients for dental operations (*Journal*, April 13, p. 855) was a timely one and of considerable interest. There is no doubt that many children require some form of sedation in order to allay their anxieties before visiting the dentist—especially if extractions are contemplated. The problem of finding a suitable preparation for use in children is not an easy one, for whatever is chosen must be generally effective, safe, and acceptable to small patients.

In the article above quoted the authors state that "methylpentynol, butobarbitone, and chlorpromazine scarcely provide the answer." After trying a few likely preparations, including methylpentynol, my own experience has led me to prefer a combination of non-barbiturate sedatives of the open-chain ureide type, such as carbromal and bromvalone, which are well tolerated and have minimal toxicity, together with a small dose of mephensin and rauwolfia extract. I have found that in most cases such a preparation does help in reducing any anxiety and restlessness and in rendering dental procedures a less frightening experience for the child. If time permits I instruct the parent to give half a dose beforehand and then the full therapeutic dose about half to one hour before the appointment to see me. The particular preparation ("sedaltine") which I myself use has the additional merit of being easy to administer to children and has no untoward side-effects in the recommended dosage.—I am, etc.,

Chingford, Essex.

R. H. MOODY.

X-rays and Bronchial Carcinoma

SIR,—Smokers develop persistent coughs. Patients with persistent coughs are more frequently x-rayed than others. X-rays are known to encourage neoplastic developments. Therefore there should be a connexion between the incidence of bronchial carcinoma and radiography of the chest. Perhaps those with access to suitable facilities might care to test this hypothesis.—I am, etc.,

Paignton.

J. F. BURDON.

Infection of Umbilical Cord

SIR,—We have been interested to read Dr. Janet Jellard's paper on reservoirs of infection in a maternity hospital (*Journal*, April 20, p. 925). Similar problems have been met in the Catterick Camp Military Hospital, and some of the findings are mentioned below.

An outbreak of breast infections in mothers and of cutaneous pustules among babies in the families wing of this hospital was first noticed in December, 1956. The organism concerned in all cases was *Staph. pyogenes*, phage type 53. Investigations to determine the source and to trace the vectors were planned, and included bacteriological examination of swabs from nose and throat of all patients, nursing, and medical staff; dust sampling; cultures of nappies, baby powder, blankets, etc. As a result it was found that the focus of infection was in the nursery. *Staph. pyogenes* of the phage type implicated was isolated from all the babies' umbilici and also from certain nappies, petroleum jelly, and

safety-pin containers. *Staph. pyogenes* was also isolated from the nasopharynx of several members of the staff, but proved to be of different phage types. The standard measures to control the epidemic were used and the infected cases were isolated. Local treatment to the cord stumps of the infected babies was given with a 2% chlortetracycline cream followed by a longer prophylactic course of dibromopropamide cream. The nursery was meanwhile thoroughly cleaned with antiseptic and finally fumigated. After these active measures we were grateful to find a sharp diminution in the number of cases of infection, and were therefore dismayed to find that about 95% of clinically healthy babies yielded positive cultures of *Staph. pyogenes* from their umbilici. These organisms all belonged to the same phage type (type 53).

More recently we have run a series of tests to find at what stage the umbilici become infected. We swabbed the umbilici of a random selection of newborn infants hourly, and found that in all cases the organisms first appeared within 1-8 hours following birth. One further interesting feature is that, despite the constant isolation of the same phage type, we have found equal proportions of penicillin-resistant and penicillin-sensitive organisms. It has not been possible, however, to relate this in any way to penicillin therapy.

It is interesting to note that in this hospital we have seen no cases of enteritis or ophthalmia neonatorum. Despite a proved reservoir of pathogenic staphylococci we have only encountered cases of mild skin infections among the babies.—We are, etc.,

H. A. DAVIS.

D. J. PARISH.

Catterick Camp, Yorks.

H-bomb Tests

SIR,—I believe that on April 23 Dr. Albert Schweitzer expressed the feelings of many, if not all, of us regarding the urgent necessity for the cessation of H-bomb tests. I further believe, therefore, that the medical profession has a moral obligation to respond to Dr. Schweitzer's appeal for world-wide public opinion to make itself known. It does not make sense that we, who profess to care for human well-being, should condone by our silence something that we know may lead to unimaginable sufferings of future generations. Most members of the profession would, I am sure, welcome some evidence of the Association's concern regarding the effects of H-bomb tests, particularly if supported publicly by those specially qualified to speak authoritatively on these effects.—I am, etc.,

Port Credit,
Ontario, Canada.

DORIS BRECHIN JAFFÉ.

Idiosyncrasy

SIR,—In hospital practice patients are often encountered who have an idiosyncrasy to a drug in common use such as iodine, penicillin, chloramphenicol, etc. Not infrequently the fact of the existence of a specific idiosyncrasy has been noted in the clinical records of previous hospital examinations, but that fact is often tucked away in a mass of notes to such an extent that it may well escape notice by a practitioner subsequently examining the notes to ascertain what they reveal.

It has occurred to me, and I have put it into practice, that a simple and reliable procedure to follow to bring the fact of established idiosyncrasy to the notice of anyone examining a patient's clinical records would be for a rubber stamp to be available in the wards and the out-patient departments. That stamp should consist of a lined rectangle 2 by 2½ in. (5.1 by 6.4 cm.) with the word IDIOSYNCRASY at the top of the space. Whenever a hospital medical officer discovers that a patient has an idiosyncrasy to any drug he should immediately arrange for that word to be stamped prominently on the front of the folder or on the cover of the clinical notes, and under the word idiosyncrasy should be written the name of the drug involved. It would be an

added advantage if this entry were initialled by the person effecting the record.

In my opinion, procedure of this kind would possibly save many a patient from the unpleasantness or danger of a widespread dermatitis, or copious vomiting, or other clinical phenomena consequent upon the administration of a drug for which there exists a sensitivity.—I am, etc.,

Bristol, 9.

D. G. C. TASKER.

Sir Victor Horsley

SIR,—The recent tributes in the *Journal* of April 20 to the life and personality of Sir Victor Horsley recalled memories of 1912, when he asked me to aid him with an article on the subject of the brave women who obeyed their leader, Mrs. Pankhurst, and used force to gain the right to vote. Several had been my patients after having adopted the hunger-strike when imprisoned and been forcibly fed. Public opinion, at first indignant, was changing to admiration and even to sympathy when the cat-and-mouse order was instituted. The exhausted sufferers were sent home to recuperate, then again imprisoned, and underwent the same ordeal of forcible feeding. Serious consequences to health resulted in many cases. In those far-off days the newspapers were filled with letters expressing many shades of opinion. During social gatherings, when conversation paused, one would often hear such questions as: "And when were you last in prison, Dr. Mabel?"

Sir Victor proved a strong arm of defence. On many evenings Sir Victor and Lady Horsley invited me to the family dinner, after which we all adjourned to the large drawing-room. There we sat round a large table and worked several hours correcting and revising notes and comments on the sufferings of the victims. I have vivid memories of the happy atmosphere which prevailed in the beautiful room of that house in Cavendish Square.—I am, etc.,

London, W.1.

AGNES SAVILL.

Mental Defect and Phenylketonuria

SIR,—The cause of the mental defect in cases of phenylketonuria, hitherto unexplained, may be related to a 5-hydroxytryptamine (5-H.T.) deficiency.¹ We are therefore treating affected patients with 5-hydroxytryptophan, which readily passes the blood-brain barrier, to be decarboxylated to 5-H.T.² The number of available patients of a suitable age group to date is small, and we appeal, therefore, to doctors who may have phenylketonuric patients (aged 3 years or under) in their care for their help. If the relatives are agreeable to such a patient entering hospital for a period of up to six months for a controlled trial, we should be grateful if the doctor would communicate with Dr. C. M. B. Pare, Maudsley Hospital, Denmark Hill, S.E.5, for further details.—We are, etc.,

B. H. KIRMAN.

M. SANDLER.

C. M. B. PARE.

R. S. STACEY.

Medico-Legal

DR. J. B. ADAMS COMMITTED FOR TRIAL

Last week at Eastbourne Dr. John Bodkin Adams was committed for trial in July at Lewes Assizes on fifteen charges under the Dangerous Drugs Act, 1951, the Forgery Act, 1913, the Cremation Act, 1902, and the Larceny Act, 1916. He was released on bail in his own recognizance of £2,000.

Obituary

H. G. TRIMBLE, M.D.

Dr. H. G. Trimble, associate professor of clinical medicine at Stanford University, California, U.S.A., and consulting chest physician at Oakland, California, died suddenly in Oakland on May 13. He was 60 years of age.

Harold Guyon Trimble was born and bred in California and had lived all his life at Oakland, having graduated from the University of Southern California and taken his specialists boards in internal medicine some years later. He was on the consulting staff of several hospitals in the San Francisco and Oakland areas and was particularly associated with the hospitals for diseases of the chest in Alameda county. He was an intrepid world traveller and had come regularly to Europe since 1950, and each year had spent some time attending conferences in Britain and visiting institutions and clinics specializing in diseases of the chest. His reputation as a physician and as a man of deep knowledge of and interest in his subject thus spread far from his home country, and he was known in Europe and in the Far East as a great scholar and as a friend of humanity.

In 1954 Trimble was awarded the Varrier-Jones gold medal and delivered the memorial lecture in London on a statistical analysis of the present-day treatment of pulmonary tuberculosis. The *British Medical Journal* was accorded the privilege of publishing his article based on the lecture, in January, 1955. He addressed the British Tuberculosis Association at Bristol as recently as June, 1956, on the subject of pneumoperitoneum therapy, to the literature of which he had contributed greatly. His monographs on this subject and on respiratory function tests are well known as standard contributions from a chest physician of great authority. In his own country Harold Trimble was a moving spirit in the American College of Chest Physicians and had recently been elected to its board of regents and was head of the board of examiners for the Fellowship of that college. He was also a member of the National Tuberculosis Association and American Trudeau Society, and his advice on tuberculosis problems was always being sought. He had an undying interest in medical research and was chairman of the research committee of the Californian Medical Association.

Harold Trimble enriched the lives of all those with whom he came in contact. His kindly bearing and his readiness to help were well known to his many friends all over the world and particularly to those in Britain. Only a few days ago he was to have been elected an honorary life member of the British Tuberculosis Association, in addition to his vice-presidency of the South-east Metropolitan Tuberculosis Society. The mode of his death—he was shot by a patient in his consulting-room—adds to the tragedy of his passing. He leaves a widow, who has been his constant companion in his home life and in all his travels abroad, five married children, and eleven grandchildren.—C. W. L. J. and M. M. N.

C. A. HUGHES, M.D.

Mr. C. Alston Hughes, formerly ophthalmic surgeon to the Eye and Ear Infirmary in Liverpool, died on April 16 at the age of 77.

Clement Alston Hughes was born in Liverpool and received his early education at St. Francis Xavier's College. As a student of medicine in Liverpool he showed early promise, winning the Gold Medal in anatomy, and when he graduated M.B., Ch.B. in 1903 he passed the examination with honours. His first posts were as house-surgeon and house-physician at the Liverpool Royal Infirmary. After a few years in general practice he joined the R.A.M.C. at the outbreak of the first world war, and in 1915 went to France. He had already by that time a leaning towards

ophthalmology, and at the hospital at Noyelles-sur-Mer he had among his patients large numbers of Chinese labourers suffering from trachoma. For his work in looking after the French civil population he received the Médaille d'Honneur from the French Government in 1919. On demobilization he returned to Liverpool and proceeded to the M.D. at the university, having chosen trachoma as the subject of his thesis. He joined the staff of the Eye and Ear Infirmary as honorary assistant ophthalmic surgeon and later he became full surgeon, a post he held until his retirement. Another of his appointments was that of ophthalmic surgeon to the Victoria Central Hospital, Wallasey. A member for many years of the North of England Ophthalmological Society, he served as its president in 1937-8. He was also a life member and English representative of the Société Française d'Ophthalmologie.

Outside his professional work he loved literature, nature, and walking and climbing in the Lake District. It was his proud boast that he had climbed every mountain and hill in the district that did not require roping. As a man, he was devout and self-effacing and believed in doing good by stealth. For some years past he had been living in retirement in the Lake District that he knew and loved so well. To his widow, son, and daughter we extend our sincere sympathy.—H. M.

Dr. J. A. McCANN writes: I first met Mr. Alston Hughes on my appointment as house-surgeon to the Liverpool Eye and Ear Infirmary twenty years ago, when he was secretary to the medical board of that infirmary. I was much in contact with him later as clinical assistant and ultimately became his assistant surgeon. I had, therefore, many opportunities of knowing him as an ophthalmologist and, in his later working years, as a friend. He had a great interest in optics and was a most expert refractionist; his thoroughness and patience in this aspect of his work was an inspiration to his juniors and students. As a diagnostician he was most conscientious, and every case of his was investigated and considered with the utmost care. I, and many other of his juniors, have every reason to be grateful for his training and guidance.

Mr. Alston Hughes was greatly interested in literature and a member of the Medico-Literary Association. He had himself written not a few plays: one, "On Clifton Moor," which he read to his colleagues at his retiral dinner, was a most interesting historical and literary work. His great and abiding interest, however, was walking and climbing in his beloved Lake District, which was for Clement Hughes the spot spoken of by his favourite author, Kipling:

God gives all men all earth to love,
But, since man's heart is small,
Ordains for each one spot shall prove
Beloved over all.

He was a sincere Roman Catholic and this always pervaded his attitude to his patients, and as a member of the Guild of St. Luke, SS. Cosmas and Damian he was most assiduous and energetic. His outstanding qualities were his thoroughness, industry, and modesty. It may be truly said that he commanded the respect and affection of all who knew him.

HAVEN EMERSON, M.D.

Dr. Haven Emerson, a former health commissioner of New York City and emeritus professor of public health at Columbia University, died at Southold, Long Island, on May 21, aged 82.

Haven Emerson was a grand-nephew of Ralph Waldo Emerson and the son of Dr. John Haven Emerson, one of the first specialists in public health to work in New York. He graduated first at Harvard and then took the degree of M.D. at Columbia in 1899. For the next few years he was in private practice in New York, holding the post of assistant visiting physician at Bellevue Hospital. One task he undertook at this time was the revision of Flint's *Manual of Auscultation and Percussion*. In the end, however, he

JOHN WYLIE, M.C., M.B., Ch.B.

Dr. John Wylie died at his home at Woodlands, near Doncaster, on May 4 after a short illness. He was 66 years of age.

Born on December 28, 1890, John Wylie graduated M.B., Ch.B. from Glasgow University in 1914, and then served in the R.A.M.C. during the first world war in Gallipoli, Egypt, and France. He was awarded the Military Cross in 1919. After the war he settled at the mining village of Woodlands and practised there for almost forty years. He was everybody's friend and never spared himself in his work; for this he was loved by his patients, and also for his quiet but genial manner. He was especially interested in midwifery. Much of his scanty spare time he gave up to work for the St. John Ambulance Brigade. The large attendance at his funeral was a measure of how much he will be missed in the community; but the triumphant tone of that service was a sign of that personal faith in Christ which had inspired and empowered much of his life's work. He leaves a widow and four children.

G. BRIDGEFORD PROCTOR, L.R.C.P.&S.Ed.

The death occurred early in May of Dr. G. Bridgeford Proctor, of Pitsea, Essex, where he had been in practice for over thirty years, being the first resident doctor in the district. He was 93 years of age.

George Bridgeford Proctor was born on May 22, 1863, and was educated at University College, Liverpool. He received his medical training at Edinburgh and the London Hospital, taking the Scottish triple qualification in 1889. On returning from a voyage as a ship surgeon he went into practice at South Norwood for a few years, until 1896, when he moved to Brighton, where he became physician to Mrs. Leopold de Rothschild's convalescent home. After the first world war, in which he served as a captain in the R.A.M.C., he settled in practice at Pitsea.

J. L. C. writes: In spite of his great age Dr. Bridgeford Proctor continued until recently to give medical advice. When 92 he underwent a successful cataract operation, and returned to normal life for another year. A physician of the old school, he was regarded by many of his patients as a friend and adviser as well as family doctor. He was held in the highest respect by all who came in contact with him. Notably good-looking and very particular about his appearance, he was a well-known figure in the district he served so faithfully for so many years. The sincerest sympathy will be extended to his widow, who survives him.

Medical Notes in Parliament

Further Report on Nuclear Hazards

Dr. BARNET STROSS (Stoke-on-Trent, Central, Lab.) asked the Prime Minister on May 23 if he would consider asking the signatories to the report on the *Hazards to Man of Nuclear and Allied Radiations* to meet again—not for a few minutes or half an hour, as he understood they had done—but to consider whether a further report was now needed, in view of further evidence which they did not have when they last reported. Mr. HAROLD MACMILLAN said that he would consider that, but he reiterated that the Medical Research Council's work was not something that was done and finished with, but was a permanent inquiry, with a standing committee appointed for the purpose. It had its own research units, and there was what might be called a continuing progress of research. Mr. H. GAITSKELL (Leeds, South, Lab.) thought the fact that this body was continuously at work was an argument in favour of inviting the Council to produce a further report. Mr. MACMILLAN agreed that, as in all these investigations, there was a moment when there might be enough new material to justify a new report.

followed his father into the public health service, being appointed a deputy commissioner of health in New York in 1914. In the following year he became commissioner and president of the board of health, holding this office in 1916 during the severe outbreak of poliomyelitis in New York. In fact, he was the first to set up an extensive investigation into the origin and possible forms of treatment of this disease. Always an advocate of mass immunization campaigns, he lived to see the introduction of vaccination against poliomyelitis on an enormous scale.

During the first world war Dr. Emerson was appointed epidemiologist to the American expeditionary forces, and after the war he was one of those whose nutritional studies were designed to help the starving populations of Europe. In 1919 he was appointed professor of preventive medicine at Cornell University, and three years later he became professor of public health practice at Columbia. From then until he retired in 1940 he led a life of great activity, becoming known as a forthright critic of everything—including alcohol—that he thought prejudicial to health. But he was constructive as well, and directed many hospital surveys in the U.S.A. and pioneered in epidemiological investigations of tuberculosis and cardiac disorders. President of the American Public Health Association in 1933, he was a member of the board of health of New York from 1937 until his death.

A few years ago thirty-five of his papers were selected for publication in book form to mark the occasion of Dr. Emerson's seventy-fifth birthday. Professor J. M. Mackintosh, reviewing the volume in this *Journal*, wrote of Dr. Emerson that he was not the first great worker in the field of public health to have forsaken a most promising career as a physician for the less obvious attraction of preventive medicine. "His rarity lies not only in his clear and able scientific work but in his constant awareness of its deeper social significance."

R. O. J. FRY, M.R.C.S., L.R.C.P., D.T.M.&H.

Major R. O. J. Fry, R.A.M.C., on posting for duty as D.A.D.M.S., 10 Armoured Division in Tripolitania, was a victim of the tragic air disaster at Blackbushe on April 30. He was 35 years of age.

Richard Oswald James Fry was born on April 11, 1922, the only son of Mrs. and the late Mr. R. B. Fry, of Wellington, Somerset. Educated at Wellington School, the University of London, and St. Thomas's Hospital, he qualified M.R.C.S., L.R.C.P. in 1946, and after house appointments at the City General Hospital, Plymouth, joined the R.A.M.C. in March, 1947. After two years in the United Kingdom, Fry saw foreign service in Hong Kong and Malaya, where, as a temporary major, he commanded the British Military Hospital, Cameron Highlands, for over two years with conspicuous success. On his return home in 1952 he was posted to Shorncliffe as D.A.D.M.S., 44 (Home Counties) Infantry Division (T.A.). When the command of 15 Field Ambulance fell vacant in May, 1954, Fry was selected to fill the appointment as a temporary measure, being granted the temporary rank of lieutenant-colonel. So successful and popular was he that, although junior in seniority, his appointment was confirmed and he remained with the unit at Shorncliffe and Lingfield until he proceeded on the R.A.M.C. senior course at Millbank in September, 1956. On completion of the latter he was granted a postgraduate period of study, which he put to good use by taking the D.T.M.&H. only a few weeks ago.

A colleague writes: "Dickie" Fry was one of the most popular young Regular officers in the Corps. Slight and of small stature, he was great in spirit and achieved his results by true leadership. His men would have followed him anywhere, because he never asked of them anything he would not willingly have tackled himself. Shy almost to the point of diffidence, he was gentle, kindly, and courageous, and his death is a great loss to the Corps. He married in 1949 Miss E. B. Sargent, of Gillingham, Kent, to whom the sympathy of his many friends goes out in her bereavement.

He did not think, as Mr. Gaitskell also suggested, there was really a great conflict of opinion—between, for example, Lord Cherwell and other scientists—but he would consider whether a supplementary report should be produced, either now or at some near date.

Edinburgh Hospitals' Consultant

Three Scottish M.P.s questioned the Secretary of State again on May 21 about the appointment of a consultant physician to the Bruntisfield Hospital for Women and Children and the Elsie Inglis Memorial Maternity Hospital, Edinburgh. Mr. J. S. MACLAY told them that the regional hospital board had recently received a deputation from the organizers of a public meeting about this case, and the whole matter was under consideration.

Mr. J. H. HOY (Leith, Lab.) said that at a conservative estimate more than 90% of the people of Scotland were against the decision of the hospital board. He asked the Secretary of State to use his authority to maintain the hospital as it was planned and paid for by the women of Scotland. Lady TWEEDSMUR (Aberdeen, South, Con.) said that everyone would be glad that a decision had not yet been taken to appoint a male consultant. She asked if there was any truth in the rumour that a woman consultant had been interviewed and was shortly to be appointed. Sir IAN CLARK HUTCHISON (Edinburgh, West, Con.) said the opinion of a great many people was that the appointment of a male consultant would contravene the spirit, and probably the terms, of the trusts on which these hospitals were founded. Mr. A. WOODBURN (Clackmannan and East Stirling, Lab.) asked the Secretary of State to keep in mind that these two hospitals were formed in memory of the entry of women into the medical profession. It was felt that part of the trouble lay in the resistance of the male members of the medical profession to the entrance of female consultants. It was important that some place should be left for women in the field of medicine which they could have as a prerogative for themselves. Mr. MACLAY repeated that the whole matter was under consideration. He could make no comment on rumours. He was well aware of the views that were held, but he thought Mr. Woodburn was drawing some conclusions that were not necessarily valid.

Preventive Medicine in Hospitals

Mr. H. E. RANDALL (Gateshead, West, Lab.) asked the Minister of Health if he would make a statement on the steps being taken to develop departments in hospitals for the practice of preventive medicine; and what progress had been made in this regard since the inception of the Health Service. Mr. J. K. VAUGHAN-MORGAN, Parliamentary Secretary, stated on May 20 that certain aspects of preventive medicine might require, and would obtain, the collaboration of any department of a hospital, but he did not think the establishment of special departments would be appropriate.

Shortage of Radiographers

Mr. D. VOSPER was faced with a dozen questions, from Dr. BARNET STROSS (Stoke-on-Trent, Central, Lab.) and Mr. SOMERVILLE HASTINGS (Barking, Lab.) among others, on May 27 about the shortage of radiographers in the Health Service. He stated that the number of radiographers in the hospital service in England and Wales at the end of 1952 was 2,652 whole-time and 199 part-time. The provisional figures at the end of 1956 were 3,087 and 289 respectively. There had therefore been a marked increase, but there was evidence to suggest that it had not been enough to meet the increased demand for x-ray services. A sample inquiry in four hospital regions a year ago indicated that there was a shortage of 16% on establishment, and that not more than half the annual loss was due to reasons other than retirement, marriage, or domestic reasons. Since then, in November last, the salaries were substantially increased and the staffing structure improved following an award of the Industrial Court. The salary of the basic grade was now

£420-£485 per annum and of the highest grade of superintendent radiographer £675-£850. In his view it was too early to assess the effect of these increases. Meanwhile he had asked hospital boards for information about the staffing of radiography departments and the intake of students in order to obtain a full up-to-date picture of the position. The last return had just been received. When he had been able to study the results of this inquiry he would consider what steps might be necessary to meet the situation it revealed. He added in further replies that the result of the inquiry would be known in a few weeks' time. He hoped that one of the results would make it possible to tell more closely the reasons for the wastage. Mr. HERBERT MORRISON (Lewisham, South, Lab.) said that doctors in Lewisham had been informed of a shortage of radiographic facilities and warned that patients could not be taken or must be restricted, and this was worrying the doctors. Mr. VOSPER replied that the inquiry would reveal the relative shortage in various parts of the country. His information was that London was generally better off than elsewhere.

Hospital for Rheumatic Diseases

Mr. I. PITMAN (Bath, Con.) asked the Minister of Health if he is aware that the premises of the Royal National Hospital for Rheumatic Diseases at Bath were in a state of decrepitude and danger by risk of fire; and, in view of the national service and importance of this hospital as a centre for the treatment of rheumatic diseases, what steps he intended to take to expedite the necessary work of reconstruction. Mr. VOSPER said he was aware that this hospital fell short of modern standards, and he was examining the proposal of the South-western Regional Hospital Board that the project to restore it should be included in the programme of major building projects which were financed centrally.

Days Lost Through Rheumatism.—In 1954-5, the last year for which complete figures are available, the number of weekdays in respect of which incapacity for work was certified as due to rheumatic fever, rheumatism, or arthritis totalled about 22 million.

Prescription Costs.—The average cost per prescription dispensed in England and Wales in February was 5s. 7.87d. Complete figures for March are not yet available, but it is estimated from a sample that the average cost was about 3d. more than in February.

Malaria Eradication.—As provision for malaria eradication is included in the regular budget of the World Health Organization to which the United Kingdom contributes, the Government does not propose to contribute to the special fund established by W.H.O.

Toxic Chemicals.—A scheme for the voluntary notification of proposals to use toxic chemicals in agriculture has been agreed between representatives of the industry and the Advisory Committee on Poisonous Substances used in Agriculture and Food Storage, and has been approved by the Secretary of State for Scotland and the Minister of Agriculture and Fisheries.

Tuberculosis Among West Indians.—Investigations have failed to show any unusual incidence of tuberculosis among West Indians in this country.

Lung Cancer and Smoking.—The Medical Research Council's review of the connexion between smoking and lung cancer should be available within a few weeks.

Medical Manpower.—The report of the Committee on Medical Manpower is expected during the summer.

Universities and Colleges

SOCIETY OF APOTHECARIES OF LONDON

The following candidates, having completed the final examination, have been granted the diploma of L.M.S.S.A.:

D. L. Oldfield, J. L. Currah, W. A. Garson, S. H. Thomas, M. L. A. B. Bancillon, M. J. Allan, A. F. Broad, R. E. Owen, A. T. Darko, R. C. Snelling, J. H. Kendall, A. G. Snart, C. Bell, G. A. Robson, R. J. L. Potts, K. C. Kewish, R. Owen.

The following candidates have been awarded the Diploma in Industrial Health:

D. E. Marchant, C. C. Molloy, R. H. Pratt, J. D. Walters.

Vital Statistics

New Influenza Strain

A new strain of influenza virus A is at present causing large outbreaks of the disease in the Far East. Cases are relatively mild, with no unusual features. The World Health Organization's Influenza Centre in London, which is under the direction of Dr. C. H. Andrewes, F.R.S., has specimens of the virus, and Dr. A. Isaacs is studying it there. Cases caused by this virus were first identified in Hong Kong. Epidemics were recorded there and in Singapore during the second half of April. At the end of April an outbreak started in Formosa, where about 100,000 cases have occurred. During May about 800 cases, with 14 deaths, have been reported from Manila in the Philippines, and the disease has also spread to Indonesia. One or two cases in air travellers from Singapore have just been detected in Australia.

Urgent work on the preparation of a vaccine with the new strain is being carried out at the Influenza Centre, with a view to helping, in the first place, countries in the southern hemisphere. Owing to their being in mid-winter, it is thought possible the disease might spread there now rather than in the northern hemisphere. While new strains of influenza virus fairly commonly arise, this is the largest variation since A-prime appeared in 1946-7.

Week Ending May 18

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 664, whooping-cough 2,258, diphtheria 4, measles 16,665, acute pneumonia 374, acute poliomyelitis 66, dysentery 750, paratyphoid fever 1, and typhoid fever 2.

Infectious Diseases

The largest fluctuations in the notifications of infectious diseases in England and Wales during the week ending May 11 were decreases of 4,923 for measles, from 23,188 to 18,265, and 37 for whooping-cough, from 2,399 to 2,362, and a rise of 95 for dysentery, from 574 to 669.

69 cases of acute poliomyelitis were notified, and these were 4 more for paralytic and 5 more for non-paralytic cases than in the preceding week. The largest returns were Essex 17 (Colchester M.B. 8, Tendring R.D. 6), London 7 (Wandsworth 4), and Lincolnshire 6 (Grimsby C.B. 2, Lincoln C.B. 2, Spalding R.D. 2).

In 13 counties the numbers of notifications of measles were 100 or more fewer than in the preceding week; the largest falls were 1,049 in Yorkshire West Riding, from 2,915 to 1,866, 662 in Lancashire, from 2,214 to 1,552, and 471 in London, from 1,640 to 1,169. The largest falls in the towns were 354 in Leeds C.B., from 558 to 204, and 198 in Manchester C.B., from 419 to 221. A rise of 64 in the notifications of measles in West Bromwich, from 52 to 116, was an exception to the general trend in large towns. 497 cases of scarlet fever were notified, being 17 more than in the preceding week; only small variations were recorded in the local trends. The only large variation in the returns of whooping-cough was a rise of 31 in Liverpool C.B., from 42 to 73.

The rise in the incidence of dysentery was due to increases in established outbreaks rather than to new outbreaks. The largest rise was 49 in Cheshire, Stalybridge M.B., from 7 to 56, and the largest fall was 25 in Shropshire, Oswestry M.B., from 31 to 6. The largest returns during the week were Lancashire 127 (Liverpool C.B. 29, Manchester C.B. 25, Ashton under Lyne M.B. 19), Yorkshire West Riding (Leeds C.B. 24, Rotherham C.B. 18, Worsborough R.D. 13, Bradford C.B. 11, Sheffield C.B. 11), Cheshire 79 (Stalybridge M.B. 56, Hyde M.B. 10), Northumberland 45 (Newcastle upon Tyne C.B. 19), Durham 34 (South Shields C.B. 13), London 31 (Islington 11), Essex 28 (Southend on Sea C.B. 14), Yorkshire East Riding 24 (Kingston upon Hull C.B. 21), and Nottinghamshire 20 (Nottingham C.B. 10).

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending May 11 (No. 19) and corresponding week 1956.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included). London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenzal pneumonia.
§ Includes puerperal pyrexia.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1948-56 are shown thus -----, the figures for 1957 -----. Except for the curves showing notifications in 1957, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Diagnosis of Smallpox

A memorandum entitled *Diagnosis of Smallpox* has been issued by the Ministry of Health and the Department of Health for Scotland to medical officers of health and others likely to be interested. It includes notes on the laboratory diagnosis of smallpox, a paper by Dr. F. O. MacCallum on the subject, and instructions for collecting and dispatching specimens. Finally, it gives a list of laboratories available for diagnosis and a list of medical practitioners designated to assist medical officers of health in the diagnosis of the disease.

Medical News

Memorial to Mr. Cecil Calvert.—The death of Mr. CECIL CALVERT, neurosurgeon to the Royal Victoria Hospital, Belfast, occurred in a motor accident last year. Last week in Belfast further tributes were paid to his memory, when Sir GEOFFREY JEFFERSON, F.R.S., unveiled at the Royal Victoria Hospital a portrait of Mr. Calvert, commissioned by the medical staff. After Dr. R. S. ALLISON, chairman of the medical staff committee, had officially presented the portrait to the hospital, Mr. VICTOR CLARENDON, chairman of the board of management, announced that a Cecil Calvert scholarship was to be provided out of the "free funds" of the hospital for research work in any field of clinical science.

Treatment of Wound Shock.—The Medical Research Council has had its *War Memorandum* on the treatment of wound shock completely rewritten. It now appears as *M.R.C. Memorandum No. 34* (H.M.S.O., price 3s. 6d. net). The rewriting has been undertaken by a working party under the chairmanship of Sir ERNEST ROCK CARLING. The 39-page booklet discusses first the assessment of the patient's condition and then treatment. Under the latter heading are reviewed general treatment, transfusion, operation and post-operative care, the metabolic consequences of injury and special complications such as fat embolism and renal lesions, and burns. There are also appendices on the transfusion fluids available from the Blood Transfusion Services, plasma substitutes, transfusion apparatus, blood grouping and the giving of transfusions, and the various types of reaction encountered after transfusion. The memorandum will be invaluable to all concerned with the care of the injured.

Scottish Campaign against Tuberculosis.—During the first five days of the mass miniature radiography campaign in Ayr Burgh 9,924 of a possible 34,100 persons over 14 years of age were examined, while in Kilmarnock Burgh 9,138 of a possible 33,800. Two M.M.R. units are in use in each of these campaigns, which end on June 15. The Scottish Department of Health's programme for the rest of the year is as follows (the number of M.M.R. units in each case is given in parentheses): May 27 to June 29, Fife County (2); June 17 to 29, Port Glasgow Burgh (3); September 2 to October 5, Lanark County (5) and Midlothian County (3); October 28 to November 30, Aberdeen Burgh (7). After the five-week Glasgow campaign, in which 30 M.M.R. units were used as well as seven other units for taking large films in doubtful cases, the campaign moved to Perth. Here four M.M.R. units were used, and 28,365 persons, the equivalent of 70% of the population over 14 years of age, were examined during the two-week campaign. During the four-week campaign in West Lothian, in which again four units participated, 37,300 persons, 56% of the population over 14, were examined.

Tenth World Health Assembly.—The Assembly ended on May 24. It had approved the executive board's budget for 1958—\$13.5 million—in spite of a move by the U.S. delegation to cut it to \$12 million; it had offered an extension of office of up to a further five years to the director-general of W.H.O., Dr. M. G. CANDAU; it had accepted an invitation

from the U.S. Government to hold the next Assembly in the United States; and it had debated various recommendations affecting W.H.O.'s future programme of work. These included requests for W.H.O. to co-ordinate evaluation of polio vaccines on an international scale and to intensify its work on leprosy and schistosomiasis. The Assembly was told that the goal of total eradication of malaria was threatened by serious lack of funds: tentative estimates put the cost of eradicating malaria "in some of the larger countries of Asia" at \$15 million a year for five years. W.H.O. was also asked to study the environmental aspects of cancer and to help improve national cancer statistics. A proposal from India to appeal for a ban on atomic bomb tests was ruled out of order by the committee on programme and budget after its earlier debate in one of the plenary sessions. W.H.O. is, however, undertaking work on the health aspects of the peaceful uses of atomic energy. Each year six of the 18 countries nominating delegates to W.H.O.'s executive board retire, and to fill their places the U.S.A., Liberia, Australia, Western Germany, Egypt, and Afghanistan were elected. (The board acts in the name of the Assembly and its members do not serve as representatives of governments.) The Léon Bernard prize was awarded to Professor MARCIN KACPRZAK, rector of the Warsaw Medical Academy, for his outstanding contribution in the field of social medicine, and the Darling Foundation medal and prize to Dr. PAUL F. RUSSELL, of the Rockefeller Foundation, for his work on malaria, particularly his early demonstration in India of the place of insecticides in controlling the disease.

R.C.O.G.—At a meeting of the council of the Royal College of Obstetricians and Gynaecologists on May 25 the following were elected to fill statutory vacancies on the council: *As representatives of the fellows*, Professor W.C.W. NIXON (London), Mr. F. E. STABLER (England and Wales, excluding London), Mr. T. N. MACGREGOR (Scotland), and Professor C. H. G. MACAFEE (Northern Ireland and Eire); *as representatives of the members*, Mr. T. L. T. LEWIS (London) and Mr. R. MURDOCK (Scotland). Sir RUSSELL BRAIN was admitted to the honorary fellowship. In addition 27 new fellows and 33 new members were admitted.

Drinking Sea-water.—In its centenary report, issued last month, the Mercantile Marine Service Association calls for an authoritative statement on whether or not survivors of shipwreck should be advised to drink sea-water. The report notes the conflicting opinions on the subject and asks for an international commission to review "the practical effects of using sea-water to supplement or replace fresh water." The report points out that the inflatable life-rafts now being developed are liable to involve survivors in long periods awaiting rescue.

Nutrition Society.—At a recent meeting Dr. R. J. L. ALLEN, Ph.D., and Dr. W. F. J. CUTHBERTSON, Ph.D., were elected respectively hon. secretary and hon. treasurer. The Society's other officers and members of council are: president, Dame Harriette Chick, D.Sc.; hon. editor, Dr. S. K. Kon, D.Sc.; hon. programmes secretary, Miss D. F. Hollingsworth; members of council, Dr. A. J. Amos, Ph.D., Mr. A. L. Bacharach; Dr. G. H. Bourne, D.Sc.; Professor C. Fraser Brockington; Professor E. W. H. Cruickshank; Professor J. N. Davidson; Dr. O. Fitzgerald; Dr. R. H. Girdwood; Miss E. M. M. Hume; Dr. T. Mann, F.R.S.; Mrs. F. S. Patton; Dr. A. T. Phillipson, Ph.D.; Professor B. S. Platt, Dr. M. Pyke, Ph.D.; Dr. J. A. B. Smith, D.Sc.; and Dr. E. M. Widdowson, D.Sc. The hon. secretary's address is c/o Beecham Foods Ltd., Brentford, Middlesex.

Psychiatric Out-patient Facilities.—A directory of adult psychiatric out-patient facilities in England and Wales has been issued by the National Association for Mental Health. The information is classified under regional hospital board areas. The address and telephone number of each hospital, the psychiatric staff, and the appointment times are given. Clinics where children also will be seen are specially indicated, but further information about facilities for children is provided in the association's separate directory on child-

guidance clinics. The directory on facilities for adults is obtainable from the National Association for Mental Health, 39, Queen Anne Street, London, W.1, price 5s. net.

Essay Competition for G.P.s.—The subject of the Hunterian Society's next Gold Medal essay competition is "The Diagnosis and Management of Coronary Disease in General Practice." The competition is open to all general practitioners, and the closing date is December 31. Further details may be obtained from the hon. secretary, Dr. C. W. KESSON, 51, Harley Street, London.

Anglo-French Exchange Bursaries.—The following have been awarded bursaries to study in France this year under the exchange arrangements between the Institut National d'Hygiène, Paris, and the Ciba Foundation, London: Dr. G. A. COLLIE-KOLIBABKA (gynaecology in Paris); Dr. F. A. L. DA CUNHA (gynaecology in Paris and Lyons); Dr. R. J. T. GARDINER (alcoholism in Paris); Mr. T. H. MORGAN (orthopaedics in Paris); Mr. W. R. PROBERT (thoracic surgery in Lyons and Marseilles); Dr. J. T. SHEPHERD (cardiology in Paris); and Dr. I. McG. STEWART (cardiology in Paris and Dijon). Dr. Collie-Kolibabka and Dr. Gardiner are general practitioners.

Awards for Research on Ageing.—The Ciba Foundation offers not less than five awards, of average value £300 each, for papers describing research "relevant to basic problems of ageing." The papers must not exceed 7,000 words in length and be accompanied by a summary in English, although they may be written in the candidate's own language. Entries must be in the hands of the director of the Ciba Foundation (41, Portland Place, London, W.1) by January 1, 1958, from whom further particulars may be obtained. The awards will be announced in July, 1958.

Faculty of Ophthalmologists.—At the council meeting on May 10 the following were elected officers for 1957-8: president, Mr. L. H. SAVIN; immediate past president, Dr. JOHN MARSHALL; vice-presidents, Mr. E. G. MACKIE and Professor G. I. SCOTT; hon. treasurer, Mr. A. MCKIE REID; and hon. secretary, Mr. E. F. KING.

Leeds University.—The following appointments were announced after the council meeting on May 15: Dr. M. ATKINSON, as lecturer in medicine; Dr. F. O'M. SHIEL, as lecturer in pathology; and Dr. R. W. SPENCER, as lecturer in chemical pathology.

Sheffield University.—The title of reader in social and industrial medicine has been conferred on Dr. J. PEMBERTON, senior lecturer in the department. Dr. J. A. GRIFFITHS has been appointed part-time instructor in anaesthetics, and Dr. R. E. CHURCH part-time clinical teacher in dermatology.

Banting Memorial Meeting.—Among the speakers at the British Diabetic Association's Banting memorial meeting at Oxford on July 12 and 13 will be Professor C. H. BEST, F.R.S., of Toronto. He will speak on "The Present State of the Oral Hypoglycaemic Agents from the Experimental Viewpoint." Professor H. A. KREBS, F.R.S., Whitley professor of biochemistry at Oxford, will deliver the tenth Banting memorial lecture. His subject will be "Some Aspects of the Intermediary Metabolism in the Diabetic Organism." The full programme of the meeting is obtainable from the secretary-general, British Diabetic Association, 152, Harley Street, London, W.1.

Therapeutic Substances Act.—Under the Therapeutic Substances (Control of Sale and Supply) Regulations, 1957, which come into operation on June 1, novobiocin, oleandomycin, spiramycin, prednisone, and prednisolone are brought under the control of Part II of the Therapeutic Substances Act, 1956. The proprietary preparation "sigmamicin," being a mixture of tetracycline and oleandomycin, is also brought under control, according to an explanatory statement from the Ministry of Health.

Hofheimer Prize.—The American Psychiatric Association has awarded the 1957 Hofheimer Prize for "an outstanding research contribution in the field of psychiatry or mental

hygiene" to Dr. C. M. HEINICKE, Ph.D., for his work on the effects of separating 2-year-old children from their parents. This formed part of the research programme of the child development research unit of the Tavistock Clinic and Tavistock Institute of Human Relations.

Scottish Society of Anaesthetists.—The prize for the best paper submitted by a registrar was awarded to Dr. D. B. SCOTT (Edinburgh) at the Society's recent annual meeting at Dunblane Hotel Hydro. Dr. ROBERT LAWRIE (Perth) discussed the reporting of deaths under anaesthesia in his presidential address, and the guest speaker was Dr. ALFRED LEE (London), who spoke on epidural anaesthesia.

Society of Physicians in Wales.—The eighth annual meeting was held at Port Meirion on May 10 and 11, under the chairmanship of Dr. JOHN FORBES. Seven scientific papers were read.

Japanese Delegation Studying N.H.S.—Dr. HIROSHI HASHIMOTO, president of St. Luke's International Hospital, Tokyo, has been visiting Britain with three colleagues to study the Health Service. With him were the vice-president of the Japanese Red Cross Society, the chief of the planning section of the Ministry of Health and Welfare, and Dr. NOBUO TSUDA, who has been studying tuberculosis control on a W.H.O. fellowship. The arrangements for this visit were made by the British Council.

Professor R. J. A. Berry, formerly professor of anatomy, University of Melbourne, and for many years member of the B.M.A. Council, celebrated his 90th birthday on May 30 this week.

Dr. T. H. M. Kerfoot, joint managing director of Thomas Kerfoot and Co., has been elected this year's president of the Association of British Pharmaceutical Industry. He graduated in medicine at St. Andrews in 1931.

COMING EVENTS

William Harvey: Wellcome Exhibition.—At the Wellcome Building, Euston Road, London, N.W.1, 10 a.m. to 5 p.m. daily from June 4, for about a month.

Paddington General Hospital.—The clinical meeting for general practitioners arranged for June 2 has now been deferred until Sunday, June 16, at 11 a.m.

Davidson Clinic.—Summer school on "Human Conflict and its Solution: An Analytic Viewpoint," July 24-30. Details from the secretary, 58, Dalkeith Road, Edinburgh, 9.

Eleventh International Congress of Dermatology.—Stockholm, July 31 to August 6. Details from Dr. MALCOLM TOTTIE, Hudliniken, Stockholm, 60, Sweden.

World Federation for Mental Health.—Annual meeting, Copenhagen, August 11-17. The main theme will be: "Growing Up in a Changing World." Details from the secretary-general, 19, Manchester Street, London, W.1.

Second International Congress for Group Psychotherapy.—Zurich, August 29-31. Details from Dr. A. GUGGENBUHL-CRAIG, 28, Lenggstrasse, Zurich, 8.

British Veterinary Association.—Annual Congress in Cambridge, August 25-31. Details from the general secretary, 7, Mansfield Street, Portland Place, London, W.1.

NEW ISSUES

British Journal of Ophthalmology.—The new issue (Vol. 41, No. 5) is now available. The contents include:
INFLUENCE OF THE FIFTH CRANIAL NERVE ON THE INTRA-OCULAR PRESSURE OF THE RABBIT EYE. E. S. PERKINS.
CORNEO-SCLERAL TONOGRAPHY. T. H. HODGSON and R. K. MACDONALD.
EXPERIMENTAL DEGENERATION OF THE RETINA. I. THIOL REACTORS AS INDUCING AGENTS. ARNOLD SORSBY, J. P. NEWHOUSE, and D. R. LUCAS.
EXPERIMENTAL DEGENERATION OF THE RETINA. II. THE LESION PRODUCED BY BROMOACETATE: OPHTHALMOSCOPIC AND HISTOLOGICAL FEATURES. D. R. LUCAS, J. P. NEWHOUSE, and J. B. DAVEY.
ORBITAL CELLULITIS WITH EXUDATIVE RETINAL DETACHMENT. Manmohan Malhotra.

Issued monthly; annual subscription £4 4s.; single copy 8s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked *. Application should be made first to the institution concerned.

Monday, June 3

MARLBOROUGH DAY HOSPITAL.—8.15 p.m., Dr. D. J. West: Hypnosis.

Tuesday, June 4

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. D. I. Williams: Ectodermal Defects.

LONDON UNIVERSITY.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., special university lecture in pathology by Dr. M. Ruiz Castañeda (Mexico): Recent Developments in Diagnosis and Treatment of Human Brucellosis.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Institute, 5 p.m., Almoth Wright Lecture by Dr. R. M. Fry: Spread of Infections in Hospitals and Institutions.

Wednesday, June 5

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. H. Haber: Benign Tumours of the Corium.

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. Margaret Macpherson: Pulmonary Collapse in Children.

INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—3 p.m., Dr. G. I. M. Swyer: Intersex.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Professor W. St. C. Symmers: Deep-seated Fungal Infections.

Thursday, June 6

FACULTY OF HOMOEOPATHY.—5.30 p.m., discussion: Homoeopathic Treatment of Asthma.

INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—4.30 p.m., Mr. L. P. Le Quesne: Post-operative Fluid and Electrolyte Balance.

NUFFIELD ORTHOPAEDIC CENTRE.—At Wingfield-Morris Orthopaedic Hospital, 8.30 p.m., Professor M. C. Mensor: Mobility Studies of the Lower Lumbar Spine in Relationship to Low Back Pain.

ROYAL SOCIETY OF HEALTH.—At Town Hall, Gateshead, 10 a.m., Dr. J. B. Tilley: Social Workers and the Health Department; Mr. J. P. Lavender: Some Observations on the Clean Air Act.

ST. ANDREW'S UNIVERSITY.—At Lecture Theatre, Department of Physiology, Queen's College, Dundee, 5 p.m., Professor G. H. Bell: In Search of Pellagra.

ST. JOHN'S HOSPITAL DERMATOLOGICAL SOCIETY.—4.30 p.m., clinical meeting and annual general meeting.

Friday, June 7

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. P. F. Borrie: clinical demonstration.

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. F. H. Young: clinical demonstration.

INSTITUTE OF NEUROLOGY.—5.30 p.m., Professor G. A. G. Mitchell: Innervation of Blood Vessels.

INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—4.30 p.m., Professor J. Chassar Moir: Diagnostic Radiology in Obstetrics.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—10 a.m., Mr. H. G. Hanley: Modern Treatment of Renal Tuberculosis.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Institute Theatre, 5 p.m., Mr. L. H. W. Williams: Use and Value of X Rays in Obstetrics.

WHIPPS CROSS HOSPITAL MEDICAL SOCIETY.—8.30 p.m., Mr. D. M. Jackson: Managing the Burned Patient.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Champ.—On May 15, 1957, at Queen Charlotte's Hospital, to Doris and Charles Champ, a son—Roderick Charles.
King.—On May 20, 1957, to Shirley, wife of Dr. John G. King, a daughter.
Manson.—On May 8, 1957, at Morriston Hospital, to Mair, M.C.S.P., and William Manson, M.B., Ch.B., a brother for Helen—Robert Fraser.

DEATHS

Cheal.—On May 15, 1957, at his home, 63, Leigh Road, Eastleigh, Hants, Percival Cheal, M.R.C.S., L.R.C.P., aged 71.
Coffey.—On May 24, 1957, William Joseph Coffey, M.B., B.Ch., of 14, Slades Hill, Enfield, Middx.
Connan.—On May 16, 1957, at Tigh-na-Mara, Albany Street, Oban, Argyll, Donald Murray Connan, M.D., D.P.H., aged 67.
Lance.—On May 6, 1957, at his home, 27, Alexandra Road, Southport, Lancs, Roy Enyat Singh Dalliwali, M.R.C.S., L.R.C.P., aged 53.
Drummond.—On May 15, 1957, at Bandarawela, Ceylon, Russell John Drummond, M.D., aged 94.
Gaskell.—On May 12, 1957, Leonard Sadgrove Gaskell, M.B., B.Ch., of Braside, Budleigh Salterton, Devon, aged 85.
Hardwick.—On May 17, 1957, at Kirton, Boston, Lincs, Philip Vincent Hardwick, M.B., Ch.B.
Jarman.—On May 3, 1957, at Knightswood, Storthes Hall Lane, Kirkburton, near Huddersfield, Yorks, David Ewart Jarman, M.R.C.S., L.R.C.P., D.P.M., aged 41.
Lawrence.—On May 18, 1957, at Somerleyton, Hartley, Kent, Charles John Montagu Lawrence, L.M.S.S.A., late of Bedford.
Logan.—On May 16, 1957, in a hospital, Lanark, Alexander Logan, M.B., F.R.C.S.Ed., late of Broadford, Skye.
McQuaid.—On May 12, 1957, in Dublin, Helena Mary Josephine McQuaid, M.R.C.S., L.R.C.P., formerly of Putney, London, S.W.
Matthews.—On May 10, 1957, at The Lodge, Entry Hill, Bath, Somerset, Samuel Ryder Russell Matthews, M.R.C.S., L.R.C.P., aged 84.
Scott.—On May 3, 1957, at Ryde, Isle of Wight, Charles Frederick Trousdale Scott, M.B., Ch.B., late of 122, Brondesbury Park, London, N.W., aged 82.
Trimble.—On May 13, 1957, at Oakland, California, U.S.A., tragically shot, Harold Guyon Trimble, M.D.
Wall.—On May 19, 1957, at Dashpurs, Brixham, Devon, James Marsden Wall, L.M.S.S.A., aged 78.
Watson.—On May 18, 1957, John Desmond Watson, M.B., B.Ch., of 25, Kensington Court, London, W.

Any Questions?

publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Streptokinase and Streptodornase

Q.—What place have streptokinase and streptodornase in the treatment of tuberculous meningitis and empyema? Are these substances effective against micro-organisms?

A.—The early claims for the value of streptokinase in tuberculous meningitis have not been substantiated by further work. In fact, to give this enzyme intrathecally is likely to do more harm than good. Streptodornase has not been used in tuberculous meningitis. Streptokinase and streptodornase have been used in empyemata, usually of non-tuberculous origin, in order to liquefy thick pus and facilitate its aspiration, streptodornase being effective on the proteins derived from the pus cells and streptokinase on the fibrin. For this purpose a freeze-dried powder containing streptokinase 1,000 to 40,000 Christensen units (equivalent to 120,000 to 1,000,000 Cathie units) and streptodornase 10,000 to 20,000 units may be dissolved in 5 to 20 ml. of normal saline and injected into the empyema, pus then being aspirated after a few hours. The process often greatly facilitates the aspiration of pus, but is apt to give rise to quite a severe irritative reaction. Under similar conditions these substances might occasionally be useful in the treatment of tuberculous empyema.

Streptokinase and streptodornase do not have any action against bacteria. They are enzymes employed to liquefy clotted blood and fibrinous and purulent exudates and effusions.

Anaemia in Old Age

Q.—What types of anaemia are particularly common in old age, and are any limited to that period of life? Do they respond as readily as their juniors to treatment for anaemia, or are special measures indicated when treating them? Does their tolerance of anaemia differ from that of those who are younger?

A.—The incidence of the various anaemias shows an age-trend which depends on the type of the anaemia. Of the anaemias encountered after the age of 65 none are confined to old age. "Secondary" anaemia, either hypochromic or normochromic in character, is the most common, with pernicious anaemia running a close second. The various idiopathic haemolytic anaemias and aplastic anaemia are uncommon. A variety of hypoplastic normochromic anaemias, usually of protracted course, may be encountered in the older patient.

If dietary defects are excluded, hypochromic anaemia in old age is almost invariably due to chronic loss of blood from the alimentary tract, particularly as a result of haemorrhoids or of a silent, and sometimes relatively slow-growing, tumour in the stomach, colon, or rectum. Two frequently overlooked causes of unexplained anaemia in old age are iron deficiency due to prostatic disease and a peculiarly benign, practically symptomless, form of chronic lymphatic leukaemia with a not unduly raised total white cell count. Nutritional anaemias usually showing iron deficiency, but occasionally megaloblastic in type and often associated with multiple vitamin deficiencies in the diet, may be encountered among the old who live alone.

The elderly patient with uncomplicated pernicious anaemia will respond as readily as younger people to specific therapy. The old patient with an idiopathic hypochromic anaemia does tend to take appreciably longer to reach normal haemo-

globin levels than his younger counterpart on oral or parenteral iron therapy, but for practical purposes this difference in the rate of haemoglobin regeneration can be ignored.

Tolerance to anaemia is much less a matter of age than of the rapidity of onset and the nature of the anaemia. Thus, the 80-year-old with a haemoglobin of 30% due to pernicious anaemia may walk into the out-patient clinic complaining only of indigestion, whereas his junior with a haemoglobin of 50% following a silent intestinal haemorrhage arrives prostrate by ambulance. It should be remembered, however, that in a long-standing anaemia the heart may be involved, and, especially in the old, the cardiac reserve can be easily overtaken by, for example, injudicious blood transfusion. This applies especially to pernicious anaemia.

Young Glass-swallowers

Q.—There have been reports recently of chips of glass being found in school milk. How should a child be managed who swallows a piece of glass, and how urgent is the emergency?

A.—The emergency referred to in the question must be relatively rare, as there is no record of such a case in the paediatric department of a large teaching hospital during the past seven years. There are, however, certain principles affecting all types of swallowed foreign body. A small rounded foreign body will pass without any trouble. If, however, the foreign body is elongated, whatever its composition, and particularly if it has a sharp point or edge, it will tend to become caught during its passage through the bowel. During the seven years already alluded to twelve patients with swallowed foreign bodies were admitted. Only two of the foreign bodies required surgical removal, and these were hair grips which had become impacted in the duodenum. In these particular cases radiography was of great value. The operations were performed several days after admission.

Most schoolchildren drink their milk through straws, I understand, in which case a piece of glass of any size is unlikely to be swallowed. In the event of a piece large or sharp enough to cause trouble being swallowed, however, x-ray examination would be of little value. Reliance would therefore have to be placed on changing clinical signs which could be properly evaluated only with the patient in hospital. A suggested method of procedure would be to admit such a child to hospital for observation and repeated clinical examination for any evidence of developing peritonitis. At the same time, stools should be kept and examined for the passage of the foreign body. If the glass is passed, then the problem is solved. If, however, the glass becomes caught up and penetrates the bowel, laparotomy would have to be performed to remove it. The glass should be readily located owing to the development of peritonitis and exudation at the point of penetration. The damage to the bowel could then be repaired. To attempt to locate a foreign body at laparotomy without the help of radiography and the presence of some localizing physical signs might prove very difficult indeed, and in a considerable number of cases would in any event be unnecessary.

Endocrine Therapy after Radioactive Iodine

Q.—Does the treatment of thyrotoxicosis by radioactive iodine result in any alteration in the body's response to endocrine therapy, as, for instance, with oestrogens or androgens?

A.—Radio-iodine treatment should not affect the response of the patient to any other endocrine treatments except in so far as it may do so by altering thyroid function. In general, any lowering of thyroid function will decrease the body's response to other endocrine secretions or hormones, but not to any extent unless thyroid deficiency or myxoedema

has been caused by the radio-iodine treatment. In the latter event it would be better to treat the myxoedema with thyroid administration rather than to alter the dosage of any other endocrine treatment being given. Otherwise, any effect of the radio-iodine treatment on the dosage of other endocrine preparations needed would be so small that it could be ignored.

Sitosterol and Atherosclerosis

Q.—I have seen it stated that a preparation known as sitosterol has the property of eliminating cholesterol from the blood stream. Is there any truth in this, and, if so, is sitosterol of value in the treatment of atherosclerosis?

A.—Sitosterol is the generic term for the sterols present mainly in cereals; β -sitosterol is related chemically to cholesterol. One mode of action suggested is that it "competes" with cholesterol for the pancreatic cholesterol-esterase or other enzymes needed for the absorption of cholesterol. Another suggestion is that "mixed crystals" of the two sterols are formed. For long it was considered that sitosterol was not absorbed, but it is now known that it is and that it is metabolized in the body, the main excretory products appearing in the bile. Its main action, however, would appear to be in the intestine, consisting in interference in one way or another with absorption of cholesterol.

The observation that sitosterols hinder the absorption of cholesterol in experimental animals has been extended by various workers to the effect on cholesterol absorption in man, and it has been shown that sitosterol lowers the level of cholesterol and lipoproteins in the blood plasma. This might possibly be beneficial in patients with abnormalities of cholesterol and lipoprotein metabolism.

It is as yet too early to say whether sitosterol will be of value in the treatment of atherosclerosis.

Collapse During Dressing of Boils

Q.—What is the mechanism of the collapse which sometimes occurs in patients suffering from boils? I have seen five people lately who collapsed suddenly during the dressing of their boils. In all of them there was extreme pallor, sweating, faint pulse, low blood pressure, and dyspnoea. All recovered without any treatment in from a half to two hours. The collapse occurred during simple dressing without lancing or squeezing the lesion. Could the collapse have been due to anaphylactic shock following the sudden release of staphylococcal toxins?

A.—It seems probable that these patients had peripheral circulatory failure associated with vasovagal attacks. Such attacks are more common in young people and especially in those who are feeling out of sorts, as one does with boils. The attacks may be brought on by emotion, such as from the sight of blood, the prick of a needle, or a sudden fright, or by pain or fatigue, especially in an overheated room. They rarely occur if the patient is lying down.

NOTES AND COMMENTS

"Wind" in the Young of Mammals.—Dr. ESTHER WELBOURN (Cambridge) writes: I think your expert writing in "Any Questions?" (May 18, p. 1196) on the subject of "wind" in the young of mammals has omitted one important point—one stressed by Dr. E. R. C. Walker¹ in his excellent book. Discussing the techniques of feeding infants and the young of other mammals he remarks, "... In all other mammals, whether they suckle their young standing up or lying down, the body of the young is nearly always approximately at right angles to that of the mother. The advantages of this position are apparent. The teat, the mouth of the suckling, and his gullet are more or less in one straight line, which facilitates the process of swallowing and also, to some extent, obviates the swallowing of air, and renders less difficult the eructation of such air as is swallowed."

The difficulty your questioner mentions *vis à vis* the human infant lies in the lack of appreciation of this point. The hori-

zontal or near horizontal position in which I have seen so many babies (including paediatricians') breast or bottle fed disregards such anatomical considerations completely. An infant so fed tends to have trouble "getting up wind," as the air he swallows with his feed becomes mixed with the feed in the body of the stomach. In the more vertical position the air rises in the fundus whence it can be expelled comfortably with little or none of the feed with it. As I write as a mother and an erstwhile paediatrician, my remarks are not based solely on anatomical theory.

Gynaecomastia from Oestrogen Therapy in Prostatic Cancer.—Dr. J. M. SIMISTER (Medical Adviser, Ward, Blenkinsop and Co. Ltd., London) writes: Your expert's reply ("Any Questions?" March 2, p. 353) to the doctor whose prostatic carcinoma patient was very distressed by his gynaecomastia incidental to the diethyl-oestrol treatment did not mention the alternative use of diethylstilboestrol phosphate ("hovan"). This drug is administered intravenously in a dose of 5 mg. daily to start with, later the dose and frequency of administration being reduced. In clinical work hovan has given rise to no gynaecomastia,^{1,2,3} or only occasional enlargement of the breasts,^{4,5} attributable to the drug. With this drug the oestrogenic activity appears to be negligible compared with the cystostatic effect.⁶

- ⁷ Rudnick, R., Sioli, H. G., and Altwater, G., *Dtsch. med. Wschr.*, 1955, 80, 143.

OUR EXPERT replies: It is of interest that diethylstilboestrol phosphate injected intravenously for prostatic carcinoma does not give rise to gynaecomastia. I note, however, that Flocks *et al.*¹ gave doses varying from 250 to 1,250 mg., average dose 500 mg., in 200 to 500 ml. isotonic saline infused intravenously at the rate of 300 ml. per hour; one or two infusions were given daily, usually for five days at monthly intervals. Of 66 patients treated by this method, 34 had previously failed to respond or had become refractory to the usual oestrogens. The authors reported that of the 66 patients treated by intravenous therapy "only one showed demonstrable evidence of improvement of evident metastases and 12 showed progressive bony metastases in spite of therapy." These results are not impressive. Surely for stilboestrol phosphate to exert its effect stilboestrol must be liberated from the compound by enzymatic action as occurs in the case of oestradiol benzoate and testosterone propionate, so that the end-result is the same as giving pure stilboestrol. If gynaecomastia does not occur, the conclusion is that stilboestrol phosphate is a weak oestrogen through failure of liberation of active stilboestrol and that its effect on prostatic carcinoma would be slight.

DIAMOX
REGD. TRADE MARK
ACETAZOLAMIDE
Lederle

In conditions where excess fluid accumulates in body tissues, prompt dispersal measures are called for. In such cases, by inhibiting carbonic anhydrase, DIAMOX acetazolamide produces prompt copious diuresis. It has proved its ability to control body-fluid balance in cardiac oedema, glaucoma and epilepsy. Published reports also show satisfactory results from DIAMOX in toxæmia and oedema of pregnancy, premenstrual tension, renal oedema, emphysema and drug-induced oedema. DIAMOX is a welcome departure from the mercurials and is well suited to long-term maintenance of ambulant and out-patient cases.

THE MEDICAL USE OF HYPNOTISM*

BY

ALEXANDER KENNEDY, M.D., F.R.C.P., F.B.Ps.S.
Professor of Psychological Medicine, University of Edinburgh

Although the written records describing hypnosis cover a period of over four thousand years no unifying hypothesis has emerged which can fully reconcile the facts of observation or be subjected to the test of experiment. For two centuries at least, however, there has been little doubt that use can be made of it in the treatment of functional nervous disorder. Indeed, that disorder in functions mediated by the central nervous system was possible without coexistent structural change came to be realized through a study of the illnesses which hypnosis was found to relieve. One has only to read Freud's ecstatic letters home after his first visits to Charcot's clinic in Paris to realize how much orthodox psychoanalysis must owe to the hypnotism which it now regards with a great deal of suspicion. The subject is thus one of great importance to psychiatry because of the field for research which it offers to the inquiring mind, for new principles of cerebral and mental activity will have to be developed to explain it.

Historically, too, the study of hypnosis was the starting point of present-day psychopathologies, and retrospect to this earlier stage may be helpful if we should in the future find it necessary to inquire whether at some point conventional psychotherapy may have strayed too far from the simple Hippocratic aim of making people feel better and behave better. From the point of view of education in psychotherapy we are able with the aid of hypnosis to present to the trainee an elementary version of the relationships of physician and patient which may occur in the therapeutic situation and of the ways in which these can be manipulated to the patient's advantage. If theoretical teaching is given while the trainee learns the practical management of hypnosis in suitable cases, the experience so gained can gradually be applied to more complex methods of treatment. Such a progression could be regarded as a recapitulation of the way in which Freud and many others, beginning with hypnosis and learning its valuable lessons, eventually found the way to other methods.

The use of hypnosis in the training of psychotherapists has also the advantage that it offers, without harm to the patient, the hope of providing experience of the therapeutic relationship while retaining the trainee's scientific objectivity. The principle of submitting to a personal psycho-analysis, with its incidental training in habits of self-reference and the danger of unquestioning indoctrin-

ation, must always be a matter for free individual choice. If there is a future for an objectively oriented training in psychotherapy, hypnosis might well play a useful though by no means exclusive part. Even if hypnosis in the hands of the unskilled or of those who do not accept responsibility for avoiding or resolving excessive transferences may lead to undue dependence on the hypnotist, it is on the whole a method which leaves few scars and makes no fundamental change in the personality that would not have occurred in the course of individual development. In responsible hands it is a safe method of treatment which can be combined with others and seems rarely to prejudice their use later in other hands.

Indications for Hypnosis

From the enormous literature of medical hypnotism it is difficult to extract much uniformity of opinion on the type of disability which is most likely to respond favourably. The account which follows is based on the experience of a single physician who has used it as a part, but by no means the main part, of his therapeutic armamentarium over a period of more than twenty years. During this time the opportunity has been taken to explore its possibilities in new fields. In the main, the choice of method has been governed by a wish to expose patients to the minimum of psychotherapeutic contact necessary to bring about a satisfactory readjustment. The aim has been to make a minimum of permanent impression on the patient, returning to him as soon as possible the unsupervised direction of his own life. As all psychotherapy must be opportunist in the light of the patient's response to it, hypnosis has not usually been the only technique used, for it can be combined well with the usual methods of therapeutic scrutiny and of the promotion of insight.

For the purpose of description the uses of hypnosis are divided into four groups: (1) Conditions in which hypnosis is often the method of choice. (2) Conditions and types of patient in which it ranks as one of the possible approaches or in which it may be used in combination with other methods. (3) Conditions in which hypnosis has produced useful results but in which its use is not firmly established and is worthy of further investigation. (4) Certain uses of hypnosis in subjects who are not the subject of psychiatric disorder.

Conditions in which Hypnosis is often the Treatment of Choice

(a) *States of recent onset in which there is an alteration or dissociation of consciousness which has something in common with hypnosis itself.*—These include hysterical amnesia and fugue, hysterical stupor, and also twilight states and generalized disabilities such as *astasia-abasia*,

*An address given at the Annual Meeting of the Royal Medical-Psychological Association on July 17, 1956.

which have appeared after acute stress, and the "recent hysteria" group of reactions. In these patients it is usually possible to induce a deep hypnotic state very rapidly, the patient accepting willingly this additional form of psychological retreat. Under hypnosis he is brought again into contact with the circumstances which led to his dysmnestic or dissociative reaction. This usually results in an emotional crisis, after which the depth of hypnosis can be brought under control and memory restored or the symptoms relieved by direct suggestion. This can easily be done in a hospital casualty department, and there is much to be said for thus removing the symptoms as soon as possible after their onset. Removal of the symptoms places upon the therapist the obligation of doing something about the stress or conflict he has brought to light and to which the patient has been unable consciously to adapt.

(b) *Where investigation or psychotherapy is made impossible by a symptom which prevents normal communication between patient and physician.*—Hysterical deafness and aphonia are the best examples, but tics, stammering, and choreiform movements may also conveniently be relieved temporarily in this way. An underlying organic predisposition or even a clear organic origin does not exclude the use of hypnosis; for tics, tremors, habit spasms, and rhythmic movements may be removed for a few minutes to an hour or two on the first occasion, and they can be disencumbered of any admixture of hysteria and thus brought within the range of communication.

(c) *Where in the course of treatment of a functional disability the psychological causes have become evident, even to the patient, but this insight has not led to a clearing up of the symptoms.*—Thus removal of symptoms, the psychogenesis of which has "expired," can be brought about by hypnosis when the patient has already reached a point where he can do without his disability. Hypnosis gives him a reason for recovery beyond mere talk, removes his apprehension that he may be thought to have been consciously simulating, and, by suggestion, supplies the critical initiative for recovery. In such patients the results are dramatic and permanent provided that the foregoing psychotherapy has really achieved its objects. When a patient is first seen it is sometimes difficult to convince him that his disability is in fact functional and that psychotherapy is indicated. Initial removal of the symptom under hypnosis, however temporary, makes it evident to the patient that his symptom can be removed by a purely psychological approach and his co-operation in deeper psychotherapy may be elicited.

(d) *In functional conditions superimposed upon and pre-disposed to by organic nervous disease.*—The hysterical superstructure found in patients with chronic encephalitis lethargica, epilepsy, and disseminated sclerosis are conveniently treated by this method. An important use of hypnosis is to remove the functional overlay which occurs in many cases suffering from extrapyramidal motor disorder. Unfortunately the success obtained has sometimes led to the mistaken view that the underlying organic disease has been helped. Hypnosis appears to be useful in the special instance of the minor functional disabilities of leucotomized patients. Relapse is common in this organic group, but the treatment is nevertheless economic, especially where other methods would not succeed at all or where life is likely to be shortened by the organic disease.

(e) *Cases of psychoneurosis unfit for psycho-analysis as judged by the usual criteria of selection for that method.*—These patients, on account of poor intelligence, personality type, or other constitutional disabilities, are unable to respond to any method dependent on their insight. In some of them it is, of course, unlikely that any permanent improvement in adjustment can be brought about by any method, and relapse is frequent.

(f) *Patients who have, as a defect of personality or as the results of organic nervous disease, a gross facilitation of the mechanism of dissociation of consciousness, motivated amnesia, and advantage-through-illness, and suffer from the*

so-called degenerative hysteria or are possessed of the hysterical character. While the results obtained are superficial enough, the relatively long periods of normal behaviour after treatment as revealed by follow-up studies make it appear that hypnosis is not only the most easily applicable treatment but that it is economic in terms of the patient's adaptation to life and of society's contribution to his welfare.

Conditions in which Hypnosis is One of the Methods which may be Used, the Choice of Method Depending on the Individual Patient

Abreaction Techniques.—Often the choice is between the use of drugs and of hypnosis. Examples are:

Patients with anxiety states in which exploration and abreaction may be achieved by the use of intravenous barbiturates. Hypnosis is at least as suitable, if it can be induced, and it allows the abreaction to be regulated and sustained far longer than is possible with drugs. It is not practicable to mix the two methods, as narcotics materially alter the response to hypnosis and make it difficult. If a satisfactory depth of hypnosis cannot be induced after two or three trials, abreaction can then be attempted with drugs.

Patients with hypertension and peptic ulcer who have been shown to be capable of normal function if given rest in bed and sedatives may also be suitable for treatment with hypnosis. It has the advantage that the patients can subsequently be taught to relax as a daily exercise and even to hypnotize themselves. This is not to say that hypnosis has anything to contribute to non-labile hypertension or non-intermittent ulcer.

In conditions such as nocturnal enuresis where the presence of the symptom induces anxiety which in turn makes it worse. Hypnosis can be used to break this vicious circle by removing the symptom for a few days by direct suggestion. A considerable number of enuretics recover in this way, and hypnosis is always a method that can be tried when others have failed. Similarly in dermatological states where scratching prevents healing of the lesion, a few days' relief from pruritus by means of hypnotic suggestion will give the skin a chance to recover. The results in generalizing dermatitis are often such as to suggest that other factors than cessation of irritation may be involved and that there is a more general calming of underlying anxiety.

Conditions in which Hypnosis is Occasionally Strikingly Successful and in which its Use is Worthy of Further Investigation

(a) *Habits.—Smoking.*—It is doubtful if hypnosis alone will permanently remove the desire for tobacco in a real smoker. It will, however, do so for a period of a day up to three weeks after a single session and will get the patient started on his abstinence if he wishes to give up the habit. Repeated hypnosis has been rather disappointing, and success must be judged against the fact that many people are able to give up smoking without its aid. *Alcoholism.*—Here again hypnosis may help if every other possible precaution is taken to reduce the desire for alcohol. Recovered alcoholics who have to report at intervals are apt to regard this essential contact as rather unnecessary, but if they are to be hypnotized they will usually come willingly enough. As it is at this stage, in the first months after "drying out," that suggestion is most necessary, it is well worth using in a suitable patient. The problem here, however, may become one of sheer boredom for the psychiatrist, and the use of a lay hypnotist to continue under his supervision may afford him welcome relief. *Obesity.*—Here the results may be quite good when there is to be a short period of reduced eating at the outset of treatment. The induction of a general distaste for food for short periods is possible in some subjects and may be used in the initial stage of dieting. The most useful objective, however, seems to be to leave the patient with the habit of ignoring certain articles, such as bread, butter, milk, potatoes, etc., once the initial reduction has been accomplished, by suggesting lack of interest in them.

(b) *Psychosomatic Disorders.*—In mucous colitis, generalizing eczema, hysterical vomiting, and hyperventilation results are often very good and there seems to be much

to be said, when underlying factors are very complicated, for preferring this approach to more time-consuming psychotherapy. I am not able to confirm the results claimed in peptic ulcer, malignant hypertension, ulcerative colitis, rheumatoid arthritis, psoriasis, etc. Others who make use of hypnosis seem to get better results than I can in these conditions. On the other hand, however it is accomplished, the evidence for the successful use of hypnosis in warts and xeroderma is very strong.

(c) *Inoperable Carcinoma and Intractable Pain.*—Patients who have prematurely been given morphine derivatives before pain is severe, or who have become agitated and anxious since being told that there is little prospect of recovery, have not infrequently been referred to me as possible subjects for prefrontal leucotomy. They have usually proved to be good subjects for hypnosis, and it has often been surprisingly easy to remove the panic attacks and also the anticipation of pain. In some cases it has been possible to stop giving analgesics or very materially to reduce them, and the patients' distress has then been seen to be due more to addiction than to pain. It appears that morphine or its equivalents has in such patients sometimes been given initially as much on the strength of the diagnosis as on their need for analgesia.

Certain Uses of Hypnosis in Psychologically Healthy Subjects

(a) *In Childbirth.*—There is a great deal to be said for the use of hypnosis as an analgesic. Not only is the pregnant woman usually an excellent subject, but in my experience it is always easier to induce deep hypnosis during labour than it is during pregnancy, so that there need be no fear of its failing during delivery. The only difficulty is the great amount of time one has to spend with the patient. Labour appears to be in no way held up by hypnosis, and the patient seems better able to co-operate, to relax, and to "use her pains" in the third stage. Certainly there is no danger of foetal anoxia when hypnosis is used to provide a painless labour, and it leaves the woman free to enjoy the ecstatic experience of labour well done and the arrival of a new child. If some means can be found for legitimately training in hypnosis someone who has to be there anyway, it would be an ideal way of having children. As it is, it can be available to few.

(b) *Anaesthesia.*—If inhalation anaesthesia had not been discovered hypnosis might by now be in common use, for a great deal of work had been done on it. I have used it at times for a variety of operations. In dental and nasal surgery it has the great advantage that the patient can be made to spit normally and the nasopharyngeal reflexes can be retained or removed at command. Only a minority of patients, however, can be given full surgical anaesthesia at the first attempt. Of these, young healthy people in the prime of life appear very frequently to be good subjects, and use was made of this in emergency operations in time of war. The hypnotic state, or the state of relaxation from which hypnosis develops, is an ideal one in which to receive an anaesthetic, and an anaesthetist with a soothing manner may unwittingly hypnotize his patient before he anaesthetizes him. There is something to be said for allowing trainee anaesthetists to learn the technique, if only because hypnotic phenomena occasionally appear uninduced in their patients. There is one type of operation in which hypnosis really seems to help in a unique way, and that is when the aged are operated upon for gangrene of the feet under refrigeration anaesthesia. Old people often make good subjects for hypnosis but easily become anxious when given local and spinal anaesthetics, so that, if time permits of a short period of initial instruction, hypnosis may be of great help in such patients.

(c) *Stammering.*—Reports on the treatment of stammering are conflicting, but my own experience, which resembles that of a number of medical hypnotists, is that it is disappointing. As a means of teaching the relaxation needed for

speech-therapy it is of value, and also for relaxing the mild stammerer on a special occasion; but the recovery, as the result of hypnosis, of a stammer which has come on in childhood must be uncommon. In the hysterical speech impediment of sudden onset in adult life, however, often in a former stammerer, hypnosis will usually remove the symptoms at once. One condition which is often helped by hypnosis is the dreaded "drying up" which may occur in public speakers and actors. Hypnosis beforehand is remarkably successful, and I have even allowed an actor with a dread of drying up to go on the stage in a state of hypnotic somnambulism. There was no outward evidence of his altered state of consciousness and he identified himself so fully with the part he was playing that there was some confusion with his own identity afterwards. Subsequent performances were given in a normal state without drying up, but, I am assured, they were lacking in the inspiration of his hypnotized display.

(d) *An Aid to Recall.*—An occasional use of hypnosis in normal individuals is to help to find lost articles which have been put somewhere and forgotten. If the individual is made to relive in detail the period during which the article was mislaid a very complete memory can sometimes be restored. Within a reasonable time-span hypnosis will thus allow of the recall of unclassified memories otherwise unavailable.

Conclusion

There is reason to think that in recent years the medical profession has taken a more liberal and objective view of hypnosis as a technique of psychotherapy and this has been given expression in the 1955 report of the British Medical Association. We are still being embarrassed by excessive claims and enthusiasms. Many of these were traceable to the public demonstrations, which are now much restricted by the Hypnotism Act. The subject is still surrounded by a good deal of mystery and magic in the minds of the general public. It has to be recalled, however, that hypnosis was the principal method of psychotherapy during the early part of the nineteenth century, and for much of this time its use and its results were taken for granted.

It seems almost impossible to make any reliable statistical assessment of the long-term results of psychotherapy, hypnotic or otherwise. In that patients have returned to their jobs and have been relieved of their symptoms it is likely that in general the results of using hypnosis in functional nervous disorders are comparable to those obtained by other techniques. In this connexion it may well be that there should be some sort of revision of our ideas of what is to be expected from psychotherapy. At present, in the analytically oriented schools the main interest is centred round full psycho-analysis. This method is, for both economic and psychiatric reasons, available to very few people, and the evidence is not strong that even if it makes these different it makes them better. Other treatments are usually regarded as falling short of classical analysis, although derivatives of Myerian distributive analysis, and "analytically oriented" and interpretative methods, account for an overwhelming proportion of the psychotherapy carried out within the Health Service.

There seems to be a place for a treatment that can remove the symptoms of which the patient complains, even if it is unsatisfactory to the therapist in terms of insight and psychopathology. If something is to be done about the enormous number of psychoneurotics who clog the wheels of civilized intercourse, it may be that our therapeutic sights should be lowered, and that we should, for the majority of patients, have a more concrete aim of relieving symptoms and making them more happy and less trouble to and less dependent on their fellows. If these are the objectives, shorter methods necessarily have a place, not as substitutes but as therapies in their own right, and in this briefer and more physician-dominated treatment hypnosis may have a considerable part to play.

SOME USES OF HYPNOSIS IN
GENERAL PRACTICE

BY

H. STEWART, M.B., B.S.

General Practitioner, Watford

Hypnosis is a form of therapy that has for many years been frowned on; nevertheless, in psychosomatic medicine and the psychoneuroses it has often produced beneficial results when more orthodox measures have failed. It is from precisely these two fields that many "problem patients" in general practice are provided—patients who have gone from consultant to consultant and from out-patient department to out-patient department and have ended with the label "incurable" or "functional," with a regular bottle of medicine or tablets. It was decided to try hypnotherapy on some of these patients to see if they would derive benefit from it; the results obtained are given below.

Method of Treatment

All patients were seen weekly for an average of 8–10 weeks for a period of from 30 to 50 minutes, the time varying with the therapeutic measures used after the hypnotic induction. The consulting-room was warm and quiet and the couch wide and comfortable. No special apparatus was required.

Before induction was started the patient was questioned for any doubts or misapprehensions about hypnosis, and any fears were allayed by a simple explanation and reassurance that the phenomenon is perfectly normal and physiological, and no harmful effects would arise.

The induction was then begun. The technique used in all cases but one was of eye fixation together with progressive relaxation and strong suggestions of sleep. This is a simple but very efficient method, and usually a trance state was induced in 5–15 minutes. At subsequent inductions the time of induction was much shorter—often instantaneously at a given signal. The one case that was an exception needed a more authoritative approach—that is, eye-gaze—as he felt unable to relax under the more soothing approach.

For this type of therapy, when analgesia or anaesthesia was not the aim of treatment, a light trance was sufficient to obtain therapeutic results (where they were obtainable). It was found that of the cases selected for treatment, 90% were able to be hypnotized, which agrees with the usually accepted figure that any one hypnotist will be able to hypnotize only 90% of his patients.

The decision on the type of treatment required when the patient was in the trance state depended on the nature of the case. Thus, in general, asthmatics were treated by suggestion, hysterics by emotional abreaction, and cases of anxiety by psychotherapy; but this was not a rigid framework, as in all cases a search for the emotional basis of the complaint was made. Experience and the "feel" of the patient gave the best guide to the approach required.

Duration of Treatment.—As stated above, the average number of sessions per patient was 8–10. Individual cases varied from one session, in which cure was achieved, to weekly sessions lasting over many months. It is, in fact, the length of treatment that makes hypnosis difficult to use in general practice.

Results

In the Table are recorded the results of treating 41 patients during the period May, 1954, to April, 1956. There were 12 cases of asthma, 7 of various skin diseases, 16 psychiatric cases, 2 of an anxiety state superimposed on an organic disease, a stammerer, an enuretic, and 2 cases of obesity.

Some working criterion for successful treatment had to be evaluated. Primarily, of course, the complete disappearance

Results of Treatment

Complaint	No. of Cases	Cure	Partial Cure	Failure
Asthma	12	9	2	1
Eczema	3	2	1	1

ance of the symptoms complained of, their non-reappearance over a period of time, and the failure of emergence of fresh symptoms would constitute complete success. Of the 41 patients treated, these criteria were fulfilled in 23. Partial success is claimed when the original condition had not disappeared but had considerably improved and no fresh symptoms had emerged. This occurred in 7 cases. Failure, of course, means no improvement at all, and this occurred in 11 cases. In no case was the patient made worse by treatment.

All cases have been followed up for periods varying from six months to two and a half years to see that the criteria listed above are fulfilled. Reports of some illustrative cases are given.

Asthma

Case 1.—A boy aged 12 had suffered from asthma since the age of 2 years. As a baby he had had infantile eczema. The asthma had severely incapacitated him, so that he was unable to participate in normal school activities, and indeed was backward from the loss of schooling. He was treated simply by hypnotic suggestion for 10 sessions and rapidly improved. He has been free of asthma entirely for 12 months, is capable of most physical exertions, and has lost no more schooling.

Case 2.—A clerk aged 17 had had asthma since an attack of pneumonia when aged 6 years. He had severe attacks only about four times a year, but he always wheezed on any undue exertion and was unable to play any games. He was treated by hypnotic suggestion for 10 sessions, and his symptoms cleared completely. There has been no relapse in 18 months.

Case 3.—A pharmaceutical chemist aged 37 had suffered from asthma since the age of 6 months, apart from a free spell between the ages of 15 and 23 years. He had attacks every night, and had tried every remedy in the *Pharmacopoeia*—all to no avail. He was treated by suggestion, together with psychotherapy under hypnosis, when his asthma restarted soon after the death of his mother, which he felt intensely. His attacks considerably lessened but did not cease altogether, and he was taught autorelaxation—to control an attack before it has developed, by breaking the vicious tension circle. This was reinforced by post-hypnotic suggestions, and after 10 sessions he has not had an attack that could not be cut short by this technique over the past two and a half years.

Case 4.—A photographer aged 58 had had asthma for six years. It started when he was cleaning a basement and had developed to daily or nocturnal attacks. No source of anxiety or guilt was uncovered, but hypnotic suggestion effected a complete cure in five sessions with no relapse over two and a half years.

Dermatology

Case 5.—A carpenter aged 71, a widower and keen amateur singer, had suffered from eczema on the glans penis

for two years that was resistant to all treatment. In addition, for the same period he experienced a tightness in the throat and chest which prevented him from drawing a deep breath, and thus his singing had deteriorated. He was in perfect health otherwise, and no cause could be adduced for his complaints when a normal history was taken. However, on questioning under hypnosis, the story emerged of sexual intercourse with a woman he believed to be a widow but who was nevertheless married. When he learnt this fact he had experienced tremendous guilt about his adultery, and anxiety that people would get to know. A couple of weeks later the eczema (guilt) and the tightness of the chest (anxiety) appeared. After unburdening his story he felt immediately relieved, and on being withdrawn from the trance he burst into a long joyous aria from *Don Giovanni*. After two more sessions the eczema and chest tightness had vanished, and two years later he remained cured.

Case 6.—A clerk aged 18 had suffered from asthma since he was five years old and an eczema of the hands and arms since starting work in a paper factory at the age of 15 ("industrial dermatitis"). In addition, for the past six months he had had warts on his hands. The asthma had caused his discharge from Army service. He was treated by hypnotic suggestion, as no emotional basis was easily to be found. The asthma cleared immediately, and after eight sessions the eczema had gone too. The warts remained and were accordingly curetted away, using hypnotic anaesthesia. He has had no recurrence of any complaint after two years three months. This case is of some interest since one complaint that is renowned for disappearance by suggestion—that is, warts—was not influenced at all by this most powerful form of suggestion.

Case 7.—A compositor aged 45 had suffered from a severe eczema for 20 years. It had a supposedly occupational aetiology and often covered most of his body. He had a very inadequate personality, feeling inferior to his workmates, lacking in initiative, and leading a solitary existence in lodgings. He was, of course, unmarried, and was afraid of women. He had received much treatment over the years, both dermatological and psychiatric, but he had not improved. He was treated by hypnotic suggestion to stop the irritation, and thus the scratching, and to allow healing to take place; in addition he was given a long course of psychotherapy extending over nine months. His skin condition improved rapidly and became 90% better, and in due course he developed a change in his personality and behaviour. He became much more aggressive at work, he developed a taste for music and poetry, lost his dreadful guilt about masturbation that made him feel dirty, and because of this he changed from a dirty, badly dressed man to a clean one with a fair degree of clothes-sense—that is, he no longer felt dirty, in both senses of the word. He terminated treatment at his own request, as he felt he no longer needed it. During the course of psychotherapy he had one relapse in his skin complaint, and that occurred when I went to hospital for an emergency appendicectomy. However, it rapidly cleared when treatment was restarted. For 18 months there has been no relapse in his skin or medical state since terminating treatment.

Psychiatric

Case 8.—A housewife aged 60 had suffered for 10 years from nervousness, lassitude, and insomnia. She never felt well, and a year before starting treatment she developed symptoms of diabetes mellitus—that is, loss of weight, polyuria, and polydipsia—but no evidence of this disease was found. The origin of her troubles was the severe emotional shock produced by the explosion of a land mine near 17 during the last war—that is, bomb-shock. She had been uninjured—physically—but some close friends and relatives had been killed. There was conscious memory of the event, but the emotional affect was missing. Under hypnosis she was abreacted to the explosion—a great emotional release obtained during the reliving of the episode. On awakening

from the trance she felt much better, and since that one session two and a half years ago she has had no further trouble and no symptoms.

Case 9.—A similar case to the above was that of a woman aged 39 who had been severely injured about the head during an air-raid. Her face and scalp were much scarred and she suffered from severe unilateral headaches on the side of the scarring, insomnia, and an inability to concentrate for long periods. She also was abreacted to the explosion with a similar vivid emotional release. After this session headaches greatly diminished in intensity and frequency, she was able to concentrate and could sleep without sedatives. Possibly the residual headaches were due to some underlying damage to the coverings of the brain which was not detectable clinically.

Case 10.—A housewife aged 54 had suffered from a partial loss of voice for six months—she was only able to whisper. This symptom had developed after a bad cold, and nothing could be found to account for this physically, since all investigations were normal. She was given a course of E.C.T. by the psychiatrists, as it was thought to be perhaps menopausal in origin; however, it did not help her. The only relevant history was the marriage of her daughter four months before the symptoms began. Under hypnosis she was taken back to the wedding and immediately began to sob and speak in her normal voice. The story emerged that she felt terribly guilty regarding the time of this marriage, since it associated with her own wedding, which had taken place when her father was dying. On emerging from the trance her voice went back to a whisper. At the next session the story continued that her father had had three strokes, and had lost his voice and been unable to speak to her. It was pointed out to her that she was identifying herself with her father, and on awakening this time her voice was perfectly normal and has remained so for the past 15 months.

Case 11.—A housewife aged 44 had been involved in a car accident six months previous to treatment and suffered from severe headaches, dizzy spells, and fits of depression. No injury apart from a little head bruising had been sustained. She was abreacted to the crash, and following this session has remained well and symptom-free for two years.

Case 12.—A male window-dresser aged 35 suffered from feelings of inadequacy and inferiority. He blushed when spoken to, and he felt unable to advance in his job as it entailed speaking at occasional company meetings, which he could not do. He was treated by simple suggestion under hypnosis for 12 sessions—no simple psychological origins being found. This resulted in a tremendous improvement in all his symptoms, and he became endowed with a strong comforting feeling of confidence in himself. This has continued with no relapse for 18 months.

Case 13.—A female cashier aged 21 had 18 months previously developed a severe tremor of the hands when holding a cup of tea. This had a sudden onset when having tea with newly married friends. This tremor was getting worse and was a source of great anxiety, and sedation would not help. There was no physical abnormality. She was a very self-conscious, awkward girl, but usually got on well with her friends. She was treated by direct suggestion under hypnosis, but some psychic probing eventually revealed that this newly married friend of hers had laughed at her for being "gawky" just before the onset of her symptoms and this had made her both very annoyed and very upset. In 12 sessions the tremor and anxiety had vanished completely, she moved with far more grace and dignity, and over the past nine months has had no recurrence.

Case 14.—A schoolgirl aged 16 had from the age of 7 years suffered from an inability to write in the normal manner. If she tried to hold a pen or pencil in the usual way the hand would jerk violently and uncontrollably so that nothing could be written. In order to write legibly—and she did attend a grammar school—the right hand had to be doubled up completely and the pencil would slope in the opposite direction from the normal. No cause had been found for this over the years. Under hypnosis she

very tearfully produced the story that at the age of 7 years, while writing on a card in the children's library to reserve a book, she saw the two librarians looking at her and laughing. She believed they were laughing at her, and from that time she had developed this abnormal hiding method of writing. On emergence from the trance she was able to write perfectly normally if the paper was sloping towards her, but she still wrote abnormally if the paper was horizontal. Further sessions revealed little fresh trouble, and no further improvement could be effected. However, she now feels, 18 months later, that, although she still cannot write perfectly normally, she no longer has any anxiety about it, as she appreciates the reason for it. Undoubtedly there is a far deeper emotional disturbance causing this symptom to persist partially, but it was not revealed during her sessions.

Case 15.—A social worker aged 27 had always picked and bitten her nails. She got worse when her fiancé was killed suddenly. Suggestion and abreaction to the death under hypnosis produced rapid results in two sessions, with no relapse after two years.

Organic Disorder with Superadded Anxiety

Case 16.—A reader's copyholder aged 52 had suffered from coronary thrombosis which occurred during an attack of pneumonia six months before treatment began. Since then he had complained of severe dyspnoea at rest, tiredness, insomnia, and an inability to do anything for himself, coupled with severe anxiety. His symptoms were out of all proportion to his cardiac efficiency, and nothing would help him. He was treated by hypnosis and immediately uncovered anxiety, not about his heart but his memory. He had always prided himself on his excellent memory, but with advancing years it had deteriorated. This caused him to fail a special examination concerning his occupation, and, even worse to him, he was unable to memorize various aspects of Freemasonry ritual and so failed to attain higher office. He felt much better after this, and his symptoms improved. A later session revealed guilt and anxiety at an episode of extramarital intercourse. He was soon back at work but unfortunately developed another coronary thrombosis, and a little later a third caused his death.

Case 17.—A printing manager aged 47 had developed disseminated sclerosis six months previously; he knew the diagnosis and prognosis. The complaint manifested itself with weakness of the face (unilateral) and legs, abdominal cramps, and various paraesthesiae. He became very tense and introspective into his complaint, lost his confidence, and was unable to work in spite of sedatives, tonics, etc. He was treated by hypnotic suggestion, as no particular anxieties were revealed apart from those associated with the disease. He rapidly improved, and within four sessions was back at work and feeling much better about his complaint. Treatment continued for nine sessions in all. He has maintained this improvement over the past 18 months apart from a spell of vertigo and facial anaesthesia caused by his complaint.

Obesity

Case 18.—A housewife aged 35 had become obese, her weight having risen from 9½ stone to 12 stone 5 lb. (60.8 to 78.5 kg.). She was unable to remain on a weight-reducing diet, even with amphetamines, as she felt a compulsion to eat the most fattening foods such as chocolates, sweets, and cream cakes, even after filling herself with a weight-reducing meal. She had had a most unhappy life: her mother had committed suicide, she was separated from a husband whom she despised, and had had two sons, one by the husband and another by a lover. She was deeply disturbed and felt that everyone was against her. Under hypnosis she had extreme emotional outbursts for the first three sessions, crying and shouting while pouring out the unhappy events in her life. After this she quietened down and was able to discuss her problems with some detachment. She was treated for six months, and at the end of this time had lost 2 stone (12.7 kg.) in weight and also her compulsion for

food: the necessary consolation and punishment was no longer necessary. Over the past nine months there has been no relapse.

Discussion

It must first be emphasized that this series of 41 cases does not allow of any statistical evaluation of the efficacy of hypnotherapy. The total number is too small and the type of complaint too varied to allow for this. The only possible significant result is obtained in the asthma group—9 out of 12 cases were completely cured and 2 partially cured. The other case relapsed soon after treatment ended and would not respond at all on a second attempt. However, the relief in individual human suffering cannot always be measured with a yardstick.

With regard to the actual therapy itself, a few points should be noted. Firstly, as previously mentioned, it is very time-consuming for the practitioner and a good deal of leisure must be forgone. This is counterbalanced, however, by the fact that successful treatment does remove the patient from continuous surgery attendance. Secondly, few unpleasant after-effects have been produced. Occasionally some light-headedness or dizziness was complained of after the first session, but this was easily countered by post-hypnotic suggestion. Thirdly, the patient does not become dependent on the therapist after treatment ceases. The dependency is a common misconception, but it did not occur to one patient in this series. However, as in orthodox psychotherapy, particularly when prolonged, a dependency relationship does develop during treatment, but this is no longer present after treatment is terminated. This point is well illustrated by Case 7.

The failures in treatment are listed in the Table, but again no conclusions can be drawn on inefficacy of treatment. These patients were all readily hypnotizable but did not respond to treatment in any form.

In addition to the 41 cases treated who were able to be induced into the trance state, five others had been selected for treatment but were un hypnotizable. This accords with the usual figure quoted (90%) for ability to induce hypnosis by any one therapist.

In this series the psychosomatic cases—that is, asthmas and eczemas—have responded well to suggestion and hypnotic psychotherapy. The teaching of autorelaxation to the asthmatics was very valuable to some of them. Among the psychiatric cases those with a history of a specific emotional trauma did particularly well after abreaction, and cures were rapidly obtained. In the pure anxiety states it was not so successful, as the deeper technique of hypnoanalysis was undoubtedly required and the time factor here became of greater importance. But in the relief of anxiety-tension complicating an organic disease, hypnosis was very useful and appears to have a wide application here, since in many organic disorders the anxiety grossly aggravates the organically determined symptoms.

Not everyone can or wants to practise medical hypnosis, but it is a valuable therapeutic measure when other methods have failed. It is only by further experience that its potentialities and limitations can be satisfactorily defined and ascertained.

Summary

A series of 41 patients have been treated by hypnosis, using varying techniques after induction. The results obtained are described and enumerated. No statistical conclusions can be drawn, but its value is suggestive.

The Medical Laboratory Technician, No. 57 in the new "Choice of Careers" series issued by the Central Youth Employment Executive, has been revised. This booklet includes chapters on work in hospital and other medical laboratories, professional training and personal qualities required, openings, and salaries. It is published by Her Majesty's Stationery Office, price 6d. net.

THE SCOPE FOR HYPNOSIS IN GENERAL PRACTICE

BY

A. FRY, M.R.C.S., L.R.C.P., D.M.R.

General Practitioner, London, S.E.

The aim of this paper is to show what uses can be made of medical hypnosis in general practice; the types of cases which may and those which will not benefit from it; and its clinical effects.

Technique

If hypnosis is to be of use in general practice the technique must be simple and the sessions not too lengthy. It is surprising how good the results can be with very short sessions of 5 to 10 minutes each in cases of dysmenorrhoea, asthma in children, and insomnia. The psychoneurotic and psychosomatic cases require much longer sessions.

For the induction of hypnosis, the method using fixed gazing and verbal suggestion was found the most successful; this, however, had to be modified occasionally according to the individual case. No drugs were used to facilitate the induction. In most of the cases treated, the hypnoidal and light trance states were found sufficient to obtain satisfactory results. Deeper states, however, were required in obsessional and anxiety cases.

The degree of hypnosis of the cases was: unsuccessful, 14%; hypnoidal and light trance states, 63%; medium trance, 9%; deep trance, 14%. These figures compare with those given by Weitzenhoffer (1953): unsuccessful, 14.70%; hypnoidal and light trance, 40.34%; medium trance, 24.92%; deep trance, 20.04%.

Before treating a patient with hypnosis very careful history-taking and clinical examination are essential; any possible organic causes must be fully investigated and treated on conventional lines.

The first interview is very important, since the method of approach to the patient may influence the effect of the treatment. He should be given a full explanation, in as simple language as possible, of his condition, the form of the treatment to be carried out, and how it may help to overcome his difficulties and remove his symptoms. Most people view hypnosis with scepticism and apprehension: it is only human, after all, to regard with a certain fear anything that is mysterious and imperfectly understood. The patient must be reassured and convinced, so far as is possible, that he cannot be harmed by it, even though it may not help him. At the outset it is advisable not to mention the word "hypnosis," but to use another term to describe the proposed treatment—for example, "suggestive relaxation." Usually the patient loses his scepticism and apprehension after the first or second session.

In cases with no deeply rooted causes or conflicts, direct suggestion in a light hypnotic state is sufficient to remove the patient's symptoms. In the neurotics and psychosomatics it is necessary to probe deeper to find the causes of the trouble, or the "crucial incident." In such cases the deeper states are required. Neurotic cases which are treated only superficially with suggestion of symptom disappearance usually relapse and develop substitution symptoms. If, however, the root of their trouble is discovered and brought up from the subcon-

scious to the conscious level of their mind, such relapses can be avoided.

At first, the patient is seen once or twice a week. The intervals between the sessions can then be lengthened gradually according to the progress of the case. In some obsessional and anxiety cases, maintenance therapy may be necessary, and patients may have to be seen once a month or once in two or three months.

It is advisable to bring the patient out gradually from the hypnotic state. Sudden waking may cause headache, drowsiness, or numbness in the limbs; these, however, do not last very long. No difficulty has been experienced in arousing the patient from the hypnotic state.

Results

Hypnosis was used in the treatment of 120 unselected cases over a period of nearly two years. Some of the cases have been followed up for two to three years. The following are the diseases and conditions in which hypnosis was used; the aims of the treatment are noted in each group.

Anxiety Neuroses (20%).—Lessening tension, discovering the cause of the conflict, and instilling confidence and reassurance.

Obsessional Neuroses (11.7%).—Discovering the underlying cause, dealing with the phobias and obsessions, inducing relaxation, giving hope of recovery, and encouraging the resumption of full activity.

Cardiovascular (10%).—Lessening anxiety, promoting general relaxation, and removing distressing symptoms such as dyspnoea, insomnia, and depression.

Heavy Smoking (9.1%).—Lessening general tension, fostering a distaste for smoking, and giving a picture of better health in the future with the loss of most of the distressing symptoms.

Bronchial Asthma (7.5%).—Attempting to discover the primary cause, reducing anxiety and general tension, training the patients in autohypnosis and relaxation, thus enabling them to overcome their attacks themselves, and arousing in them the hope of finally mastering their disability.

Skin Cases (7.5%).—Inducing anaesthesia, relieving anxiety and tension, discovering the underlying factors, and instilling hope of recovery.

Dysmenorrhoea (4.2%).—Inducing analgesia, lessening tension; training in self-relaxation.

Enuresis (3.4%).—Relieving anxiety in patient and parents, instilling hope of losing the disability, and suggesting the gradual recovery of full bladder control.

Duodenal Ulcer (2.5%).—Removing anxiety and tension, analgesia, giving up smoking.

Malignancy (2.5%).—Analgesia suggesting a peaceful state of mind and the hope of recovery, if pre-operatively.

Petit Mal (2.5%).—Removing anxiety in patient and relatives, directly suggesting a gradual diminution of the number of the attacks and their final disappearance.

Small numbers in each of the following conditions were also treated: insomnia, migraine, anxiety hysteria, psychosis, pregnancy, stammering, ulcerative colitis, examination "jitters," behaviour problems in children, "dentist" phobias.

The predominance of the psychoneurotic and psychosomatic cases conforms to the usual pattern met with in general practice. The results of hypnotherapy in those cases were as follows:

Fourteen patients stopped attending after one or two sessions. This may have been due to their dislike of the treatment or to other psychological causes. Twenty-three cases were resistant to hypnosis. However, if more-prolonged attempts had been made some of them would have eventually responded. Twenty-six cases partially improved. These did not entirely lose their symptoms and anxieties, but they ceased worrying about them, became more relaxed, were able to resume or continue their normal work, and felt generally much better. Fifty-seven cases fully improved and had no relapses, in some cases for two or three years. These included 20 patients who had not responded well to other methods of treatment but were able to resume full work after being treated with hypnosis.

The obsessional cases were the most difficult to treat, and most of the failures were encountered in this group. The border-line psychotics previously treated in hospitals did not improve. Patients over 60 were particularly difficult, but children responded very well.

Twenty-four patients were able to stop or to reduce drastically the taking of hypnotic and analgesic drugs.

The various post-hypnotic effects manifested in the treated cases were marked relaxation, diminished depression, sounder and more natural sleep, increased self-confidence, improved appetite, marked physical improvement (especially in cardiac cases), antipruritic action, analgesia, greater feeling of contentment, and lessened anxiety.

The following case histories will illustrate the reactions to hypnotherapy, the clinical progress, and the results.

Case 1

Man aged 46. Anxiety neurosis for 10 years. Persistent pain in the head caused by worry, to which he was inclined. Slight stammer. Paraesthesia in left temporal region. Very erratic at work owing to poor concentration. Attacks of depression with feeling of inferiority. Six years ago he had a "nervous breakdown" and was absent from work for 11 months. He slept badly, and had to stay away from work very often. He had attended a psychiatric out-patient department five times a year ago, but did not improve. A history of unhappy childhood was obtained. After treatment twice a week for three weeks he lost his depression, and said that his head felt clear for the first time for 10 years. He took his wife to a show for the first time for many years. His employer became satisfied with his efficiency. He was treated for three months and finally lost all his symptoms. He was also able to give up smoking after indulging in it for 31 years. Two years later he remained well and was working regularly.

Case 2

Woman aged 36. Company secretary. Long-standing obsessional case with superimposed depression. Her recent attack started in the summer six months previously, and she attributed it to a heatstroke. She had had pain on the top of her head ever since. She complained of depression, palpitation, inability to concentrate, cancerophobia and various other fears, insomnia, and fear of being left on her own. She was very worried about herself, and had been away from work more than six months. She had had empyema at the age of 5, at which time her mother died; her father had died when she was 12. She had been brought up in a "home" and had had a very unhappy childhood.

She did not respond to sedation (amphetamine, chlorpromazine, etc.). She was referred to the psychiatric department of the local hospital, where she was given E.C.T. She had three treatments and became much worse. Her depression increased and she felt that she was going mad. She described with horror her experience with E.C.T., and the scene on coming round after the treatment; she refused to have any further treatment at the hospital. She was a good subject for hypnosis, and was able to recall under it the origin of her recent attack. She developed her pains in the head after exposure to the sun and too much sea-bathing, and felt dizzy. Her friends at work told her that she was probably undergoing the menopause, and as her mother died from cancer when she was 40, and she herself was nearing this age, she thought that her symptoms were probably those of cancer.

Her fears and all the other symptoms gradually resolved with hypnosis, and she became very much more relaxed. It was explained to her that the lack of security and the loss of her parents when she was a child had a good deal to do with her present state. She was able to resume part-time work after the sixth session, three weeks after the beginning of hypnosis. She became interested in her work and gradually came to like it more and more. Her fear of travelling on buses disappeared. She regained interest in her housework and began to have more social contacts, which she

had been avoiding before. Eventually she resumed full-time work and had no relapse. The intervals between the hypnotic sessions were gradually increased from twice a week to once a month. She has remained well ever since.

Case 3

Housewife aged 39. An obsessional type with severe agoraphobia. Her symptoms began 13 years ago following an unfortunate incident when a soldier made an attempt to assault her while she was waiting for a train. At the same time her first husband suddenly left her and she found herself alone, as her relatives had been evacuated to the country. She married again a few years later, had two children, and was quite happy, but the intense fear made it impossible for her to go out. Even when she used to ride with her husband in the car, she became panic-stricken if she went too far from home, and had to return. She had never been away with her children on holiday, had not been to a theatre or cinema for over five years, and she was very unhappy.

She had had two courses of treatment by psychiatrists. One was in 1943, for 12 months, at the rate of two or three sessions a week; the other in 1946 for eight months, at two sessions a week. She did not improve. She was again seen three years ago in consultation with another psychiatrist. In his opinion it was notoriously difficult to do much with such cases. He suggested that the patient should take amylobarbitone sodium and methylamphetamine half an hour before going out. If this should fail, he advised a trial of E.C.T. The prescribed drugs had no effect on her condition. It was then decided to give hypnotherapy a chance. The patient was a very good hypnotic subject and was able to reach a fairly deep state. She was abreasted under hypnosis; her problems were explained to her and she gradually improved. After the fifth session she was able to go to a theatre without experiencing any fear. She had two sessions a week during the first three months and one a week after that. She has not lost her phobia completely, but she is now able to lead a more normal life, and is no longer a "prisoner." She can go out anywhere, and has been to the seaside several times, which she had been unable to do since her illness started. All this made a remarkable impression on the patient's mental attitude. She is now able to enjoy life nearly as much as any normal person.

On one occasion the patient developed an attack of migraine with severe headache and vomiting. It came at a very inconvenient time, as she was busy with her son's birthday party. The symptoms completely disappeared after she was hypnotized, and she was able to carry on with her work within a very short time without the slightest trace of headache, nausea, or vomiting.

Case 4

Housewife aged 48. A severe obsessional, with a strong family history of mental ill-health. Very depressed, with a fear of insanity. Very tense and unable to relax. She used to get violent hysterical attacks, which were difficult to control. She had two courses of E.C.T. as an in-patient, but was no better. Several unsuccessful attempts were made to induce hypnosis. She had to be admitted later into a mental hospital, and after 12 months' treatment there she was still in the same state.

Case 5

Man aged 54. Senior fire officer. An obsessional type with depression and hypochondriasis. There was a five-years history of dyspnoea, generalized pruritus, poor concentration, depression, nosophobia (especially cancer), lack of self-confidence, and fear of making mistakes while carrying out his duties. He had been fully investigated in hospital. Psychiatrist advised E.C.T. and he had seven treatments. He improved for three weeks and then relapsed. With superficial analysis under hypnosis some past incidents were discovered, which gave him a feeling of guilt. This was

JUNE 8, 1957

dealt with and he soon began to improve. The hypnotic suggestions and analysis gradually disposed of some of his symptoms. He was able to resume full duties five months later, having previously been on part-time duties for eight months before treatment. He is still occasionally depressed and has feelings of guilt, but has been able to continue full duties without a break. He has been followed up for 2½ years.

Case 6

Housewife aged 46. A severe obsessional, with three years' history. She had suffered from migraine all her life, and had hysterectomy for fibroids two years ago. She developed "creepy" feelings all over, cancerophobia, severe depression, insomnia, and some agoraphobia. She had been an in-patient in a psychiatric teaching hospital for three months, and had E.C.T. She was told on discharge by a psychiatrist that she would "always have her pains in the head, as she was born with them."

She only slightly improved with hypnotherapy. She remained resistant and was not able to reach a deep state of hypnosis. The attempts were given up after two months' trial. For the last two years she has been attending a psychiatric out-patient department of a hospital and remains unchanged.

Case 7

A general practitioner aged 62. Angina of effort for 10 years. No history of coronary occlusion. He consulted a cardiologist five years ago, the electrocardiogram was negative, and a diagnosis was made of some left ventricular failure. The symptoms were precordial discomfort on exertion and after meals, with some mild pain. He had always been over-anxious and tense, and had "played hard and worked hard." He had been doing a good deal of communal work apart from his medical practice. Two of his brothers had coronary disease. He had been advised to take tab. "mycardol" four times a day and one tablet of trinitrin when required. His blood pressure was 180/110. When first seen he was unable to walk a few hundred yards without some discomfort in his chest.

The aim of hypnosis in this case was relaxation and reassurance. He felt much better after the first session, having no more discomfort after meals. After the third session he said that he could walk slowly for 2½ miles without any chest discomfort. He had seven sessions during 3½ months. As a result he said that he had more confidence in himself, and felt very much better generally. He no longer had to take trinitrin tablets, and when seen last he had discontinued taking the mycardol tablets as well. His blood-pressure reading remained the same, but subjectively he was very much better.

Case 8

A business man aged 48. In March, 1954, he had right-sided heart failure, auricular fibrillation with an incalculable ventricular rate, and inversion of the T-wave in chest leads V2-4. In 1949 he had been treated in hospital for ?endocarditis. In March, 1954, he was an in-patient in a teaching hospital for three weeks with heart failure. When first seen, six months later, he was very dyspnoeic and orthopnoeic, with considerable oedema of his feet and ankles. He had not had any proper sleep for over 12 months, because he was unable to lie down, and was having heroin injections for his sleeplessness. He was also a very tense and worrying type. He had already tried hypnotic treatment for six sessions, but did not benefit from it.

After a prolonged first interview he was hypnotized with a very good response. That same night he was able to go to bed properly, to lie down, and to sleep with a few small interruptions until 7 a.m. without heroin. He said that he felt fine the following morning. The oedema of the feet and ankles subsided after two days. He received treatment twice a week in the beginning, and after six weeks this was reduced to one. The consultant cardiologist saw the patient two weeks after hypnotherapy had begun, and was amazed with the result. According to him, there was

no more oedema of his ankles or engorgement of the veins in the neck, and the liver was no longer palpable. When he saw the patient again after three months he was well satisfied, and remarked that the electrocardiogram was "the best ever." The patient continued to keep well, except for some slight dyspnoea due to his excessive weight, which was very difficult to reduce. He was able to attend to his business regularly and to lead a fairly active life, including masonic duties. Eighteen months later he still remained well.

The consultant's final opinion was that "the patient, who became virtually resistant to any form of conventional treatment, would have died some months ago if he had not been treated in the way he was."

Case 9

A woman factory worker aged 20 had begun to smoke when 7 years old, and had smoked 10 to 20 cigarettes a day since the age of 13. When seen first she was smoking up to 80 cigarettes a day and spending nearly £4 a week on them. She had a craving for cigarettes which she could not control. She wanted to be able to break this habit, as it was ruining her financially. After only two sessions she was able to stop smoking entirely. When she was offered a cigarette subsequently, she refused it. When seen three months later she had not smoked a cigarette since she was treated.

Case 10

A builder's foreman aged 52. He had been a heavy smoker for 38 years, consuming on the average 40 to 50 cigarettes a day. He had chronic bronchitis, was emphysematous, and was a rather heavy beer-drinker. He expressed a wish to give up smoking. He was a very tense subject and found it difficult to relax; even light hypnosis could not be induced. No satisfactory results could be obtained after six sessions, as he proved very resistant. He was, however, able to cut down the number of cigarettes to 20 a day, but could not get any further. No other attempts at hypnosis were made.

Case 11

A very anxious girl aged 13. She had had bronchial asthma since the age of 18 months, and eczema in childhood. The onset of the asthma coincided with an accident, when she was scalded by an overturned teapot. The attacks sometimes lasted three to four days, and used to occur when she exerted herself or was emotionally upset. She was a good hypnotic subject. At the first session suggestions were given to her not to worry about the attacks, and to relax well. She was trained in autorelaxation by mild hypnosis, and told to use this when an attack occurred. It proved to be quite effective. When she had an attack of asthma she was able to relax, counting slowly up to ten and using autosuggestion, with the result that the spasm was very soon relieved. She was seen only three times. Six months later she was free from any attacks. This could be explained by her conviction that she had an effective remedy in her hands, and was able to make use of it when necessary.

Case 12

A garage proprietor aged 33 had had bronchial asthma since 2 years of age, which interfered with his schooling. He was the only child. His father died some years ago, and he was managing the business with his mother, who was a domineering type, and treated her grown-up son like a child. He had been using an inhaler for over 17 years. He had been in several hospitals, had undergone a sinus operation, and had had allergy tests, which were all negative. He was unmarried, was very shy, and did not have many friends. He was a very tense subject, difficult to relax. Several attempts were made to get him into a state of deep hypnosis, but without success. Any further attempts to alter his tension, the mother-son relationship, and his outlook had to be given up. He was treated altogether over a period of six weeks.

Case 13

A housewife aged 52 had pruritus ani and vulvae for five years, had a perineal repair four years ago, local x-ray treatment to the perineal region three years ago, and hysterectomy for severe metrorrhagia two years ago. The pruritus had resisted all treatments so far, and was worse when she became warm. She was very "nervy," tense, depressed, and anxious owing to her complaint. She could not sleep, because the itching was so intense. She could not take part in any social activities, and when she was talking to anybody she had to run off suddenly to relieve her itching by scratching. It was also upsetting her family life. There was no history of any possible psychological cause, and her urine was normal.

She was very sceptical when I first explained the proposed treatment to her. The first session was not very successful, but she began to feel better after the second treatment. The pruritus round the anus ceased completely, and there was only slight itching in the vulvar region. After the third session she was able to sleep throughout the night. The perianal skin, which was at first macerated and raw, gradually became darker and drier. After six sessions she had no more pruritus, felt remarkably better, was very happy, and was enjoying life fully. She could not believe that she was so relaxed. She ceased using any local applications, and stopped taking the sedatives and hypnotics, which she had done for the last five years. When followed up a few months later she remained symptom-free.

Case 14

A housewife aged 43. Ten years' history of cheilosis. There were deep cracks at both angles of her mouth, which were always moist and very sore. She had tried various treatments, including vitamins. Direct suggestion under hypnosis in two sessions cleared up her condition completely, and there was no recurrence. When seen six weeks later, she stated that she never felt so well. She stopped using any local applications. Six months later she remained free from cheilosis.

Case 15

A typist aged 25, with dysmenorrhoea for 11 years. The intense pain and incapacity usually lasted four to five days, and was interfering with her work. She had been treated on general lines with anti-spasmodics and analgesics, with poor response. She was referred in March, 1950, to a gynaecological department. The gynaecologist suggested trying tab. stilboestrol, 1 mg., at night and "synapoidin" injections. These had no effect. Her name was then put down for operative treatment. She had a D. & C. performed, after waiting two and a half years for the operation. The first subsequent menstruation was just as painful and incapacitating as the one before. Hypnotherapy was suggested to her, and she decided to give it a chance. She was treated with direct suggestions of analgesia and relaxation. When she came for the first treatment she was in agony; half an hour later she walked out free from pain. When seen again on the following day, she said that she was able to stop the pain by self-relaxation in the way she was taught at the first session. She said that as soon as she closed her eyes she imagined seeing the object which she was looking at when she was hypnotized, and her pain then soon disappeared. During her next menstruation she was seen three times, and during the following one twice only. She has had no further treatment since, and stopped taking any drugs for the relief of pain. Two years later she was still free from dysmenorrhoea.

Case 16

A boy aged 12 had a 12-months history of enuresis since he changed schools. At one time he was a sleep-walker and had nightmares. Amphetamine, etc., were tried without success, and no psychological cause could be found. Direct suggestion, under hypnosis, to stop worrying, and of

improved control of the bladder was very effective. He had a completely dry week after the first session, and stopped taking amphetamine after the third session. He was seen six times, and has since remained free from enuresis.

Case 17

An engineer aged 43 had had chronic duodenal ulcer since 1938. He had medical treatment in hospital for six weeks in 1939, and two further courses in 1942 and 1943. In 1944 he had a partial gastrectomy. He made a good recovery, and was told on discharge that he would have no further worry, would require no more special treatment or diet, except smaller and more frequent meals. He remained well for 12 months, and then the pain, nausea, and the rest of the symptoms recurred. The pain used to wake him up five to six times during the night, and he could not do his work regularly. Alkalis, belladonna, and anticholinergics had very little effect. A barium meal showed a constant fleck in the duodenal region, probably due to an ulcer. He was a worrying type, and this aggravated his condition. However, he agreed to try hypnosis, and was a very good subject. After the first session he said that he felt more relaxed than he had been for years. He slept well that night and was free from pain. He stopped his heavy smoking as a result of suggestion given to him during the first session. He had some slight pain the following night. After the second session he had his first real breakfast for years. Altogether, he was seen four times. He now stopped taking mixtures, tablets, etc., and was on a liberal diet. When seen three months later his weight had increased by over three stones (19 kg.). He remained free from pain, slept well, did not smoke, and felt fine. Three months later he said that he had never been so well for years. A year later he remained symptom-free and did not smoke.

Case 18

A man aged 78 had a partial oesophago-gastrectomy for carcinoma of the lower end of the oesophagus. He developed a secondary growth six months later in the left sternoclavicular region, and was deteriorating rapidly. He was taking methadone hydrochloride for the relief of his pain. Hypnosis was tried in order to make him more comfortable. He had three sessions, which were partially successful. He remained free from pain, did not need any more methadone, and felt much better generally. He died three weeks later. His relatives stated that he felt much better after hypnosis, and remained in a much more peaceful state of mind until his end.

Case 19

A housewife aged 21 had had petit mal since the age of 12. The attacks were aggravated by any emotional upset and by menstruation, and occurred mostly in the mornings. For about two hours she would look vacant, but was able to continue work and converse. She had four major attacks when pregnant, and one during labour. She was a tense and very excitable type. Her relatives were very anxious about her condition, which did not help matters.

She had been under continuous treatment since the attacks began, and had been fully investigated in different hospitals. Anticonvulsants and sedatives had little effect, except to make her feel drowsy. Lately she had been taking epanutin-and-phenobarbitone capsules. Her anxiety was increased by the fact that she had a young baby to look after. Her mother used to come early every morning to take care of the housework, as the attacks made it impossible for her daughter to do so.

She was a good hypnotic subject. Direct suggestions were used to lessen her anxiety and tension, and to control the number of the attacks. She felt much brighter after the first session; the attacks decreased from 40 to about 10 a day, and she said that she did not worry so much about them. She was more cheerful and hopeful, seeing a form of treatment that might help her. Until then, no one had encouraged her to believe she would ever lose the

attacks. Treatment was continued at intervals of two to three weeks, as she was living some distance away. Altogether she had nine sessions in five months. The attacks were finally reduced to only two or three a day, but on most days she was free from them. They used to be more frequent during menstruation, but towards the end even this did not affect them. She had also been suffering from dysmenorrhoea, which was treated with hypnosis at the same time, and after three months she was having completely painless menstruation. It is possible that the pain may have been responsible for the increased number of attacks. When seen a year later, she stated that she was feeling fine, and had hardly any attacks. She also reduced the number of the capsules she had been taking.

Case 20

A factory worker aged 19 with a history of nightmares and sleep-walking since childhood. Her mother was a very neurotic type. The patient had been treated in 1949 for 12 months as an out-patient in a psychiatric hospital. She improved for three years and then relapsed. When first seen, the mother stated that her screaming at night disturbed the other members of the household, as well as the neighbours. The girl was very tense. During the week following her first hypnotic session she had only one disturbed night, and she felt less tense. She was seen altogether five times at weekly intervals. As a result she was sleeping normally, and had no more disturbing dreams. When followed up two years later she was still sleeping normally.

Case 21

A 3-para aged 27 had labour under hypnosis. She was first seen when three months pregnant. She had eight sessions. She was trained in autorelaxation and to reach a hypnotic state by slow count up to 10, in deep breathing, and in autosuggestion. She responded well to the training. She was 10 days overdue. At 2 a.m. she began to have slight pains, which lasted till 7.30 a.m. At 2 p.m. the pains started again. At 3 p.m. they became stronger, and the patient gently clenched her right hand—a prearranged signal. She then became fully relaxed and felt no more pain. She was fully co-operative, and at 5 p.m. a 9½-lb. (4.3-kg.) infant was born without difficulty. There was no need for pethidine or gas-and-air analgesia. She was not seen until after the third stage was completed. She felt fine, and said that she would not mind having a few more babies in the same way. She had no after-pains at all. The perineum remained intact.

Discussion

Hypnosis used carefully and sensibly can be of great help in general practice. It may achieve results in cases which have resisted more conventional methods of treatment.

It is not suggested that hypnosis is a panacea which will cure every disease or disability, but far more can be done with it than has been supposed. Many conditions can be controlled by hypnosis alone, and in most conditions the patient can be made far more comfortable and more able to carry out his normal duties. It is also possible (Lloyd, 1934) to enhance the effects of other forms of treatment by appropriate suggestion under hypnosis.

It is difficult to change completely an obsessional personality, but it is possible with hypnotherapy to enable sufferers to lead a reasonably happy life. If hypnosis will not help a psychoneurotic, at least it will not aggravate his condition. The Subcommittee of the Psychological Medicine Group Committee of the B.M.A. stated in a report (*British Medical Journal*, 1955), that they "had no clear evidence upon the extent of the danger or the quality of the danger to a patient which some psychiatrists claimed inevitably followed the induction of hypnosis."

I did not encounter any deterioration in the patients' condition when treated with hypnosis. Kuhn and Russo (1947) make the following statement about any possible dangers of hypnosis: "Moral—there is no surrendering of the will,

there is only co-operation. Psychological—does not weaken the mind. Physical—there are none."

The possible use of hypnosis in alleviating pain in malignant conditions is worthy of study. Case 18 illustrates this well. Wolberg (1948) states that hypnosis can eliminate pain in incurable progressive fatal ailments and reduce or eliminate the necessity of analgesic drugs.

The value of hypnosis in skin affections is based on its effect on the emotional state of the patient. Bonjour (1929) maintains that the skin is a mirror of the mind. Some patients suffer from certain skin diseases which may be due to emotional disturbances—for example, erythroderma, hyperidrosis, urticaria, and eczema.

The removal of anxiety and other disturbing symptoms in psychosomatic cases by hypnotherapy offers great possibilities. The anxiety which follows a coronary occlusion or other cardiac affections is a particular example. Dr. Morgan Jones (1955) states that in cases recovering after a coronary occlusion there is often far more residual disability from fear than from myocardial damage. This fear can be dealt with by hypnosis.

The good results from hypnotherapy in cases of dysmenorrhoea, petit mal, migraine, and asthma should encourage its further use in such patients.

The possibility of helping heavy smokers, especially young people, to give up this habit through hypnosis may play an important part in the prevention of bronchial carcinoma.

The general practitioner is particularly well suited to use hypnosis, as he is usually familiar with the patient's background, and enjoys his confidence, which is so essential for successful hypnotherapy.

To enable patients who have been regarded as incurable to resume work, to regain their self-confidence, and to dispense with drugs for the relief of their symptoms is a worthy achievement, and should stimulate further application and research in the use of hypnosis.

It is hoped that this paper may stimulate research and interest in this branch of medicine, especially in its application to general practice, and it may help to overcome the prejudice and scepticism of some members of the medical profession.

Summary

A report is presented of 120 cases treated by hypnosis in general practice. The technique and clinical effects of hypnosis are briefly described. Twenty-three cases were resistant to hypnosis.

The largest group of cases were the psychosomatics and psychoneurotics: 57 cases fully improved and 26 only partially did so.

Most of the resistant cases were amongst the obsessional and adult asthmatics.

Cases of asthma in children, dysmenorrhoea, duodenal ulcer, petit mal, cardiac anxiety following an organic lesion of the heart, anxiety neurosis, and skin affection gave the best results.

Twenty patients who had resisted other methods of treatment recovered and were able to resume work after treatment with hypnosis.

Twenty-four patients were able to stop taking hypnotic, analgesic, and anticholinergic drugs, or drastically reduce their use, as a result of hypnotherapy.

Hypnosis, used carefully and sensibly, can be of great help in general practice, achieving results in cases which resisted more conventional methods of treatment.

Hypnotherapy compares favourably with psycho-analytical and physical methods in the treatment of psychoneuroses.

None of the treated cases showed any deterioration of their original condition as a result of hypnotherapy.

There is no evidence that any danger may arise from the use of hypnosis in medical treatment.

There is no special "gift" required to induce hypnosis.

The general practitioner is particularly well suited to use hypnosis as a method of treatment, as he is usually familiar with the patient's background and has his confidence, which is important for successful hypnotherapy.

FLUCTUATION OF ARTERIAL BLOOD PRESSURE IN ASTHMA

BY

KLAUS A. J. JÄRVINEN, M.D.

Lecturer in Medicine and Assistant Physician-in-Chief at the First Medical Clinic, University of Helsinki, Finland

If the arterial pressure is measured by the ordinary auscultatory method during an attack of bronchial asthma, a few beats, usually two or three, will be heard at a higher level of pressure than the others. If the cuff pressure is kept at this level for several respiratory cycles, it will be noticed that these two or three beats of higher pressure occur at the beginning of each expiration. Usually the cuff pressure has to be lowered 20–30 mm. Hg before the point is reached where all the beats are heard. These fluctuations in the systolic pressure in bronchial asthma have been studied by Gauchat and Katz (1924), Katz and Gauchat (1924), Tinel and Jacquelin (1931), Rackemann (1931), Osgood (1943), Osgood and Ehret (1943). The following is a further study.

Material

The material comprises 33 patients (19 women and 14 men) with bronchial asthma. The diagnosis was clinically certain in all cases. Patients with other concurrent disease, or in whom severe emphysema or cor pulmonale had developed, were excluded. The mean age of the women was 47.8 years, and of the men 41.7 years.

On the basis of the severity of the clinical symptoms the cases were divided into three groups: (1) *Mild bronchial asthma*:—Only a few sibilant rales in the lungs; subjectively, no real dyspnoea; physical activity unrestricted. (2) *Moderately severe bronchial asthma*:—Sibilant rales throughout both lungs; subjectively, definite although not severe dyspnoea; auxiliary respiratory muscles not much used; hard exercise impossible. (3) *Severe bronchial asthma* (involving primarily an attack or status asthmaticus):—Wheezing heard without a stethoscope; numerous sibilant rales and noises; dyspnoea so severe that the patient had to sit upright or lean forward to secure maximum use of the accessory muscles of respiration; patient hardly able to move.

The fluctuations in arterial pressure were measured by the ordinary auscultatory method with a mercury sphygmomanometer. As the changes in systolic pressure proved much easier to detect than those in the diastolic it was decided to observe only the former in this part of the study. Measurement was effected by finding, in the usual

way, the maximum pressure at which the first beats began to be heard. As noted above, the one to three beats coinciding with the beginning of the expiration were heard, especially in cases of severe asthma, at a considerably higher pressure than the other beats. These few higher beats are easily overlooked unless each even-number pressure-reading near the maximum is observed long enough—for not less than two complete respiratory cycles. Subsequently the cuff pressure was lowered by 5 mm. Hg at a time until all the beats could be heard continuously irrespective of the phase of respiration; the difference in pressure between the few higher beats and this pressure was recorded. The lowest beats (two or three) were found at the end of expiration and/or at the beginning of inspiration. During the most severe attacks of asthma, however, it was sometimes impossible to obtain a reading at which all the beats could be heard continuously during the whole respiratory cycle: before the lowest beats at the end of expiration were heard the ones at the beginning of expiration had vanished. In these few cases the systolic pressures at the beginning and end of expiration were measured separately. However, this was much more inaccurate than the method of measuring described above.

Results

As can be seen from Table I, the fluctuation in systolic blood pressure due to respiration increased with the severity of the bronchial asthma. In cases where the fluctuations were

TABLE I.—Fluctuation of Systolic Blood Pressure Due to Respiration in Patients with Bronchial Asthma, Measured With a Mercury Sphygmomanometer

Severity of Bronchial Asthma	No. of Cases	Fluctuation of Systolic Blood Pressure Due to Respiration (mm. Hg)
Mild	19	4 ± 0.6
Moderately severe	9	13 ± 1.5
Severe	5	25 ± 1.7

recorded while the asthmatic symptoms were being relieved by adrenaline, there was a clear correlation between the range of pressure fluctuation and the severity of the symptoms. In three patients with severe bronchial asthma the fluctuation in systolic pressure was 25 (E. V.), 20 (A. N.), and 20 mm. Hg (L. E.). The corresponding pressure readings after the relief of symptoms by adrenaline were: E. V., 15 mm. Hg (symptoms still moderately severe); A. N., 5 mm. Hg (symptoms mild); L. E., 5 mm. Hg (symptoms nearly subsided). In two moderately severe cases of bronchial asthma the fluctuation in systolic pressure was 10 mm. Hg. After adrenaline had produced a nearly complete disappearance of the asthmatic symptoms none of the cases showed any demonstrable pressure fluctuation.

To investigate further the connexion between these fluctuations in arterial pressure and the degree of respiratory obstruction present, clinically healthy persons were asked to breathe through glass tubes of various diameters. The ratio of the resistance to respiration produced in this way (taken as corresponding to that during an attack of bronchial asthma) to arterial pressure was studied.

To start with, the intra-arterial pressure of the femoral artery of the test subject was followed during "tube respiration." The pressure was recorded by Sandborn's electromanometer. All the tubes through which respiration took place were 10 cm. long. The largest diameter was 10 mm.; the tubes then successively narrowed in diameter (see Table II). During respiration the nose was pinched and the tube, fitted with a special mouthpiece, was held between the lips. The results are shown in Table II, which gives only the variation occurring in the course of single respiratory cycles, as pressure recordings obtained over a longer period were not considered fully comparable; for when an ordinary pressure a change in its position in relation to the arterial walls may affect the results.

TABLE II.—Continuous Recording of Intra-arterial Pressure of Femoral Artery of Healthy Man Aged 30 During Respiration Through Tubes of Different Diameters. Blood Pressure Before Test, Measured by Mercury Sphygmomanometer, was 115/75 mm. Hg. The Maximum and Minimum Values are Given in Parentheses

Tube No.	Diameter	Fluctuation of Systolic Blood Pressure Due to Respiration (mm. Hg). Mean of Three Respirations	Fluctuation of Diastolic Blood Pressure Due to Respiration (mm. Hg). Mean of Three Respirations
1	10 mm.	5 (3–7)	4 (2–5)
2	8 "	8 (5–11)	6 (5–8)
3	6 "	13 (12–14)	10 (5–15)
4	4 "	47 (35–54)	33 (24–38)
5	2.5 "	78 (73–85)	59 (58–60)

As Table II shows, fluctuation due to respiration occurs in systolic, diastolic, and pulse pressure, and the fluctuations increase as the diameter of the tube used for respiration diminishes. The systolic pressure varied most. The lowest pressures were recorded at the end of expiration and at the moment of changing to inspiration. The highest values coincided with the beginning of expiration. The Chart illustrates samples of the pressure curves. They show, for example, that the three pulse waves coinciding with the beginning of expiration had the highest systolic pressure. The phenomenon was particularly clear when the narrow tubes were used. The pulse pressure, highest at the beginning of expiration, was sometimes reduced to nearly zero with tubes 4 and 5.

The fluctuations in arterial pressure due to respiration through the tubes were recorded also by mercury sphygmomanometer, as in cases of asthma. Only the fluctuation in systolic pressure was recorded, as this had proved much easier to detect than the diastolic in the asthmatic cases and because the intra-arterial measurements had shown that the changes in the systolic pressure were the larger. When tubes 4 and 5 were used, no pressure reading could usually be obtained at which all the beats could be heard continuously irrespective of the phase of respiration. The reason for this phenomenon—the same as that sometimes observed in severe bronchial asthma—is clear from the pres-

sure curves shown in the Chart. With tubes 4 and 5 the systolic pressure dropped at the end of expiration below the diastolic pressure recorded at the beginning of expiration. (In some cases the pulse pressure even dropped to zero at the end of expiration.) In these cases the systolic pressures at the beginning and the end of expiration were, if possible, measured separately as described. The results are given in Table III, which shows that the fluctuation of the systolic pressure increased with the resistance of respiration.

TABLE III.—Effect of Respiration Through Tubes of Different Diameter on Fluctuation of Systolic Blood Pressure as Measured with a Mercury Sphygmomanometer. The Six Test Subjects Employed, Aged 15 to 50, Were Clinically Healthy. They were Requested to Breathe as Calmly as Possible, Without any Forcing

No obstruction in airways	Difference in mm. Hg between Maximum Systolic Pressure Value at Beginning of Expiration and Minimum Systolic Pressure Value at End of Expiration. Mean Values. Maximum and Minimum Values are Given in Parentheses
Tube 1 (10 mm.)	0 (0–0)
" 2 (8 ")	0 (0–0)
" 3 (6 ")	4 (10–0)
" 4 (4 ")	17 (35–5)
" 5 (2.5 ")	30 (50–15)
" 5 (2.5 ")	40 (60–25)

Discussion

The results obtained in bronchial asthma for fluctuations of systolic blood pressure due to respiration corresponded closely to those reported by Osgood (1943). The method evolved in the present investigation to determine this fluctuation was also fairly similar to that used by Osgood. As I was not aware of Osgood's investigations until my own study was completed, this similarity deserves special emphasis.

Measurements of arterial pressure during respiration through tubes of varying calibre showed clearly the close correlation between the severity of obstruction to the respiratory tract and the degree of fluctuation in arterial pressure

Fluctuation of arterial blood pressure due to respiration. Recording by intra-arterial method. Samples of the pressure curves.—Top: Respiration through tube 5 (length 10 cm., diameter 2.5 mm.). Middle: Respiration through tube 4 (length 10 cm., diameter 4 mm.). Bottom: Respiration through tube 3 (length 10 cm., diameter 6 mm.). (E.C.G. changes apparently correspond to changes in the electrical axis.)

due to respiration. In practice, the degree of obstruction to the respiratory tract can be assessed from the fluctuation in arterial pressure in both asthma and other conditions. Although the intra-arterial pressure is a more accurate guide in such cases, its measurement even to-day places such a strain on the patient that I regard the corresponding fluctuation in systolic pressure easily obtainable with an ordinary sphygmomanometer, as adequate for practical purposes.

Although the severity of bronchial asthma can usually be readily assessed from the other clinical symptoms, the determination of this fluctuation in blood pressure may assist in the assessment; in addition, it may provide a clearer picture than the other symptoms of the extent of the respiratory obstruction. It also gives an idea of the extent, so important in bronchial asthma, of fluctuations in intrathoracic pressure during respiration. Fluctuation in arterial pressure due to respiration is considered to be closely correlated with the corresponding fluctuation in intrathoracic pressure. In strong expiration, increased intrathoracic pressure results in the blood from the lung-bed travelling at increased speed into the left side of the heart and from there into the systemic circulation. With the start of expiratory strain a transient rise in systolic and diastolic pressure is observable. If the venous return to the heart is obstructed, however, this is followed immediately by a reduction in the stroke volume of the heart and also by a drop in the systolic and diastolic pressures (Judson *et al.*, 1955; Jones *et al.*, 1956). The negative intrathoracic pressure associated with inspiration again increases the venous return to the heart, and as a result the systolic discharge of the left ventricle begins again to increase.

TABLE IV.—Effect of Respiration Through Tubes of Different Diameters on Fluctuation of Intra-oesophageal and Systolic Blood Pressure. Four Series of Measurements on the Same Clinically Healthy Test Subject Aged 38

No obstruction in airways	Difference, in mm. Hg, Between Rise of Intra-oesophageal Pressure Due to Expiration and Pressure Drop in Connexion with Inspiration. Maximum Values Obtained in Different Measurements	Fluctuation of Systolic Blood Pressure in mm. Hg. Maximum Values Obtained in Different Measurements
Tube 1 (10 mm.)	0-5	0-0
" 2 (8 ")	0-10	0-5
" 3 (6 ")	10-15	5-10
" 4 (4 ")	10-20	35-45
" 5 (2.5 ")	30-40	40-50
	30-50	55-60

Table IV gives an idea of the correlation between the fluctuations in the systolic blood pressure and the intrathoracic pressure when the respiratory tract is obstructed (respiration through the tubes). Observation of the intrathoracic pressure was effected by measuring the intra-oesophageal pressure. These pressures have been found to correspond closely. Intra-oesophageal pressures were obtained by means of a balloon (4 ml. capacity) on a 100-cm. length of polyethylene tubing (3 mm. in diameter) passed through the nose and into the oesophagus to a distance of 40 mm. from the nose. The system was air-filled, and the pressure was measured by a torsionmanometer.

In severe bronchial asthma even, the variations in systolic blood pressure were not nearly so extensive as the greatest noted on respiration through the tubes. This is attributed to the fact that in bronchial asthma a rise in intrathoracic pressure, while it forces air out of the alveoli, also constricts the bronchioli. There is, however, a certain limit above which the intrathoracic pressure interferes with expiration (Wyss, 1955).

Summary

The fluctuation in systolic blood pressure during respiration was studied in 33 patients with bronchial asthma by means of an ordinary mercury sphygmomano-

meter. In mild bronchial asthma the systolic blood pressure fluctuated by 4 ± 0.6 mm. Hg; in moderately severe asthma by 13 ± 1.5 mm. Hg; and during an asthmatic attack by 25 ± 1.7 mm. Hg. If the symptoms of bronchial asthma were relieved by adrenaline, the fluctuation in systolic blood pressure was reduced correspondingly.

The correlation between the degree of respiratory obstruction and the fluctuation of arterial pressure during respiration was studied. Test subjects breathed through tubes of fixed length but different diameter. The arterial pressure was recorded in six by a mercury sphygmomanometer and in one by intra-arterial measurement. In addition, changes in intrathoracic pressure were observed by measuring the intra-oesophageal pressure. It was found that the greater the obstruction to the respiratory tract the more extensive were the fluctuations in the arterial pressure. The same applied to intrathoracic pressure. The maximum arterial pressure readings were obtained at the beginning of expiration, during one to three beats, the lowest values (two to three beats) at the end of expiration. The systolic pressure fluctuated more than the diastolic. The maximum fluctuation recorded in a single subject, when breathing through the narrowest tube, was 78 mm. Hg by the intra-arterial method and 60 mm. Hg by mercury sphygmomanometer. The corresponding maximum fluctuation in the systolic blood pressure of six healthy persons aged 15-50 years, obtained by mercury sphygmomanometer, was 40 mm. Hg.

The National Coal Board has published a report entitled "The Coal Industry in the U.S.S.R." The report is based on the observations of a technical mission which visited the U.S.S.R. in 1956, and includes a section on health and welfare. In the U.S.S.R. considerable importance is attached to industrial health services, especially in heavy industry; in 1956 24,000 doctors were stated to be employed as industrial medical officers. In 1955 some 1,300 in mining areas serve the whole population there. Large collieries had "health points" at the surface, and sometimes underground first-aid rooms. Each colliery visited had its own ambulance; and a strikingly high proportion of women doctors was noticed. All new entrants to the industry are medically examined; subsequently surface workers are examined yearly, and underground workers twice yearly. Efforts are made to screen the chest of all coal-miners annually, about 70-80% being so examined. In 1955, it was stated, 1.6% of underground workers were certified as suffering from silicosis (roughly equivalent to pneumoconiosis in British terminology). The Ministry of Health runs a large number of sanatoria, some of which specialize in the treatment of silicosis. Admission is granted according to both the medical need and the work record of the miner in question; an outstanding mining record entitles the patient to free treatment. The report is obtainable from the National Coal Board, Hobart House, Grosvenor Place, London, S.W.1; price 8s., post free.

EFFECT OF VITAMIN-B COMPLEX ON HEALTHY PEOPLE IN A WARM CLIMATE

BY

E. M. GLASER, M.C., M.D., Ph.D., M.R.C.P.

AND

B. H. LIVETT, B.Sc.

From the Department of Physiology, University of Malaya, Singapore

The question whether there is an increased need for vitamins of the B complex among people living in a warm climate has not been clearly answered as yet, but such vitamins are often prescribed in the tropics and elsewhere to people who show no signs of vitamin deficiency and whose diets are apparently adequate. More thiamine is excreted in the urine during hot than during cold weather (Holt, 1943), and this could be interpreted to mean that increased amounts of the vitamin should be taken in warm climates; but sweating does not increase the losses of thiamine through the skin (Lugg and Ellis, 1954), and there is no evidence of any prevalence of anaemia in an equatorial climate when economic conditions are good (Wadsworth, 1952a, 1952b, 1954). Since, however, the deep body temperature of healthy people at rest tends to be a little higher in a warm than in a cool climate (Adam and Ferres, 1954), while the rise of the deep body temperature which takes place during exercise is also enhanced in a warm environment (Martin, 1930), it is possible that the increase in enzyme activity resulting from such a raising of the body temperature would increase the demands for various vitamins, especially those of the B complex, and that mild symptoms of lassitude would follow which could explain the syndrome of tropical fatigue (Macpherson, 1949).

Mild general symptoms associated with slight vitamin deficiencies were, indeed, observed among soldiers serving overseas during the last war (Glaser, 1953b). A further possibility is that some inhabitants of the tropics may be suffering from undiagnosed sprue-like conditions, and that they could thus benefit from vitamin-B supplements.

In the absence of conclusive findings, it seemed important to ascertain whether there was any need for the excessive prescription of vitamin preparations prevalent in many tropical and equatorial areas, so that wasteful therapy should be avoided if it was of value. Since the level of serum cholinesterase is a sensitive indicator of the state of nutrition (McCance *et al.*, 1948; Hutchinson *et al.*, 1951), it was of interest to estimate at the same time the levels of cholinesterase in the blood.

Methods

In order to assess whether vitamins altered the incidence of mild subjective symptoms, a technique was modified which had been previously shown to allow unbiased assessment of subjective responses and their variations (Glaser, 1953a; Glaser and Whittow, 1954; Glaser and Newling, 1955). A class of 79 medical students took part in the experiment. Their ages ranged from 19 to 23 years and nine of them were women. Two-thirds of the subjects were Chinese and the rest were Indians, Sinhalese, Malays, or Eurasians. About half the students lived in university hostels and the other half in their own homes. The diet taken

by the middle-class population of Singapore and by students living in hostels contains a variety of lightly cooked fresh vegetables as well as salads, fruit, fresh meat (mostly pork), and some vitamin-enriched bread, so that it is likely to be adequate in vitamins of the B complex, even though polished rice forms the basis of most meals.

The subjects were told nothing about the purpose or the design of the investigation, except that they would be given vitamins, that they should take one tablet daily, and that they should take no other vitamin supplements of any kind before and during the experiment. They were also casually told that lost or damaged tablets would be replaced and that mutual borrowing of tablets was not a good thing. Previous experience with similar classes of students has shown that Singapore students co-operate most conscientiously in such experiments (Glaser, 1953a; Glaser and Whittow, 1954; Glaser and Newling, 1955) and there was every evidence that they did so in the present investigation. The students were divided at random into two groups, and the experiment was conducted in two periods of eight weeks separated by an interval of six weeks. At the beginning of each experimental period every subject received one dummy tablet daily for 14 days, after which half the subjects continued to receive dummy tablets and the other half were given one vitamin-B complex tablet daily, so that each subject took vitamins for the last six weeks of one experimental period and dummy tablets throughout the other period.

The vitamin tablets were made by a well-established firm, and their composition was claimed to be:

Thiamine hydrochloride	..	..	..	2 mg.
Riboflavin	..	..	..	2 mg.
Niacinamide	..	..	..	10 mg.
Pyridoxine hydrochloride	..	..	..	0.1 mg.
Calcium pantothenate	..	..	..	3 mg.
Folic acid	..	..	..	0.2 mg.
Vitamin B ₁₂	..	..	..	1 µg.
Insoluble liver fraction	..	..	..	250 mg.

The dummies were indistinguishable and contained nothing but lactose. All tablets were sugar-coated and were stored in airtight containers at 21° C. They were issued weekly in screw-top bottles labelled with each subject's name. Known dummy tablets were available to us while all subjects were taking dummies, but when vitamins were being taken all issuing of tablets was done from coded containers, so that we did not know which were the vitamins until all the results had been calculated.

The sensations and illnesses of the subjects were assessed before each experimental period and at intervals of one week thereafter, always at the same time of the day. Questionnaires were similar to those described before (Glaser and Whittow, 1954), and they were designed to avoid errors so far as was possible. Questions were included about skin lesions and illnesses, both at the moment of filling in the questionnaires and during the preceding six days.

Estimations of Cholinesterase

At the end of the experiment 35 subjects were asked to provide a sample of finger blood. In order to obtain a homogeneous group, these subjects were selected at random from among the largest single group in the experiment, Chinese men. Thirty-three of these subjects agreed to participate, and after the results had been worked out it was found that 15 had been taking vitamins for the last six weeks.

The red-cell ("true") cholinesterase was estimated as acetylcholinesterase and the plasma ("pseudo") cholinesterase as butyrylcholinesterase on samples of whole blood. Preliminary tests had shown that 87% of the activity of whole blood with regard to acetylcholine perchlorate was due to red cells and 82% of the activity with regard to butyrylcholine chloride was due to plasma. For estimations of the acetylcholinesterase, samples of 20 µl. of blood were run from the finger into 0.98 ml. of a 0.01% solution of saponin, identical samples being used for duplicate and control determinations. To duplicate diluted blood samples,

Symptoms and Illnesses Reported After Taking Dummy Tablets and After Taking Vitamin-B Complex Supplements in a Crossed-over Experiment

	No. Completing Questionnaires	Minor Illnesses During Last 6 Days		Condition at Moment of Completing Questionnaires											
				At Least One Symptom		Unhealed Cuts or Abrasions		Sleepiness		Fatigue		Feeling Better		Feeling Worse	
				No.	%	No.	%	No.	%	No.	%	No.	%	No.	%
Two weeks on dummy tablets ..	79	8	10	49	62	8	10	31	39	34	43	7	9	2	3
Eight weeks on dummy tablets ..	70	2	3	28	40	2	3	19	27	19	27	7	10	3	4
Six weeks on vitamin tablets ..	73	8	11	49	67	6	8	21	29	28	38	6	8	1	1

1 ml. of 0.004 M acetylcholine perchlorate in 0.134 M phosphate buffer (pH 7.2) was added and the solutions were then thoroughly mixed and incubated in a water-bath at 30° C. ($\pm 0.1^\circ$ C.) for 10 minutes. A separate tube containing 1 ml. of the acetylcholine solution was incubated at the same time, and at the end of 10 minutes the control blood solution was poured into this tube.

The three solutions were now assayed for residual acetylcholine according to the method of Hestrin (1949), with the following modifications. Double the volume of the recommended reagents was used and the ferric chloride solution was 0.74 M. Protein precipitated in the final stages of the estimation was removed by filtration through Whatman No. 40 filter paper. Estimations were made in a Spekker photoelectric absorptiometer, using an OGI filter. The same technique was used for the estimation of butyrylcholinesterase, except that the substrate used was 0.004 M *n*-butyrylcholine chloride in 0.134 M phosphate buffer. Preliminary experiments had shown that no measurable non-enzymic hydrolysis occurred in the control tubes, that under the experimental conditions employed the amount of acetylcholine and butyrylcholine hydrolysed by the whole blood was linearly related to the time of incubation, and that in both estimations the results obtained with whole blood compared well with the summation of the results obtained when plasma and cells were separated in the normal way. The packed red-cell volumes were estimated from finger blood in duplicate heparinized haematocrit tubes and spun at 3,000 r.p.m. for 30 minutes. The results were expressed as μ M ester hydrolysed by 20 μ l. of whole blood in 10 minutes at 30° C. and at a pH of 7.2, and the values were corrected to a packed red-cell volume of 50%.

Results

There were no consistent differences between the incidence of subjective symptoms or of minor illnesses when the subjects were taking dummies and when they were taking vitamins. Indeed, slightly more symptoms and illnesses were recorded by the same subjects after taking vitamins than after taking dummies (see Table). It was impossible also to demonstrate any advantages of the vitamin supplements when comparisons were made between the responses of different subjects who had been taking vitamins and dummies at the same time. There were no illnesses involving hospital treatment, or absence from classes for more than one week. Mild symptoms were regularly reported, however (see Table), and this conforms with previous observations when subjects were given questionnaires but no pharmacologically active substances (Glaser, 1953a; Glaser and Whittow, 1954; Glaser and Newling, 1955). The incidence of symptoms gradually diminished when all subjects were given dummies only, and this also conforms with previous experience. Nevertheless, in the present investigation fewer symptoms were reported by subjects receiving dummies than in previous experiments, presumably because the subjects knew that they were to be given vitamins, whereas in the earlier experiments they were expecting to take drugs, so that they may have expected fewer symptoms in the present investigation than in previous ones. This aspect of the problem has been discussed elsewhere (Glaser and Whittow, 1957).

In 15 subjects who had been taking vitamins for six weeks the mean acetylcholinesterase level was 1.54μ M (S.E., ± 0.05)

of ester hydrolysed, and in 18 subjects who had had dummies for three months the mean figure was 1.55μ M (± 0.05). The mean butyrylcholinesterase level of the 15 subjects who had had vitamins was 0.74μ M (± 0.05) and that of the 18 subjects who had had no vitamins for three months was 0.54μ M (± 0.04), and the difference was statistically highly significant ($t=3.24$; $P<0.01$). Further control samples of 10 normal people working in the Faculty of Medicine of the University of Malaya gave average levels of 1.50μ M (± 0.05) for acetylcholinesterase and 0.60μ M (± 0.03) for butyrylcholinesterase.

Discussion

The results clearly show that supplements of vitamins of the B complex do not improve the health or enhance the subjective sense of well-being in normal people who do not know when they are taking vitamins. Since the method used to assess subjective responses is very sensitive, while the present results did not even indicate the possibility that the vitamins might have caused any improvement, it is improbable that larger doses of these vitamin supplements plasma cholinesterase level was significantly raised by the giving of a vitamin-B complex preparation are difficult to explain at the moment. Davis (1946) found that folic acid serum, both when these substances were given by injection *in vivo* or added to the serum *in vitro*, but Hawkins (1948) was unable to confirm this with regard to folic acid. It will be necessary to investigate in detail which of the components of the tablets given in the present investigation caused or aided the increase of the plasma cholinesterase level and what were the underlying mechanisms of action.

Summary

In a tropical climate supplements of vitamin-B complex and insoluble liver fraction produced no improvement of the subjective sense of well-being and no decline in the incidence of minor illnesses among apparently healthy people on an adequate diet. Such supplements of vitamins raised the serum cholinesterase level significantly above normal.

We are indebted to Messrs. F. E. Zuellig (Malaya) Ltd. for supplies of vitamin-B complex tablets and indistinguishable dummy tablets. Mr. Yap Tian Beng kindly coded the vitamin and dummy tablets.

Alder Hey Children's Hospital, and the Departments of Child Health and Anaesthesia, University of Liverpool

The returns of the Registrar-General for England and Wales (1950-2) indicate that in this country aspirin and its derivatives remain an important cause of death from poisoning in children. During the three years 1950-2, 21 children lost their lives in this manner. In the United States of America in 1952 there were 86 deaths from this cause in children under the age of 5 years (Committee on Toxicology, American Academy of Pediatrics, 1955). Many such cases are the result of accidental ingestion of the drug. In the experience of Heymann *et al.* (1954), however, the danger of intoxication following therapeutic administration of the drug is much greater. Holt (1954) has shown that the dose of salicylate administered does not bear a constant relationship to the resulting blood level and, furthermore, that the blood level at which toxic symptoms appear varies greatly from patient to patient.

Various therapeutic measures have been recommended for the condition, but there appears to be no previous report of the use of intermittent positive pressure respiration. This paper is presented in order to show that this procedure may have an important place in the treatment of salicylate intoxication.

Symptoms

Among the more common and important symptoms of salicylism is hyperventilation. Graham and Parker (1948) have shown that this is due to reflex stimulation of the central respiratory mechanism through the afferent fibres of the vagus nerve, and is independent of the blood acid-base relationship. As the reaction of the blood, however, depends to a large extent on the proportion of bicarbonate to carbonic acid in the plasma, the rapid elimination of carbon dioxide which occurs in hyperventilation quickly causes a state of respiratory alkalosis. This is the first disturbance of the acid-base equilibrium that occurs in salicylism. Thus the hyperventilation is the cause of the acid-base disturbance and not vice versa. Singer (1954) has shown that later, probably owing to the accumulation of unidentified organic acids, a true metabolic acidosis may supervene. The gross hyperactivity of the respiratory musculature may play a part in this. Hyperpnoea may also be a factor in the production of various other phenomena occurring in salicylism, including tachycardia, and a reduction of the cerebral blood flow (Kety and Schmidt, 1946).

As stated above, the hyperventilation is responsible for the state of alkalosis, and this in turn may be clinically manifest as tetany. This is believed to occur independently of the level of diffusible calcium in the blood (Wright, 1952), and is, in our experience, not affected by the administration of calcium gluconate.

Treatment

Apart from immediate withdrawal of the drug and washing out of the stomach, treatment has usually been directed towards the correction of the biochemical changes when these have become established. Most authorities (Williams and Panting, 1937; Barnett *et al.*, 1942; Heymann *et al.*, 1954) have recommended the use of appropriate intravenous infusions. The difficulty and uncertainty of such therapy, however, have led Heymann *et al.* (1954) and Done and Otterness (1956) to use exchange transfusion, and Doolan *et al.* (1951) have gone so far as to recommend the use of the artificial kidney.

In view of the fact that the electrolyte disturbances are secondary to the hyperpnoea, it would appear more rational to direct therapy towards a reduction of the respiratory exchange and of the hyperactivity of the respiratory musculature. One obvious means of obtaining this end is the use of drugs known to have a depressant effect on the central respiratory mechanism. In their experimental studies, Rapoport and Guest (1945) were able to limit the hyperpnoea and the secondary biochemical changes with barbiturates and opiates. They found, however, that salicylates appeared to sensitize their animals to the action of these drugs, and that their administration in doses normally well tolerated resulted in prolonged coma or in death. This would seem to preclude the use of such drugs in salicylism.

In order to limit the output of carbon dioxide, Harvie and Singer (1955) proposed that the patient be made to breathe a gas mixture with a high carbon dioxide content. Obviously in a patient with an active central respiratory mechanism this raises the blood carbon dioxide tension only when the patient is already ventilating at his maximum breathing capacity, or when carbon dioxide is administered in such high concentrations as to produce depression of the central nervous system. Our experiences, described below, illustrate the limitations of this therapeutic measure, in that any reduction of tetany occurs only at the expense of accentuated respiratory dysfunction. These limitations led us to consider the value of neuromuscular block in overcoming the respiratory and biochemical effects of salicylate poisoning.

Therefore, when we were presented with a case in which a child, as the result of salicylate poisoning, was comatose, hyperpnoeic, suffering from tetany, and clearly *in extremis*, this method of treatment was applied and its value is shown by the following case report.

Case History

A 6-year-old boy complained of sore throat early in January, 1956. One week later he developed painful swellings of both knees, and a patchy erythema with well-defined margins was noted on the upper parts of both arms and on the thighs. He was thought to be suffering from rheumatic fever, and sodium salicylate, $7\frac{1}{2}$ gr. (0.5 g.) was prescribed, to be given two-hourly, the total daily dose being 75 gr. (5 g.). He was not given any alkali. This was taken regularly up to the time of his admission to Alder Hey Children's Hospital 11 days later, on January 20. On the day preceding admission he had become a little drowsy and seemed somewhat irrational. That evening he vomited once and had two nose bleeds. The following afternoon his respiratory rate increased and he was admitted the same evening.

On admission he weighed only 35 lb. (15.9 kg.); he had thus received a little over 2 gr. of salicylate per pound (280 mg. per kg.) body weight per day for 11 days. He was conscious and co-operative and did not appear to be particularly ill, although his respiration was somewhat increased

in both amplitude and rate (50 a minute). The temperature was 97.8° F. (36.5° C.) and his pulse rate 148 a minute. There was no evidence of carditis or of any other manifestation of rheumatic fever.

He was given 10 mg. of vitamin K intramuscularly in view of the epistaxis and known capacity of salicylate to induce hypoprothrombinaemia. Drinks of orange juice with added sodium bicarbonate were offered and he was kept under observation overnight. No marked change was noticed during the night, but the next morning, January 21, it became obvious that he was deteriorating. He became deeply unconscious and began to sweat profusely. Muscular tetany then appeared; there was spasmodic arching of the back accompanied by marked stiffness of the limbs, the arms being extended at the elbows, the forearms pronated, the wrists flexed, the fingers flexed at the proximal interphalangeal joints, and the thumbs adducted; the hips and knees were extended and the feet plantar-flexed; the jaw was tightly clenched.

At this stage a report was received showing that the blood salicylate concentration of the previous evening had reached the extraordinarily high level of 66 mg./100 ml. Blood taken at 9.30 a.m. on January 21 showed the level of salicylate to have fallen to 40 mg./100 ml. while the alkali reserve was 30.9 vols./100 ml. (13.8 mEq/l.); serum chlorides, 529 mg./100 ml. (90.3 mEq/l.); blood urea, 36 mg./100 ml.; serum protein, 6.8 g./100 ml. (16.3 mEq/l.); serum potassium, 13.1 mg./100 ml. (3.3 mEq/l.); serum calcium, 9.3 mg./100 ml. (4.6 mEq/l.); serum calcium ions, 4.2 mg./100 ml. (2.1 mEq/l.); unfortunately neither serum pH nor carbon dioxide tension was estimated.

Despite the falling plasma salicylate concentration the patient's clinical condition continued to worsen during the day. Therapy at this stage consisted of an intravenous infusion of N/5 sodium chloride with 5% dextrose, given at the rate of 30 ml. an hour, and a gastric milk drip, containing 50 g. of glucose to the pint, at the rate of 1 pint (570 ml.) in 24 hours. Alkalinizing solutions were not used at this stage because the patient was still tetanic and therefore presumably still alkalotic. Intravenous injections of 0.3 g. and 0.4 g. of calcium gluconate failed to affect the tetany.

By 7 p.m. he was still comatose, tetanic spasm was almost constantly present, the temperature had risen to 102° F. (38.9° C.), and the respirations had increased to 70 a minute and were extremely deep.

In view of the gross clinical tetany, presumably due to respiratory alkalosis, it was decided to try to conserve and increase the patient's serum carbon dioxide concentration. Initially an attempt was made to encourage rebreathing through a length of corrugated rubber tubing, and after several minutes there was a slight fall in the respiratory rate and slight lessening of limb rigidity, but no notable beneficial effect. With a mixture of 5% carbon dioxide in oxygen the respiratory rate again fell somewhat after several minutes, but the respiratory effort was still very great. The respiratory rhythm changed, his expirations becoming more forceful. Within four minutes the limb rigidity had diminished until the arms were quite flaccid and convulsive spasms became infrequent. After 20 minutes, however, the limbs again became rigid and the spasms increased. The raising of the concentration of carbon dioxide to 10% produced a similar transient effect. Despite these manoeuvres respiration remained violent and exhausting and the severe tetany recurred.

Neuromuscular Block and Control of Respiration

It was then decided to try to reduce the respiratory excursion and effort by neuromuscular block. Five milligrams of suxamethonium was injected intravenously. The respiratory excursion diminished greatly and a "see-saw" type of rhythm developed, there being no change in respiratory rate. Two further injections of 5 mg. were given at intervals of five minutes. With these the respiratory excursion diminished until ventilation became quite ineffec-

tive. Despite this, however, the trismus persisted and difficulty was experienced in maintaining an airway. It was apparent that incomplete myoneural blockade would not be effective as a means of controlling hyperventilation. Therefore, at 11 p.m. on January 21, 27 hours after the patient's admission to hospital, the decision was taken to curarize the patient fully and to control his respiration.

The head was lowered and 10 mg. of D-tubocurarine was injected intravenously, while the patient was made to breathe oxygen. As the jaw relaxed accumulated secretions were aspirated from the pharynx. A No. 3 uncuffed McGill endotracheal tube was inserted and copious yellowish mucoid secretion aspirated from the trachea and bronchi. The tube was then connected to an Ayre T-piece and controlled intermittent positive-pressure respiration was instituted, with 3 litres a minute each of oxygen and nitrous oxide.

Progress

With this treatment sweating soon ceased, his pulse rate fell from 140 to 100 beats a minute and the temperature from 101 to 99.4° F. (38.3 to 37.4° C.). The patient was carefully observed and 3 to 6 mg. of D-tubocurarine was given intravenously at intervals as required, a total of 36 mg. being administered within the next 12 hours. One and a half hours after the last dose of D-tubocurarine artificial respiration was discontinued and the endotracheal tube was removed. A bronchoscope was passed and bronchial secretions were aspirated. He was then placed in an oxygen tent.

Soon after the cessation of intermittent positive-pressure respiration the patient's breathing was normal in rhythm and depth and settled at a rate of 24 a minute. His pulse was 110 a minute and the temperature had fallen to normal. His coma, however, persisted and the tone of his limbs was still slightly increased, but there were no further tetanic spasms. On examination of his eyes it was noticed that the arteries in the left fundus were constricted.

At this time (10 a.m. on January 22) his blood salicylate level was 29.5 mg./100 ml. Other values were as follows: alkali reserve, 32.8 vols./100 ml. (14.8 mEq/l.); serum chloride, 542 mg./100 ml. (92.4 mEq/l.); serum potassium, 10.2 mg./100 ml. (2.5 mEq/l.); serum sodium 310 mg./100 ml. (134 mEq/l.); blood urea, 39 mg./100 ml.; serum protein 7 g./100 ml. (16.8 mEq/l.); blood sugar, 120 mg./100 ml.

At 11.30 a.m. his intravenous infusion was changed from N/5 saline to 1/6 molar lactate, as at this stage he was thought to have entered the phase of metabolic acidosis. He was given a total of 300 ml. in the space of 10 hours. His gastric drip was continued at the rate of 1 pint (570 ml.) per 24 hours, and 2 g. of potassium was added to it in order to correct the deficiency of this electrolyte.

At 7 p.m. on that day his alkali reserve had risen to 53.8 vols./100 ml. (24 mEq/l.); his serum salicylate level was 24 mg./100 ml. Other blood levels estimated at this time were: serum chloride, 538 mg./100 ml. (93 mEq/l.); serum sodium, 326 mg./100 ml. (142 mEq/l.); serum potassium, 10.5 mg./100 ml. (2.64 mEq/l.); red-cell sodium, 64 mg./100 ml. (28 mEq/l.) (normal 36–58 mg./100 ml., 15.7–25.3 mEq/l.); red-cell potassium, 330 mg./100 ml. (84.6 mEq/l.) (normal 358–390 mg./100 ml., 98.1–100 mEq/l.).

On the following morning, January 23, 24 hours after the end of controlled respiration, consciousness returned, though he was still very listless and drowsy. His temperature had remained normal; his pulse rate was 100 a minute and his respirations 30 a minute. By then his blood salicylate level had fallen to less than 5 mg./100 ml.; serum chlorides were 542 mg./100 ml. (93 mEq/l.); serum potassium, 11.6 mg./100 ml. (2.9 mEq/l.); and alkali reserve 55.7 vols./100 ml. (25 mEq/l.). Thereafter he rapidly improved, and he was discharged home eight days after admission, having made a complete recovery from his salicylate intoxication. Clinically and radiologically his lungs were normal. The mixture of salicylate which he had been taking was analysed and found to contain the prescribed dose of the drug.

Comment

Apart from the successful control of hyperpnoea, the following points in the above case history are considered to be significant.

At the time when intermittent positive-pressure respiration was instituted copious mucopus was present in the trachea. With our form of treatment, however, tracheo-bronchial toilet could be performed with ease, and bronchial aspiration was prevented. Thus one of the major hazards of coma was eliminated. Another advantage was that intragastric feeding could be continued in safety.

Following the institution of our form of treatment, the raised temperature and pulse rate moved rapidly towards normal, suggesting that they were caused by the heightened respiratory muscular activity.

The response of this boy to the inhalation of carbon dioxide shows that it has no place in the treatment of salicylate intoxication.

Tetany in our patient was a manifestation of alkalosis, and was not related to the level of ionized calcium in the blood, as this was within normal limits. It is therefore not surprising that the administration of calcium gluconate had no beneficial effect.

Summary

Salicylate intoxication causes an appreciable number of deaths among children. Gross hyperpnoea is one of the more serious toxic effects of salicylate poisoning; it is caused by reflex stimulation of the respiratory centre through the afferent fibres of the vagus nerves. The hyperpnoea gives rise to respiratory alkalosis and this may be accompanied by tetany and convulsions.

A case is described in which the hyperpnoea of salicylate poisoning was treated successfully by neuromuscular block and manually controlled intermittent positive-pressure respiration. It is believed that this method of treatment contributed materially to the patient's recovery. In addition, the administration of intravenous fluids is essential in order to conserve the body's water balance; milk can be given by gastric drip with impunity, as aspiration of fluid is prevented by a cuffed endotracheal tube.

The inhalation of carbon dioxide and the administration of calcium gluconate were not found to be effective therapeutic measures.

We are indebted to Dr. R. W. Brookfield for permission to treat and publish this case; we thank him and Professor Norman B. Capon for their advice in the preparation of this paper. We are also grateful to Mr. J. T. Ireland for the biochemical estimations; and to Dr. K. M. MacWilliam, the resident students, and Sister Ismay and her staff for their part in the management of this patient.

USE OF HYPOTHERMIA IN NON-VASCULAR INTRACRANIAL TUMOURS

BY

J. McNAUGHT INGLIS, M.B., F.F.A.R.C.S., D.A.

Anaesthetist, Queen Elizabeth Hospital, Birmingham

AND

ERIC TURNER, F.R.C.S.

Neurosurgeon, Queen Elizabeth Hospital, Birmingham

During recent years the value of hypothermia as an aid to certain types of surgery has become established. In cardiac surgery when temporary occlusion of one or more of the great vessels is required, and in cerebral surgery when the main arteries supplying vital structures are occluded, or when a period of prolonged induced hypotension is desired, hypothermia has been found to be of undisputed value (Lougheed *et al.*, 1955; Botterell *et al.*, 1956).

One mechanism by which reduced body temperature safeguards vital organs is known to be that of metabolic depression with resulting reduced vulnerability to anoxia, and where arterial occlusion is practised this mechanism is clearly the prime one (Ralston *et al.*, 1955; Rosomoff, 1956). Where no deliberately induced ischaemia of this type is involved, however, hypothermia would still appear to have certain benefits, the exact mechanism of which is less clearly understood, although the basic theory of reduction of susceptibility to anoxia is still no doubt a major consideration (Lundberg *et al.*, 1956).

The use of hypothermia in the management of head injuries has had recent publicity and is an example of this "non-vascular" indication for a lowered body temperature. We have recently gained the impression that reduction of temperature is also of value when operative procedures involving the hypothalamus, diencephalon, and brain stem are contemplated, even though neither carotid occlusion nor prolonged hypotension is to be employed as part of the technique. Operative intervention in the brain-stem region is known to carry a high post-operative mortality, and the reasons for such deaths are not always clear. It is suggested that the commonly seen post-operative coma and hyperpyrexia are due, in part at least, to tissue-swelling resulting from trauma with consequent cellular damage, in which case it is probable that anoxia plays a not unimportant part. Indeed, such anoxia might conceivably result from operative retraction itself, as the arteries supplying the midline structures are often end arteries. It is not at all unknown for an actual thrombosis of the lenticulostriate artery to occur on one or other side during the course of such an operation.

Whatever the causes of such injury may be, however, whether they be anoxia or indirect or direct trauma, we have come to the opinion that hypothermia protects cells of the brain stem and diencephalon during operative procedures.

This is obviously a point which would require statistical proof, and such will not be possible until large numbers of cases are available; even then advances in other directions render a control series almost impossible. No further comment can therefore be made than to say that it is now our routine to use hypothermia in all cases

where operations on the brain stem are required, and that we have been favourably impressed with results. It has been our opinion that cases so managed have had fewer post-operative complications in the form of prolonged unconsciousness and hyperpyrexia. Some patients have survived who would, we think, have died without the method. The introduction of hypothermia has been the only change in method that we have made in the period in question.

Method

The hypothermia in this series has been induced by surface cooling, using the Birmingham hypothermia unit previously described (Inglis *et al.*, 1954). Briefly this unit consists of a pair of tubulated blankets through which refrigerated ethylene glycol is circulated by means of a pump. The temperature of the glycol can be predetermined and the patient can be rewarmed as soon as the vital operative period is over. Anaesthesia has been in all cases by means of nitrous oxide and oxygen with intravenous thiopentone and pethidine, while chlorpromazine has been used to facilitate the fall in temperature. Corticotrophin or cortisone has been employed as a routine, so maintaining a standard management for all such cases operated upon in the past five years.

Two cases of craniopharyngioma are described. They were two consecutive examples of the condition; both had a large craniopharyngioma completely removed under hypothermia, with survival. They serve as examples to show our present favourable impression, and to encourage others to try a method which may help in a rather difficult surgical field.

Case 1

A boy aged 5 was admitted in July, 1956. Three months previously a change in his personality had been noted—from a quiet, placid child he had become excitable, careless, dirty in his habits, and rather irritable. A month before admission he had begun to complain of headaches, and from that time to his admission he had occasional morning vomiting, with increasing apathy, which gradually progressed to drowsiness and finally to stupor. On examination he was found to be lightly stuporous. He could be roused temporarily to co-operate in examination, and it was then found he had an increase of tone with some spasticity in all four limbs and a frank left hemiparesis. Both plantars were abnormal, the left being more frankly extensor than the right. There was bilateral ptosis and the pupils reacted sluggishly to light, the right one being slightly larger than the left. No papilloedema was present.

FIG. 1.—Ventriculogram of Case 1 showing elevation of the floor of the third ventricle.

A ventriculogram showed gross elevation of the floor of the third ventricle by a mass protruding into it from the suprasellar position (Fig. 1). At operation under hypothermia to 29° C. a right frontal craniotomy was performed and the frontal lobe was elevated until the right optic nerve was seen. Medial to it a mass protruded forwards between the two optic nerves. This mass proved to be partially cystic, and 30 ml. of golden glistening fluid was aspirated. The base of the cyst was firmly fixed to the suprasellar region, but the superior wall was gently coaxed downwards and pulled off the hypothalamus by gentle blunt dissection and removed through the aperture below the chiasma. The solid portion of the tumour was now thoroughly scraped off the dura, and the diaphragma sellae and any vestiges of tissue in this situation were thoroughly treated with diathermy. The operation was completed and the patient was then gradually rewarmed to 36° C. over the course of four hours, when consciousness returned. Although he was drowsy for a few days, his post-operative progress was extremely smooth. From the day of operation he received corticotrophin in physiological doses; this was gradually changed to cortisone.

A fortnight after the operation he was shown to have a progressive anaemia. A blood transfusion was given and thyroid was added to the hormone medication. At this stage he made a dramatic improvement, and from being drowsy, somewhat spastic, tremulous, and rather irritable, he became in the course of a few days a normal boy for his age—intelligent, co-operative, with only a mild bilateral ptosis to be remarked upon in his general appearance. Histology had confirmed that the cyst was lined with squamous epithelium overlying collagenous fibrous tissue. In a few places the lining consisted of lipogranulomatous tissue infiltrated with chronic inflammatory cells. The solid nodule was composed of squamous epithelium. The appearances were those of a craniopharyngioma.

During the post-operative period there had been a fairly brisk diuresis to about two to three times the normal, with a corresponding increase in thirst; no special measures had to be employed to counteract this mild diabetes insipidus. His further progress has been satisfactory, and he was instructed to go back to school in October, as he did not require further hormonal treatment.

Case 2

A boy aged 15 was admitted in September, 1956, because of progressive and latterly alarming impairment of vision. In the month before his admission visual acuity fell from 6/9 to 6/60; he was obviously in great danger of losing his sight.

On examination he was obese, with small extremities and markedly tapering fingers, and the genitalia were

FIG. 2.—Ventriculogram of Case 2 showing upward displacement of the third ventricle.

IMMUNITY TO DIPHTHERIA EVALUATION OF SCHICK TEST AS A PRELIMINARY TO IMMUNIZATION

BY

MOLLIE BARR, M.Sc., A.R.I.C.

Head of the Department of Immunology, Wellcome Research Laboratories

W. P. STAMM, F.R.C.P., D.C.P., D.T.M.&H.
Group Captain, Royal Air Force; Principal Specialist in Pathology

AND

P. J. STEVENS, M.B., Ch.B., D.C.P.

Squadron Leader, Royal Air Force; Pathologist

An investigation was carried out to determine the immunity to diphtheria of R.A.F. recruits, to assess the value of Schick-testing as a routine Service procedure, and to correlate the results of Schick tests with circulating antitoxin titres.

A total of 991 recruits from five recruit centres were Schick-tested in a survey which took place in March and April, 1956. Nearly all the men were 17½ to 18½ years old and belonged to the 5–6 years age group in 1943, when most children were immunized against diphtheria by local authorities. There was no geographical selection of the recruits at the different centres, though some selection by trade. It is just possible, therefore, that there may have been a slight social selection at the different centres. It is felt that the group as a whole was a reasonable cross-section of the young men of this country. Each volunteer had 5 ml. of blood taken by venepuncture and then a Schick test. All the Schick tests were performed and read by one person (P. J. S.).

The Schick Test

The materials used were Schick test toxin and Schick control fluid (a heated diluted toxin) prepared by Evans Medical Supplies, Limited. The dose of each was 0.2 ml., and this was administered intradermally, the test dose being put into the anterior aspect of the right forearm and control into the left. The Schick tests were read after 48–72 hours (first reading) and on the fifth, sixth, or seventh day (second reading). On each occasion the reactions to both test and control were recorded in the following way: 0=no visible reaction at all or merely a tiny red spot of 1–2 mm. marking the needle puncture. 1=a faint flush, barely discernible up to 15 mm. diameter. 2=a more definite flush

TABLE I.—Interpretation of First Schick Reading

Test	Control	Result
0	0	Negative (—)
1 or 2	0	Weak positive (w+)
3 or more	0	Positive (+)
1 or more	1 or more	Pseudonegative (ps—)
(both reactions equal)		
2 or more	1 or more	Pseudopositive (ps+)
(test reaction greater than control)

Summary

A preliminary note is put forward to suggest an extension of the value of hypothermia in neurosurgical cases. In addition to the accepted advantages of lowered metabolism when arterial occlusion or prolonged hypotension is employed, there would appear to be a *prima facie* case for reducing the patient's body temperature when operations on the brain stem or diencephalon are contemplated.

Two consecutive cases are described of large craniopharyngioma completely removed; they illustrate the smooth post-operative course to be expected in operations under hypothermia.

We are indebted to Dr. Gilbert Hall, under whose care the second case was admitted, and to Mr. W. H. Biffen for technical help with the hypothermia.

into which the fluid is injected cannot be guaranteed in the absence of great care and special training (Palmer and Edwards, 1953; Guld and Rud, 1953).

On the basis of the first reading a recruit was assessed according to Table I. Each recruit was similarly assessed at the second reading and then given a final reading of Schick status according to Table II. It will be noted that by this method of final assessment the first reading is ignored except for identification of pseudoreactors. The justification for this is discussed below.

Antitoxin Estimations

Diphtheria antitoxin titres were estimated at the Wellcome Research Laboratories by a modification of the Römer and

but less than 10 mm. or a faint flush over 15 mm. 3=a very definite erythema of 10 mm. or over, with or without some induration, brown pigmentation, or desquamation. 4=3 but larger.

It should be emphasized that the grading was a fairly quick assessment made in about 5 to 10 seconds. The exact size of reactions was not accurately measured. It was considered unnecessary to do so, since a reaction just less than the arbitrary minimum size usually required for a positive was noted as a grade 1 or 2 reaction and so not lost as a negative. Further, to attempt an exact measurement of such a reaction seems a waste of time and is apt to give results a false appearance of scientific accuracy, since the constant factors involved in the test are themselves inevitably inaccurate—for example, the size of the inoculum cannot be measured very accurately and the exact layer of dermis

immunization campaign, as judged by the immunization returns of local authorities, was in 1943, and by 1945 there was a considerable falling off in its intensity. It is generally agreed that in recent years, for various reasons, there has been a marked decrease in the numbers immunized (Gray and Cartwright, 1952). Figures are given in the *Medical Officer*

The results, which show a Schick-positive rate of 28%, excluding pseudoreactors, seem to confirm this, particularly when it is remembered that this figure includes weak positives (20% of the total positives).

Goldsworthy and Wilson (1943) reviewed the literature up to 1942 and found Schick-positive rates varying between 30 and 80%, the majority being 50 to 60%. These surveys were almost all on young adults. Their own survey gave figures of 46% Schick-positive and was made on 335 young adults who had no history of either diphtheria or immunization. It is not stated what definition of a positive reaction was used. Cheever (1948) found an average of 34% Schick-positives among 18,000 U.S. naval recruits, but an analysis of these on a geographic basis indicated considerable differences between groups from different areas, ranging from 16 to 47%. Again, no details of the definition of a positive reaction were given. Thomas *et al.* (1940) found that 70% of university students from well-to-do families but only 36% of military youths from poor families were Schick-positive.

Liao (1954) recorded that among 3,000 U.S. military recruits in 1951 35% were Schick-positive (definition of positive was 10-mm. erythema with induration and negative was "no definite response"). Fraser (1952) tested 1,000 naval recruits aged 17-20 in this country, but gave no details of the definition of positive. He found 32% positive, 51% negative, and 17% pseudoreactors.

Antitoxin Titres and Immunity

The Schick level of circulating antitoxins has been variously regarded as being about 0.002 unit/ml. (Cameron, 1941), 0.004 unit/ml. (Greenberg and Roblin, 1949), and about 0.01 unit/ml. (Barr and Cunliffe, 1954). The workers quoted were not all using the same

(1946a, 1946b) for the percentages of children under 15 immunized during the years to 1945, and these vary between 50% and 67%.

Our survey has therefore been made upon a group of young adults who are likely to have had as good an immunization history as any similar group in recent years or any we shall have in the next 15 years at least.

Schick-testing materials. Our series would appear to support a level at about 0.004 unit/ml., since from Table VII 90% of 231 Schick-positives had titres of less than 0.004 unit/ml. and 91% of 359 Schick-negatives had titres over 0.004 unit/ml. Therefore if it is of value to divide a group of people into those who probably have less than 0.004 unit/ml. and those who probably have more than 0.004 unit/ml.

ml., then the Schick test with the material used is a good one.

The value of a test giving the dividing line at as low a level as 0.004 unit/ml. has been discussed by Barr and Glenny (1951), and they gave it as their opinion "that before artificial immunization became general, when the population relied upon natural infection to stimulate immunity, the great majority of Schick-negative persons had high titres of antitoxin and most Schick-positives had none." A test, therefore, with a dividing line at 0.004 unit/ml. was quite satisfactory. They had found during recent years many people with antitoxin titres just around the Schick level, and to-day, therefore, Schick-negative reactors may nevertheless have titres the adequacy of which is doubtful.

The Chart indicates that our results agree with Barr and Glenny's findings. There are two peaks, and one is around the Schick level. Barr and Glenny were strongly of the opinion that a good level of circulating antitoxin as well as a good immunity were necessary for complete protection against diphtheria, and Barr and Cunliffe (1954) assumed that those with less than 0.01 unit/ml. were in need of boosting. Marshall (1950) discussed these points and suggested that the strength of the Schick-test toxin might be altered with advantage to give a positive reaction at a rather higher level.

Hartley *et al.* (1950) concluded, as a result of a study of outbreaks of diphtheria in two areas of Great Britain and its occurrence in non-inoculated and inoculated persons, that the incidence, mortality, frequency, and severity of complications bore a striking relationship to previous inoculation and to circulating antitoxin, though the correlation was not complete. They considered that unless "the proportion of the immunized population is kept up to the 75% level, protection against epidemic diphtheria cannot be reasonably assured," and they showed that clinical diphtheria could occur in those with as much as 0.02 unit/ml. of circulating antitoxin. Fanning (1947) described an outbreak in a community of children in which there was a 94% history of immunization and an 80% Schick-negative rate.

It is possible that a level of immunity such as we have found in R.A.F. recruits is adequate to prevent any major outbreak of diphtheria in this country, where the disease is now rare, but it must be remembered that our sample probably represents the peak of achievement of the immunization campaign. Furthermore, many overseas areas have a high diphtheria rate among the civilian population, and we believe it is important for the armed Forces to maintain immunity at a much higher level as a necessary part of their preparation for service anywhere in the world.

While use of test toxin at the present strength followed by immunization of positive reactors will leave some individuals imperfectly protected, our figures suggest that this practice will adequately increase the level of immunity to prevent epidemics. If it is assumed that immunization will raise the antitoxin level above 0.02 unit/ml., then after immunization of all Schick-positives, excluding pseudoreactors, only 55 (28%) of the 193 recruits at Centre 1 (Table VI) would have remained with less than 0.02 unit/ml., 6% with less than 0.004 unit/ml., and only 3 (1½%) with no circulating antitoxin. If in addition one takes into account the probability that the Schick test itself would stimulate a number of the 55 whose antitoxin titres were just less than 0.02 unit/ml. to produce more antitoxin (Barr and Parish, 1950), then probably approximately 80% of the recruits would be left with high titres (over 0.02 unit/ml.) and only 2 or 3% would be left without detectable antitoxin.

Weak-positive Reactors

It is important not to neglect the weak-positive reactions—that is, those we scored as 1 or 2. In our study of 53 weak-positive reactors—that is, first reading w+, second reading w+, or first reading —, second reading w+, 39 (74%) had less than 0.004 unit/ml., and from Table IV it will be seen that weak-positive reactors are 20% of our total positives. We strongly recommend that, with the reagents we used, the usual practice of defining a positive reaction as one at

least 10 mm. in diameter should be discontinued and that any flush extending beyond the needle puncture should be recorded as positive.

Comparison of First and Second Readings

Examination of Table VII shows that the second reading is a much more reliable index of immunity than the first. Of 41 who were negative at the first reading and positive or weak positive at the second, 34 (83%) had titres less than 0.004 unit/ml., whereas of 23 who were positive or weak positive at the first reading and negative at the second, only 5 (22%) had titres less than 0.004 unit/ml. We consider that these results justify the exclusive use of the second reading for the assessment of the Schick test apart from the recognition of pseudoreactors.

Pseudoreactors

It is well recognized that immunization of adults with the various preparations in current use is attended by undesirable reactions in a considerable proportion of cases and that a preliminary screening for sensitive subjects should be made by Schick-testing (Cockburn, 1947; Scheibel *et al.*, 1948; and many others). A study of the antitoxin titres of those recruits giving various pseudoreactions indicates that 70% of those showing a pseudopositive reaction at one or both readings and 79% of those showing pseudonegative reaction at one or both readings, were highly immune—that is, more than 0.02 unit/ml. There seems little point, therefore, in distinguishing between pseudopositive and pseudonegative.

It is true that consideration of both Schick readings may indicate pseudoreactors who have low titres of antitoxin. Those who were pseudopositive on each occasion and those showing a positive pseudoreaction followed by a strong positive all had low titres. That this is generally so is well recognized (Parish, 1954). In addition, there was a suggestion from our results that a pseudonegative of grade 3 or 4 at the second reading is associated with low antitoxin titres. There were four such cases in our series and all had low antitoxin titres (three were less than 0.001 unit/ml. and one between 0.001 and 0.002 unit/ml.). Though these points are of interest, they have little practical importance. The numbers are too few to worry about with regard to herd immunity, and in the event of an epidemic such people would be given a temporary passive immunity with antitoxin.

The possibility of inducing adequate immunity by minimal doses of antigen, insufficient to cause reactions even in sensitive subjects, is to be the subject of further work and a subsequent report. In the meantime we think that when concerned with herd immunity it is best to withhold immunization from all pseudoreactors. Here lies the importance of the first reading. Omission of the first reading would have missed 65 of the 102 pseudoreactors, and 11 of these would have been immunized, since they had become uncomplicated positive reactors at the second reading. Any administrative objection to conducting two readings should therefore be firmly opposed.

Summary

A total of 991 R.A.F. recruits were Schick-tested, and on 699 of them estimations of circulating diphtheria antitoxin were performed.

The comparatively low rate of Schick-positives (28%, comprising 22% "classical" positives and 6% weak positives) was in keeping with the fact that these recruits were schoolchildren when the diphtheria immunization of schoolchildren was at its height.

An analysis suggests that the herd immunity was below the desirable level for Service men, though possibly adequate for residents in this country.

Weak-positive reactions should not be ignored, since 74% of these reactors had less than 0.004 unit/ml. of circulating antitoxin.

It is strongly recommended that, with the reagents we used, any flush extending beyond the needle puncture should be recorded as positive.

To increase herd immunity only Schick-positives should be immunized, all pseudoreactors being treated as immune.

The second reading of Schick tests showed a closer correlation with the level of circulating antitoxin than the first, but the first must not be omitted owing to the danger of missing pseudoreactors.

It is possible, though of little practical value, to detect many of the pseudoreactors who have low antitoxin titres.

Our thanks are due to Air Commodore J. Hill, principal medical officer, Home Command, and the senior medical officers and station sick-quarters staff of the recruit centres for their help and co-operation, and to the Director-General of Medical Services for permission to publish.

NEPHROTIC SYNDROME ASSOCIATED WITH RENAL VENOUS THROMBOSIS AND BRONCHIAL CARCINOMA

BY

J. de SWIET, M.D., M.R.C.P.
Consultant Physician, Llanelly Hospital

AND

A. L. WELLS, M.D., M.R.C.P.I., D.C.P.
Consultant Pathologist, Llanelly Hospital

The recognition of an association between long-standing renal venous thrombosis and persistent albuminuria has existed for over forty years (Rowntree *et al.*, 1913; Shattock, 1913). Blainey *et al.* (1954) describe three cases of the nephrotic syndrome, in one of which renal venous thrombosis was confirmed at necropsy. They point out that, while in many cases the aetiology of the syndrome is obscure, it may be caused by interference with venous return from the kidney. Most cases—for example, Derow *et al.* (1939), Moschowitz (1948), and Bell (1950)—have shown involvement of the inferior vena cava.

Thrombophlebitis (often of migratory type) has been known to be associated with malignant disease since

Trousseau (1877) drew attention to its occurrence in visceral carcinoma. Williams (1954) describes three cases of thrombophlebitis migrans associated with bronchial carcinoma, and points out that up to 1951 Gross *et al.* found only nine such cases so associated.

The following case presents an association of the nephrotic syndrome, renal venous thrombosis, and bronchial carcinoma. The inferior vena cava was not involved.

Case Report

A fireman aged 39 was admitted to hospital on December 28, 1954, with a history of dull backache for a fortnight, followed a week prior to admission by marked swelling of

FIG. 1.—Chest x-ray film taken on January 28, after aspiration of chylopleurothorax.

the legs and feet, and moderate swelling of the face, hands, and abdomen. There had been oliguria, headache, and tightness of the chest for a similar period. His previous medical history was limited to chronic dyspepsia of about eight years' duration. A barium-meal x-ray examination in 1949 had shown chronic gastritis. There was no significant family history.

On examination his general condition was fairly good, with slight pallor and slight puffiness of the face, and marked pitting oedema of the whole of both legs. He had moderate ascites and the liver was just palpable and tender, but the spleen was not felt. There was no cardiovascular abnormality and his B.P. was 140/90. There were signs of fluid at the base of the left lung.

The following investigations were carried out during the week immediately following admission. Urine: protein + + +, with numerous hyaline casts and a few pus and red cells, and sterile on culture. Blood urea, 90 mg. per 100 ml.; urea clearance, 4.5% normal; total plasma proteins, 4.4 g. per 100 ml. (albumin 3 g., globulin 1.4 g.). A/G ratio 2.14:1; blood cholesterol, 310 mg. per 100 ml. A blood count showed: Hb, 119%; W.B.C., 11,400 per c.mm. (neutrophil polymorphs 87%, eosinophils 1%, lymphocytes 9%, monocytes 3%); E.S.R., 11 mm. at one hour (Wintrobe); normal morphology of red and white cells. Serum sodium 139 mEq/l.; serum potassium, 6.1 mEq/l.; serum chlorides, 101 mEq/l. Blood W.R. and Kahn tests negative.

He was given 2 pints (1,140 ml.) of dextran intravenously on January 3, 1955, with no diuretic effect, but repetition of a similar transfusion on January 8 resulted in a diuresis of 76 oz. (2.16 litres). A further 2 pints (1,140 ml.) of plasma was given on January 11, but caused no diuretic effect. In spite of these transfusions his total plasma proteins

never exceeded 4.4 g./100 ml., and in fact fell to 3.3 g. on January 13, with albumin 2.2 g. and globulin 1.1 g. (A/G ratio 2:1).

A chest x-ray examination on January 24 showed the appearances of a left hydropneumothorax, with some consolidation in the right mid-zone next to the hilum. Aspiration of the left chest showed that the condition was a chylopleurorrhoea, milky opalescent fluid being withdrawn. The stained deposit showed polymorphs, eosinophils, and lymphocytes in approximately equal proportions and a few endothelial cells, and also strongly sudanophilic isotropic droplets. No pyogenic bacteria or acid-fast bacilli were seen and cultures were sterile. The total protein content was 600 mg. per 100 ml. and the pH 7. A chest x-ray film taken on January 28 (Fig. 1) showed an increase in size of the tumour shadow in the right lower zone.

The blood-urea level gradually rose to 284 mg. per 100 ml. on January 31, and the patient died on February 3 at 2 p.m.

Post-mortem Findings

Necropsy was performed 22 hours after death. The changes of most interest were seen in the lungs and kidneys. The hilar region of the right lung was the seat of a white, partly necrotic tumour 4 cm. in maximum dimension, blocking all three lobar branches. There were obstructive infective changes in the peripheral parts, mainly in the lower lobe. Lymphatic spread to the right hilar, tracheal, and upper abdominal lymph nodes had occurred. Neither tumour involvement of the thoracic duct nor a bronchial fistula could be demonstrated. Blood-borne secondary nodules were present in the liver and left adrenal. A small serofibrinous effusion was present in the left pleural cavity, not now demonstrably chyliform.

Further, many pulmonary arterial branches in both lungs contained partly organized thrombi, apparently embolic in type. There was a solitary recent infarct in the left lower lobe.

The kidneys weighed 140 g. each. The capsules stripped easily from smooth pale surfaces. On the cut surfaces there was marked pallor and swelling of the cortical zones. The medullary areas were slightly congested. The tributaries of each renal vein and each main vein contained partly organized thrombus, the medial extremities of which projected slightly into the lumen of the inferior vena cava. The latter channel contained only post-mortem thrombus. The renal arteries and the pelves and ureters were macroscopically normal.

Other findings included fat necrosis of the pancreas and a small active peptic ulcer in the pyloric antrum.

Histologically, the lung tumour was composed of large, somewhat anaplastic, undifferentiated epithelial cells with eosinophilic cytoplasm. The appearances suggested a squamous growth. The stroma was scanty, and foci of necrosis and mitotic figures were numerous. The liver and

FIG. 2.—Hilar region of left kidney (x20). Elastic van Gieson. Normal renal artery. Medium-sized vein almost completely filled with well-organized thrombus.

adrenal deposits showed a similar structure. Microscopical study of the kidneys showed that thrombi were confined to extrarenal venous channels. Small eccentrically placed fibrin thrombi, not occluding the lumen completely, were seen in venules between 400 and 700 μ in diameter. They were of some duration, being encapsulated and partially penetrated by argyrophilic fibrils springing from the endothelium. In larger vessels (1–2 mm. diameter) the lumen was more severely occluded and more advanced stages of organization were observed, with pronounced condensation of the fibrin (Fig. 2). In the large tributaries and main renal veins, both partially organized and recently formed thrombus material was present, extensively but not completely blocking the lumen.

The cortical zones showed separation of the tubules due to oedema and fine fibrosis. A few pyramidal subcapsular scars with lymphocytic infiltration were present. The glomeruli were slightly swollen. Occasional capillary loops contained small hyaline thrombi, and in others small foci of polymorphs were present. Slight thickening of capillary basement membrane could be demonstrated by the periodic-acid-Schiff technique. The tubular epithelium was generally atrophic. Many tubules contained highly proteinous casts. A few contained granular debris and purulent material. The pelvis showed mild chronic inflammatory changes.

Thrombi were not found in the body apart from those in the renal and pulmonary vessels.

Comment

The occurrence in combination of the lesions described above is of interest on the basis of its rarity alone, as we are not aware of the existence of similar published examples.

A dogmatic opinion cannot be given regarding which lesion came first in time, but the probability is that this is another example of malignant disease presenting as a thrombotic state. The observation of Wright (1952) is important—namely, that a diagnosis of malignancy must be considered when thrombophlebitis persists, or is migratory, despite adequate anticoagulant therapy in adults over 30; or when unexpected bleeding occurs in such patients whose prothrombin times are within the therapeutic range. Although the presence of metastasizing bronchial carcinoma in the present case rendered the final outlook hopeless from the beginning, other cases not induced by any form of malignancy might respond to anticoagulant treatment. Early recognition of the pathogenesis of the nephrotic syndrome in such cases would be essential, if serious impairment of renal functions were not to preclude successful control of such treatment. Renal biopsy would have been of no positive value in establishing the underlying pathogenesis in this case, since thrombi were confined to extrarenal veins, but it might have served to exclude other causes. Further information on the value of this investigation, and of renal venography, would seem desirable. Possibly the process, the blood urea level rising quickly. The picture, we feel, was thus one of a "nephrotic" patient passing unusually rapidly into an azotaemic state.

Summary

A case of the nephrotic syndrome is presented, in which the underlying aetiology was bilateral thrombosis of the renal veins, associated with, and probably attributable to, bronchial carcinoma.

ADDENDUM.—Since the submission of this article for publication, Harrison *et al.* (1956) have recorded 11 cases with radiological or necropsy evidence of renal vein thrombosis. They described in detail two methods of radiological diagnosis. One case is reported in which biopsy showed a carcinoma distal to the orifice of the right upper-lobe bronchus, and in which a subacute glomerulonephritis has been diagnosed for two and a half years. Biochemical changes were typical of the nephrotic syndrome. Inferior caval venography demonstrated blockage of the lower end

of the vena cava, but not the upper limit. There was no necropsy. A case with great similarity to our own has been reported by Brumfitt and O'Brien (1956).

We are indebted to Mr. J. P. Napper for the photographs.

INTRAHEPATIC CALCIFICATION

BY

ROBERT BRUCE, M.B., B.S.

Medical Registrar, General Hospital, Chester-le-Street,
Co. Durham

The finding of intrahepatic calcification on routine chest radiography is felt to be unusual enough to arouse interesting speculative discussion as regards aetiological factors. The following case is recorded in view of the relative rarity of the lesion, the absence of symptoms, and the associated diagnostic problem.

Case Report

A white man aged 37 attended for routine medical examination prior to re-enlistment in the Army. On questioning he was completely asymptomatic and admitted to no upset of any individual system. His appetite was good and his weight steady. In particular there were no symptoms referable to the gastro-intestinal system. He smoked 30 to 40 cigarettes a day and drank an average of 2 pints (1.1 litres) of beer a day.

His previous history revealed the following: B.T. malaria in 1943 while in Assam; treated with quinine; none since 1943. Amoebic dysentery and hepatitis in 1945, while in

Postero-anterior view of upper abdomen.

Assam; he was treated in hospital for one month and received two injections (? emetine) and made an uneventful recovery. He had never worked with dogs or other animals and had never been in Australia or abroad apart from Assam. He had no recollection of ever having jaundice save the attack in 1945, in Assam, and had never suffered from urticaria or skin rashes. The family and social histories revealed nothing relevant.

Clinical examination showed no abnormality in any of the systems; in particular there was nothing to suggest hepatic disease. A routine chest x-ray examination revealed multiple streaks of calcification under the right diaphragmatic leaf, these areas of calcification being arranged in an arcuate manner suggesting the wall of a cyst in the liver area.

A tentative diagnosis of a calcified cyst of uncertain aetiology in the right lobe of the liver was made and the following investigations were undertaken: haemoglobin, R.B.C., and E.S.R. normal; W.B.C., 5,400 (polymorphs 46%, lymphocytes 54%); W.R. and Kahn, negative; liver-function tests and serum protein values normal; M.S.U., normal; examination of stools for cysts, amoebae, ova, and pathogens, negative; Mantoux 1/1,000 positive; Cassoni test negative; complement-fixation test for hydatid disease was positive, titre 1:4.

X-ray examination of the upper abdomen, to show diaphragm and liver area, revealed a rounded calcified shadow about 3 in. (7.5 cm.) in diameter and clearly demarcated (see Fig.). Lateral views showed this to be situated in the posterior part of the right lobe of the liver. Screening added no further information, the lesion appearing solitary. There was no overlying deformity of the diaphragm, which moved equally on both sides, and the right lower zone of the lung fields was clear. Unfortunately it was not possible to perform tomography.

Discussion

Intrahepatic calcification is not common, and raises an interesting diagnostic problem. There are several possible explanations, although none is by any means common. Thus F. W. Konzelmann, in a series of 8,000 necropsies, detected hepatic calcification to any marked extent in only one case (Heilbrun and Klein, 1946).

Hydatid Disease.—This can often give rise to intrahepatic calcification, and is of two types. (a) Solitary, showing on radiography as a smooth, well-defined unilocular lesion, the calcium appearing as reticulated streaks or more solid areas throughout the cyst wall. (b) Alveolar hydatid disease (echinococcosis-bavaro-tyrolienne). This is far less well known, largely because of its fairly limited geographic distribution (South Germany, Switzerland, Czechoslovakia, Tyrol, and East Russia). Walshe (1954) reported what was probably the first case in Britain, occurring in a person who had never been abroad. Opinion is swinging towards the acceptance now that alveolar hydatid disease is due to the same parasite as the common hydatid lesion, the differing pathological process being due to the larval variant. This type of hydatid lesion is far commoner in the right lobe of the liver, and the original "mother" lesion does not encapsulate but evaginates, with the resulting formation of multiple minute cysts in the surrounding liver substance. Each lesion is surrounded by a zone of granulomatous reaction, and the lesion is progressive and of fatal outcome. Because of the progressive nature and its ill-defined limits, this form is not amenable to surgery. The reason for this "alveolar" form as distinct from the commoner hydatid lesion is thought to be its original failure to encapsulate, so allowing leakage of contents and infiltration into surrounding tissues. Spread may proceed via blood and lymphatic channels to any part of the body. In cases where calcification occurs, radiological appearances of the liver show multiple irregular calcified areas around the main original lesion.

Hepatic Abscess.—This may be of pyogenic origin, including subdiaphragmatic foci, or may follow on

amoebiasis. The appearances on radiography vary and may show single or multiple calcified areas, but rarely so clean-cut and regular as in cases of hydatid disease.

Gummatous Calcification.—This is rare, and shows as irregular area of calcification in association with stigmata of the disease process elsewhere.

Hepatic Cysts.—These are very rare, and it is uncommon for them to be calcified so as to be visible on radiography. They may be single or multiple, but are much smaller than the previously discussed lesions.

Haemangioma and Lymphangioma.—These may be large or small, single or multiple. There is often evidence of similar lesions elsewhere in the body; and those of the liver, when calcified, show as circumscribed areas in which fronds of calcium appear to radiate from a central point like the spokes of a wheel.

Calcified Tuberculosis.—This also is rare, and there is usually evidence of the disease process elsewhere. Radiologically it is revealed as a spherical shadow, dense in the centre, with a translucent surrounding zone or moat. Such lesions are usually small. Tiny multiple foci of calcification may appear in rare cases of "healed" miliary tuberculosis.

Primary Neoplasms of Liver.—These may occasionally show as irregularly calcified areas.

Secondary Deposits.—Occasionally metastases may calcify, but evidence elsewhere of the primary lesion points to the diagnosis.

Hepatic Calculi.—These are extremely rare and very minute. They may be multiple or single.

Other Causes.—Hodgkin's disease, chronic renal disease, diabetes mellitus, eclampsia, and disease with bony destruction have all been reported as giving rise to intrahepatic calcification on occasion, although in each case the appropriate diagnosis can be reached by concurrent signs of the disease elsewhere.

The case described is felt to be one of amoebic origin in view of the past history of amoebiasis and in the absence of evidence of venereological disease, reticulosis, neoplasm, tuberculosis, or hydatid disease. The size, shape, and configuration of the area of calcification do not conform with the typical appearances of haemangioma, and there was no evidence of such lesions elsewhere. The fact that the lesion was so large and solitary virtually rules out hepatic cysts and calculi. The finding of a positive hydatid complement-fixation test, titre 1:4, is not felt to be relevant in this case in view of the low titre, negative Cassoni test, and absence of any other evidence of hydatid disease. The complement-fixation test is said to give 83% reliable positive results in hydatid disease in which the embryo is alive. The case here recorded showed an apparently completely inert lesion of the liver, and, although it is appreciated that hydatid disease cannot be completely ruled out, on balance of available evidence calcification of an amoebic abscess appears the more likely.

Summary

A case of intrahepatic calcification thought to be subsequent to amoebiasis is reported.
The differential diagnosis is discussed briefly.

I thank Colonel J. D. P. MacPherson, O.C., B.M.H., Hamburg, for permission to publish this case, and R.A.M. College, Millbank, London, for the result of the hydatid complement-fixation test.

THE DELAYED-ACTION STAB

BY

HARRY M. WINDSOR, M.S., F.R.C.S.

Thoracic Surgeon, St. Vincent's Hospital, Sydney

The following cases are of interest if for no other reason than their medico-legal significance. The first two cases were seen in hospital practice, the third in private practice.

Case 1

It is customary for many Sydney housewives to leave on the doorstep the empty milk bottles and, beside them, payment for replacements. A youth in one of the northern suburbs was making quite a good thing out of this by doing rounds immediately prior to the milkman. One morning the milkman (aged 27) surprised him, and received for his intrusion a stab below the ninth left costochondral junction. He was admitted to a north-side hospital but was allowed to leave a few days later, when all, including chest x-ray film, was found to be normal.

One year later, on February 23, 1954, he was admitted to St. Vincent's Hospital under the care of Mr. Victor Kinsella. He complained of cramp-like epigastric pains of two days' duration. Upon admission the pain settled, but it recurred after 24 hours. X-ray examination of his chest revealed no abnormality. During the next week he had a number of similar attacks of pain.

An exploratory laparotomy was carried out on March 2. The greater curvature of the stomach, the splenic flexure, and a considerable quantity of omentum were found to have passed through a small opening in the diaphragm. They were adherent to the lung. After reduction of the viscera and closure of the diaphragmatic opening the patient made a good recovery.

Case 2

A native of Bogota aged 22 was involved in a fracas at a party in Surry Hills. He was stabbed in the left anterior axillary line between the eighth and ninth ribs. So far as could be ascertained the weapon was a pair of scissors. He was admitted to St. Vincent's Hospital on May 1, 1956. He complained of mild shoulder pain, but no significance was attached to this when it was found that his chest x-ray picture was normal. He was discharged on May 5.

Seven weeks later, on June 26, he presented at the casualty department complaining of pain in his left lower chest. His chest x-ray picture was again found to be normal and he was allowed to leave. He returned on June 29 complaining of vomiting and colicky pain in the left upper abdomen. A further chest x-ray film was taken. A number of small fluid levels could now be seen above the dome of the left diaphragm. A diagnosis of strangulated diaphragmatic hernia was made and left thoracotomy was performed at once.

Six inches (15 cm.) of transverse colon was found to have passed through an opening in the diaphragm $\frac{1}{2}$ in. (1.9 cm.) in diameter. They were adherent to lung and margins of diaphragmatic opening. The colon was reduced and the diaphragm repaired, following which the patient made a good recovery.

Case 3

Sheep crutching is largely carried out in the following manner. The sheep are herded into a yard, the operator arms himself with a pair of hand shears and takes up a position near the gate. With the shears held in the right hand he lunges at the back leg of the nearest animal, up-ends it, crutches it, and pushes it through the gate. He then successively repeats the manoeuvre until all have been treated.

A man aged 41 was doing this when he slipped, the shears penetrating his left lower chest below the ninth rib in the

mid-axillary line. After overcoming his initial surprise he went along and had two stitches inserted in the wound. Nothing further eventuated.

Seven months later, whilst on holiday in Sydney, he developed pains in the left upper abdomen and left chest. They were not particularly severe and allowed of a barium examination, which revealed large bowel in the left thoracic cavity.

A left thoracotomy was carried out on October 26, 1955. Transverse colon was found in the chest. It was densely adherent to the lung and margins of the opening in the diaphragm. This opening was not greater than $\frac{1}{2}$ in. (1.9 cm.) in diameter. The abdominal contents were replaced and the diaphragm was repaired. The patient made a good recovery.

Comment

These three cases have certain features in common. (1) The injury was relatively mild. (2) It was situated in the left lower thoracic region. (3) The suspicion of injury to the diaphragm did not arise at the time of the initial incident. (4) The x-ray picture of the chest following the initial injury in Cases 1 and 2 was quite normal. No evidence of pneumothorax or lung damage was to be seen. The history in Case 3 suggests that had an x-ray film of the chest been taken this would likewise have been normal. (5) The latent period. In the three cases, one year, two months, and seven months respectively elapsed between the original injury and the onset of intestinal obstruction. It is assumed that negative intrathoracic pressure and positive intra-abdominal pressure were the factors responsible for the gradual ascent of the bowel. (6) All cases did well following surgery. However, it is easy to imagine such cases having a fatal termination. The opening is small, the amount of bowel that can ascend is large, and irreversible damage to the bowel is quite likely. (7) The medico-legal aspects, combining as they do a minor injury, a latent period, and then a strangulated diaphragmatic hernia, are of obvious importance. It is felt that in each of these cases the opening in the diaphragm was due to trauma. In no case was it felt that the opening was of congenital nature.

Summary

Three cases of strangulated diaphragmatic hernia are presented. In each case the strangulation followed a latent period consequent upon an apparently trivial stab wound in the left lower chest. It is suggested that the question of thoracotomy should receive consideration following similar injuries.

Medical Memoranda

Posterior Dislocation of Shoulder-joint

This report is on a case of acute backward displacement of the head of the humerus, complicated by arterial and nerve involvement and followed by initial reduction to the sub-coracoid position. From all other sources it appears that this type of injury is unusual. Sir Astley Cooper (1842) recorded retroglenoid dislocation following a convulsion, while Malgaigne in 1855 made mention of 34 cases dating from 1804, only three of these being from his own practice. More recent reports add emphasis to the rarity of the injury. Thomas (1937) saw 4 cases in 6,000 and reports 3 other cases with which he was associated. Wood (1941) gives 3 cases in 115 from the Massachusetts General Hospital between 1930 and 1938. Hindenach (1947) reports one case, and Taylor and Wright (1952) six. McLaughlin (1952) finds a percentage of 3.8 amongst 581 dislocated shoulders, which corresponds with the 3 per 100 given by Fèvre and Mialaret (1938) from their series of cases.

CASE REPORT

A general labourer aged 48 was seen in the casualty department following an accident to his right arm. He had caught a large oxygen cylinder in the crook of the arm, and the sudden impact had forced the arm backwards. He was in intense pain, being unable to move the affected limb.

On examination his right arm was fixed in external rotation with 20 degrees of abduction; the shoulder sloped markedly downwards and was hollowed-out anteriorly. Palpation revealed an increased prominence of the acromion process, with a loss of the anterior prominence of the humeral head. Brachial, radial, and ulnar pulses were absent. Movement of the arm was completely lost, together with cutaneous sensation.

Radiographs showed that the head of the humerus was seated posteriorly to the glenoid fossa (see Fig.). No bony injury was evident.

Treatment was instituted immediately in order to restore the blood flow. Gentle traction was applied to the line of the abducted arm, some degree of adduction being given at the same time. A sudden internal rotation took place with a loud series of crepitations. It was then found that the humeral head had displaced forwards and was now in a subcoracoid position. There was relief from the agonizing pain immediately the posterior displacement had been rectified, while at the same time the blood supply was restored to the limb. The anterior dislocation was later reduced under general anaesthesia owing to the greatly increased degree of muscle spasm.

Subsequent treatment consisted in resting the shoulder by means of a sling for a period of three weeks. Hand and elbow exercises were started on the third day after the injury. When the three weeks had elapsed the patient was allowed to begin active shoulder movements with the proviso that he did nothing to produce pain in the affected shoulder and did not raise the arm above the line of the shoulder.

The follow-up proved uneventful. He began light work (painting and decorating) nine weeks after the accident, and by the twelfth week had progressed to heavier work, carrying out his normal duties using a pick and shovel. Seven months after the accident he had no complaints and stated that his shoulder gave no trouble whatsoever. On examination, movement was full, painless, and unrestricted. There were no crepitations, weakness, or disability. Whether the stability of the joint will be continued, and whether osteoarthritic changes will appear as the years go by, remain to be seen.

COMMENT

Taylor and Wright (1952) stated that the type of injury is generally the result of direct violence. This is confirmed from all sources. Hindenach (1947) reports the case of the injury done during physical training, while McLaughlin (1952) gives a number of cases associated with epilepsy, shock treatment, and strenuous sports. Congenital and developmental anomalies do not appear to figure prominently in the aetiology of the injury.

The prognosis is good except where the condition has remained untreated for any length of time. Of the 22 cases reported by McLaughlin, 6 first injuries which were diagnosed

Radiograph in the antero-posterior axis, showing the appearance of the humeral head in posterior dislocation.

soon after being incurred responded well, while the prognosis was poor in the 16 cases which had remained untreated for periods extending from weeks to years.

I wish to thank Mr. B. H. Burns, orthopaedic surgeon to St. George's Hospital, for permission to publish this paper.

Diabetes Mellitus with Acute Polyneuritis

A true symmetrical polyneuritis is rare in diabetes mellitus (Hirson, Feinmann, and Wade, 1953). In the following case a symmetrical polyneuritis developed rapidly in a patient with recently stabilized diabetes.

CASE REPORT

A bus conductor aged 60 was discovered to have mild diabetes in September, 1954. The presenting symptoms were pruritus and a mild urethritis of about six weeks' duration. There was no relevant past or family history. Examination showed no abnormality except for obesity (weight 12 st. 7½ lb.—79.6 kg.) and slight hypertension (B.P. 180/100 mm. Hg). The knee- and ankle-jerks were present and vibration sense was normal in the legs. The diagnosis was confirmed by a glucose-tolerance test. (Capillary blood sugars:—fasting, 141 mg.; at half-hour intervals after 50 g. of glucose by mouth: 290 mg., 232 mg., 219 mg., 175 mg. per 100 ml.) Treatment was started with a reducing diet containing 120 g. of carbohydrate daily. His symptoms were relieved and his diabetes was easily controlled without insulin.

On December 2 he was admitted to Addenbrooke's Hospital under Dr. Leslie Cole, as an emergency, complaining of severe weakness of the legs, associated with pain and numbness, which had developed rapidly over the previous two days. There was no history of recent infection, sore throat, or alcoholism.

On examination he was found to have signs of a bilaterally symmetrical peripheral neuritis affecting the legs and to a less extent the arms. He was unable to walk. Voluntary movements in the legs were very weak in all muscle groups, particularly the dorsiflexors of the feet. Movements were severely ataxic. The knee- and ankle-jerks were absent. Plantar responses were flexor, but later became difficult to obtain, with occasional equivocal extensor responses. Vibration sense was absent at the knees and ankles. Position sense was grossly impaired in the toes. Sensation to light touch and pinprick was impaired over the feet and lower legs. The calf muscles were tender to deep pressure. Similar but less extensive signs were present in the arms. The abdominal reflexes were absent. The cranial nerves were normal. No other abnormal signs were found.

His mental state was good, and, although he later became depressed, he developed no signs of dementia. He had lost 10½ lb. (4.8 kg.) in weight. The cardiovascular system was normal (B.P. 160/90 mm. Hg). His diabetes appeared well controlled (fasting blood sugar 150 mg. per 100 ml.). His pulse rate was 80 a minute on admission. He later developed a persistent tachycardia (90–100 a minute). His temperature was 97.8° F. (36.6° C.), and he remained afebrile throughout his illness except for occasional spikes of fever during later episodes of intercurrent infection.

Lumbar puncture on December 8 was normal except for a raised protein (over 200 mg. per 100 ml.) in the cerebrospinal fluid with a practically normal cell count (4

lymphocytes per c.mm.); W.R. negative. Other investigations, including a full blood count, throat swab, blood W.R. and Kahn, examination of the urine for porphyrins, and x-ray pictures of the chest and lumbar spine, showed no significant abnormality.

His condition rapidly deteriorated. Paraesthesiae in the legs became intensely painful. Light pressure on the legs was enough to cause pain. He developed severe abdominal pain, constipation, and abdominal distension. Within one week of admission he had developed an almost complete flaccid paralysis of the limbs. He had a bilateral facial weakness of lower motor neurone type. He could not sit up or turn over in bed. He had retention of urine and needed catheterization.

During the second, third, and fourth weeks (December 9–30) his condition deteriorated still further and at times appeared hopeless. Respiration became embarrassed. Swallowing was difficult and nasal regurgitation of fluids occurred. He developed a right basal pneumonia and a urinary infection. Adequate relief of pain was difficult and required frequent injections of pethidine hydrochloride (50–100 mg.).

A gradual improvement was noticeable during the fifth week. By the sixth week he had regained a considerable amount of muscular power but still suffered a good deal of pain in the legs. Catheterization was no longer needed.

He was able to start walking with assistance in the seventh and eighth weeks (January 14–27, 1955) and was discharged home, to continue physiotherapy as an out-patient, on February 2, nine weeks after admission.

He had made an almost complete recovery six months later. He was able to walk easily and had returned to work. The knee- and ankle-jerks were absent.

Treatment was largely symptomatic and involved extremely careful nursing and physiotherapy. His diabetes was easily controlled with a small amount of insulin (I.Z.S. 20 units) and a diet containing about 120 g. of carbohydrate daily. Frequent courses of antibiotics were needed to control intercurrent infection. He was also given vitamin B₁₂ in large doses (500 µg. daily), parenteral aneurine hydrochloride (100 mg. daily), and nicotinamide (10 mg. daily) during most of the first six weeks of his illness.

COMMENT

Muscular paralysis is relatively rare in diabetes (Martin, 1953). It is usually asymmetrical and often involves one limb or muscle group only. A bilaterally symmetrical polyneuritis involving motor and sensory fibres, similar to that occurring in diphtheria, alcoholism, or infective polyneuritis, is extremely rare (Kraus, 1920), but occasional cases have been reported. Buzzard (1890) described a case of this type with a prolonged course. More severe cases with a relatively acute onset were described by Pitres and Marchand (1917) and Root (1922).

Particularly unusual features in the present case were the rapidity of onset and severity of the paralysis, the involvement of muscles of respiration and swallowing, the involvement of the bladder, and the bilateral facial weakness.

The polyneuritis in this case was not necessarily diabetic in origin, although no other cause was apparent. The clinical features were similar to those of infective polyneuritis in practically all respects except the absence of fever. This disease, or some unknown factor, may have been the cause of the symptoms.

I thank Dr. Leslie Cole for permission to publish this case.

RADIOISOTOPES IN MEDICINE

Medical Sciences. Volume I in Series VII of *Progress in Nuclear Energy*. Edited by J. C. Bugher, J. Coursaget, and J. F. Loutit. (Pp. 165+xii. 42s.) London: Pergamon Press Ltd. 1956.

The 1955 Geneva Conference on the Peaceful Uses of Atomic Energy has been described as a landmark in the progress of science and human affairs. It was an occasion for a general release of information, particularly in physical and engineering science, and an exchange of views by the major nations participating. Exchange of medical information, especially on radiotherapeutic methods, had, however, been virtually unrestricted, so that from the medical aspect the conference was a time for review and assessment rather than an occasion for the publication of new and major advances. An important new series of books on "Progress in Nuclear Energy" was already planned before the Geneva Conference, but because of the amount of material presented and "declassified" at the conference it was decided that the first volumes should deal with the papers given there. Of the eight series, Series VII deals with "Medical Sciences," and the first volume presents an admirable review of the latest applications of nuclear science to medicine. A vast field is surveyed, and the topics include the diagnosis and investigation of disease with radioactive isotopes, the use of nuclear radiations from external and internal sources in therapy, the principles and practice of radiation protection, and radiation dosimetry. In each chapter, by an international authority, the status of the techniques is reviewed with particular reference to the relevant conference papers. The uses of radioisotopes in diagnosis and investigation have become almost bewildering in their potentialities. Scientists from seven nations gave accounts of the application of radioisotopes to such diverse subjects as the intermediary metabolism of carbohydrates in normal and diabetic subjects; the localization of tissue antibodies; thyroid function; dynamic aspects of erythropoiesis; the dispersal and flight range of cockroaches, flies, and mosquitoes; food sterilization; and the pharmacology of antilepromatous drugs.

In the radiotherapeutic chapters it is pointed out that throughout the world the largest use of radioisotopes in radiotherapy is for gamma-ray sources, and from the practical viewpoint this is a far-reaching achievement. Internally administered radioisotopes are regarded as of more fundamental interest, the problem being to develop effective methods of selective localization in malignant tumours—at present limited to the use of a few isotopes in inorganic form. It is of interest to compare the papers originating in Russia with those from the Western Hemisphere. While ostensibly the materials and methods are similar, there are two statements in the Russian papers which reveal great differences of orientation. One paper states that bilateral one-stage ligation of the external carotids proved most effective in reducing local manifestations of radiation reaction in tumours of the mouth, jaws, and lower lip; observation of 340 patients revealed no complications, and the skin resistance to irradiation increased by an average of 50%. It is claimed that the impaired blood supply of the tumour caused its degeneration, making it more susceptible to injury during irradiation. In the West, however, and particularly in this country, every effort is made to conserve the integrity of the tumour bed, as both clinical and experimental evidence indicates that adequate blood supply and high oxygen tension increase the radiosensitivity of tumours. Again, with regard to the treatment of haemangioma in children it is stated that treatment with telecobalt of 450 children with cavernous angioma was effective in 92% of cases; the treatment was administered in fractions, with daily doses of 400–500 r and a total dose of 2,000–3,000 r depending on the age of the child. These are considerable doses, and because of possible late sequelae the tendency in this country is to reduce to a minimum the dose of radiation for a non-malignant condition in childhood.

A remarkable amount of information is contained within seven chapters, and the lists of references make this volume a ready key to the world literature of radioactive isotopes in medicine. The editors and authors are to be congratulated on this compact presentation of such comprehensive and varied reviews.

ARTHUR JONES.

FEMALE FERTILITY

Human Ovulation and Fertility. By Edmond J. Farris, Ph.D. (Pp. 159+xiii; illustrated. 50s.) London: Pitman Medical Publishing Co. Ltd. 1956.

A previous volume by Dr. Farris on male fertility collected much of the author's researches which had been published in various scientific and medical journals. The present volume, which may be regarded as a companion to the former, does much the same thing for his work on female fertility. His earlier book was concerned mainly with the elaboration of techniques and criteria whereby the fertility of men might be classified with precision; the work published in this volume represents a comparable quest for precision in the diagnosis of the occurrence of ovulation, and especially the close timing of that event—a matter of much importance for determining the success or failure of both natural and artificial insemination. For this purpose Dr. Farris has made extensive use of his "rat ovary hyperaemia test," which he first reported in 1946. Essentially, the test consists in the injection of 2 ml. of first morning urine into immature female rats of the Wistar strain, killing the animals two hours later with coal gas, and comparing the colours of the ovaries with a set of standards. In normally ovulating women a positive colour response is produced for four or five consecutive days, at the end of which time ovulation occurs. An impressive array of evidence of various kinds, detailed in the book, has been collected by Farris to substantiate this statement. Having had the privilege of observing the test in operation in Farris's laboratory, I have no doubt that the responses mentioned do occur in the author's hands; but, for reasons which remain largely obscure, few other workers have been able to duplicate Farris's findings. From the point of view of practical application, it has also to be borne in mind that, without a very large breeding colony such as exists at the Wistar Institute, the supply of suitable rats is unlikely to meet the demands which the attempt to apply the test clinically on any scale would make. And then, of course, there is the question of expense.

Apart from the material mentioned above, the book contains much else that is original. Farris has devised a formula, based on his experiences with the rat test, for determining the optimum time of conception, and another which he considers to be an improvement on the usual methods of determining the "safe period" for contraceptive purposes. Data are provided on the effects of thyroid medication and of pituitary irradiation on the ovulation response as reflected by the rat test; and a simple pregnancy diagnosis test is described, depending upon matching the colour of the cervix with a series of standards. Undoubtedly the book contains much of interest for anyone concerned with problems of human reproduction.

G. I. M. SWYER.

CANCER OF FEMALE GENITALIA

Gynecologic Cancer. By James A. Corscaden, Ph.B., M.D. Second edition. (Pp. 546+ix; illustrated. 80s.) London: Baillière, Tindall and Cox Ltd. 1956.

Dr. J. A. Corscaden, a well-known New York gynaecologist, attributes the success of the first edition of his book to the fact that it represents "the conclusions of an individual." Certainly it is the personal approach, based on an extensive clinical experience and a judicious sifting of the literature (mainly North American), which makes the work unusually attractive. Each organ of the female genitalia is considered separately, and emphasis is placed on the aetiology, diagnosis, and treatment of cancer rather than on its pathology. The details of irradiation as well as of

surgical techniques will be especially welcome to practising gynaecologists. Incidentally, it is of interest to note that Dr. Corscaden favours radiotherapy rather than surgery in practically all cases of invasive cancer of the cervix, while for cancer *in situ* in the young woman he advises very conservative surgery. There is a particularly interesting introduction containing a wealth of statistical information on the incidence of various growths, on the expectation of an individual developing such growths, on delays in diagnosis, and on the effect of educating the public in cancer. Indeed, statistics abound in all chapters. This is not to say that the interests of individual patients become lost in figures. On the contrary, considerable attention is paid to the general care of the afflicted woman; particularly to the management of the woman whose tumour has defeated medical science, of the woman who has had to sacrifice ovarian function in the struggle, and of the woman who is afraid of cancer.

Dr. Corscaden is something of a crusader who aims to conquer defeatism amongst the medical profession faced with the problem of cancer. He sets out to show what can be done—to prolong life if not to cure—if the disease is tackled courageously and early. His motto is, "Fight cancer with knowledge," and in this book, by disseminating rather than by adding to knowledge, he fights the good fight. I have looked at Fig. 51 many times and am still uncertain whether it is intended to be upside down or not; otherwise the production is excellent.

T. N. A. JEFFCOATE.

CONSERVATIVE GYNAECOLOGY

H. Kahr: *Konservative Therapie der Frauenkrankheiten*. By H. A. Müller. Foreword by H. Huber. Eighth edition. (Pp. 425+xii. 54s. 6d.) Wien: Springer-Verlag. 1956.

Kahr's "Conservative Gynaecology," for twenty years the standard work of this kind in German, now reappears in an enlarged ninth edition, this time under the directorship of Müller of Marburg. This transfer from Vienna to Germany has resulted in the dropping of some of the more romantic aspects of Austrian treatment, such as vaginal ultraviolet light, "hot air" therapy, and the double water circulator so dear to Kahr himself. A few anachronisms, like valerian and *Bauchdeckenhyperästhesie*, survive, but on the whole the highly theoretical dead wood of earlier editions has been eliminated. The style is also more succinct and the phraseology clipped, a welcome change from the interminable sentences and complicated phraseology usual to German textbooks. It must be admitted that most British and American gynaecologists show little enthusiasm for purely medical treatment, and that many useful non-operative methods are largely neglected here. This may be partly the fault of training, which remains basically surgical, or the national suspicion of theory. But it denies many new ideas a reasonable trial and deprives many women of the chance of non-operative relief. Conservative gynaecology remains for many specialists a relatively closed chapter, and this textbook, ranging through all aspects of the subject, makes salutary reading.

A. DAVIS.

UROLOGY

Textbook of Urology. By Victor F. Marshall, M.D., F.A.C.S. (Pp. 268+x; illustrated. \$5.50.) New York: Hoeber-Harper. 1956.

This textbook is primarily written for medical students and practitioners who have not specialized in urology. It has been evolved from a series of lectures for third-year students and reflects the experience gained thereby. It is restricted to fundamental principles and to accepted theories and methods of treatment. The need for an accurate history and a thorough clinical examination before starting the more elaborate radiological and biochemical investigations is emphasized throughout the book. All the methods of urinary investigation are described, but in some cases so briefly that most students would have to refer to other textbooks in order to understand them and their application. The main emphasis is placed upon the occurrence and

importance of obstruction and the resulting infection in many of the diseases of the urinary tract. This is followed by chapters on malformation, tuberculosis, trauma, inflammation, and neoplasms as they affect each portion of the genito-urinary tract. The last chapter is devoted to a description of urological operations. The chapters on neurogenic bladder and male infertility are particularly clear and helpful. The author has deliberately omitted all radiographic illustrations, and advocates that the reader should use a large radiological atlas when reading the book. Unfortunately I feel that this is a counsel of perfection; one may not always be readily available. There are a number of illustrations graphically showing the symptoms, investigation, and treatment in a most amusing manner. But the author has tried so hard to be concise that some aetiology, pathology, and methods of treatment which would be required in the final examination have been omitted or so briefly mentioned that reference to other textbooks would have to be made if these omissions are to be rectified. Nevertheless this textbook is very pleasant to read, and the more complicated urological problems are explained in a simple manner, so that many will find this a very helpful book.

J. E. SEMPLE.

FIRST AID

Fundamentals of First Aid. By Robert A. Mustard, B.A., M.D., F.R.C.S.(C.). (Pp. 116; illustrated. No price.) Toronto: The Priory of Canada of the Most Venerable Order of the Hospital of St. John of Jerusalem. 1955.

This is an interesting and courageous attempt to provide a short manual of first aid which shall be more in line with modern teaching and with the increased facilities now available. There is even a section on how to avoid damage from the atom or hydrogen bomb and from bacteriological and chemical weapons. In places the statements are provocative. Those who have been brought up in the older school of first aid may shake their heads when they find all mention of pressure points omitted and the tourniquet frowned upon; they may have to refer to a medical dictionary when they come across the word "atrium," which displaces the time-honoured word "auricle"; they may even refuse to accept the teaching that "iodine and other antiseptics should not, under any circumstances, be poured into or on a wound"; but they will find the main doctrines of first aid clearly stated and illustrated. Most doubt will be expressed about the complete omission of "shock" as a symptom. The reasons adduced for this are that it is imperfectly understood, difficult to define, and that its omission greatly simplifies teaching and does not in any way reduce the effectiveness of first-aid measures. It is stated that common sense will induce the first-aid-er to institute the first-aid measures required "without recourse to the bogey of shock." It might be answered that the person who has enough common sense (which is undefined) to carry out all these measures is likely to be sufficiently intelligent to understand an elementary description of the main circulatory changes which occur in shock. In spite of this, as we think, unnecessary omission, the teaching given is sound and practical. The writing is pithy, the illustrations are numerous and apposite, and the manual can easily be put into the pocket.

ZACHARY COPE.

Messrs. Eschmann Bros. and Walsh, the wholesale surgical instrument manufacturers, whose experience extends back for over a century, have produced a new catalogue of their products which will be found both interesting and instructive to surgeons. It is exceptionally well produced, fully illustrated throughout with half-tone blocks, and the information provided on materials, sizes, and so on of the various instruments is all that can be required. There is also a good index which enables any particular instrument to be found easily. In addition to metal instruments the products of this firm include appliances made of gum elastic, latex rubber, and plastics, and for these separate illustrated catalogues are available. In this connexion it is interesting to note the increasing use of the more modern plastics such as "nylon" and "terylene" in the manufacture of bougies, catheters, and other flexible appliances, all of which can be safely sterilized by boiling.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY JUNE 8 1957

TO-DAY AND TO-MORROW

The Conference of Local Medical Committees met on Thursday this week, the day after this issue of the *Journal* went to press. A special meeting of the Representative Body will be held on Wednesday next week, as well as special meetings of the Council. Addressing the Annual Conference of Honorary Secretaries of Branches and Divisions on May 10, the Chairman of Council, Dr. S. Wand, said that opinion in the profession on what action to take was divided, but that there was complete unanimity on the objective to be achieved—agreement on ends but disagreement on means. He admitted that the Government "had succeeded in its purpose of dividing and confusing the profession"; unfortunately it has seemed all too easy to do this. But the Government has retreated from its position in refusing to consider the claim for increased pay; junior hospital staff have received an increase of 10% and the rest of those working in the Health Service 5% pending the final report of the Royal Commission. Certainly these advances would not have been made if the G.M.S. Committee had not at the outset taken a firm line and if the Guild machinery had not been set in motion. The lamentable thing was that the Government made the increases in a completely arbitrary manner and without consulting the profession. The profession in the coming months must never forget that the Government refused to use the customary methods of consultation, conciliation, and negotiation, or to allow, in the event of failure of these, arbitration. If the Royal Commission completes its task we may hope there will not be a repetition of this pattern, and that the full consultation promised will be such as to restore part of the trust the Government has so regrettably forfeited. But the decision to give evidence has yet to be made, and, as Dr. Wand said (*Supplement*, May 25): "Even if we decide to give evidence the struggle clearly might come in the next few months after the Royal Commission has reported." Our correspondence columns suggest that at least many doctors would be reluctant to withdraw from the N.H.S. simply to enforce a wage claim, with the intention of rejoining the Service when the claim had been met. Many think that the proposition if it

were to withdraw on a matter of principle unmixed with a pay claim. As Dr. Wand reiterated on May 10, "The time is coming when we have seriously to consider not whether we withdraw from the Service for a short time, but whether we can continue to serve in such a Service at all"—a statement that was received with applause. Apart altogether from the present conflict, it is plain that a root-and-branch investigation into the Health Service as a whole is much needed, and the decision of the B.M.A. to institute such an inquiry under an independent chairman is being widely welcomed.

In the meantime the Conference and the Representative Meeting have to decide whether or not to give evidence to the Royal Commission, the Royal College of Physicians and the C.C.&S. Committee of the B.M.A. having already decided to do so. The onlooker may be surprised to see an autonomous committee of the B.M.A. decide on a course of action before any similar decision has been reached either by the Council or by the Representative Body, and a correspondent, Mr. N. Ross Smith, last week drew attention to "the lamentable weakness of multiple representation." "It cannot be said," he wrote, "that though illogical it works, because it is obvious that it does not." Whether or not everyone agrees with this view, no one can feel happy at the way events have unfolded. All these things—including the dispute itself—are symptomatic of the faulty structure of the N.H.S. and of the consequent unsatisfactory relationship between doctors working in it and those who administer it. Whatever decision may be reached about giving evidence to the Royal Commission, the Association has two big tasks in front of it: the inquiry into the N.H.S., and the reform of its own constitution, and on this there will be a whole day debate at the Annual Meeting of the B.M.A. at Newcastle in July. Whatever may be the outcome of the latter, it is much to be hoped that in the future there may be evolved a more satisfactory way of co-ordinating policies and decisions between various medical bodies without there being any sacrifice of independence.

SOCIETY AND MENTAL DISORDER

Two beliefs stand as foundations to the Report of the Royal Commission on the Law Relating to Mental Illness and Mental Deficiency, now published¹ after three years' deliberations. The first is that mental disorder of all kinds must be viewed primarily as a matter of the sufferer's health and well-being and not as a matter of protecting society; in other words, it is largely a medical rather than a legal concern. The second is the need for decentralization, for increasing

the links between mental hospitals and the communities they serve, and especially for local authorities to play a much larger part in the mental health services. The report recommends the complete repeal of the Lunacy and Mental Treatment Acts and the Mental Deficiency Acts, and the abolition of the Board of Control. These Acts are in the main a complicated patchwork of nineteenth-century ideas which appeal neither to the general public, who find them incomprehensible, nor to psychiatrists, whose views have changed so greatly since then; nor do they agree with administrative realities since 1948, when mental hospitals became a part of the National Health Service. The report recommends that admission to a mental hospital, and discharge from it, should be as informal as with a general hospital; compulsory powers, with somewhat improved legal safeguards, should be reserved for the very few cases in which they are essential. How few these are is shown by the experience of Mapperley Hospital, which serves Nottingham. On March 1 this year out of a total of 1,054 in-patients only one was certified, and four more were held for observation on three- or fourteen-day orders; the rest were voluntary or non-statutory (informal) patients. The report points out that mental deficiency hospitals could drop all formalities for admission straight away. Changes in terminology are also among its suggestions—the abolition of “certified” and “mental deficiency,” while “duly authorized officer” should be “mental welfare officer.”

Three categories of mental disorder are envisaged—mental illness, severe subnormality (or mental deficiency), and psychopathy. Under the concept of psychopathy the report makes official recognition of the existence of people with grossly abnormal personalities who drift from job to job, have a general inability to take an interest in any form of occupation, and are guilty of ill-considered sexual behaviour, pathological lying, or poorly controlled aggression, even though intellectually normal. These psychopaths should be offered mental hospital treatment or training, or even compulsorily admitted for a maximum of four weeks. The intention is that the law should not try to include them among those “of unsound mind” or “feeble-minded” (both of which terms are to be abolished). The principle here is excellent, but the practice may prove difficult. The humour of the remark that “a psychopath is anyone a psychiatrist doesn’t like” lies precisely in its element of truth. There is no problem in recognizing the extremes of aberrant behaviour, but in deciding on the boundary between amiable eccentricity and pathological deviation. The judgment is subjective, and

determined in part by the norms of conventionality and the organization of the society in which both patient and doctor live. If psychiatrists find difficulty in the diagnosis and treatment of psychopaths, how much more difficult it must be for prison medical officers and general practitioners who will also be called upon to recognize them. This draws attention to the need for a wider training in psychiatry for medical students and for the provision of refresher courses in the subject for general practitioners.

Many will welcome the proposals that compulsory admission, when it has to be used, will not require a magistrate unless the nearest relative as well as the patient object, and that the duly authorized officer will always need the approval of at least one doctor before removing a patient for observation. This implies, though the report does not say so, the further development of domiciliary psychiatric services. Since there is at present a shortage of psychiatrists, the alternative is to develop more psychiatric treatment in general practice. Where there is compulsion, however little, there must also be safeguards. Those provided by the magistrates and by the Board of Control the Commission thinks are inadequate, and it proposes instead the creation of regional appeal tribunals which could investigate on the spot patients’ complaints of unjustified detention. The aim here is to forge a local link and use local knowledge, but clearly the risk is a judgment biased by local prejudice, in appearance if not in fact; it might be wiser, especially since the number of cases should be small, to have a central but peripatetic tribunal. With the removal of all its legal work, the Board of Control no longer need exist, its administrative functions and the collection of statistics becoming part of the work of the Ministry of Health. Likewise, in the hospital the special legal function of the medical superintendent vanishes, and his duties will come to resemble closely those of the superintendent of a general hospital.

The Royal Commission recommends “a general re-orientation away from institutional care in its present form and towards community care.” By this it means the expansion of local authority services under medical officers of health to provide occupational or training centres, sheltered workshops, social centres, and hostels for patients with some residual disability, as well as for children and young people who cannot benefit from the ordinary schools and colleges. It suggests this expanded work should be a positive duty of county and county borough councils, and be carried out in close collaboration at all levels with the hospital service. This would restore to local authorities some of the important welfare functions they lost in

1948, and would do something to redress the balance between the three divisions of the Health Service, provided the new projects can be adequately financed. But ratepayers may not be so enthusiastic about this. In general, the report will be warmly welcomed in medical circles. Many of its recommendations give expression to the suggestions put before it by the Psychological Medicine Group Committee of the B.M.A.² It is gratifying to find the legal and lay members of the Commission unanimously adopting an up-to-date medical viewpoint, and it is to be hoped that the Government will accept the substance of the recommendations.

CONGESTED CURRICULUM

Last week the General Medical Council published one of its periodical reviews of the medical curriculum.¹ The previous review took place in 1947, and the recommendations then made were the most detailed ever issued by the Council. Because they were so detailed they have been criticized as a hindrance rather than a help to those licensing bodies and medical schools prepared to make experimental changes in the curriculum. The B.M.A.’s Committee on Medical Education described the recommendations as too rigid and too detailed and emphasized that they should state objectives, not prescribe means.² The General Medical Council has taken these criticisms to heart, for the new recommendations are shorter and more flexible, and will allow the medical schools more scope to make reforms on their own initiative.

After passing a preliminary examination in general education and examinations in physics, chemistry, and biology, the student must still face a minimum period of professional study of five years. The General Medical Council considered the possibility of reducing this minimum period, but decided that the time was not opportune for this.³ By “lightening” the recommendations and keeping to the minimum of five years for the period of professional study the General Medical Council felt that it was performing its primary task, at the present time, of reducing the congestion in the curriculum. The recommendations encourage the extension of interdepartmental teaching throughout the whole period of professional study. It is no longer a requirement that the student should

dissect the whole body. In the section devoted to “medicine,” the stress on preventive medicine is notable, and it is stated as desirable that “the student should be given opportunities to learn something of the work of the general practitioner.” The B.M.A.’s Committee on Education specially drew attention to the excessive detail in the old recommendations concerning midwifery and gynaecology. These are now much shorter and less rigid: though the student has still to spend a set period (“not less than two months”) in residence while receiving clinical instruction in midwifery, he has to conduct only an “adequate number of cases of labour,” compared with the “not less than 12 cases” laid down in the old recommendations. A modern note appears in the suggestions that the student should be given ample opportunity to attend clinico-pathological conferences and should be acquainted with the principles governing the design and interpretation of clinical trials. As to examinations, the General Medical Council now specifies ten subjects, five less than ten years ago, and has refrained from designating subjects in which separate examinations should be held.

Now they are freed from some ancient shackles, how will the medical schools put into effect the G.M.C.’s exhortation “to instruct less and to educate more”?³ There is no shortage of suggestions. The Royal College of Physicians has issued reports⁴ on the subject, and the *Proceedings of the First World Conference of Medical Education*⁵ contains a mass of information about the experiments in medical education going on all over the world—except in Britain, which, as an American observer remarked, has produced many wise reports on the improvement of medical education, yet has done little about it. In his thoughtful and constructive paper on the “Aims and Content of the Medical Curriculum” in the Education Number last year, Dr. A. Morgan Jones⁶ stressed the need for a really thorough reorganization of the medical curriculum: the danger is, as he sees it, that only details will be changed, leaving the antiquated structure basically unaltered. Though the new recommendations of the General Medical Council are not revolutionary—their main purpose, as has been stated, is to relieve congestion—they are certainly to be welcomed for removing some of the obstructions in the way of reform.

THERAPEUTIC HYPNOTISM

The place of hypnotism in medicine is still somewhat ambiguous. It may have become more respectable since the 1955 report of the British Medical Association¹ encouraged its use by doctors and the Hypnotism Act of 1952 discouraged its use by charlatans. But it remains

⁷ *Proceedings of the First World Conference on Medical Education*, 1954, Oxford University Press.

⁸ Jones, A. Morgan, *British Medical Journal*, 1956, 2, 494.

an inescapably personal method of treatment; in fact, the personalities of two people are engaged. Some patients can be easily hypnotized and carried on to almost any degree of dissociation; others prove more difficult or even impossible to influence. Some physicians have a particular interest and a particular gift; others find that hypnotism lacks all appeal and could not easily employ it. Most patients are fairly good subjects; and it is probably true that most medical men, perhaps with the aid of a little training, could acquire a competent facility. Naturally doctors prefer to use methods whose rationale is explicable and whose results are as independent as possible of the personal factor—at least on the physician's side—but we cannot afford to ignore any methods if in practice they give promise of benefit.

Since most patients can be hypnotized, the question arises which are the cases most likely to benefit from it. The three articles which we publish in the *Journal* this week show that the range of conditions in which something worth while can be achieved is remarkably wide. Professor Alexander Kennedy gives a helpful analysis of the indications for treatment by hypnosis (p. 1317). His first class of cases, in which hypnosis is often the treatment of choice, consists of those hysterical or psychogenic cases which are commonly regarded as the province of the psychiatrist. The fact that in his experienced judgment hypnosis is often the treatment of choice in such states suggests that more use should be made of it than actually is in our psychiatric clinics and hospitals. This does not mean that the family doctor should not also treat such cases by hypnosis in the first place. There appears to be only one serious danger in the therapeutic use of hypnosis—that the patient may be relieved of an organically determined symptom as a result of the suggestion applied, and that organic disease may accordingly be missed. As this is a danger of all symptomatic treatment, it is one which is familiar, but the possibility of it in this rather unusual context may be worth bearing in mind. Professor Kennedy goes on to list conditions in which hypnosis is particularly beneficial, and some in which it can claim occasional striking successes. These include conditions in which habit formation is defective, such as enuresis, smoking, and alcoholism; diseases in which emotional tension plays a part, such as hypertension, peptic ulcer, mucous colitis; a heterogeneous mixture of conditions of unknown pathogenesis, such as warts and certain dermatoses; and normal persons in whom for some specific purpose, such as anaesthesia, the temporary production of a hysterical symptom is desired. This great variety of states in which, at least on occasion, valuable results have been obtained by hypnosis is further illustrated in abundant detail in the papers by Dr. A. Fry (p. 1323) and Dr. H. Stewart (p. 1320) describing their experience in general practice.

In the treatment of some conditions, such as warts, the undoubted, though not invariable, success of hypnosis is impossible to explain. R. Asher² cured some patients after simple suggestion had already failed, and

he got better results in patients who were brought to a deep trance than in those who were only lightly hypnotized. This points to the unsolved problem of what the hypnotic state is in neurophysiological terms. Asher says that at least it is not sleep; but, as we still do not know what sleep is, even this small definition by exclusion is of little help. Hypnotism apparently produces its results mainly by suggestion, whatever that may be, and therapeutic trials including inert drugs have shown in recent years how potent a force it sometimes is. Yet the results of hypnotism are apt to be much better than those obtained by ordinary suggestion. Dr. Fry proposes as an alternative name for hypnotic therapy the term "suggestive relaxation," and this emphasizes what is probably an important element in the favourable effects of hypnotism. It may well be the main factor in the management of childbirth. Hypnotism may also be applied in abreactive therapies, but is then a means to an end. We are faced with a number of riddles, some of which will need systematic neurophysiological study for solution, while others may be clarified by further clinical experience.

Asher has expressed the views of many medical men that there is no need for "specialists" in hypnotic therapy, but it might be of value to the public if there were more therapeutic clinics specially organized for giving this treatment in conjunction with general medical and psychiatric out-patient services. Psychotherapy as conducted by the analytic schools is economically out of the question for all but a small handful of patients; nevertheless, psychotherapy of some reasonably effective kind is required by very many. Professor Kennedy makes the important point that it is the first duty of doctors to relieve illness, and in this the shorter methods, including hypnotism, have a rightful place.

POLIOMYELITIS AND PREGNANCY

In 1941 W. L. Aycock¹ suggested that pregnant women are more likely to contract poliomyelitis than women of similar ages who are not pregnant. Evidence in support of this hypothesis has appeared from time to time, and some more has recently been published. By inserting a question about the date of the last menstrual period on the record form of every case of poliomyelitis occurring in Connecticut since 1951, M. E. Rindge² was able to show that 17.3% of women over 15 years of age were pregnant when they became ill. She compares this with an estimate that 7% of women aged 20–40 are pregnant at any one time. In addition she has pointed out certain other factors which confirm the findings of previous workers, notably those of M. Siegel and M. Greenberg.³ She reports that women were apparently more susceptible in the second trimester of pregnancy, and par-

ticularly so if they were multiparae; and she agrees with Siegel and Greenberg that this increased incidence might be due in part to increased contact with young children in the household who are themselves highly susceptible to the disease. But this does not seem likely to provide the complete explanation, and probably endocrine factors come into it. The World Health Organization's Expert Committee on Poliomyelitis⁴ has stated that it is reasonably well established that poliomyelitis during pregnancy may run a severe course, and suggests that this may be an example of the effect of endocrine factors in increasing susceptibility just as cortisone increases the susceptibility of experimental animals. Siegel and Greenberg laid stress on the fact that the paralytic cases included an unusual number of the spinal type of disease, the lower limbs being chiefly affected. They use this fact to explain the low death rate in their series, since deaths are commoner among bulbar cases. Against this, in Rindge's series 7 patients out of 79 died, all with the bulbar form of the disease.

Evidence from Great Britain is scanty. W. H. Bradley and A. H. Gale⁵ found in 1949 no evidence of a high incidence of the disease among pregnant women. Mortality figures culled from the Registrar-General's publications^{6–9} show that during 1947–53 14 deaths were assigned to poliomyelitis associated with pregnancy; the disease caused 1.05% of the deaths of pregnant women aged 15–44. On the other hand, deaths from poliomyelitis among non-pregnant women of the same age numbered 699 and comprised 0.64% of their deaths. Such figures are open to some objections, not least that of being proportional mortality rates, but they are suggestive of either a high incidence or an increased mortality from the disease among pregnant women. Owing to the comparative rarity of poliomyelitis in adults its association with pregnancy is difficult to study. Much work remains to be done. Meanwhile the problem arises of whether pregnant women should have prior claim on poliomyelitis vaccines.

THE WORLD'S HEALTH

"The Work of W.H.O." is the apt title for the Annual Report for 1956 of the Director-General of the World Health Organization,¹ for it describes at length the strikingly varied activities of this truly international body. In its efforts to promote world health the eradication of communicable diseases plays a leading part—such diseases as malaria, poliomyelitis, rabies, leprosy, endemic syphilis, yaws, and smallpox. But the recent developments in the field of atomic energy, the study of nutritional and mental health problems, the prevention of endemic goitre, and many aspects of public health have continued to receive close attention. New drugs and vaccines have improved the prospects of controlling many communicable diseases, such as the sulphone drugs for leprosy, vaccines for poliomyelitis, hyper-immune serum for rabies, and B.C.G. vaccine for tuberculosis. For the completion of all these and many other

projects, however, the essential need is research, the stimulation and co-ordination of which "constitutes the real backbone" of W.H.O.'s many activities.

The expert committees have a primary role; here they either initiate a research programme or work in consultation with the Organization's technical staff. An example of their approach to a problem is the attempt to counteract the development of resistance to insecticides, particularly with regard to malaria. It has been shown that when anopheles become resistant to insecticides of the D.D.T. group they can sometimes be controlled by those of the B.H.C. group, but in Greece they were resistant to both. The fundamental facts about insecticide resistance had therefore to be further studied before the control and eradication of malaria, as of other communicable diseases, could be completed. The problem was submitted to an expert committee, whose members considered the results of a survey carried out by consultants in 1955; they were able to draw up a plan for additional research programmes, which, with the help of several scientific institutions, have developed methods of measuring susceptibility or resistance of disease vectors. The results of these studies have enabled W.H.O. to give information to the governments concerned on the best methods for controlling typhus fever in resistant areas, and to establish an extensive system of exchanging information on problems of resistance in general.

The field of activity of W.H.O. is divided into six regions—Africa, the Americas, South-east Asia, Europe, Eastern Mediterranean, and Western Pacific—with certain problems specific to each region. In the African region, for example, malaria, treponematoses, leprosy, tuberculosis, and malnutrition have received special attention, while in the European region the effort to achieve complete control of trachoma by means of antibiotics has been greatly assisted by schoolchildren serving on "health committees" with duties which include the regular treatment of their infected classmates. The report contains some interesting maps showing the various stages in control and eradication of communicable disease in the different regions, and some excellent photographs illustrating the way in which the work of this very human organization ministers to the needs of individuals belonging to every nationality.

COHORT ANALYSIS

A golden rule in statistics is to "compare like with like." As is the way with golden rules, it is difficult to interpret, and even when interpreted difficult to follow. In practice we usually have to set up a more or less arbitrary scale of likeness. If, for example, we wish to study the changing trends of mortality, the first step is to count the number of people dying in one period of time, relate this number to the number alive, and compare the death rate so calculated with a death rate calculated in the same way for another period. As a refinement we take into account the different age distributions by calculating standardized death rates or by studying the death rates

¹ Case, R. A. M., *Brit. J. prev. soc. Med.*, 1956, 10, 159.

² Springett, V. H., *J. Hyg. (Lond.)*, 1950, 48, 361.

for separate age groups. This method assumes a fundamental likeness in certain chosen respects between people dying, or at risk of dying, at a particular period of time. But, unless we are concerned with mortality due to epidemics or wars, it is often more fruitful to take account of the similarities between people born in the same year than of those between people dying in the same year. It is possible to calculate the death rates at various ages of people born in a five- or ten-year period, and to compare them with the death rates of people born in a subsequent period. This method has come to be known as cohort analysis, a possibly rather pretentious name for an approach which, as R. A. M. Case¹ points out in a recent review of the method, is one which would be used unhesitatingly, if unwittingly, by any experimental biologist working with animals.

Case has performed a useful task in setting out the method in its proper perspective. For its introduction into medical fields it is clear that much of the credit must go to the Scandinavians such as R. Korteweg and to V. H. Springett in Great Britain. Case draws on Korteweg for a striking example: if conventional age-specific death rates for cancer of the lung in men are studied, it appears that mortality reaches a peak between the ages of 60 and 70 and then falls off. In fact mortality due to lung cancer has recently been increasing in such a way that the death rate of men in the 70-79 age group has been higher than the rate, recorded ten years earlier, for those in the 60-69 group. Thus the cohort method shows a continuous increase with age; in terms of the individual's chance of dying from lung cancer as he grows older, this is clearly a more realistic picture. Springett² has studied the opposite problem, the effect of the sharply falling death rate due to pulmonary tuberculosis on the age distribution of mortality.

In a second paper Case³ has applied the method in an analysis of mortality in England and Wales for 21 sites of cancer over the years 1911-1954. This study admirably shows the value of the method in extracting the maximum of information from past records, and the results should be examined by anyone interested in the epidemiology of cancer. Even so, no method of analysis can compensate for faulty data. Conclusions drawn from a cohort analysis are equally subject to error due to inaccurate or changing methods of death certification as are those from any other method. Nor can cohort analysis supplant the conventional methods of presenting current statistics—any more than the methods of the historian can supplant those of the journalist.

PSORIASIS AND RHEUMATISM

Rheumatism, from its christening by Galen, has been gradually differentiated over the centuries so that the word is now almost meaningless except as an indicator of pain or discomfort. In its place we have a series of nosological entities, each laboriously separated from the matrix and given a separate name and "existence." Rheumatoid arthritis has emerged only in recent times, being finally distinguished from osteoarthritis in the early years of this century, and there is no guarantee that

it will not be split again. A nearly specific test, the differential sheep cell agglutination test¹ (known as the Rose-Waaler test, from Waaler who first noticed the phenomenon in 1940 and from Rose who rediscovered it and realized its importance in 1948), has allowed us to take stock afresh of many rheumatoid conditions, such as Reiter's syndrome or ankylosing spondylitis, and surprisingly has shown that most of the patients with such conditions differ from those with rheumatoid arthritis in giving a negative response to the test. One of the most interesting of these conditions is psoriatic arthropathy, a rheumatoid-like syndrome occurring in about 5-7% of psoriatic patients.

V. Wright² has recently surveyed this field and reported on 42 patients with psoriasis and arthritis seen at the rheumatism unit at Stoke Mandeville Hospital. He wisely uses the term "erosive arthritis" in preference to rheumatoid arthritis in order not to prejudge the issue, and found this change in 34 of the 42 patients (the other 8 having gout, rheumatic fever, or degenerative joint disease). All except two of these 34 patients had a negative response to the Rose-Waaler test; one of the two exceptions was the only patient with subcutaneous nodules, probably representing coincident rheumatoid arthritis. Thus either the arthritis may be a distinct entity or the psoriasis may considerably modify the expression of rheumatoid arthritis. Other interesting findings were the often good prognosis and the clear association of disease in the terminal interphalangeal joint with nail changes rather than with skin changes. A parallel study of the radiological changes³ emphasizes this point again. Disease of the terminal joint was much more common in the psoriatics (52%) than in patients with rheumatoid arthritis alone (11%), and in addition another feature was present (remarked previously only by J. F. Brailsford⁴), erosion of the tips of the terminal phalanges. Ankylosing spondylitis was present by clinical criteria in only three patients of the series, but radiological changes in the sacro-iliac joints were found in 20%. In a more recent survey of atypical spondylitis, J. Sharp⁵ has found that 16 out of 66 patients with psoriasis and polyarthritis had a painful back with limited movement, but the sacro-iliac joints in these patients with clinical spinal symptoms, contrary to Wright's findings, were often radiologically normal. It appears possible, as various people have claimed, that ankylosing spondylitis, as well as rheumatoid, may yet be differentiated into various groups; if the prognosis of these groups with or without treatment differs, as Sharp claims, this splitting may be useful. But differential diagnosis is of practical value only when aetiologicaly founded or there is a difference in treatment or prognosis.

We record with regret the death on June 3 of Dr. George F. Buchan, for many years medical officer of health of Willesden and a past president and treasurer of the Society of Medical Officers of Health.

LAW ON MENTAL ILLNESS AND MENTAL DEFICIENCY

ROYAL COMMISSION'S REPORT

The Royal Commission on the Law Relating to Mental Illness and Mental Deficiency presented its report* last week. The Commission was appointed four years ago under the chairmanship of Lord PERCY OF NEWCASTLE, and included four medical members†—Sir RUSSELL BRAIN, Dr. T. P. REES, Dr. D. H. H. THOMAS, and Dr. J. GREENWOOD WILSON. It met on 44 full days and 13 half-days and cost nearly £27,000 gross. It received written evidence from 68 and oral evidence from 42 interested bodies, including the B.M.A.‡ In addition, numerous individuals submitted evidence, four of whom are anonymous, being either former mental hospital patients or spokesmen for such patients. Except for these four last witnesses, all the oral evidence was heard in public, the minutes being published daily.§ No formal visit by the Commission as such was paid to any hospital or local authority establishment, but its members, singly or in small groups, visited hospitals and other centres informally.

Form of the Report

The Commission's report runs to 302 pages and four appendices and carries a short index. Immediately after the formal introductory matter come the Commission's main conclusions and recommendations, summarized in 18 pages. We record the principal ones below. There was no minority report. Then follow the seven parts of the report as follows: (1) Introductory survey of the present mental health services. (2) The need for new legislation and the general form it should take. (3) Distinctions between various groups of patients, and recommendations for new terminology. (4) The procedures applied to individual patients (this is much the longest section of the report—123 pages). (5) The local administration of the mental health services. (6) Powers and duties of the central Government. (7) Hospitals and homes outside the National Health Service and other private care. The four appendices deal respectively with procedure and sources of evidence and information; procedures applied to patients under the present law (summarized in a large table); the Commission's proposals for when compulsory powers are used in future (in a similar table); and statistics on the incidence of mental disorder in England and Wales and on its treatment, mostly provided by the Ministry of Health and the General Register Office.

Since the turn of the century two previous Royal Commissions have inquired into various aspects of our mental health legislation and administration—the Royal Commission on the Care and Control of the Feeble-minded (1904-8) and the Royal Commission on Lunacy and Mental Disorder (1924-6).

Commission's General Approach

Great progress has been made during the present century in developing methods of treatment for many forms of mental disorder, states the Commission. In some cases treatment could quite well be given without powers of detention if the law allowed mental and mental deficiency hospitals, like all other hospitals, to admit patients informally. In other cases, however, the patients' judgment might be so affected that they did not appreciate their need for care, and they might be positively unwilling to receive it;

*Cmd. 169, H.M.S.O. Price 10s. 6d. net.

†The other members of the Commission were Sir Cecil Oakes, Lady Adrian, Mr. Claude Bartlett, Mrs. E. M. Braddock, M.P., Sir Harry Hylton-Foster, Q.C., M.P. (until October, 1954), Mr. R. M. Jackson, and Mr. J. E. S. Simon, Q.C. (from October, 1954, to January, 1957).

‡The B.M.A.'s written evidence to the Royal Commission is set out in the *Supplement* of May 7, 1955, p. 211. The oral evidence was given before the Commission by Dr. N. H. M. Burke, Dr. H. M. Cohen, Dr. M. J. Brookes, Dr. Doris Odium, and Dr. S. Wand on April 27, 1955.

§See *Index to Minutes of Evidence* (H.M.S.O., price 2s. net) and *Minutes of Evidence Taken in Private* (H.M.S.O., price 3s. net).

and some might be dangerous to themselves or others, or incapable of protecting themselves. If proper care was to be provided for these patients, it could only be done by using compulsory powers.

The Commission recommends, therefore, that the law should be altered so that, whenever possible, suitable care may be provided for mentally disordered patients with no more restriction of liberty or legal formality than for other types of patient. Compulsory powers should be used only if "positively necessary" to override the patient's or his relatives' unwillingness. For such cases there must be special procedures and safeguards. The Commission would like to see the term "certification," and the ideas associated with it, fall completely into disuse.

Classification of Mental Patients

For many centuries a broad distinction had been drawn between patients described as "mentally ill" and "mentally defective." Each term covered a wide range of types and degrees of disorder and there was no clear-cut medical distinction between the two; the terms were legal and administrative rather than clinical.

Most defectives did not require admission to hospital but lived in the general community, many of the feeble-minded earning their living in simple forms of employment. But, while the Mental Deficiency Acts authorized detention of defectives, no explicit provision was made for their admission on a voluntary or informal basis. In practice, however, they were now admitted for short periods without legal formality. The majority of mentally ill patients also did not need in-patient treatment. A few hospitals now provided in-patient treatment quite informally, but hospitals "designated" under the Lunacy and Mental Treatment Acts, 1890-1930, could admit in-patients only through the procedures laid down in these Acts. Since the passing of the first Mental Deficiency Act in 1913, it had become usual for mentally defective patients to be admitted to mental deficiency hospitals only, leaving the mental hospitals for the treatment of mentally ill patients only.

Medicine also recognized a group of mental disorders known as psychopathic states, for which the law made no special provision. Some patients certified as feeble-minded or moral defectives under the Mental Deficiency Acts were medically very similar to some psychopaths at present uncertifiable as either mentally defective or of unsound mind. But the latter could only be compelled to submit to medical treatment if after conviction of a criminal offence this was made a condition of probation.

In the Commission's view the administrative distinction between mental illness and mental deficiency had a sound practical basis, but the rigidity with which it had been enforced through two separate legal codes had had some unfortunate results. There were also unnecessary differences between the procedures applied to the two types of patient under the present law.

Commission's Terminology

The Commission recommends that three main groups of patients should be recognized in future for legal and administrative purposes:

(a) *Mentally Ill Patients*.—The term "mental illness" would be used in the same sense as at present, including the mental infirmity of old age. The term "person of unsound mind" would no longer be used.

(b) *Psychopathic Patients, or Patients with Psychopathic Personality*.—The term "psychopathic personality" is used in a wider sense than usual. It was intended to include any type of aggressive or inadequate personality which did not render the patient severely subnormal in the sense of group (c) below but which was recognized medically as a pathological condition. The term "feeble-minded psychopath" is used to denote psychopaths whose disorder included a marked limitation of intelligence but still did not bring them into group (c).

(c) *Patients of Severely Subnormal Personality*.—This term would be used when the general personality was so severely

When he married, like all wise physicians Harvey chose the daughter of a successful physician, Dr. Lancelot Browne, physician to Queen Elizabeth, and they had on display at the College two newly discovered letters written by Dr. Browne to Robert, first Earl of Salisbury, in 1605, soliciting a post for his son-in-law, William Harvey, at the Tower of London. In 1616, the year in which Shakespeare died, Harvey wrote his famous book. The work was not published until 1628, however, and when it did appear it was produced by a printer who was nearly bankrupt and who used all sorts of scraps of paper to make it, so that the thickness of the book varied greatly from copy to copy. Costing only 6s. 2d. on publication, a first edition was worth now at least £5,000. Copies of Harvey's works, including a first edition of the *De Motu Cordis*, were on view at the College.

New Portrait of Harvey

But they were also fortunate in having on view a hitherto unknown picture of Harvey, continued Mr. Dickson Wright, which had been discovered at Berkeley Castle, Gloucestershire, and had been lent to them specially for the occasion. [The portrait, which was discovered by Dr. STUART W. HINDS, reader in public health at the London School of Hygiene and Tropical Medicine, is an oil painting about 24 in. by 30 in., inscribed at the top right-hand corner: "Dr Harvey famous physition that found out of circulation of the blood." Its subject is shown at half-length seated, wearing a black gown fastened with black buttons from neck to waist. He has a plain white collar with small tassels at the neck. The portrait has suffered from considerable overpainting and restoration, but in a descriptive note Dr. Hinds states that the Curator of the Bristol City Art Gallery believes it to have been painted about 1640 by a follower of Van Dyck. However, inquiries about the portrait are still far from complete. It is on loan to the Congress by courtesy of the owner, Mr. R. G. Berkeley, of Berkeley Castle.]

From Harvey's initial discovery a wonderful field had opened up, went on the president. Even now there was no end to what could be discovered about the circulation; we still did not fully understand it. "Could Harvey come back to-day," said the president, "I am sure he would think of some crucial experiments which would help us greatly."

Harvey's Latest Translator on His Work

Following the president's opening address, four papers were presented on the general topic of the "Knowledge of the Circulation of the Blood from the 17th to the 20th Centuries." In the first of these, Professor K. J. FRANKLIN, F.R.S., of St. Bartholomew's Hospital Medical College, suggested that for Harvey's discovery to be made a number of preparatory events had to take place. In particular, the University of Padua had to develop into the leading medical and teaching centre in the world. There Vesalius had fostered an atmosphere favourable to modern anatomy and experimental physiology, and had drawn attention to the cardiovascular system. In his notes for his Lumleian Lectures to the College of Physicians in April, 1616, Harvey, a student of Padua, wrote that it "was plain from the structure of the heart that the blood passed continuously through the lungs to the aorta as by the two clacks of a water bellows to raise water." His next reference to the matter came in his book *De Motu Cordis*, published in 1628 when he was 50.

Professor Franklin then referred to his own new translation of *De Motu Cordis*. His aim while making it, he said, had been to approach as closely as he could to the account Harvey himself would have given had he written in English. He found it rather exciting to think that three hundred years after Harvey's death it might be possible to get a better insight into his thought simply by a more painstaking translation of his Latin script, but that did indeed seem to have been the case.

Until his present venture, said Professor Franklin, he had left direct dealings with Harvey and his work to others.

because he felt there were so many more competent than himself in that rather congested field. Now, however, he wished to pay tribute to one whom he had got to know so much better through the labour of translation. He had been astonished at the insight and competence with which Harvey must have seen what was needed to be done at Padua in 1600-2, and by the celerity with which he had carried out the essential task. Personally he had found Harvey serene, appearing effortlessly great, dedicated, and sure, even with final anatomical proof of his thesis still, in 1628, to come. The royal dedication of the book was completely apposite, because Harvey's qualities were so above those of ordinary folk that he had much in common with his royal master.

The Confirmation of Harvey's Work

Professor J. F. FULTON, of Yale University, then spoke on "The Reception of the Harveian Discovery in Europe." Harvey's work, for its completion, needed the discovery of the capillaries, said Professor Fulton. Harvey himself had realized that his observation on the flow of the blood in the arteries and veins did not constitute a final proof of the circulation, and it had remained for three of his followers to provide the confirmatory evidence—Malpighi, Leeuwenhoek, and Hales.

The first of these—Malpighi—said Professor Fulton, had started using the microscope for his anatomical work and demonstrated the flow of blood through a frog's lung. Leeuwenhoek, the Dutch linen-draper from Delft with a passion for grinding microscope lenses, made possible the discovery of the capillaries; while Hales, an English parson, offered the final proof and demonstrated the existence of the capillaries. His work on the determination of the blood pressure came later.

Harvey as a Physician

SIR CHARLES DODDS, F.R.S., speaking on Harvey as a scientist and physician, said that Harvey's discovery of the circulation was the foundation of the modern idea of medicine.

Harvey's period was very fully documented, said Sir Charles Dodds, and it was easy to get a picture of how medicine was practised in his day. Conditions in town and country were quite different. The College of Physicians existed largely to license physicians to practise in London. In the country, the great houses, by reason of the poor roads, were largely cut off from the villages and the towns, and to these houses the physician only went if specially called. The physician having made his diagnosis passed his instructions for treatment to the apothecary, who made up the medicine and carried out the treatment. There were also lists of recommended treatments, "pharmacopoeias," which the officers of the great houses in the country could consult in cases of illness. Medical teaching of the day considered the body to be controlled by four humours and a lack of balance between these four was believed to be the cause of all illness. The treatment prescribed sought to restore the balance.

At St. Bartholomew's Hospital were preserved a number of prescriptions that Harvey had written, and all of them were in accord with the practice of his day. Faced with the picture of that penetrating intelligence still practising medicine as it had survived since the days of Galen, one could not help but ask what was the reason for the paradox. It appeared from a study of Harvey's discussions with his contemporaries that Harvey did not associate his discovery of the circulation with the practice of medicine, but regarded it as an entirely disconnected study in no way related to treatment. That was not perhaps so surprising considering the centuries of indoctrination in the Galenical tradition. There was also another reason: the pharmacopoeia of Harvey's day did not contain any active substance other than opium and a few purgatives. One had to wait for a hundred years after Harvey's death before digitalis was added. No progress could really be made in therapeutics

until the causes of disease had begun to be established at the end of the last century. What was surprising, however, was that the use of the ancient cures continued up to the eighteenth century and even into the nineteenth. Some maintained that a little of the old practices had lingered on into the present century.

Debts to the Past

The final address of the morning, prepared by Dr. F. A. WILLIUS, of the Mayo Clinic, was delivered by Dr. T. F. COTTON, as ill-health prevented Dr. Willius from attending the Congress.

In his paper, Dr. Willius declared that Harvey's work had opened the door for all subsequent studies dealing with the cardiovascular system. It remained a matter for astonishment that Galen's fallacious concept of the heart and circulation was almost universally accepted for nearly fourteen and a half centuries. That protracted reverence had had a profound effect in retarding knowledge of the heart and circulation. But, following the publication of Harvey's monumental work, the record showed an ever increasing amount of observation, and to-day many conditions, described long ago, were now being recognized and classified as diseases. Dr. Willius gave as examples of this the tetralogy of Fallot, first described by Niels Stensen in 1673 and redescribed by Fallot in 1888; coarctation of the aorta, first described by Morgagni in 1761 but only correctly classified in 1903 by Bonnet; patent ductus arteriosus, first described by Giulio Cesare Aranzio (1530-89); a Boston surgeon, John C. Munro, had predicted in 1907 that this condition could be treated surgically, but it was not until 1939 that an operation was successfully performed along the lines he suggested.

It was evident, said Dr. Willius, in conclusion, that our medical forebears had built wisely and well. Without that foundation of knowledge present-day scientists could not possibly have achieved the amazing progress of the last two decades.

Nova et Vetera

LINNAEUS

NATURALIST AND DOCTOR, 1707-78

There are few men in history whose fame is so universally recognized as that of Linnaeus. The significance of the single letter L which follows so many botanical and zoological names is quickly learnt by the youngest students of biology. They are soon told that Linnaeus was one of the greatest naturalists of all time. As readers of this *Journal* were reminded about a year ago, "he was also a physician with a remarkably wide range of interests, including pathology, chemistry, pharmacology, surgery, gynaecology, zoology, mineralogy, anatomy, physiology, veterinary medicine, and farming." It sounds a formidable list, but is perhaps merely the modern way of saying that he was a good all-round doctor with a love of country life. It is for his fundamental contributions to botany and not to medicine that during the past two weeks the 250th anniversary of his birth has been celebrated by the learned and noted by the newspapers throughout the world.

Carolus Linnaeus, whose Latin name is more familiar than the Swedish Carl von Linné which he adopted after he was ennobled, was born at the little village of Stenbrohult in southern Sweden on May 23, 1707. He was the eldest child of a country parson, Nicolaus Linnaeus, whose own family was of poor peasant stock but whose wife's included a number of learned theologians. He first learned to walk in his father's garden, which was celebrated throughout the district for the number and variety of its flowering plants, over two hundred of which were imported, and it was in this garden that his father taught him the names of all the plants to be found in it. At the age of 7 he left home for school in Wexjö, and there soon met a certain

Dr. Rothman, a friend of the headmaster, who persuaded the boy that he should train for a career in medicine, a profession that was not particularly lucrative in Sweden at that time. In spite of their disappointment, for they had intended him for the Church, his parents allowed him to become Rothman's private pupil, and by the time he left school at the age of 19 he was already acquainted with the writings of the great Boerhaave and had acquired some knowledge of physiology and a greater knowledge of botany, then an important part of medical studies. After a year at the university at Lund, where he lived with the professor, Dr. Kilian Stobaeus, but found little otherwise to attract the student, he transferred to Upsala, 300 miles away. There, too, the medical teaching left much room for improvement. In order to see an anatomical demonstration he had to make the journey to Stockholm, where the cadaver of a woman who had been hanged was being dissected. In 1729, at a time when poverty and actual hardship threatened to end his studies, he had the first of those many lucky encounters which played such an important part in his life.

Fair Botanist

It seems that he had great personal charm, which, combined with his unusual knowledge and earnest enthusiasm, attracted the interest of rich and powerful patrons. Rothman had first turned his steps towards medicine, but now the well-known Professor Olof Celsius, who found him studying specimens in the botanical gardens and who was astonished to learn that the shabby youth possessed his own collection, took him under his wing. Grants were obtained for him to complete his studies, and before long he was earning money by demonstrating the collections to students and conducting botanical excursions into the surrounding country. Teaching in the day, he spent his nights studying and writing, and in particular in developing his ideas on the sexual system of plants, work which he completed before he was 24, but had first approached two years earlier in an essay entitled *Nuptia Plantarum*. Admitting that he was "not a poet born, but a fair botanist," he yet wrote in terms which are no longer associated with scientific exposition. After arguing the analogy between animals and plants, he goes on:

"From this we conclude that even with plants there exist organs of generation. That these organs are to be found in the flowers is proved by the fact that when there is no fruit there was previously no flower. The petals contribute nothing to generation but serve only as bridal beds which the great Creator has arranged so beautifully, with the purest bed curtains, and perfumed with such delicious fragrance that the bride and groom may there celebrate their nuptials with so much greater ecstasy."

Phrases such as this gave the tone for one of the few public opponents of Linnaeus's new sexual theory, Professor Siegesbeck, of St. Petersburg, who wrote:

"God would never permit, in the kingdom of plant life, such detestable unchastity as that of several men [stamens] owning a common wife [pistil]; or that married men would [as in certain plants], besides their legitimate wife, have additional legitimate ones in neighbouring flowers. Such an unchaste system could never be presented to young students without causing righteous indignation."

Far from causing "righteous indignation" the new theory aroused the greatest enthusiasm, and Linnaeus found himself lecturing to audiences of 400 while the senior professors had difficulty in mustering their normal 80.

Visit to Lapland

Still mindful of his ultimate aim to obtain a medical degree, he studied therapeutics under Nils Rosen at Upsala and he spent the summer of 1731 in the pharmaceutical laboratory at Stockholm, but quite a different project now captured his imagination and further postponed his formal enrolment as a physician. He had been living at Upsala with the professor of medicine, Olof Rudbeck, jun., who often talked of his journey into Lapland in 1695 and spoke of the wealth of material for the naturalist to be found in that almost unknown region of Europe. Fired with

Linnaeus in his Lapp costume. Painted by M. Hoffman about 1737. By courtesy of the Wellcome Historical Medical Library.

enthusiasm, Linnaeus worked out proposals for an expedition, which received official sanction and secured a modest grant from the Government. This journey, carried out in 1732, occupied four months and took him great distances, a feat of endurance which was remarkable for one whose health was never robust. From the notes and records which he kept he produced his *Flora Lapponica* as well as a pioneer work on the life and customs of the Lapps entitled *Iter Lapponicum*. One of his souvenirs of this journey which he always treasured was the Lapp costume which he wore for the portrait painted after his return.

For another two years he continued to combine study and teaching at Upsala with excursions, one of which took him to the old mining town of Falun, where he fed his new interest in mineralogy by exploring the famous old copper mine, and where too he met his future wife, Sara, daughter of Dr. Johan Moraeus, one of the best-known practitioners in Sweden. He was still as far as ever from obtaining a medical degree, but this meeting resulted in his deciding to travel abroad and to graduate at one of the Dutch universities.

Leaving Sweden in February, 1735, he travelled first to Hamburg and then to Amsterdam and Harderwijk, taking with him a number of manuscripts for which he hoped to find publishers, a mounted collection of nearly a thousand insects from Lapland and Dalarne, and his famous Lapp costume with its curious ornaments. The impression he created is reported in contemporary accounts and was everywhere most favourable. The small university at Harderwijk had many links with Swedish doctors who went there for their medical degrees as English practitioners of the time went to Aberdeen or St. Andrews, to pay a comparatively low fee, to pass a short examination, and to return within a few days with the long-desired M.D. Linnaeus was asked some questions in general medicine, explained the diagnosis and treatment of jaundice, wrote a review of the aphorisms of Hippocrates, and submitted a thesis (already written in Sweden) on the cause of intermittent

fever. His bearing and knowledge impressed not only his examiners, chief of whom was Johan de Gorter, but all who were present when he successfully defended his thesis, and he made many new friends. Among them was Dr. J. F. Gronovius, one of the greatest collectors of plants in Holland, who, when he was shown the manuscript of the *Systema Naturae* immediately offered to bear the expense of publication, an offer in which he was joined by a rich Scot named Lawson. The slim atlas folio, filled with tables of classification, now one of the treasures of scientific literature, appeared in December, 1735. It went through 16 editions during the lifetime of Linnaeus, being improved and enlarged each time.

Binomial Nomenclature

Its importance lies in the fact that it established the universal application of the binomial system of nomenclature to all animals and plants, the generic name being followed by the descriptive epithet which singles out the species within the genus. Previously suggested by Joachim Jung, Bauhin, and Ray, it required the industry and learning of Linnaeus to demonstrate its value on the scale necessary to secure its general acceptance. Modern zoological nomenclature is regarded as beginning with the tenth edition of this work, published in 1758, just as botanical nomenclature dates from his *Species Plantarum* of 1753.

The *Systema Naturae* was the first of many important works which Linnaeus published during his three years in Holland. Leisure and opportunity for carrying out his labours were afforded him by the outcome of his meeting with Boerhaave, who warmly recommended him as personal physician and botanist to the wealthy director-general of the Dutch East India Company, Dr. George Clifford, former burgomaster of Amsterdam, who had a large and important private botanical and zoological garden situated between Leyden and Haarlem. Linnaeus lived like a lord on Clifford's grand estate, making every use of the fine library and museum, as well as of the gardens, with their plants from every part of the world and their extraordinary collection of birds and rare animals. In 1736 he paid a short visit to England, bringing with him a letter of intro-

Linnaeus in 1774. Portrait after Per Krafft the Elder. By courtesy of the Wellcome Historical Medical Library.

Correspondence

Coal-gas Poisoning

SIR,—The report of the British Medical Association's sub-committee on coal-gas poisoning has received considerable publicity. The medical officers in the industry have considered this report and feel that there are some parts of it in which the emphasis has been misplaced, so that people ignorant of the hazards of carbon monoxide might easily be misled. I am therefore sending this letter on behalf of the chief medical officers of the area gas boards.

The report says: "An air-line or oxygen breathing apparatus is the only safeguard for *more than short exposures* [to gas]" (my italics). This would seem to imply that, if the exposure to gas is short, no air-line or other breathing apparatus is necessary. Scientifically this is a true statement, but it is an extremely bad working rule, because a man working with gas can very rarely know when the exposure is going to be so short that he will not need to take precautions.

"A canister gas mask is of strictly limited benefit." This sentence is also open to criticism, because it implies that there are certain circumstances in which it is a safe appliance. Such appliances are not approved by the factory department of the Ministry of Labour, and for very good reason. They are dangerous because: (1) the catalyst wears out and there is no means of knowing when it is worn out; (2) if the catalyst breaks down the wearer is likely to come to serious harm without finding this out; (3) they are, of course, quite useless in an atmosphere which contains less than the amount of oxygen necessary to maintain life.

"This process of elimination is hastened by the administration of pure oxygen: if the patient's breathing is weak the oxygen administration should be supplemented by some form of artificial respiration." This again is an accurate statement, but it places the emphasis upon the administration of oxygen and not of artificial respiration. A man who needs oxygen may well recover without it: a man who needs artificial respiration *must* be given this treatment. Undue emphasis on the administration of oxygen might well lead to artificial respiration being delayed in order to fetch an oxygen apparatus, or even omitted while oxygen is being given.

It is unfortunate that the recommendations of the committee make no mention of the importance of manual artificial respiration or the importance of training in this. It is a pity that the compressed air breathing apparatus is not mentioned in the report.—I am, etc.,

G. O. HUGHES,

Convener,

Medical Officers Committee
of the Gas Council.

Macroglobulinaemia

SIR,—We are indebted to Dr. D. W. Oxbrow for his comments (*Journal*, March 30, p. 759) on our paper (*Journal*, March 9, p. 561). The presence of high-molecular-weight globulins has been described in serum unassociated with lymphoma or with the recognized features of macroglobulinaemia; nevertheless, in all our cases the syndrome of macroglobulinaemia had an intimate relationship to malignant lymphocytic proliferation.

Lymphosarcoma was, without doubt, the histological diagnosis in our cases 1, 2, and 4. Case 3, in whom lymphosarcoma had been diagnosed by splenic biopsy, has subsequently, on the advice of Professor L. J. Witts, had a splenectomy for anaemia and gross splenomegaly; sections of spleen and abdominal lymph nodes corroborated the diagnosis. Three further cases have now come to our attention; one of these has a proved lymphosarcoma, and in two others this diagnosis is likely but unconfirmed. We omitted detailed microscopic descriptions from our paper, because the histology was that of lymphocytic lymphosarcoma.

duction from Boerhaave to Hans Sloane. He also visited Oxford, where he saw the physic garden and met the naturalist Dillenius.

After a severe attack of cholera in the spring of 1738 he decided to return home, and, after a short visit to Paris, where he was urged to remain, he arrived in Stockholm in September. There, after the usual discouraging start, he soon built up a flourishing practice, and, through the support of a new friend and admirer, Count Carl Gustaf Tessin, one of the most important men in Sweden, secured several profitable official appointments. In 1739, with four others, he founded the Swedish Royal Academy of Science and became its first president. Thus well established at the age of 32, he was married in June of the same year to Sara Moraeus, of Falun, and for the next two years he was probably the busiest practitioner in Stockholm. Yet he lectured as well as practised and found time to establish a physic garden. He was given official permission to carry out post-mortem examinations and is regarded in Sweden as that country's first morbid anatomist.

Professor of Medicine

When, in 1741, the chance came of succeeding to the post of professor of medicine and botany at Upsala, it was eagerly seized, for he still regarded botany as his life-work. He held this post until he died in 1778. His death was announced in Parliament by the King of Sweden and his body was buried in the cathedral of Upsala. The house which he occupied as professor, the same house which he had first known as a poor student, is still kept as a memorial to Linnaeus, and so too is his country home at Hammarby, six miles away, where he spent the last 20 years of his life. But his finest memorial is probably the wonderful collection of his correspondence and manuscripts: his heirs sold it to a medical student, James Edward Smith, for 1,000 guineas in 1784, and it is now the most valued treasure of the Linnaean Society of London, which Smith founded.

It is as the unrivalled systematist that he will always be remembered in the history of the natural sciences. His sexual system, of the greatest importance in its time, has now given place to other systems which express more clearly the facts as we now know them, but we cannot put too highly the debt we owe him for our system of biological nomenclature. His genius for classification extended even to diseases—he published a *Genera Morborum* in 1763—and, as Dr. Henry Viets recently pointed out, we are indebted to him also for the original description of aphasia. It is fitting, then, that he should be commemorated in this *Journal* not only as a naturalist but also as doctor.

F. N. L. POYNTER.

THE VACANT CHAIR

"January 14th, 1851.—To Windsor, and walked up to the Castle. . . . I had a few words with the Prince about the Regius Professorship of Medicine at Cambridge now vacant by Haviland's death. I remarked that it was impossible to make either Oxford or Cambridge a great medical school. He said, truly enough, that Oxford and Cambridge are larger towns than Heidelberg, and yet that Heidelberg is eminent as a place of medical education. He added, however, something which explained why this was. There was hardly, he said, a physician in Germany, even at Berlin, even at Vienna, who made £1,000 a year by his profession. In that case a professorship at Heidelberg may well be worth as much as the best practice in the great cities. Here where Brodie and Bright make more than £10,000 a year, and where if settled at Cambridge or Oxford, they probably could not make £1,500 there is no chance that the Academic chairs will be filled by the heads of the profession."—From Sir G. O. Trevelyan's *Life and Letters of Lord Macaulay*, Vol. II, page 290.

¹ Lillingston, C., *British Medical Journal*, 1956, 1, 1041.
² Viets, H., *Bull. Hist. Med.*, 1943, 13, 328. (Facsimile reproduction of an English translation of a case report published in

The course of macroglobulinaemia is not "comparatively benign" as Dr. Oxbrow states—two of our patients (cases 2 and 4) have died of the disease, and one (case 1) is now very ill. We know that some lymphosarcomata may run quite a protracted course, and indeed it is in such cases that the greatest opportunity for mutations will occur. The clinical picture is quite consistent with a slow-growing lymphosarcoma complicated by effects produced by the circulating abnormal protein, the synthesis of which represents an activity just as autonomous and "purposeless" as malignant cell proliferation itself.—We are, etc.,

IAN R. MACKAY,
L. I. TAFT.

Melbourne, Australia.

Adder Bite

SIR,—There has recently been reported an increase in the numbers of the British adder, probably due to the very mild winter we have just experienced. The following personal incident may therefore be of some interest.

After picnicking this month in a Worcestershire forest with my family I was walking up a sunny woodland path when I was struck from behind over the lower third of my tendo achillis by an adder. The immediate pain precluded any attempt to kill the snake. After contemplating the situation for about half an hour I decided to try and drive my car the 20 miles to home. By the time I had done four miles the ankle was grossly swollen, there was some pain in my loins, and shortly afterwards I had to be helped out of the car in a very shocked and dyspnoeic condition. My admission to a general hospital was quickly arranged, and there the bite was opened by cruciate incision, the wound irrigated with potassium permanganate solution, and repeatedly dry-cupped with a preheated bottle. Polyvalent antivenin, together with antitetanic serum, was given subcutaneously. The next day the whole limb was grossly swollen and there were large perilymphatic haemorrhages up to the groin. Despite a week's treatment with oral antihistamines, serum sickness developed on the eighth day and was only controlled by subcutaneous injections of adrenaline.

My conclusions from this experience are that this snake's proteolytic venom can cause severe systemic effects in an adult, and that, unless attention were promptly given, could easily prove fatal to a child.—I am, etc.,

Birmingham, 6.

K. W. BREWSTER.

Appendicitis in Young People

SIR,—In his article (*Journal*, May 25, p. 1217) Dr. J. A. H. Lee contrasts the high rate of appendicectomies in young women with the low death rate from appendicitis in that group. I have seen a number of cases recently in which the possibility of ovarian pain was overlooked in the differential diagnosis of pain in the right iliac fossa. Such pain is very common in young women, and may be due to physiological congestion in a healthy ovary (1) at the time of ovulation, or (2) when sexual excitement is unrelieved.

The ovarian origin of this type of pain is presumably overlooked so often because it would be expected to be bilateral. One can explain the predominance of right-sided pain by postulating some "appendix-consciousness" in most intelligent young people to-day. Several of the cases I have seen were in nurses and ex-nurses, who could be expected to give first preference to the appendix in their search for the culprit-organ when experiencing low abdominal pain.—I am, etc.,

Maidstone, Kent.

R. SANDER.

Scapulo-thoracic Crackling in Youth

SIR,—This is not uncommon, and occurs, as Dr. F. Parkes Weber says (*Journal*, May 18, p. 1181), usually in late adolescence, more in the female. There is no pathological change, but it is usually assumed by the patient to be a precursor of arthritis. It is due to hypermobility of the scapula and is associated with faulty posture such as thoracic

kyphosis and scoliosis, and attempts at self-adjustment haul the scapula through an abnormal range.

The treatment, after the correction of the mechanical disabilities by manipulation, as far as this is possible, is to give shoulder girdle exercises combined with deep breathing, and as long as these are done meticulously recurrence is rare. The patient, of course, should be persuaded that there is no point in producing the grating. It was, I think, Smith-Petersen who said to a mutual patient, "This is a disagreeable noise, neither amusing nor useful, and we do not have to do it."—I am, etc.,

London, W.1.

GUY BEAUCHAMP.

The H-bomb

SIR,—I wish to support Mr. N. Capener's plea for the ending of nuclear-bomb tests (*Journal*, May 25, p. 1246). Like him, "I have failed to observe any serious move by the B.M.A." or any other influential medical body in this matter. Several years ago (*Journal*, February 13, 1954, p. 394) I expressed the opinion that the control of nuclear weapons was the urgent concern of preventive medicine. But though there have been informative articles in the medical press on the pathological effects of bomb tests, these must be supplemented by purposive action (as in every branch of preventive medicine) if any result is to be expected. Could not the B.M.A. point the way at its annual meeting in July?

It is the duty of the medical world to be constantly reminding politicians of two salient facts about nuclear weapons: (1) that continuous nuclear tests will damage world health, and (2) that actual nuclear warfare would produce a catastrophe which no medical organization could cope with. Medical leadership in each country should "bombard" their respective governments with these doctrines at regular intervals, until international control is achieved. Unless we bestir ourselves in such ways we shall fail in our duty as guardians of the public health.—I am, etc.,

Hove.

W. V. CRUDEN.

SIR,—I am sure I am only one among many who welcome Mr. Norman Capener's letter (*Journal*, May 25, p. 1246) with its appeal to the medical profession to make a protest against the continuation of nuclear bomb tests. Unlike physicists and engineers, we are not burdened with the heavy responsibility involved in having had a direct part in the making and testing of these weapons of mass destruction. We must accept responsibility for "public health" in the widest sense of the term, and we are neglecting our duty if we fail to appeal to those in authority to end these tests. The degree of dangerous radiation can only be measured by damage to human life, not to volunteers in laboratory tests but to chance victims. In this case we must not wait for the collection of results before we act. Can we refuse to make our position clear when so much is at stake?—I am, etc.,

Loughton, Essex.

RACHEL HUNTER.

Is This a Record?

SIR,—On Wednesday a boy aged 3 was thought to have swallowed a screw which was found to be missing from something which he was playing with in the garden. He said, "Hurt," and pointed to his throat, but was otherwise quite unconcerned. An hour or two later I examined his throat quite easily and could see no sign of any abrasion. He remained well on the Thursday, Friday, and Saturday, with a good appetite, no abdominal pain, and passing a regular motion each morning, which was carefully searched. On Sunday, to quote from his grandmother's letter, "the screw reappeared from C's inside. . . . He complained of pain as it came out, but only for a moment and no scratching is apparent. I underestimated the length: it measured just over 2½ in. (5.4 cm.)—not quite 2½ in. (5.7 cm.), and was ancient and rusty and stout to match its length. I feel we have had a wonderful escape."

I wonder if your readers would agree with my line of reasoning. In keeping with my habit of limiting the amount of x-radiation to which my patients are exposed, particularly children, I refrained from asking for a radiological search for the screw, knowing full well that if any untoward symptoms occurred such an examination would then be necessary. If an x-ray had been taken in the absence of symptoms, parental anxiety would have been increased rather than otherwise. In these cases, which are not infrequent in general practice, the important thing seems to be the examination of all faeces passed for at least a week. What is the largest solid body which has passed unscathed through the intestine of a child of 3, and what is the longest that a foreign body has remained hidden from view before ultimately being evacuated?—I am, etc.,

Peaslake, Surrey.

G. I. WATSON.

Pseudomonas pyocyanea in Cetrimide

SIR,—Referring to your recent correspondence regarding the growth of *Pseudomonas pyocyanea* in cetrimide solution, I have had some experience of this while serving as a pharmacist with the Royal Air Force at Halton in 1953. It was first discovered in wounds in the surgical wards. On this discovery the pathological laboratories also took samples from ward and theatre antiseptics used for preparing and cleaning the skin pre- and post-operatively. Cultures of *Pseudomonas pyocyanea* were obtained from stock solutions of 1% cetrimide from both ward and theatre. Our stock solution of 10% cetrimide in the dispensary from which these solutions had originally been prepared was then tested, and found also to be infected. It was noticed that some of the containers were closed with corks, including those in the dispensary, and it was suggested that the corks were the source of the infection. When demobilized the wards, theatre, and dispensary were all changing to containers with ground-glass stoppers for all such antiseptics. Unfortunately I did not have the opportunity of following this experiment to its conclusion.—I am, etc.,

Hillingdon, Middlesex.

P. J. KEEN,
Pharmacist.

Pharmaceutical Research

SIR,—I have awaited with impatience the expected protest from those better qualified to speak than am I against the implications contained in the sentence which I quote from your leading article (*Journal*, May 11, p. 1107): "This being so, the question arises whether more in the way of useful as distinct from academic research could be done in the universities." Do you consider that fundamental research is "of no use," or is this just a singularly unhappy choice of words?—I am, etc.,

Cardiff.

J. D. P. GRAHAM.

**The O.E.D. defines "academic" as: "Not leading to a decision; unpractical." The word "practical" might have been more apt than the word "useful."—ED., *B.M.J.*

Antibiotic Combinations

SIR,—The appearance of two leading articles on antibiotics within the past few months—namely, "Antibiotics Galore" (*Journal*, January 19, p. 150) and "Fourth Symposium on Antibiotics" (*Journal*, May 4, p. 1050)—has prompted us to write this letter, since it seemed to us that only one side of an important research and therapeutic problem has been presented.

The use of combinations of antibiotics is a subject over which there is much controversy, but there are nevertheless two fundamental facts about which there is no disagreement. These are that (1) combinations of drugs have become the logical approach to the treatment of tuberculosis; (2) the widespread use of antibiotic drugs has in some cases resulted in the emergence of a bacterial population resistant to certain antibiotics. Combined antibiotic therapy is a positive attempt to deal with the problem of resistance.

Finland¹ has not questioned the fundamental theoretical validity of antibiotic synergism, but questions whether such synergism can be optimally obtained with fixed combinations. While the practising physician may be desirous of using two different antibiotics simultaneously in the treatment of any case, it is unlikely that he will be in a position to decide what proportions of antibiotics would be likely to give the best results. In hospitals where laboratory facilities are available, the proper combination to use can be determined by performing sensitivity tests with the infecting organisms. The delay in waiting for these results, however, means that time is lost in the treatment of the patient, and the use of a combination which has been shown to be effective eliminates this difficulty; further, the general practitioner is usually not in a position to perform sensitivity tests.

On the basis of intensive bacteriological research it was found that the combination of tetracycline and oleandomycin in a certain proportion exhibited the phenomenon of synergism.² As a result of this discovery it was decided to make available to physicians a fixed combination comprising these two antibiotics. Such a combination is also shown to delay the emergence of resistant strains in much the same manner in which streptomycin and I.N.H. are used in combination in tuberculosis. It may be argued that fixed proportions are undesirable and that the physician may wish to vary the doses, but, though this may be so in many cases, it certainly is not a practical possibility in all,^{3,4} and once again the question is posed: Who is in the position to decide on these relative dose recommendations? While there has been much adverse criticism against fixed combinations of antibiotics, there has been no published work to show that these combinations are undesirable, and the criticism has been evolved on theoretical considerations. The ultimate verdict on fixed combinations is surely the clinical effectiveness of the compound. The practising physician himself will decide in the light of experience whether antibiotic combinations are of value or not.—We are, etc.,

Acute Immediate Reactions to Penicillin

SIR,—I was most interested in Dr. G. W. Lewis's careful and painstaking study of penicillin reactions (*Journal*, May 18, p. 1153). I am, however, unable to agree with his and other workers' conclusions that accidental intravenous injection or seepage of penicillin is an important cause of anaphylactic episodes. Once an individual has become sensitized against a certain substance it does not matter how the offending substance (chemical or serum or any other protein) is reintroduced—e.g., the very alarming reactions after tetanus or diphtheria serum, or after hay fever desensitization—when reactions may occur with almost homeopathic dilutions injected subcutaneously or intradermally.

Venereologists will agree that in the days of intravenous salvarsan therapy one of the most common causes of sensitization against this chemical was an imperfect intravenous technique (paravenous, subcutaneous infiltration). This fact was well illustrated in the studies of Frei¹ and Nathan, Munk, and Grundmann² (experimental salvarsan sensitization), when it could be shown that with an intradermal injection of 1 ml. of a 1:100 solution of a primary non-toxic salvarsan derivative—e.g., myosalvarsan—approximately 30% to 35% of tested subjects could be sensitized, whereas spontaneous sensitization occurred only in 3% to 5% of patients during antiluetic treatment.

From these considerations I am almost sure that if cutaneous contamination with penicillin could be avoided

(injecting $\frac{1}{2}$ ml. or so of normal saline through the needle at the end of the penicillin injection) the number of penicillin sensitizations could be appreciably reduced. Perhaps it is worth trying.—I am, etc.,

Sheffield, 10.

Hospital Confinement

SIR,—I have no desire to engage in controversy with Dr. F. Stabler (*Journal*, May 18, p. 1182) on the relative safety of hospital versus domiciliary confinement. I have the greatest respect for people who can perform good work with the poor facilities afforded by the average home, but it should be apparent that this work could be done with greater safety for mother and baby under the optimum conditions of a modern delivery room. It would be discourteous to a senior colleague to elaborate this point any further. The object of my original letter (*Journal*, April 20, p. 947) was merely to point to an obvious solution of the maternity bed shortage in this country—namely, early ambulation and early discharge from hospital. May I add that, not being in the National Health Service, my interest in the matter is entirely academic?—I am, etc.,

Pinner, Middx.

J. P. O'DWYER.

Budgerigars in Wards

SIR,—As a breeder of budgerigars for the past twenty years, I was interested in Dr. N. A. Thorne's letter in the *Journal* of April 27 (p. 1008). I agree with Dr. Alex. Watt (*Journal*, May 18, p. 1182) that these birds should not be kept in wards. They do, as he says, create a fine dust in and around their cages which could adversely affect any patient allergic to such dusts. Also, I am strongly opposed to budgerigars being kept in cages unless they have free egress to fly about the room throughout the daylight hours. In my opinion it is little short of cruelty to keep a budgerigar shut up in a small cage. Budgerigars are essentially gregarious birds, and the only place for them is in an aviary (which could face the ward windows), the flights being at least 14 ft. (4.2 m.) long by 6 ft. (1.8 m.) high.

Dr. Thorne may be interested to know that a proved case of psittacosis in an aviary-bred budgerigar has never been known.—I am, etc.,

Fairford, Glos.

S. B. S. SMITH.

Televised Operations

SIR,—In your issue dated May 25 (p. 1252) it is reported, in connexion with demonstrations of operative technique, relayed from St. Bartholomew's Hospital on closed-circuit colour television: "This is stated to be the first occasion in Britain on which colour television has been used for a medical programme of this sort." You may be interested to know that in 1950 Pye Limited, of Cambridge, installed equipment at St. Thomas's Hospital, London, for a five-week series of operations, televised in full colour to audiences which included an international convention of ophthalmic surgeons. This successful demonstration of the value of colour television excited considerable interest and was, in fact, the first time that colour television had been put to such a use in this country.—I am, etc.,

Cambridge.

J. M. GORST,
Public Relations Officer,
Pye Limited.

Range of Movement of Testicle

SIR,—I read the article on range of movement of testicle (*Journal*, May 18, p. 1165) with interest. For years I have been teaching house-surgeons about Mr. Denis Browne's superficial inguinal pouch. Mr. Browne complains that the anatomists have not described any cavity into which the testes can go when they are retracted upwards out of the scrotum. The reason for this is that there is no "cavity." If an account

of the anterior abdominal fasciae¹ be studied it will be obvious that there is no cavity. The superficial inguinal pouch is a clinical entity. When the testicle is retracted, I agree, it cannot and does not enter the inguinal canal. It cannot pass medial to the external ring because the fascia of Scarpa is firmly fixed to the linea alba. It cannot pass downwards and laterally into the thigh because Scarpa's fascia fuses with the inguinal ligament at its attachment to the pubic tubercle—i.e., the medial end of Holden's line. It can only pass upwards and lateral to the external ring where it is allowed to do so by the loose areolar tissue that binds Scarpa's fascia to the external oblique aponeurosis. The size of the superficial inguinal pouch into which the testis is retracted is determined solely by the size of the testis.

The description by Mr. Browne of the findings at operation in an infant with inguinal hernia is perfectly accurate. However, when the testis is allowed to return to the scrotum the loose areolar tissue space disappears. The superficial inguinal pouch is therefore an accommodation space allowed by the laxity of the areolar tissue deep to Scarpa's fascia. This loose areolar tissue is designed to permit a considerable mobility between the skin and superficial fascia and the deep fascia and muscles.² I would say that the proper place for a description of the superficial inguinal pouch is a manual of surgical anatomy and not a textbook of topographical anatomy.—I am, etc.,

Middlesbrough.

SIR,—Mr. Denis Browne (*Journal*, May 18, p. 1165) raises some interesting points. The continuity of what we now call the membranous layer of the superficial fascia of the abdomen (Scarpa's fascia) with the superficial fascia of the scrotum, and the very loose texture of the areolar tissue deep to it, were described by "the laborious and indefatigable M. Winslow."¹ I suppose, however, that it is Abraham Colles² that English textbooks of anatomy are saluting in their descriptions. A glance at the 30th edition of *Gray's Anatomy*³ will convince most readers that anatomists have not failed to describe a loose areolar tissue—continuous with the cavity of the scrotum—anterior to the lower part of the external oblique. It is true, however, that the accounts of the anatomy of the region have not been influenced by Browne's paper of 1938,⁴ for they have been substantially the same for a hundred years. "The deep layer of superficial fascia should be divided . . . separated from the aponeurosis of the External Oblique, to which it is connected by delicate areolar tissue. . . . It is thin and aponeurotic in structure. . . . It forms a thin tubular prolongation around the outer surface of the cord . . . and is continuous with the dartos of the scrotum"—thus *Gray's Anatomy* in 1858.⁵ There is also a figure illustrating the anatomy.

Textbooks of embryology describe the position of the genital folds (labio-scrotal folds) correctly and demonstrate that the skin and superficial fascia at the side and slightly headward of the penis are embryologically of the same origin as the scrotum. The illustrations in Mr. Browne's clinical memorandum could be interpreted as an instance of the testis being pushed from a lower to a higher position in the scrotal fold.

As for the mobility of the testis, it can be moved in three ways: (1) by the cremaster, (2) by the dartos, (3) by hand. The cremaster was described in Charles Bell's *Anatomy of the Human Body* in 1803⁶: "Its use is to suspend the testicle and prevent it from dragging on the vessels of the chord . . . sometimes this muscle draws the testicle spasmodically to the groin." Not many would quarrel with this description to-day. The cause of Mr. Browne's philippic is the belief that the cremaster may draw the testicle back into the inguinal canal. It is indisputable that contraction of the cremaster must shorten the cord, must pull the testis towards the superficial inguinal ring. Whether the testis is

JUNE 8, 1957

pulled back into the canal, the cord preceding it, will depend on the relative sizes of testis and superficial ring, and on the relative lengths of the parts of cremaster inside and outside of the inguinal canal. It is plain that in normal circumstances, in man, conditions will be right only for a short time during the later stages of descent of the testis—that is, in some infants and in children in whom descent is occurring late. I believe I have seen such cases. Mr. Browne says I have not. The dartos and hand can move the testis in its subcutaneous position and cannot push it into the superficial because that structure is occupied by the cord and protected by the reflection of external spermatic fascia on to the cord. It is rather like trying to pot the black when the pink is in the jaws of the pocket. The little experiment described in Mr. Browne's second paragraph proves that the experiment can be performed but does not test the action of the cremaster as he claims. In medicine, as in physics and chemistry, it is desirable to test hypotheses only by properly designed experiments.—I am, etc.,

JOHN GRAY.

Trichomonas Vaginitis

SIR,—Dr. Josephine Barnes (*Journal*, May 18, p. 1160) and her colleagues show that there is still no effective oral treatment for trichomonas vaginitis. Their findings are similar to those obtained by Dr. P. A. Manolis in the Saint Mary's Hospitals for Women and Children (*Journal*, March 2, p. 517) a detailed report of which is being prepared.

I would, however, like to comment on their remarks concerning the culture of *T. vaginalis*. For some years now we have been able to grow trichomonads and maintain subcultures for several months. We use a medium based on that of Feinberg¹ but considerably modified to make use of readily available constituents. Batches of medium vary in their ability to support growth, and strains of *T. vaginalis* also vary in their ability to grow well in primary cultures, but after several subcultures at three-day intervals growth is usually abundant. All specimens of vaginal discharge for culture are collected in pipettes and inoculated into 10 ml. of the media without the addition of saline. The medium used by Dr. Barnes was autoclaved twice during preparation, and we have found that over-heating is an important factor in the failure of any batch of our medium.

While I would agree that the carefully examined wet preparation is as useful as a culture in routine work, for tests of cure following the use of trichomonocidal drugs the addition of a cultural technique is most valuable. Similarly in the examination of males, when specimens are scanty and are likely to contain very few protozoa, a cultural technique is essential, and at the time of writing by using our medium Dr. Leslie Watt and I have isolated trichomonads from more than half of the male consorts of women with trichomonas infection. This investigation is still proceeding and will be published in due course.—I am, etc.,

R. F. JENNISON.

SIR,—I would like to make some comments on the article on *Trichomonas vaginalis* by Dr. Josephine Barnes *et al.* (*Journal*, May 18, p. 1160). These writers say that their "second object was to test the use of the simplified trypticase serum medium for the culture of *Trichomonas vaginalis*." All the medium used in their work was supplied by myself (though this is not stated), half a batch being kept for our use and half sent to the Garrett Anderson Laboratory. The trypticase (pancreatic digest of casein), unobtainable in this

country, was generously given by Ortho Pharmaceuticals Ltd. We had the most satisfactory results, both with direct culture, subculture, and keeping cultures at bench temperature and in the refrigerator for several days. I can only suppose that the Garrett Anderson incubator, which was known to be at too high a temperature, was never successfully lowered to 35–37° C., which is the optimum for growing *Trichomonas vaginalis*.¹

Hearing of Dr. Haram's (the pathologist's) difficulties, I rang her up and offered any help that we could give, and I think it is unfortunate that this was not accepted, as it might have brought her results into line with the other workers. I could also have told her that the medium we were supplying was modified both in constituents and preparation from Kupferberg's original medium,² which she claims to have been using and describes in her paper. I feel that, as a test of simplified trypticase serum medium, this work should be ignored.—I am, etc.,

High Wycombe, Bucks.

SIR,—Since reporting (*Journal*, May 18, p. 1160) a trial of culture medium for *Trichomonas vaginalis*, I have had the opportunity of meeting Dr. A. B. Kupferberg, who formulated the simplified trypticase serum medium which has been widely used in America with great success over a number of years. Dr. Kupferberg finds that the medium with which I was supplied for the trial had been considerably modified and not prepared as indicated in the report. This may well account for the disappointing results achieved.—I am, etc.,

B. JOAN HARAM.

Sir Ronald Ross

SIR,—Observing your leading article (*Journal*, May 11, p. 1108) on malaria control, in which you refer to Sir Ronald Ross as one of the great benefactors of mankind, prompts me to ask why the centenary of this great man is not being officially commemorated this year. I recall that the issue of *The Times* published the day after Sir Ronald Ross died in 1932 stated in a leading article that by his death the greatest figure in contemporary British medicine had passed away. That being so, one would have thought that in this centenary year of his birth special celebrations would have been held to remember the man and his work. These would have included a church service at which his hymns—for he was a hymn-writer—could have been sung. Perhaps the Ross Institute of the School of Tropical Medicine and Hygiene has something in mind.

If the tercentenary of the death of William Harvey is to be elaborately celebrated, as it is this year, surely Ross's work ought to be remembered too. After all, the conquest of the scourge of malaria was as epoch-making as was the discovery of the circulation of the blood. One hopes something will be done to show that Ross's name and his work are not forgotten. His discovery certainly ranks as famous as that of Simpson's in connexion with anaesthesia and Lister's in connexion with antiseptics.—I am, etc.,

J. B. GURNEY SMITH.

Notification of Infectious Diseases

SIR,—We should like to lend our support to the suggestion by Drs. R. M. Emrys-Roberts and E. O. Gibson (*Journal*, May 25, p. 1241) that measles, whooping-cough, scarlet fever, and acute pneumonia should cease to be notifiable diseases, and to add the suggestion that rubella should replace them. As the one known cause of congenital defects in man where a definite aetiological relationship can

be established in an individual case, the notification of this disease becomes vitally important at a time when the effects of increased background radiation due to thermonuclear explosions remain to be determined. The possession of these statistics would provide at least some semblance of a base line of variations due to other causes in the incidence of these conditions.—We are, etc.,

London, S.W.11.

J. FERGUS KING.

Calcium Chloride for Scorpion Bites

SIR.—Being a private practitioner in a slum area of Calcutta, I have been coming across a large number of scorpion-bite cases every year, especially during the monsoons. I have tried all the standard treatments for this condition, but the results have been far from satisfactory. Local infiltration with procaine hydrochloride and adrenaline almost always brings the patient back within a few hours. This was my experience in the emergency room of the hospital also.

Recently I tried in four cases of scorpion bites a very unorthodox method of treatment. I injected 5 ml. of a 10% solution of calcium chloride intravenously, and in each of the four cases the relief was dramatically quick, complete, and permanent. The pain and burning sensation disappeared by the time the feeling of warmth due to the injection subsided. All these four patients were adults between the age of 24 and 48 years. All of them were in great agony and extremely restless when they came for treatment. All of them were able to go about their business within a few hours of the treatment, and one of them attended a whole-night entertainment just three hours after having the injection.

I admit that the treatment is absolutely empirical at this stage. It seems that calcium chloride has some chemically neutralizing effect on the scorpion venom. It will be very interesting to see whether it is also effective in cases of other insects' bites and stings—and even perhaps in some cases of snake poisoning. Light thrown on this subject by other colleagues will be most welcome.—I am, etc.,

Calcutta.

SYED ABDULLAH.

Psycho-endocrine Association

SIR.—May I claim the hospitality of your columns to make an announcement which may be of interest to a number of your readers? On May 21, at a meeting of the Psycho-endocrine Research Group, a Psycho-endocrine Association was formally constituted. The aims and objects of the association are to promote the study of the relationship between the endocrine system and mental functions, normal and disordered; to apply the knowledge of these principles to psychological medicine; and to provide a forum for the discussion of psycho-endocrinological and related knowledge.

Will any reader, at home or abroad, who is interested in these aims and objects, and who would like to apply for membership, please write to the Hon. Secretary, Psycho-endocrine Association, St. Ebba's Hospital, Epsom, Surrey. The annual subscription has been provisionally fixed at 10s.—I am, etc.,

London, W.1.

E. B. STRAUSS.

POINTS FROM LETTERS

A Disclaimer

Professor R. A. GREGORY (Liverpool) writes: In a recent issue of a local newspaper there appeared an article describing the work in the department of physiology, University of Liverpool, including research in which I am concerned and which may have eventual application in regard to the problem of peptic ulcer. This article was based on an interview given some months ago to a representative of the newspaper concerned at the suggestion of the university authorities. I should like to make it known that several statements in this article referring to possible therapeutic applications of the research concerned were altered without my knowledge or permission after the interview, and I therefore wish to disclaim any responsibility for them.

Obituary

A. G. MAITLAND-JONES, O.B.E., M.C., M.D.,
F.R.C.P.

Dr. A. G. Maitland-Jones, consulting physician to the children's department of the London Hospital, was drowned on May 17 while salmon fishing in the river Usk. He was 67 years of age.

Arthur Griffith Maitland-Jones was born on March 8, 1890, the son of the Rev. Joseph Maitland-Jones, and was educated at Taunton School and at the London Hospital. He qualified M.R.C.S., L.R.C.P. in 1914, and then joined the R.A.M.C. for service in the first world war. Twice mentioned in dispatches, he was awarded the Croix de Guerre in 1917, and the Military Cross in 1918, the official citation covering the latter award reading as follows: "During the operations he repeatedly reconnoitred the roads under heavy shell fire. By his example and leading he established communication with the most forward dressing stations, and succeeded in bringing up his ambulances and rapidly evacuating the wounded from very exposed positions." He was appointed O.B.E. in 1919 as a further recognition of his war services.

Returning to the London Hospital after the war, Maitland-Jones held various house appointments there before becoming second assistant in the medical unit. After holding a research fellowship at Johns Hopkins Hospital, Baltimore, he became first assistant in the medical unit at "The London." During this period he took the M.R.C.P., graduated M.B., B.S. with honours, and distinction in medicine, from London University in 1921, and proceeded to the M.D. in 1922. He was admitted F.R.C.P. in 1933. Maitland-Jones was appointed physician to the children's department at the London Hospital in 1925, becoming consulting physician 20 years later, and from 1928 to 1931 he was assistant physician to the Infants Hospital (now the Westminster Children's Hospital), Vincent Square, and thenceforward was physician to the hospital until he retired in 1945. For a time he served as chairman of the hospital medical committee. He was also consulting physician to Dr. Barnardo's Homes, the Royal Merchant Navy School, and the National Adoption Society. He was the author of sections on the diseases of children in a number of textbooks; and in the years before the second world war he was a member of the expert committee on infant and child nutrition of the League of Nations. Maitland-Jones was president of the Section for the Study of Disease in Children of the Royal Society of Medicine from 1940 to 1942, having been honorary secretary of the section from 1929 to 1931. A member of the British Paediatric Association, he was its secretary from 1934 until the end of the second world war, and in 1949-50 its president.

In 1926 Dr. Maitland-Jones married Miss Miriam Ritchey, daughter of Dr. John Ritchey, of Oil City, Pennsylvania. They had a son and a daughter.

Dr. KENNETH TALLERMAN writes: I should like to pay a tribute to Arthur G. Maitland-Jones, a dear and respected friend for more than 30 years, during most of which time I was associated with him professionally at the London Hospital and elsewhere. As physician in charge of the children's department at the London Hospital, and a member of the staff of the Infants' Hospital, he showed himself an able and wise paediatrician, and his opinion, based on wide training and extensive clinical experience, was always greatly valued. His election to the presidency of the British Paediatric Association and of the Paediatric Section of the Royal Society of Medicine was a recognition of the position which he had achieved. It is, however, of the man himself that most of us, who are saddened by his sudden and tragic loss, must be thinking, and it is in this connexion that I would like to say something.

Integrity and courage were always treated by Arthur with high regard, and these are two characteristics which he himself exhibited. During the first world war, in which he served with distinction in the R.A.M.C., he was not only twice mentioned in dispatches, but was awarded the Military Cross, the Croix de Guerre, and finally the O.B.E. During the second world war he held the position of a sector officer in the E.M.S., and was also attached to the Southern Command of the Army. This gave scope for his administrative talents, and he exercised his authority, which he enjoyed, with tact and success.

He was always loyal to his juniors, rendering them unstinting support, and he was generous to a degree. Never would he consider taking credit for any work which was not wholly his own, and he encouraged those who worked with him and gave them open-handedly every possible assistance. He stood out at all times for what he thought to be right, but showed consideration for the opinions and feelings of others. He had a great love for the London Hospital, with which he had been associated since his student days, and he took the greatest interest in all its activities, and pride in its achievements. He was a most congenial and popular person, with a wide circle of friends. He was fond of open-air games and sports, and was good at them himself; until his eyesight troubled him he was a keen shot, but particularly he was an enthusiastic fisherman and a very knowledgeable one. He especially enjoyed the country, and took the greatest interest in his garden and in the farm which occupied his time for some years after his retirement. He liked the good things of life as much as anyone, but he was a home-loving man, and his family was an exceedingly happy one.

All of us have our foibles, but in Arthur's case his small mannerisms and prejudices only helped to enhance the warmth of feeling towards him of those who knew him well. He will be deeply missed by his many friends, who regarded him with great affection.

CHRISTOPHER ELLIOTT, M.R.C.S., L.R.C.P.

Dr. Christopher Elliott, who died at his home at Bidborough Ridge on February 16 at the age of 76, had had a long association with Tunbridge Wells, where he joined his father in practice some fifty years ago.

Christopher Elliott was born at Mansfield, Nottinghamshire, the eldest son of Dr. Thomas Elliott, and was educated at Tonbridge School and at St. Bartholomew's Hospital. Qualifying M.R.C.S., L.R.C.P. in 1905, he worked as a house-surgeon at the Leicester Royal Infirmary before beginning practice at Tunbridge Wells. He remained there until his death, except for the period of his service as a temporary captain in the R.A.M.C. in the first world war. He was honorary anaesthetist to the Tunbridge Wells General Hospital (now the Kent and Sussex Hospital) from 1921 to 1940, when he was appointed honorary consulting anaesthetist, but continued active work until 1946. He also held part-time appointments as deputy medical officer of health for the district, assistant school medical officer, and police surgeon from 1920 to 1933. A member of the British Medical Association for over forty years, he represented the Tunbridge Wells Division on the Kent Branch council for a number of years, and was chairman of the Division in 1923-4. His Christian faith meant much to him and he took an active part in evangelical work. He is survived by his widow, two daughters, and one son.

HELENA M. J. McQUAID, M.R.C.S., L.R.C.P.

Dr. Helena McQuaid, who was in general practice at Putney for more than twenty-five years, died suddenly in Dublin on May 12. She was 62 years of age.

Helena Mary Josephine McQuaid was born on August 20, 1894, and came of a medical family, her father, brother, uncle, and several cousins being in the profession. She joined the London School of Medicine for Women, where

she did the early part of her training, and went to St. Mary's in 1920. After qualifying M.R.C.S., L.R.C.P. in 1925 she was obstetric house-surgeon to Mr. T. G. Stevens at St. Mary's. She began in general practice at Fulham, and after about five years joined Dr. Grace D. Chambers and Dr. Dorothy M. Stewart in a practice in Putney, where she stayed until her retirement in 1955. She then went to live with her family in Dublin.

O. J. E. G. M. writes: Despite a very busy and exacting practice, Dr. Helena McQuaid worked as a part-time school medical officer under the L.C.C. for twenty-five years. She was a very fine physician, with a marvellous clinical instinct. She spent herself unsparingly for her patients and brought with her warm and friendly personality comfort and help to innumerable people. She was excellent company and had many friends who loved to listen to her charming Irish voice, with its infectious chuckle, telling stories grave and gay in her own inimitable fashion. She was one of those exceptional people who had no enemies, only friends. Hundreds of people will feel her death as a personal loss and sorrow. As one of her patients put it, "All Putney is mourning her."

P. V. HARDWICK, M.B., Ch.B.

Dr. P. V. Hardwick, who was in practice at Kirton, near Boston, Lincolnshire, for nearly thirty years, died at Woodlands Court Hospital, Kirton, on May 17 at the age of 62.

Philip Vincent Hardwick was born at Bournemouth on February 20, 1895, and, after service in the first world war in the Hampshire Regiment, entered the medical school at Leeds, graduating M.B., Ch.B. in 1925. After house appointments at the General Infirmary and Maternity Hospital in Leeds he entered general practice, first at Hovingham and Filey, until, in 1928, he settled in Kirton. He was an assistant anaesthetist to the Boston group of hospitals and medical officer of Woodlands Court, Kirton. He was chairman of the Holland Division of the British Medical Association in 1932-3. His medicine was sound and practical and he showed the same qualities in his everyday life. Few general practitioners can have given more to the village in which their work lay. He was as generous with the little leisure a widely scattered agricultural practice allowed him as he was attentive in times of illness. He was chairman of the parish council, and, among many other public appointments and offices, was chairman of the football club, president of the tennis club, and a vice-president of the cricket club and of the British Legion. He took a special interest in the fine old parish church, of which he was vicar's warden. His village was devoted to him and he to it. He married in 1938 Rosalind Mary, daughter of the late Dr. C. W. Pilcher, and he leaves a widow and two daughters.—R. E. M. P.

P. F. COOPER, M.R.C.S.

Dr. Peter Cooper died suddenly on May 28 while sailing at Falmouth. He was 42 years of age.

Peter Francis Cooper was born on September 29, 1914, and was educated at Brighton College and at St. George's Hospital Medical School. Qualifying in 1942, he held the posts of house-physician and resident anaesthetist at St. George's Hospital and was later house-physician at Slough Emergency Hospital. After the war he went into private practice in London and became medical officer to a number of large businesses and insurance companies. As a young man Peter Cooper had been a keen Rugby footballer, and had captained Rosslyn Park and played for Middlesex. In recent years he had become well known as a referee at international matches and other important games.

A colleague writes: The sudden and unexpected death of Dr. Peter Cooper while on holiday will have come as a profound shock to his many friends and acquaintances. His medico-legal work brought him into contact with many doctors in and around London and with others in all walks of life. He had another great circle of friends connected

with his many sporting activities; he was a good golfer, but his main love was Rugby football, and he did much to encourage younger players. Peter Cooper possessed an enormous zest for life; he was always cheerful and could never bear to be inactive. His death from a heart attack at a time when he appeared to be in the best of health and in the prime of his life has been a very great loss.

E. T. H. DAVIES, M.D., M.S., F.R.C.S.

The obituary of Mr. E. T. H. Davies was printed in the *Journal* of May 25 (p. 1248).

H. G. D. writes: There is no doubt that Mr. E. T. H. Davies would have obtained a surgical registrarship at St. Mary's Hospital, and would later have been a strong candidate for a surgical vacancy there, but economic factors prompted him to leave the metropolis. He was appointed consulting surgeon to the Tredegar Medical Aid Society, then in its infancy. Mr. Aneurin Bevan was closely associated with the society, which under Dr. Davies's guidance was to become an embryonic State medical service in 1924. At Tredegar, under the terms of his appointment, Mr. Davies was in sole charge of the hospital, an institution of 52 surgical beds, and was available in a consultative capacity to the general practitioners in the area who worked under the scheme. In addition to what is now known as general surgery, he did all the ear, nose, and throat, ophthalmic, gynaecological, and orthopaedic surgery of the area, and showed the same skill, deftness, and gentleness in his abdominal surgery as he did in his ophthalmic work. It was, indeed, an edification to see him wiring, pinning, and plating the atypical fractures inseparable from the dangerous industry of coal-mining, and to watch him make the "no-touch" technique appear so simple. During the years from 1926 to 1932 it was my privilege to be associated with him in his hospital work. In addition to all this work in surgery he was his own radiologist in the days when x-ray equipment was not so easy and safe to handle as in later years. Beneath an apparently frail physique and quiet manner there was, when occasion demanded, speed, courage, and boldness. He brought to a colliery district of some 30,000 inhabitants surgery of a teaching hospital standard, and his retirement was a great loss to the community which he had served so well. His death removes from our midst one of the last of the truly general surgeons. To his wife and son, a consultant anaesthetist, we offer our deep sympathy in their loss.

Medical Notes in Parliament

Radiostrontium in a Stillborn Child

Mr. D. HOWELL (Birmingham, All Saints, Lab.) asked the Prime Minister on May 30 what advice he had received from his medical and scientific advisers about the fact contained in the report of the Atomic Energy Research survey that the bones of a stillborn child in Carlisle contained about seven times as much radiostrontium as that found in older people examined about the same time. Mr. H. MACMILLAN stated in reply that the heavier concentration of radiostrontium in the bones of children compared with adults was fully considered in the Medical Research Council's report. It was for this and other cognate reasons that the maximum permissible level of radiostrontium in the human skeleton accepted by the International Commission on Radiological Protection was regarded as being too high for the general population. The Medical Research Council considered that the maximum concentration of radiostrontium in the bones of the general population, with its proportion of young children, should not be greater than a tenth of the maximum permissible level for adults in special occupations. He added, when Mr. Howell pressed for further very careful scrutiny by the Government's advisers, that the figure in the case mentioned was 0.45 unit, which was still 100 times less than the average allowable level of radiostrontium in bones. Mr. H. GAITSKELL (Leeds, South, Lab.) renewed the pro-

posal for a further report from the Medical Research Council. Mr. MACMILLAN: "Yes, and when it comes I hope that it will be given the weight that is due to it."

Protection for Radiographers

Mr. SOMERVILLE HASTINGS (Barking, Lab.) asked the Minister of Health on May 27 to what extent the shortage of radiographers in Health Service hospitals had resulted in overtime working; and if he was satisfied that this would not be deleterious to the health of those concerned. Mr. D. VOSPER said the information was not available. Health hazards did not necessarily depend on the number of hours worked, but on the protection arrangements made by hospitals. If evidence was produced that radiographers were suffering excessive exposure he would be glad to investigate the matter.

Vaccination of Troops

Mr. S. P. VIANI (Willesden, West, Lab.) asked the Secretary of State for War on May 28 why the soldiers at the Tidworth Camp were vaccinated during the recent smallpox outbreak, seeing that the majority of them had already been recently vaccinated. Mr. JULIAN AMERY, the Under Secretary, stated that vaccination of all presumptive contacts of a case of suspected smallpox, irrespective of previous vaccinations, was a protective measure which conformed with accepted public health practice. At Perham Down and Tidworth it was offered to those who had not been vaccinated within the previous month. He stated in another reply that troops were revaccinated in the United Kingdom and North-west Europe every three years, in other areas every two years or at shorter intervals; and on medical advice in an epidemic or undue prevalence of smallpox.

Mental Health Report Welcomed

The MINISTER OF HEALTH was asked on June 3 for a statement on the report of the Royal Commission on the law relating to mental illness and deficiency. He said he welcomed this valuable and comprehensive report, and was studying the many recommendations made in it. He must have time to consider them before making any further statement. Dr. DONALD JOHNSON (Carlisle, Con.) asked if the Minister would take some action before legislation, which it was realized must take time, on the regulations which did not require legislation, particularly the review of patients at present in hospital. Mr. VOSPER said that he would certainly consider what could be done by administrative means in advance of any legislation. Mr. A. BLENKINSOP (Newcastle upon Tyne, East, Lab.) expressed the welcome of the Opposition for the report. Mrs. E. BRADDOCK (Liverpool, Exchange, Lab.), a member of the Commission, thanked the Minister for his kind words about the Commission's work. She said there seemed to be a great amount of agreement on both sides of the House about the report, and a full debate would be much appreciated. Mr. KENNETH ROBINSON (St. Pancras, North, Lab.) commented that as a result of the recommendations the present procedures would give rise to increased anxiety and frustration on the part of parents, psychiatrists, and patients. This was an added reason for early action. Mr. VOSPER said that was certainly true, but the legislation would be of a very complicated and prolonged nature, and must receive adequate consideration before it was introduced.

N.H.S. Facilities for Private Patients

Mr. JOHN HALL (Wycombe, Con.) asked the Minister of Health if he would amend the National Health Service Act, 1946, so as to allow those who elected to become private patients to utilize the other facilities provided by the Act. He also asked if the Minister would amend the Act to allow the provision to all private patients, free of charge, other than the prescription charge, of a selected list of preventive and life-saving drugs, and drugs designed for the alleviation and treatment of lethal diseases. Mr. VOSPER replied that the private patients of general practitioners had full access to all the facilities of the Health Service, other than the supply of drugs, as part of the general medical services.

The provision of a selected list of drugs for private patients would raise many problems of great difficulty.

Mr. HALL said that all insured persons paid for the Health Service through their contributions, rates, and taxes. Should they not be entitled to the benefits for which they had paid, even though they may opt to be private patients and pay the doctor out of their own pocket? Mr. VOSPER said that it raised many problems of great difficulty, one being that it would require legislation, and, secondly, that it would require some form of control of doctors not at present in the Health Service. His predecessor invited the British Medical Association to discuss this matter with him, and those discussions were about to take place.

Dr. EDITH SUMMERSKILL (Warrington, Lab.) said that if an amendment of this kind were made it would create an especially privileged category of Health Service patients. Furthermore, it would tend to encourage overprescribing. Mr. VOSPER: I am not prepared to accept these allegations. The matter is to be discussed with the British Medical Association, who have some proposals to make.

Mr. W. M. F. VANE (Westmorland, Con.) asked the Minister not to be diverted from his purpose by Dr. Summerskill. He should assure himself that these difficulties were real and not just imaginary bureaucratic difficulties. Why should not those who had paid the full contribution towards the Health Service be allowed just part of the benefits for them? Surely it would be in the national interest, instead of forcing them to have the whole or none? Mr. VOSPER repeated that the difficulties were very real. He would examine the suggestion.

Reasons for Higher Prescription Costs

Mr. VOSPER informed Mr. R. W. SORESENSEN (Leyton, Lab.) that examination of a sample of prescriptions dispensed in December had shown that the increase in the average cost of about 5d. was probably due almost entirely to doctors prescribing larger quantities. The trend since December suggested that this had continued. The number of prescriptions had also been much lower than a year ago, but this must be partly due to the low incidence of sickness. Mr. A. BLENKINSOP asked whether the Minister did not recognize the real danger and waste involved in prescribing larger quantities, which he was encouraging. Mr. VOSPER said he could not accept that, and it suggested that the general practitioner was not competent to exercise his discretion. The ordering of larger quantities was not wasteful if there was a continuing need. It helped people with chronic or continuing illness, and that was what he believed to be happening. He also informed Mrs. EIRENE WHITE (East Flint, Lab.) that suggestions for multiple packs were received from the B.M.A. a fortnight before and were being studied.

Greater London Survey.—The report on the survey of hospital facilities in Greater London recently made by officers of the Ministry of Health will be an administrative document for the Minister's information, which it is not intended to publish.

Ambulance Service.—The average number of miles travelled per patient by the ambulance services in 1950-1 was 9, and the cost 15s. 1d. In 1955-6 the mileage was 6.8 and the cost 15s. 5d.

Factory Inspections.—Since June 1, 1956, there have been at least 300 inspections of factories working with radioactive materials such as radium or radiothorium. Most of these factories are covered by the Factories (Luminizing) Special Regulations, 1947, and in most cases the standard of compliance with the regulations is good.

Statistical Urge.—Statistics sought by M.P.s on May 27 and 28 included the following: There were about 17,250,000 visits made by district nurses in 1949, and about 24m. last year. There were 5,592 domiciliary psychiatric visits in 1950, and 11,224 in 1955. The attendances at mental-illness and mental-deficiency out-patient clinics at hospitals numbered 523,218 in 1950, and 714,014 in 1955. In 1949 there were 1,787 local authority ante-natal clinics, and 1,955 last year. Local authority domestic help was provided in 139,816 instances in 1949, and 235,132 last year. There were in 1949 about 137,000 whole-time and 27,000 part-time nursing and midwifery staff in the Health Service; in 1956 the numbers were 160,000 and 41,000.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending May 18 (No. 20) and corresponding week 1956.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES in Countries and London	1957					1956

* Measles not notifiable in Scotland, whence returns are approximate.

† Includes primary and influenza pneumonia.

§ Includes puerperal pyrexia.

Vital Statistics

New Influenza Strain

Outbreaks of influenza due to the new strain of virus A continue to be reported in the Far East, and some mild cases have also occurred in Australia among aircraft passengers who travelled from Europe via Singapore. The disease has not yet been identified in Europe. Investigations are being concentrated particularly at Rotterdam, where a ship recently arrived from the Far East. About 30% of the passengers had influenza on the voyage, but by the time they reached port the disease had died out. The symptoms remain mild and only relatively few deaths have been reported.

Industrial Accidents and Diseases

The number of workpeople (other than seamen) in the United Kingdom whose deaths from accidents in the course of their employment were reported in April was 142, compared with 123 in the previous month and 90 (revised figure) in April, 1956.

The numbers of cases of industrial diseases in the United Kingdom reported during April, 1957, were as follows: lead poisoning 3, aniline poisoning 1, anthrax 2, epitheliomatous ulceration 24, chrome ulceration 26; total 56. There were no deaths.—*Ministry of Labour Gazette*, May, 1957.

Week Ending May 25

The notifications of infectious diseases in England and Wales during the week included: scarlet fever, 618, whooping-cough 2,019, diphtheria 3, measles 19,513, acute pneumonia 349, acute poliomyelitis 52, dysentery 773, paratyphoid fever 2, and typhoid fever 4.

Infectious Diseases

The largest variations in the notifications of infectious diseases in England and Wales during the week ending May 18 were decreases of 1,600 for measles, from 18,265 to 16,665, and 104 for whooping-cough, from 2,362 to 2,258, and increases of 167 for scarlet fever, from 497 to 664, and 81 for dysentery, from 669 to 750.

66 cases of acute poliomyelitis were notified during the week, and these were 9 more for paralytic and 12 fewer for non-paralytic cases than in the preceding week. The largest returns were Essex 9 (Colchester M.B. 6), London 6 (Islington 2, Wandsworth 2), Warwickshire 6 (Coventry C.B. 4), and Glamorganshire 6 (Cardiff C.B. 2).

The incidence of measles fell in ten counties by 100 or more, the largest fall in notifications being 300 in London, from 1,169 to 869. The chief exceptions to a falling incidence were rises of 463 in Yorkshire West Riding, from 1,816 to 2,279; the largest rises in this county were 124 in Leeds C.B., from 204 to 328, and 81 in Sheffield C.B., from 243 to 324. Notifications of measles also rose 140 in Kent, from 528 to 668, and 89 in Cornwall, from 35 to 124, mainly owing to rises of 70 in Saltash M.B., from 0 to 70, and 30 in Liskeard R.D., from 8 to 38. The largest rise in the notifications of scarlet fever was 31 in Yorkshire West Riding, from 53 to 84, and was due to a small rise throughout the county. The largest fall in the incidence of whooping-cough was 46 in Sussex, from 98 to 52. 4 cases of diphtheria were notified, being 1 more than in the preceding week.

The chief centres of dysentery were Lancashire 156 (Liverpool C.B. 33, Blackpool C.B. 18, Manchester C.B. 17, Ashton under Lyne M.B. 14, Salford C.B. 11), Yorkshire West Riding 117 (Leeds C.B. 40, Bradford C.B. 19, Sheffield C.B. 14, Rotherham C.B. 12), Cheshire 46 (Dukinfield M.B. 22, Hyde M.B. 12, Stalybridge M.B. 10), London 41, Durham 35 (South Shields C.B. 15), Nottinghamshire 31 (Nottingham C.B. 19), Bedfordshire 30 (Luton M.B. 21), Warwickshire 29

(Birmingham C.B. 24), Northumberland 27 (Newcastle upon Tyne C.B. 17), Shropshire 26 (Oswestry R.D. 19), Southampton County 25 (Southampton C.B. 20), and Glamorganshire 21 (Penybont R.D. 20).

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1948-56 are shown thus ----, the figures for 1957 are shown as a solid line. Except for the curves showing notifications in 1957, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Medical News

Ross Centenary Luncheon.—The Ross Institute of Tropical Hygiene is holding a centenary luncheon on June 13 to celebrate the birth of Sir Ronald Ross, the discoverer of the role of anopheline mosquitoes in the transmission of malaria. The luncheon will be held at the London School of Hygiene and Tropical Medicine, and Dr. M. G. CANDAU, director-general of W.H.O., will propose the toast to Ross's memory. Among those who have accepted invitations are the Minister of State for Colonial Affairs and the High Commissioners for India, Ceylon, and the Union of South Africa. Sir Ronald Ross was born on May 13, 1857, in India, where 40 years later he made his discovery.

Tribute to Sir Robert Jones.—The current issue of the *Journal of Bone and Joint Surgery* (May, 1957) appears as a "Robert Jones Centenary Volume." Sir Robert Jones was born at Rhyl in North Wales on June 28, 1857. He came of a long line of unqualified bone-setters who had practised thereabouts, serving his apprenticeship under his uncle, Hugh Owen Thomas, the first of the family to become medically qualified. Successively founder, president, and president-emeritus of the British Orthopaedic Association, Sir Robert Jones is known to-day as the "founder of modern orthopaedic surgery." On the cover of the commemorative volume is a reproduction of the gold medal he established for postgraduate orthopaedic students at Liverpool University; within are personal tributes from those who knew and worked with him. His life is briefly sketched by Sir REGINALD WATSON-JONES, one of his distinguished pupils. Others who record their recollections of him include LORD MALVERN, LORD COHEN of BIRKENHEAD, Sir THOMAS FAIRBANK, Dr. JOEL E. GOLDTHWAIT, "doyen of orthopaedic surgery in the United States of America," and Dr. W. E. GALLIE, of Toronto.

Wellcome Harveian Exhibition.—On Monday Sir RUSSELL BRAIN opened the exhibition at the Wellcome Historical Medical Museum, London, illustrating Harvey's life and the growth of the ideas that led up to his discovery. His early days at Folkestone and Canterbury, Cambridge and Padua, are illustrated by means of photographs and documents. One exhibit depicts the "new anatomy" at Padua, and there is a scale model of the famous anatomy theatre there; another exhibit is concerned with Harvey's teacher Fabricius. There is a collection of textbooks current in Harvey's student days, and portraits of his supporters and opponents are shown. Nor is Harvey's embryological and obstetrical work overlooked. There are also exhibits on the medicine, surgery, pathology, and materia medica of his times. A map traces his travels through Europe. Finally there is a reminder of the later work on the cardiovascular system made possible by Harvey's discovery and still continuing. The books displayed include all editions of the *De Motu Cordis* and various editions of the *De Generatione Animalium*. The exhibition stays open for about a month.

Colour Television at R.C.S.—A large audience of French and British surgeons watched from the College last week a demonstration on colour television of operations being performed at St. Bartholomew's Hospital. The occasion was the joint meeting of the Royal College of Surgeons of England with the Académie de Chirurgie de Paris. The demonstration was sponsored by Messrs. Smith Kline and French Laboratories Ltd., who provided the television unit. One camera in the theatre covered the operation, the surgeon being equipped with a microphone under his mask; another camera photographed a panel of experts watching, in the nurses' home, a telecast of the operation. At the College of Surgeons the moderator of the meeting could cast on the screen at will the picture of either the operation or the expert panel. The panel answered questions put to them from the meeting. Operations were demonstrated by Mr.

H. T. SIMMONS, Mr. BASIL HUME, Mr. F. B. COCKETT, Mr. C. NAUNTON MORGAN, Mr. B. W. RYCROFT, Mr. R. G. PULVERTAFT, Mr. E. W. RICHES, Mr. NORMAN TANNER, Sir ARCHIBALD MCINDOE, and Sir RUSSELL BROCK.

Lord Adrian Nominated for Vice-Chancellorship.—On June 8 members of the Regent at House at Cambridge will elect the University's Vice-Chancellor for the coming academic year. Lord ADRIAN, O.M., F.R.S., Master of Trinity, is one of the two persons nominated for the office by the council of the Senate. The other is Professor H. BUTTERFIELD, Master of Peterhouse, the professor of modern history.

British Cardiac Society.—The thirty-sixth annual general meeting was held at Adam House, Edinburgh, under the chairmanship of Dr. RAE GILCHRIST on May 16. In the morning there was a symposium on coronary artery disease, which was followed in the afternoon by demonstrations and short communications. Dr. SAMUEL LEVINE, of Boston, who is a corresponding member of the society, was among the distinguished speakers invited to take part in the symposium. The annual dinner was held at the Royal College of Physicians, Edinburgh.

Heberden Society.—Dr. J. J. R. DUTHIE gave the Society's annual Heberden Round at the Northern General Hospital, Edinburgh, on May 16. The theme was "Haematological Complications of Rheumatic Diseases." Subsequently six papers on subjects related to the rheumatic disorders were presented.

Diagnosis of Phenylketonuria.—The Hospital for Sick Children, Great Ormond Street, London, W.C.1, has prepared a card (8 by 10 in.—20 by 25 cm.) describing a simple urine test for phenylketonuria. A limited supply of these cards is obtainable from the secretary of the hospital, price 6d. The test consists simply in adding a little 5% ferric chloride to a fresh specimen of urine, and could quite well be performed in the surgery. The importance of the test is that it is diagnostic of a liability to a preventable type of mental defect. "Every child," states the test card, "should have his urine tested at the age of 21 days, or as soon as possible after. If the test is positive, dietary treatment can be started at once with the object of preventing the mental deterioration that is otherwise inevitable." Last week we printed a letter appealing for phenylketonuric infants under 3 years of age (see *Journal*, June 1, p. 1307) for admittance to a clinical trial of 5-hydroxytryptophan.

F.R.C.O.G.—At a council meeting of the Royal College of Obstetricians and Gynaecologists on May 25 the following were admitted fellows: P. C. Barkla (Nottingham), T. S. M. Barnett (Portsmouth), F. A. Bellingham (Australia), N. B. Capon (Liverpool), D. W. C. Chun (Hong Kong), A. Culiner (California), W. D. Cunningham (Australia), J. P. O. Erskine (Helensburgh, Dunbartonshire), M. Evans (Manchester), W. R. Foote (Canada), F. D. Johnston (Canada), K. T. Macfarlane (Canada), T. A. Macfarlane (New Zealand), G. B. Maughan (Canada), D. Y. May (Burma), W. G. Mills (Birmingham), K. N. Mitra (India), J. G. O'Donoghue (Australia), H. E. Pellew (Australia), P. I. Peltz (South Africa), D. A. Ranasinghe (Ceylon), W. J. Rawlings (Australia), R. McK. Rome (Australia), D. W. Sparling (Canada), D. M. Stewart (New Zealand), J. Walker (Dundee), and J. F. B. Wyper (Aberdeen).

U.S. Scientists and Nuclear Explosions.—Dr. LINUS PAULING, 1954 Nobel laureate in chemistry, announced on Monday that 2,000 U.S. scientists had signed an appeal for an international agreement to stop the testing of nuclear bombs. According to agency reports, the signatures were collected in four days, and included those of two other Nobel prize winners—Professor H. J. MULLER, of Indiana, who discovered that penetrating radiations produce mutations in plants and animals, and Emeritus Professor JOSEPH ERLANGER, of Washington University, St. Louis, who won the 1944 prize in physiology and medicine.

Family Planning Association.—At the annual general meeting of the Family Planning Association on June 1 the principal speaker was Mrs. MARY STOCKS, Vice-chancellor of Liverpool University, who compared the public attitude to the work of the association to-day with that at its foundation in 1930. The association now has 250 clinics in England, Scotland, and Wales. Advice is given on family planning, and many clinics also advise on infertility, sex education, and sex difficulties in marriage. During 1956 about 300,000 patients visited these clinics. The first clinic in Britain for the investigation of male infertility, states the association, was the F.P.A. Centre in London, which has now dealt with some 24,000 cases. The association has a pregnancy diagnosis laboratory at its headquarters at 64, Sloane Street, London, S.W.1, and also maintains an approved list of proprietary contraceptives.

Rumania and W.H.O.—The Government of Rumania has decided to resume active membership of the World Health Organization as from this year. This follows similar announcements by Albania, Bulgaria, Poland, and the U.S.S.R. earlier this year.

Professor F. A. E. Crew, F.R.S., has declined an invitation to resume teaching at present at Ein Shams University, Cairo, where he was professor of preventive and social medicine. Instead he is going, under the auspices of W.H.O., to a similar post at Rangoon University.

COMING EVENTS

Harveian Exhibition at R.C.P.—An exhibition of books and manuscripts illustrating Harvey's life and work will remain on view in the library of the Royal College of Physicians of London until the beginning of July. It may be seen by arrangement with the library staff.

"Radiations and Their Effects on the Individual."—Open lecture by Dr. F. G. SPEAR, June 12, 2.30 p.m., at the Royal Society of Health, 90, Buckingham Palace Road, London, S.W.1.

"Perspectives in Endocrinology."—Discussion on research, B.B.C. Third Programme, June 12, 7.45 p.m., repeated June 17. Among the speakers are Professor G. F. MARRIAN, F.R.S., and Professor F. G. YOUNG, F.R.S.

Maternal and Child Welfare.—Annual conference of the National Association for Maternal and Child Welfare, June 26–28, at Church House, Westminster, London, S.W.1. Details from the Secretary, N.A.M.C.W., Tavistock House North, Tavistock Square, London, W.C.1.

Hospitals' Symphony Orchestra.—Concert, June 26, in St. Mary's Hospital Medical School Library, Paddington. Works by Wagner, Verdi, Sibelius, and Beethoven; tickets (7s. 6d., 5s., 3s. 6d.) obtainable from Miss M. WHIPP, South Western Hospital, Landor Road, Stockwell, London, S.W.9.

British Tuberculosis Association and Tuberculosis Society of Scotland.—Annual conference, Glasgow, June 26 to 29. Details from the administrative secretary, British Tuberculosis Association, 59, Portland Place, London, W.1, before June 24.

Institute of Social Psychiatry.—Course on "Social Approach to Mental and Emotional Difficulties," July 26–28, at Moor Park College, Farnham, Surrey. This course replaces the one announced in this column on April 20 (p. 959). Details from Institute of Social Psychiatry, 9, Fellows Road, London, N.W.3.

NEW ISSUES

Abstracts of World Medicine.—Issued in the first week of each month, this journal contains abstracts of important papers selected from the current medical literature of the world. Annual subscription £4 4s., single copy 8s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Tuesday, June 11

INSTITUTE OF CHILD HEALTH.—5 p.m., Professor T. P. Magill (New York): Recurrence of Epidemic Disease.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. H. Meara: Less Common Skin Diseases of Infancy and Children.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Joseph Henry Lecture by Mr. L. W. Plewes: The Orthopaedic Surgeon and Industry.

Wednesday, June 12

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. H. Haber: Histopathology of Some Rare Skin Conditions.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. W. D. W. Brooks: Prevention of Pulmonary Tuberculosis.
LONDON UNIVERSITY.—At Westminster Medical School, 5 p.m., special university lecture in medicine by Professor André Cournaud (New York): Syndrome of Alveolar Hypoventilation: Its Causes, Complications, and Treatment.
OXFORD UNIVERSITY.—At Radcliffe Infirmary, 5 p.m., Litchfield Lecture by Professor H. de Waele: Nutritional Deficiencies During Pregnancy and Their Influence on Foetal Development.
ROYAL SOCIETY OF HEALTH.—At 90, Buckingham Palace Road, S.W., 2.30 p.m., Dr. F. G. Spear: Effects of Radiation on the Individual.

Thursday, June 13

HILL END HOSPITAL MEDICAL SOCIETY, ST. ALBANS.—8.45 p.m., lecture by Mr. E. Stanley Lee.
HONYMAN GILLESPIE LECTURE.—At Anatomy Theatre, University New Buildings, Edinburgh, 5 p.m., Dr. J. G. MacLeod: Unsuspected Thrombosis.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. C. D. Calnan: Haemangiomas—Classification and Treatment.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Professor M. Makin: Surgical Management of Friedrich's Ataxia.
ROYAL MEDICO-PSYCHOLOGICAL ASSOCIATION, PSYCHOTHERAPY AND SOCIAL PSYCHIATRY SECTION.—At 11, Chandos Street, W., 8 p.m., Miss Anna Freud: Termination of Treatment in Child Analysis. (Open to members and guests.)

Friday, June 14

COLLEGE OF GENERAL PRACTITIONERS: YORKSHIRE FACULTY.—At Littlewood Hall, General Infirmary at Leeds, 8.30 p.m., clinical lecture and discussion: Breast Cancer at the Crossroads. Speakers, Mr. H. S. Shucksmith, Dr. Georgiana M. Bonser, and Dr. J. R. MacLeod.
● INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. G. C. Wells: clinical demonstration.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. F. H. Young: clinical demonstration.
● INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—3 p.m., Dr. Elizabeth Tylden: Psychiatric Problems in Pregnancy.
MIDLAND CENTRE FOR NEUROSURGERY, HOLLY LANE, SMETHWICK, NR. BIRMINGHAM.—8 p.m., Professor K. J. Zülch (Cologne): Clinical Value of the Morphological Classification of Cerebral Tumours.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—10 a.m., Professor D. M. Douglas and Dr. K. G. Lowe: Some Aspects of Patent Ductus Arteriosus, 4 p.m., Dr. J. D. N. Nabarro: Modern Methods of Assessing Adrenal Cortical Function.
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Institute Theatre, 5 p.m., Mr. Aleck Bourne: Physiology of Menstruation.

Saturday, June 15

● INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—11.15 a.m., Mr. K. V. Bailey: Utero-vaginal Prolapse.

Sunday, June 16

PADDINGTON GENERAL HOSPITAL.—11 a.m., clinical meeting for general practitioners.

APPOINTMENTS

SOUTH-WESTERN REGIONAL HOSPITAL BOARD.—J. A. Cosh, M.D., M.R.C.P., Consultant Physician to Bath Clinical Area; M. S. I. Chandra Sekaram, M.B., B.S., D.L.O. (Part I), Registrar in Ear, Nose, and Throat Surgery to Bath Group of Hospitals; B. N. Foy, M.B., B.S., Registrar in Obstetrics and Gynaecology at Gloucestershire Royal Hospital, Gloucester; J. K. Trotter, F.F.A.R.C.S., M.R.C.S., L.R.C.P., Dr. A. Consultant Anaesthetist to West Cornwall Clinical Area; John Crossley, M.B., B.Chir., F.R.C.S., M.R.C.O.G., and Mrs. Marjorie O. Bennett, M.D., Ch.M., logists in Bristol Clinical Area; B. S. Dhillon, M.B., B.S., F.R.C.S., F.R.C.S.Ed., Senior Surgical Registrar to Thoracic Unit at Hawke Moor Chest Hospital, Bovey Tracey; John Ferguson, M.B., B.S., Medical Registrar at Gloucestershire Royal Hospital, Gloucester; M. C. R. Solling, L. J. H. Arthur, M.B., B.Chir., M.R.C.P., D.Obst.R.C.O.G., Registrar in Paediatrics at South Devon and East Cornwall Hospital, Plymouth (joint appointment with United Bristol Hospitals).

BIRTHS, MARRIAGES, AND DEATHS

DEATHS

Davison.—On May 20, 1957, Hubert Davison, M.B., B.S., of Nuneston, Warwick, formerly of Newcastle upon Tyne, aged 31.
Dunning.—On May 21, 1957, at Wootton, Isle of Wight, Matthew Dunning, D.S.O., T.D., M.B., C.M., Lieutenant-Colonel, R.A.M.C., T.A. retired.
Mackintosh.—On May 22, 1957, in London, George Seymour Munro Mackintosh, M.B., Ch.B., of The Little House, Seer Green, Bucks.
Mogoveny.—On May 25, 1957, at Willowgarth, Pool-in-Wharfedale, Yorks.
Marshall.—On May 20, 1957, Claude Herbert Marshall, M.B., F.R.C.S.Ed., of Mombasa, Kenya, late of Uganda.
Stevens.—On May 20, 1957, at Little Mead, St. Saviour, Jersey, Channel Islands, Alfred Edward Stevens, M.D., aged 84.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Incidence and Diagnosis of Mumps Orchitis

Q.—How often is orchitis the sole clinical manifestation of mumps? Is there any rapid way of clinching the diagnosis in such cases?

A.—In young males orchitis occurs in about 20% of cases of mumps: it is impossible to say how often it occurs without preceding parotitis, but this is certainly not a rarity. In venereal diseases clinics during the last world war one had constantly to keep this possibility in mind, especially in men who had no history of urethral discharge but who had recently been home on leave and possibly in contact with children suffering from mumps.

Antibody is probably present in most patients by the time orchitis develops, but a rise in antibody is of more value than a single titration, so that a second specimen of blood in a fortnight's time is required to clinch the diagnosis. If a hydrocele is present, antibody may be present in large amounts in the fluid, and it might be of value to have this estimated by the laboratory. Estimations of serum lipase have proved disappointing; a high level would be of some value, but the levels even in patients with bilateral parotitis are often normal.

Borborygmi

Q.—What is the explanation of periodical attacks of abdominal distension and "rumbling" in a patient whose alimentary function appears otherwise perfectly normal? The symptoms are most troublesome in the evenings, and no association with any dietary habit has been observed. What treatment is advised?

A.—Gurgling or rumbling noises coming from the abdomen (borborygmi) are commonly of little clinical significance, but occasionally are an indication of gross organic disease. They are noises caused by the agitation of a mixture of gas and liquid in the intestines, usually in the colon, but sometimes in the small intestine. Any condition which causes an excess of gas and liquid or increased intestinal activity may bring them about.

It is a commonplace that a person who is shy in society may find his embarrassment further increased by his developing borborygmi. This is an example of emotion increasing intestinal motility which is seen in an extreme form among those public performers such as athletes or boxers who suffer from diarrhoea before an important event. Certain foods may bring on the trouble, and peas and beans have a bad name for their gas-producing powers. Merely eating a large or indigestible meal may do the same. Yet again there may be a specific sensitivity to some item of food. In all these dietary disturbances there may be some abdominal distension as well as borborygmi. However, the questioner already appears to have considered the diet as a possible source of the trouble.

But the combination of abdominal distension and borborygmi also occurs with mechanical obstruction of the intestine, such as is found in diseases such as carcinoma of the colon or regional ileitis. It may occur if both absorption and motility of the intestine are disturbed as in steatorrhoea from any cause. Increased intestinal motility may result as a reflex manifestation of disease elsewhere in the gastrointestinal system—for example, in chronic cholecystitis or appendicitis. It is occasionally the first symptom of carcinoma of the stomach. It may be a manifestation of amoebiasis.

If these symptoms are of recent origin it might therefore be wise to investigate the gastrointestinal tract fully in

order to be sure that they are not the first evidence of serious disease, especially if the patient is middle-aged or elderly. The haemoglobin level, erythrocyte sedimentation rate, examination of the stools for occult blood and parasites, complete barium studies, and possibly sigmoidoscopy should be done. If these are negative, or if the symptoms are of long standing and the general health is excellent, it will probably be sufficient to see that the evening meal is eaten fairly dry and is not rich in gas-forming foods or roughage. If necessary, these measures can be supplemented with a sedative such as phenobarbitone or an agent which diminishes gastrointestinal motility, such as atropine, gr. 1/100 (0.65 mg.) three times a day, or propantheline bromide, 15 mg. four times a day. Yet another approach to symptomatic relief would be the use of activated charcoal as an absorber of gas, and this could be given as charcoal biscuits or as tablets of medicinal charcoal.

Olive Oil and Fried Fish in Ulcer Diets

Q.—How is it that people on a gastric ulcer diet may be given olive oil to take before meals, but are forbidden fish fried in olive oil?

A.—The taking of olive oil before meals in patients with gastric ulcer was advised, in the past, in the forlorn hope that it would coat the gastric mucosa and ulcer crater with an impervious layer, and so protect the crater against the action of the acid gastric contents. A further rationalization of its use in both gastric and duodenal ulcer was that fat entering the small gut would release enterogastrone, which would inhibit both gastric secretion and motility. Both arguments seem to have been based more on theoretical than on practical grounds, and the treatment is probably of little value in ulcer therapy.

Fried food of all types is poorly tolerated by most dyspeptics, and this has led to the omission of fish fried in oil from most dietary regimes.

Effect of Artificial Menopause on Sexual Life

Q.—Are the physical changes from an artificial menopause induced by radiotherapy more pronounced than with a natural menopause, and is there likely to be any appreciable change in libido?

A.—There is some difference of opinion about this because the number of adequately controlled investigations which have been reported are few. Such as there are deal almost entirely with the effect of intracavity radium rather than of deep x-ray therapy to the ovaries. H. C. McLaren^{1,2} concluded that the radiation menopause often precipitates menopausal symptoms, is followed by sudden loss of sex desire, and sometimes results in dyspareunia because of stenosis of the upper vagina. A more recent and possibly better controlled study is that of A. C. Turnbull.^{3,4} His reports, which also review the literature, go to show that the effects of a radiation menopause are little different from those of the natural climacteric.

Turnbull found that libido was decreased before the menopause in 60% of all women, and half of them showed a further reduction after the menopause. Of those women retaining a normal urge up to the menopause, 50% experienced a decrease immediately afterwards. The findings were the same irrespective of whether the menopause was natural or induced with radium. With regard to dyspareunia, the incidences in the treated and the controls were again similar—suggesting that radiation did not cause significant structural change. Libido is determined as much by the psyche as by the endocrine system, and, in regard to the latter, the adrenal cortex is probably more important than the ovary. Turnbull's results tend to confirm what has been generally recognized on other evidence, that sex urge decreases with advancing years rather than with the cessation of ovarian function. It may be added that the effect on libido of either the natural or the radiation menopause depends a good deal

on a woman's outlook. If she expects the menopause to decrease libido, her expectation is likely to be realized; if she does not, however, libido will probably be retained.

Amphetamine Inhalers

Q.—In the past a man in a responsible position involving considerable mental strain made habitual use of amphetamine inhalers, which he says helped him greatly. Now they are no longer available, he misses them greatly and has been given instead amphetamine by mouth in the usual doses. He says, however, that he does not experience the same beneficial effect. (1) Is there a pharmacological explanation for this failure to respond? (2) What advice should be given to this patient?

A.—In the normal course of events the systemic administration of amphetamine has a greater effect upon the central nervous system than that obtained when the drug is inhaled. It is well known, however, that patients may develop a considerable degree of tolerance for amphetamine, and this patient has obviously been accustomed to using it for a long period of time. It may be, therefore, that he will not respond to an average dose of oral amphetamine, but will require an unusually heavy dosage to obtain a satisfactory result. Since, however, the amount of amphetamine absorbed from an inhaler is usually small, this explanation of the failure to respond to oral medication seems improbable. It would appear more likely that the benefits obtained from inhaled amphetamine were in part of purely psychological origin connected with the use of the inhaler itself.

If the patient has actually developed a mild degree of addiction to amphetamine, it is important that the drug should be withdrawn. During the process of withdrawal small doses of caffeine might possibly be of some benefit. If on the other hand the problem is mainly a psychological one, reassurance, coupled if necessary with the administration of a suitable placebo, would be the best form of management.

Unilateral Neuroretinitis

Q.—What is the differential diagnosis of a unilateral neuroretinitis? There is no known aetiological factor.

A.—It all depends on what is meant by "neuroretinitis." This term is rarely used nowadays, as it could be used to cover a variety of different pathological processes. Presumably the writer implies oedema of the optic disk, with evidence of retinal involvement (oedema, haemorrhages, exudates), confined to one eye.

Syphilitic neuroretinitis has been described in the secondary stage of syphilis, but is very rare. Unilateral papilloedema, due to intracranial tumour or some other cause of raised intracranial pressure, is by no means uncommon, and on occasion the oedema may spread beyond the optic disk on to the surrounding retina, and be accompanied by haemorrhages around the disk and even macular oedema and macular fan. Vision is usually little affected in the early stages. Papilloedema associated with malignant hypertension and chronic nephritis is almost always bilateral. A glioma of the optic nerve may be associated with papilloedema (more usually optic atrophy) and severe loss of vision.

Unilateral retrobulbar neuritis may be associated with swelling of the optic disk (papillitis), usually slight but occasionally severe, and macular oedema and even a macular fan have been known to occur. Gross visual loss, usually with a central scotoma, is the rule. The common cause of unilateral retrobulbar neuritis is a plaque of multiple sclerosis in the optic nerve, and, if this is just behind the nerve head, swelling of the disk may occur. Recovery to almost normal vision occurs in most cases, though a small percentage of

cases are left with a permanent central scotoma and optic atrophy. There may be no other signs of disseminated sclerosis on general neurological examination.

Other conditions causing oedema of one optic disk with some retinal oedema include localized choroiditis (Jensen's juxtapapillary choroiditis), the pathogenesis of which is unknown; partial occlusion of the central retinal vein, usually with scattered retinal haemorrhages along the course of the dilated retinal veins; and the papilloedema which occasionally accompanies acute iritis. The vitreous haze in the last instance may give rise to a misleading appearance of abnormality in the optic fundus.

Hormone-dependence in Breast Cancer

Q.—In the treatment of cases of cancer of the breast, besides surgery and radiotherapy, should steps be taken routinely to determine whether the growth is hormone-dependent? If so, how should this be done and what further therapy is advised should the growth prove hormone-dependent?

A.—There is unfortunately no fully satisfactory way of discovering whether a growth of the breast is hormone-dependent, although there are some interesting researches going on at the moment into this matter. Certainly the histological picture of the growth is no guide. This difficulty does not matter very much, however, when it comes to the question of administering more or less innocuous hormones by mouth or by injection, because it is a relatively simple matter to try the hormone and see if it works, very little harm being done if it fails to do so. The real problem arises in connexion with adrenalectomy and hypophysectomy, because here clearly a criterion of hormone-dependence would be of the greatest possible value. It is for this reason that the biochemical researches now being prosecuted on the urine of these patients are being followed with such great interest.

Your questioner's query therefore hardly arises as a practical problem at the moment; but, even if in the future hormone-dependency can be diagnosed other than by the method of trial and error, it would probably prove wise to defer treatment based on it until recurrences occur.

Treatment of Iron-deficiency Anaemia

Q.—Is the use of liver extract or cyanocobalamin (vitamin B₁₂) ever justified in cases of simple iron-deficiency anaemia? In some countries these agents are used indiscriminately.

A.—The use of liver extract or cyanocobalamin is never justified in cases of simple iron-deficiency anaemia.

Books of "Any Questions?" and Refresher Course Articles.—The following books are available through booksellers or from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1. Telephone: EUSTON 4499. Telegrams: *Any Questions?*, Volumes 2 and 3 (8s. each); *Refresher Course for General Practitioners*, Volumes 2 and 3 (26s. 6d. each inland, 26s. overseas); *Clinical Pathology in General Practice* (22s. 3d. inland, 21s. 9d. overseas).

THE PROGNOSIS OF ATRIAL SEPTAL DEFECT

BY

MAURICE CAMPBELL, D.M., F.R.C.P.

CATHERINE NEILL, M.D., M.R.C.P., D.C.H.

AND

S. SUZMAN, M.R.C.P.

From the Cardiac Department, Guy's Hospital, and the Institute of Cardiology, London

[WITH SPECIAL PLATE]

Physical Signs

Atrial septal defect as an entity that could be recognized clinically was first described in this country by Bedford *et al.* (1941). Since then the diagnosis has been made with confidence and increasing frequency. The patients of earlier series were mostly between 20 and 40 years old, an age incidence very different from that of most congenital lesions: many in early life had noticed few symptoms, and often the physical signs had not even drawn attention to their hearts. We were therefore surprised when we began to see so many young patients with the classic picture, and thought that children with such large hearts, even when they had few symptoms, must have a more severe type of defect and a worse prognosis than patients seen in adult life. But this has not proved so, and hardly a child in this group has lost ground over the subsequent ten years. We have, of course, seen patients becoming worse during this time, but they were older, generally over 30 or even 40 years of age.

In view of the progress of surgical treatment, we wish to consider the natural prognosis of atrial septal defect. We have included some cases where the diagnosis was made on clinical grounds alone, as this gives a more balanced picture. If we include only those where it has been proved by catheterization there is a bias of selection, as most physicians do not advise this without some special reason, or did not until recently when surgical treatment became more practicable. We have included all patients where catheterization proved a left-to-right shunt into the right atrium, even if the shunt was partly due to anomalous pulmonary veins or if there was some degree of pulmonary stenosis (see Table II).

Diagnosis

The contrast between the paucity of symptoms and the large heart is characteristic of atrial septal defect. Nearly all the children are thin and slightly built, with a long, narrow chest and long limbs (the gracile habitus), but true arachnodactyly is rare. They often have a pigeon-chest with more prominence of the left side, and the more severe this deformity the greater the likelihood of a large heart and a large shunt.

A good account of the auscultatory signs has been given by Leatham and Gray (1956). The most characteristic sign is the discrepancy between the small pulse and the widespread overactive precordial pulsation, seen all the more easily because of the thin chest. The excessive pulsation has three components: (1) an apex beat that is tapping in character and displaced outwards; (2) a right ventricular thrust or lift that is usually visible and almost always palpable in the third left intercostal space; and (3) a large pulmonary artery that may give rise to visible systolic pulsation in the second space and may be felt to thrust against the hand. A precordial thrill is frequently felt, but a striking "cat's purr" thrill is uncommon in atrial septal defect.

The radial pulse is small. The pulse pressure is rarely more than 40 mm. Hg and the systolic pressure usually 120 mm. or less, with lower levels in children. The jugular venous pressure is increased only if cardiac failure supervenes, but Reinhold (1955) has noted that in the jugular venous pulse there are often large v waves, frequently exceeding the a waves in amplitude.

The first sound may be abrupt and loud. The second sound is widely split and is slightly, but not much, louder than normal; it is not easily palpable unless the pressure is high. Wood (1950) and Barber *et al.* (1950) described wide splitting of the second sound as an important physical sign, and we have found it most valuable, but it is not common in children under 3 years of age or in patients with much pulmonary hypertension.

The systolic murmur of atrial septal defect is often heard first some months after birth rather than from birth; it is generally heard best in the second or third left spaces, but may be difficult to localize sharply. It is blowing rather than rasping, soft rather than loud. Considering how soft it is, it is well heard in the interscapular region at the back (Taussig, personal communication), perhaps owing to backward conduction through the large left pulmonary artery, as well as to the large heart and thin chest.

A blowing murmur in early diastole was heard at and below the pulmonary area in about one-eighth of our

patients, more often in older ones but once in a woman aged 20; it was thought to indicate pulmonary regurgitation. A short diastolic murmur at the apex was heard in half our patients, and more frequently in those who were seen several times and in those with a large shunt and a large heart. When this murmur becomes prolonged and continues to the first heart sound it is hard to exclude associated mitral stenosis, but this is less common than was thought, and cannot be diagnosed with certainty in life unless the catheter confirms a gradient across the mitral valve.

The physical signs are altered if severe pulmonary hypertension develops. The systolic murmur is softer and the second sound louder and easily palpable; the patient may be cyanotic and is more likely to have a pulmonary diastolic murmur. It may then be difficult to decide the site of the shunt, sometimes even after catheterization.

Radiology

This shows the triad of a large right side of the heart, large pulmonary arteries, and a hilar dance with expansile pulsation spreading to the smaller branches—features that were emphasized by Bedford *et al.* (1941). The negative findings on radiography—namely, absence of enlargement of the aorta, of the left ventricle, and of the left atrium—are equally important for diagnosis. The pulmonary arteries may become aneurysmal; later if they become thrombosed the pulsation may diminish.

As in most conditions, no heart shape is pathognomonic, though a film with the above features should suggest the possibility of an atrial septal defect, but can be due to mitral stenosis or other left-to-right shunts with secondary pulmonary hypertension. Typical examples are shown in the Special Plate: in Fig. 1 for children, in Fig. 4 for adults, and in Fig. 2 for those where the large right atrium is more prominent than in Fig. 1. The pulmonary trunk is often large before there is any rise of pulmonary arterial pressure (P.A.P.). The heart is sometimes smaller with the same prominent pulmonary arc, presumably when the left-to-right shunt is smaller.

Some less usual shapes are shown in Special Plate, Figs. 3 and 5. The heart is very large with a straight left border in Fig. 3 A, the pulmonary artery is so large that the heart looks rectangular in Fig. 3 B, and the right-sided enlargement is enough to make the heart appear tilted in Fig. 3 C. The pulmonary artery is often very large—in Fig. 5 A with a large heart and in Fig. 5 B with a heart that is smaller

GRAPH 1.—Diagram showing changes with age in the cardio-thoracic ratio of hearts in atrial septal defect, and the average curve for all our patients. Some decrease is more common than an increase in the school period, and the average figure, after dipping from 59%, returns to this at 17 and is no more than 62% at 30 years. After this it increases more rapidly, but patients seen then are not likely to be doing well and others may not show this rise.

than usual, from a woman, now aged 43, who has been under observation with a large pulmonary artery for 30 years. Aneurysmal dilatation of the right atrium is seen in Fig. 5 C; the positions of the catheter on two separate films are both included to show that all this enlargement was the right atrium.

The Size of the Heart

At first we were surprised to see children with such large hearts, often with cardio-thoracic ratios (C.T.R.) of 60%, and thought that they must have unusually large defects and a poor prognosis, but this is not so. Large hearts are common at all ages, and the only striking difference is that hearts that are not very large (C.T.R. below 55%) are seen in about one-quarter of the patients under 30 but rarely after this age; and that enormous hearts (C.T.R. 70%) become common after 30 but not before. This might suggest that the heart increases slowly but progressively throughout life, but this does not happen for a long time. Generally it is large in infancy and childhood (C.T.R. 55-64%), and, having reached a position of equilibrium, remains about this size for 20 or 30 years, and only then starts getting larger as the patient gets more severe symptoms. The size of the heart as measured by the cardio-thoracic ratio at various ages is shown in Graph 1; the average is about 58% in the first decade, and does not pass above 62% till the start of the fourth decade. It was under 60% in two-thirds of those under 20 years, but over 60% in more than two-thirds of those over 30 years (Table I).

TABLE I.—Heart Size with Age in Atrial Septal Defect

Age (Years)	Cardio-thoracic Ratio				
	Up to 54%	55-59%	60-64%	65-69%	70% and Over
0-19	25	42	20	11	2
20-29	22	10	30	30	8
30-39	0	31	23	16	30
40-59	0	14	20	20	46

Many of the children have been followed up for five to ten years, and generally the heart size has remained the same during this time. In fact it has more often become smaller than larger. The only exception in the first decade in Graph 1 is wrongly included, as a clinical diagnosis of ventricular septal defect was wrongly changed to one of atrial septal defect after the first catheterization (see Case 2 below). There were, however, two exceptions in the second decade—two girls aged 13 and 18—where it increased during five years (C.T.R. 57-61% and 65-70% respectively). Otherwise an increase was never seen before the age of 18 and rarely before 25 years.

Against this there were several cases, all in schoolchildren under 17, where the heart became smaller. This is too late for the change that takes place normally with growth when the heart assumes a lower and more vertical position; perhaps it becomes accustomed to the large flow when the children are not allowed to play energetic games, though leading a normal life otherwise.

To sum up, the heart is very large in infancy and childhood and remains the same until about 25 or 35, when, with the onset of increasing symptoms, it may become still larger.

The Electrocardiogram

Bedford *et al.* (1941) found the P wave large or bifid in a quarter of their cases and the P-R interval prolonged in a third, but in our series of, in the main, younger subjects these changes have been less

common; they found the QRS width over 0.10 sec. in more than half. Barber *et al.* (1950) thought that "partial or complete bundle-branch block" was present in 95% of cases, and that the diagnosis should not be made without this unless proved by catheterization. The validity of this has been widely accepted, but it depends on the meaning to be attached to the term, and this has rarely been defined. We think the term should be avoided and a direct statement made about the presence of primary and secondary R waves and the width of QRS, for the pattern is one that is easy to accept at sight but more difficult to define. We define a primary R wave as one visible to the naked eye where the downstroke returns to or below the isoelectric line. Even the width of the QRS complex can be difficult owing to uncertainty about the exact end-point, especially with direct-writing machines; there may be an error of at least 0.10 sec. where R or S is slurred as it reaches the isoelectric line. When there has been any doubt we have taken the shorter estimate.

In 47 of our cases where the diagnosis was proved by catheterization or by necropsy the QRS width was no more than 0.09 sec. in 13, 0.10 sec. in 11, 0.11 in 8, and 0.12 sec. or over in 15. Where the QRS width was 0.10 sec. or less, there was neither a primary r wave nor notching of the R wave in four cases (Graph 2 B; Graph 3 A); there were

GRAPH 2.—Five electrocardiograms from proved cases of atrial septal defect showing less usual patterns. In each case the upper figure is Lead V1. (A) The primary r wave is very small in V1 but larger in V3. (B) Both leads V1 and V2 show only a qR complex. (C) qR complex only in V1, but enough notching of R in V2 to signify primary and secondary R waves. (D) Right ventricular hypertrophy due to pulmonary hypertension where the notching of R is shown in V3R but hardly in V1. (E) qR only or perhaps rSR', with a very minute primary r in V1 and a less usual type of rSR' in V2.

GRAPH 3.—Four electrocardiograms from proved cases of atrial septal defect with less usual patterns. In A there are QR waves only in V1 and V2. In B there is an unusual notched R wave preceded by a small q, and in C only qr waves, but in B and C the QRS width is 0.12 sec. In D there are only a very minute r and a small s before a large R, but again the QRS is nearly or quite 0.12 sec. in width.

only notched R waves in six (Graph 2 C and D), and in the remaining 14 there was a primary r wave with or without notching of R in addition, most often in V1 but sometimes in other chest leads. The primary r wave was generally small, often only 1 or 2 mm., and sometimes so minute that it was difficult to be sure about its presence (Graph 2 A, C, and E). Where the QRS was 0.11 sec. or more there was almost invariably a primary r wave, and when the QRS was 0.12 sec. or more it was generally fairly large. Of the 40 examples of V1 illustrated by Barber *et al.* (1950), 17 had moderate or large primary and secondary R waves often with some widening of the QRS complex, and 14 had a small primary r wave, but in our opinion three had only qr waves and six had only notched R waves, figures very similar to those in our series.

We agree that the emphasis on this rSR' pattern often with a wide QRS is valuable, and that in its absence the diagnosis should be made only after careful consideration; but some cases even with a large defect do not show features (Graph 2, B and C; Graph 3, A and C). Although a distinction has been made between true primary r waves and notching of R, the presence of either, however small, can help when there is doubt about the site of the defect; both may occur without any increase in the QRS width in normal hearts (Sokolow and Friedlander, 1949) and in other forms of congenital heart disease—perhaps in one-tenth of the cases—but are not so common in ventricular septal defect. Notching of the S wave alone is uncommon in atrial septal defect, and if this is the only change the diagnosis should be reconsidered in favour of a ventricular septal defect.

Neither the height of the primary r wave nor the degree of notching of R is closely related to the size of the heart or to the size of the shunt. Nor do they seem to have increased during the time many of these cases have been under observation. We do not know at what age these changes first appear, but it is early in childhood, and thereafter they remain static until progressive myocardial disease changes the pattern.

S-T depression and T-wave inversion occur in the older patients, especially where auricular fibrillation or cardiac failure supervenes. In younger patients such changes are uncommon in uncomplicated atrial septal defect, but occurred in one boy aged 18 without, and in one girl aged 16 with, pulmonary hypertension. They were, however, found in 3 of 6 patients with anomalous pulmonary venous drainage, all under 20 years of age. The greater frequency of S-T depression and T inversion was the only difference in the cardiograms of the two groups.

Differential Diagnosis

Failures to diagnose mild pulmonary stenosis or to recognize that a large septal defect might be ventricular were the most frequent errors. Now that surgical closure is possible, recognition of a left-to-right shunt at atrial level is not enough, for this may be partly or entirely from anomalous pulmonary veins or through a more primitive defect such as an ostium primum or a common A-V canal.

Ostium primum is important since severe symptoms may develop early, but it is fortunately uncommon after infancy. The defect extends downwards to the A-V valve and complete surgical closure may be impossible. A jet of blood from the left ventricle into the right atrium may be felt at operation, and this suggests the clues to a correct clinical diagnosis. The patient has all the signs and catheter findings of an atrial defect, but in addition there may be a pansystolic murmur due to mitral regurgitation, an enlarged left ventricle on screening, and a bizarre electrocardiogram showing left ventricular hypertrophy as well as the rSR' pattern.

Anomalous pulmonary venous drainage is discussed later with the cases included in our series.

Ventricular septal defect is differentiated by the harsher and longer systolic murmur and the more purring thrill, maximal lower down the left sternal border. The second sound in the pulmonary area is not widely split, and this was the only sign militating against the defect being atrial in two cases where catheterization proved it to be ventricular. Where there was difficulty in deciding the site before catheterization, any suggestion of left ventricular hypertrophy on screening or electrocardiography was found to be a correct guide. A little apparent fullness of the left ventricle may be due to the heart's being pushed over by a large right ventricle, but if both seem about the same size the defect is almost certainly ventricular.

Simple pulmonary stenosis with a closed ventricular septum gives rise to a more rasping systolic murmur and thrill in the pulmonary area. We have confused these on occasion, before we realized how much pulsation there might be in the left pulmonary artery beyond the stenosis; this, however, rarely applies to the right pulmonary artery. In any case, there is no difficulty unless the pulmonary stenosis is slight or the atrial septal defect small, when the differentiation is not of so much practical importance.

General Difficulties

Even after investigations the diagnosis may still be difficult. In three cases the increase in oxygen saturation suggested a ventricular as well as an atrial septal defect; in one of these the clinical diagnosis of atrial septal defect alone was confirmed by necropsy, so well-mixed blood that included the flow through the defect was not obtained in the atrial sample, but only in the ventricular one; in the other two cases samples were obtained from the superior but not from the inferior vena cava, and this led to a wrong deduction that there was an atrial as well as a ventricular septal defect.

Generally, when there is pulmonary hypertension the left-to-right shunt persists, but may not do so always. In two patients who we feel sure have an atrial septal defect and pulmonary hypertension, catheterization confirmed the latter but showed no shunt. We think we have seen patients with a small atrial septal defect and with less distinctive signs, comparable with the *maladie de Roger*, but a shunt cannot be proved by catheterization unless it is 2 or 3 litres a minute. Cases of these two groups have been excluded.

No patients with cyanosis from infancy have been included, for we do not think that any of these had a reversed shunt secondary to pulmonary hypertension from an uncomplicated atrial septal defect. Of two cases where the final answer is known, one had a common A-V canal (Campbell and Missen, 1957), and a second had a left-to-right shunt into the atrium from anomalous pulmonary veins and a right-to-left shunt through the atrial septal defect owing to the presence of pulmonary stenosis (Case 1, Deucher and Zak, 1952).

TABLE II.—Age and Sex Incidence of Atrial Septal Defect

Total both sexes		8	25	19	15	20	13	100

* Includes 7 cases with anomalous pulmonary venous drainage.

† One case in each of these groups has been omitted because the shunt was small and the stenosis dominant.

Sex and Age Incidence

We have 66 cases where the diagnosis was proved by catheterization or necropsy, including seven with added anomalous pulmonary venous drainage and eight others with pulmonary valvular stenosis in addition. To these we have added the first 34 where the diagnosis seemed certain on clinical grounds, to make 100 in all (Table II).

Sex Incidence

There were 72 girls and women and 28 boys and men, a proportion of 2.5:1. The female preponderance was less among those with additional pulmonary stenosis or with anomalous pulmonary venous drainage, but these numbers are small. Taking all ages together, however, hides an interesting difference, for in those under 20 the sex incidence was more equal (30 girls and 22 boys), while in those over 20 it was very unequal (42 women and only 6 men). The mortality seems, therefore, to be more serious in men, though we have no direct evidence of this and the following figures are against it.

Brigden (1956), among patients referred to him after mass radiography, saw 52 where the diagnosis seemed certain after full clinical examination; their ages ranged from 17 to 65 years. The female preponderance (1.5:1) was not so high as in our series; it was the same in those under 30 and those over 30, and if they were divided into those under and over 35 it increased from 1.35:1 to 1.75:1 only. This is against any heavier mortality among men and makes our figures difficult to explain.

Age Incidence

Patients who have and those who have not had catheterization have been combined, since most of the former were children under 10 or women over 30, while more of the latter were 20 to 29—an age when most patients are too well to need investigation. Those who had pulmonary stenosis as well were, however, all under 14, except one woman, aged 22. Combining the figures, 33 were 9 years of age or less, 19 were between 10 and 19, 15 between 20 and 29, and 33 over 30, 13 of these being over 40—a much older age incidence than for most congenital diseases, although many more children were seen than in most previous series of atrial septal defect.

Course and Prognosis

Infancy

Many small children with a large shunt and a large defect suffer from recurrent respiratory infections and a slow gain in weight; often they show less dyspnoea, less susceptibility to infection, and less difficulty in gaining weight, after 2 years of age. Occasionally a large defect seems to be the cause of death in an infant; the reason is not obvious, as most patients survive without difficulty. Brinton and Campbell (1953) included two such infants, aged 2 and 7 months, among 55 necropsies of patients with congenital heart disease, and Bonham-Carter informs us that he has seen several examples. Apart from these we have seen no deaths from uncomplicated atrial septal defect before the age of 27 years, though two children with anomalous pulmonary venous drainage in addition have died.

First Decade

We have seen 33 children between 2 and 9 years of age and many have been followed up for six to ten years; 22 have had catheterization. With two exceptions all these have done well, without any loss of ground, without a raised pulmonary arterial pressure, and without any further increase in the size of the heart. The first exception, a girl aged 5, was admitted for attacks of cyanosis in three of which she had been semiconscious, and had a pulmonary arterial pressure of 74/10 mm., so that her outlook is uncertain. The second, a girl aged 8, with anomalous pulmonary venous drainage and probably an atrial septal defect in addition, seemed well, but had a large heart (C.T.R.

70%) and a P.A.P. of 100/65 mm.; she was not cyanosed and not much disabled, but died a year later at home with "bronchitis" which may really have been pulmonary arterial thrombosis (Case 1*).

A third patient whose septal defect had been thought to be ventricular was included because catheterization seemed to show that it was atrial; during eight years he was often in hospital and his heart became larger (C.T.R. 62 to 68%), but recatheterization when his parents agreed to operation confirmed the original clinical diagnosis (Case 2).

Nearly all these patients have large hearts (C.T.R. generally 54-65%; one-third over 60%), but two have hearts of normal size and one of these had a large shunt.

Second Decade

Most of these patients were children under 15, and had been referred to hospital because of a murmur heard at school rather than because of symptoms; 9 of the 19 had catheterization. All but one are leading normal, quiet lives without increasing symptoms, and their pulmonary arterial pressures are normal although they have large shunts. All but three have large hearts (C.T.R. 56-68%).

The exception, a girl aged 12, had a very large heart, signs of mitral incompetence, and right-sided failure. Investigations showed a large atrial septal defect, at least one pulmonary vein entering the right atrium, and a pulmonary arterial pressure of 85/25 mm., that was due to the large flow and not to a raised resistance. She died after operation, and veins from the upper and middle right lobes drained into the right superior vena cava near its junction with the right atrium; opposite this there was a large atrial septal defect, and there was also slight mitral stenosis (Ross, 1956) (Case 3).

Third Decade

Even at this age, 10 of the 15 patients were sent to hospital because of a murmur and had few symptoms. Most of them had a large heart (C.T.R. 60-70%), though in three it was still no more than 54%. Five of the six who had catheterization, however, were increasingly dyspnoeic, three so much so that they had to give up work. Two had pulmonary hypertension severe enough to produce some reversal of the shunt and central cyanosis, one had a raised pressure of 87/27 mm., and the other two had right-sided failure soon after the onset of fibrillation, at 22 and 24 years. One of these died when she was only 27; true, this was after operation, but she had been in congestive failure for two years and would not have lived long (see Table III). One girl with a large heart (C.T.R. 68%) already had pulmonary regurgitation when she was 20, and a central cyanosis (arterial oxygen saturation 84%) from a partially reversed shunt before she was 25; she said she felt well, but her pulmonary arterial pressure was 115/35 mm., and it is remarkable that she was able to do so much (Case 4).

These are the earliest ages at which we have seen auricular fibrillation, pulmonary regurgitation, or a reversal of the shunt in uncomplicated atrial septal defect, but cyanosis became apparent in three others near the end of this decade, and one of these died when 29 with extensive pulmonary thrombosis.

One-third of our patients lost ground seriously during the third decade, but the true proportion is certainly less, for there are others who had few symptoms till the next decade and those who were too well to seek medical advice at any time.

Fourth Decade

Of the 20 patients, 15 have had catheterization. Their hearts were very large, with cardio-thoracic ratios of 62-79%, and only two, both still well, had figures as low as 56%. Nine had little increase in their symptoms when they were seen, and the pulmonary arterial pressure seemed normal in two and was proved to be so in seven. The other 11

*Five patients are numbered as Cases 1-5 to save repetition when they are referred to again.

became severely disabled during this decade. Six of the 11 died: one with pulmonary embolism after pregnancy, one with acute pulmonary oedema, one with right-sided heart failure, and three with central cyanosis and pulmonary hypertension. The first two will be discussed later (see p. 1380); the third died with heart failure three years after the onset of fibrillation; and the other three, who died within four years of the onset of severe symptoms, had pulmonary hypertension and a reversed shunt. One of them, a man aged 34 with anomalous pulmonary venous drainage, had the usual picture of atrial septal defect and carried on his work till he was 32; he then became increasingly cyanosed and disabled and died with extensive pulmonary arterial thrombosis (Trounce, 1953) (Case 5). Of the remaining five, two had pulmonary hypertension with a reversed shunt and also right-sided heart failure, but in one of these the cyanosis was slight. The other three were handicapped by severe dyspnoea and right-sided failure; the pulmonary pressure was still normal in two, and was 72/18 mm. in the third, who has had a successful operation.

Fifth and Sixth Decades

Among the 13 patients, only two, aged 42 and 46, are still without severe symptoms, but both have large hearts and one has paroxysms of fibrillation.

Of the eight who had catheterization, two have pulmonary pressures at about the systemic level, and both have reversed shunts and are severely disabled, though one, now 45, had remained well without any mention of her heart till she was 40. Four had pulmonary systolic pressures between 56 and 80 mm.; in one of these the disability followed "pneumonia" which may have been pulmonary arterial thrombosis, but in the others it seemed due to the onset of auricular fibrillation rather than the rise of pulmonary pressure. Of the remaining two, one was still well and one was disabled by right-sided failure.

Of the five who did not have catheterization, one was well and one was still working with failure that had started soon after the onset of fibrillation. This was followed closely by severe symptoms in two others, but not for 10 years in the fifth. In the last of these we have no doubt that the pulmonary pressure was high and the shunt reversed (she has since died), but in the others cyanosis was no more than terminal.

Of the four patients who died, two died within a few years of the onset of severe symptoms, but the third lived for 10 years, and the fourth was well till she was 46, developed fibrillation at 56, and lived till she was 63. She was the oldest patient in our series, but since then we have seen a typical case in a woman, aged 66, who came to hospital only because of a urinary infection and was still leading an active life as manageress and was on her feet most of the day. She looked younger and was doing more work than most people of her age.

Coulshed and Littler (1957) have reported five typical cases of atrial septal defect in elderly patients: a woman aged 79, who was unaware of any cardiac defect till she was 54; two men aged 68 and 67, one of whom was still working as a fitter; and two younger patients, aged 58. Some of these were getting congestive failure, but all had been well and active during the greater part of their lives. Similarly, four of the patients of Brigden (1956) seen at mass radiography were over 55 and two were over 60 years of age.

Mode of Heart Failure and Death

In what ways do these patients become worse? We have taken all age groups together, and, including those with anomalous pulmonary venous drainage, 31 patients have reached a stage of incapacity that suggests how the heart is likely to fail or have already died. The most common cause is right-sided heart failure, and the next pulmonary hypertension with central cyanosis and some reversal of the shunt. Where a necropsy was available, some results are given in Table III.

With Right-sided Heart Failure (13 Patients)

Underdevelopment and recurrent respiratory infections had been present in five of the ten patients with large shunts, but not in the two with dominant pulmonary stenosis. In all ten the cardiac murmur was typical of pulmonary stenosis, even when the stenosis was mild with a pressure gradient of only 20–40 mm.; the harsh grating murmur and thrill maximal in the second left space, produced by the narrowed valve, might indeed be expected to obscure the more diffuse and fainter murmur typical of atrial defect. The pulmonary component of the second sound was diminished in the five with more severe stenosis, and was widely split in four of the seven with a large shunt and mild stenosis.

The physical signs were thus predominantly those of pulmonary stenosis, even where this was the minor lesion. Screening, however, revealed increased pulmonary arterial pulsation seen farther out in the lung fields than in pulmonary stenosis, though only in three a hilar dance. The discrepancy between physical signs and radiology was the usual reason for catheterization. The cardio-thoracic ratio ranged from 52 to 65% in those with a large shunt, but was normal in the two with dominant stenosis.

The electrocardiogram showed the usual rSR' pattern in VI in eight patients, but in three of these the tall secondary R wave and slight S–T depression or T inversion indicated more right ventricular preponderance than in most children with uncomplicated atrial septal defect. The case of the child with infundibular stenosis was unusual and had dominant S waves all across the chest leads. The usual picture of right ventricular preponderance was found in the two patients with dominant stenosis and in one of the three with a large shunt and moderate stenosis.

Only three of the group were over 20 years of age, but during the three to nine years they have been followed up they have shown no progressive symptoms and, with one exception, no increase in heart size.

Haemodynamic Findings

We have adequate data of cardiac catheterization in 46 patients, excluding those with added pulmonary stenosis. A large left-to-right shunt and a large pulmonary flow without any rise in pulmonary arterial pressure or resistance were found in nearly all the children and in nearly half the adults (Group A). In the remainder the haemodynamic findings were different: instead of being normal, the pulmonary arterial pressure was increased, the systolic pressure being at least 50 mm. and generally much more, and often the resistance also was increased. These can be divided into two groups: eight who still had a large left-to-right shunt and were clinically acyanotic (Group B), and nine who had a pulmonary pressure high enough to make the left-to-right shunt smaller, though sometimes still large, and to cause a right-to-left shunt and varying degrees of central cyanosis (Group C).

Group A: With a Large Left-to-right Shunt but no Increase of Pulmonary Arterial Pressure or Resistance (29 Patients).—This group included 17 of the 19 children and 12 of the 27 adults. The children were all between 6 and 13 except one boy aged 17, since we have had little occasion to investigate, or even to see, patients between their leaving school and reaching 25 years of age. Only two of the adults were under 30, and the average age was 36 years.

Most of the physiological data were normal, including the systemic flow and the pulmonary arterial pressure and resistance. Clinically, the patients were without central cyanosis, and the arterial oxygen saturation was always 94% or more. The systemic flow was normal, averaging 4.7 litres a minute in the adults and 4.0 litres a minute in the children, and the cardiac index (cardiac output per unit of surface area) was normal in the children but lower, and sometimes a little below normal, in the adults. Naturally the pulmonary flow was greatly increased. In the children it was generally between 8 and 12 litres and averaged 10 litres a minute, and in the adults it was generally between 10 and 16 litres and averaged 13.3 litres a minute. This means the shunt was large, and on the average 62% (generally between

50 and 75%) of the blood that reached the left atrium from the lungs passed to the right atrium and back to the lungs, and only 38% passed to the left ventricle. The pulmonary resistance was always normal or reduced; it averaged 1.1 units and was never above 2.0 units. Thus in spite of the very large flow the pulmonary arterial pressure was normal or only slightly raised, the highest figures being 44/10, 42/7, and 40/12 mm. Hg; it averaged 30/11 mm. in the children and 30/10 mm. in the adults.

All the children and several of the adults were still leading a fairly active life, but four of the latter had suffered from congestive failure. Clearly, congestive failure can occur, and it seems likely that it can prove fatal, before there is any great rise of pulmonary arterial pressure or any great reduction in the large left-to-right shunt.

Group B: With a High Pulmonary Arterial Pressure, but Still with a Large Left-to-right Shunt and no Right-to-left Shunt (8 Patients).—Five of these were adults with an average age of 39 years, but a boy aged 19, and two girls aged 5 and 12, reached this group earlier in life. We do not know why they behaved in this way—unusual for their age—but patients with a large pulmonary flow vary greatly in the length of time needed to develop any progressive rise of pulmonary arteriolar resistance, depending perhaps on the degree of intra-arterial thrombosis. Some have not done this after 50 years; about half our patients did so after 25–40 years, and a few did so sooner. These differences are the same as those we have found in cases with a large left-to-right shunt through a persistent ductus arteriosus where the tendency to develop increasing pulmonary resistance seems even less. In one girl who also had anomalous pulmonary venous drainage (Case 3) the flow was so large that the pulmonary pressure was 85/25 mm. though the resistance was only 2.0 units; in the other girl it was 3.5 units and the pressure (in the right ventricle) 74/4 mm.

In these eight patients the systemic flow was only a little lower than in the first group—3.9 instead of 4.7 litres. There was as yet no change in the size of the left-to-right shunt or of the pulmonary flow, which averaged 12.3 litres a minute. This means that 68% of the inflow to the left atrium shunted through the atrial septal defect—at least as high a proportion as in the first group. The pulmonary arterial pressure had increased to an average figure of 82/30 mm., but in spite of this the pulmonary resistance was normal or only slightly increased. Clinically, most of these patients were acyanotic, but two showed the degree of cyanosis that may be seen with mitral stenosis when the heart is failing. The arterial oxygen saturation was always between 90 and 95%, so a small right-to-left shunt may have been developing although the shunt was still predominantly left-to-right.

Group C: With a High Pulmonary Vascular Resistance, a Diminishing Left-to-right Shunt, and Increasing Right-to-left Shunt (9 Patients).—All these were between 33 and 52 except two, aged 24 and 27 years. Most of them were developing a tinge of cyanosis, and many showed deep central cyanosis. The arterial oxygen saturation averaged 86%; it was between 72 and 88% in all but three, where it was between 91 and 93%.

The systemic flow was further reduced; it averaged 3.4 litres a minute, and was above 4.0 litres in one patient only. The pulmonary flow was larger than the systemic, but small compared with the previous groups; it averaged 5.2 litres a minute and was never above 7.0 litres. The shunt was more difficult to calculate because of the additional right-to-left shunt, but, except perhaps in two patients, it was always present, and on the average 34% of the blood reaching the left atrium from the lungs shunted to the right atrium.

The pulmonary arterial pressure was always high, generally about the same as the systemic pressure; it averaged 104/39 mm., but once it was lower and once a good deal higher (140/62 mm. against 120/85 mm.). The pulmonary resistance was greatly increased, generally to 5–10 units and once much more than this.

The Pressures in the Atria

Generally the pressure in the left atrium is a little, if at all, above that in the right to account for the large left-to-right shunt. We agree with the view of Barger *et al.* (1948) and Dexter (1956) that the atria act as a single chamber, the flow depending on the resistance in the two ventricles and their circuits.

We did not find any significant difference between the pressures in the right and left atria. In no case was the difference in the systolic pressure more than 3 mm., and sometimes it seemed slightly higher in the right. On the average the pressure was 10.1/3.2 mm. in the left atrium and 9.6/2.4 mm. in the right, and, where only mean pressures were measured, 5.7 mm. in the left and 5.5 mm. in the right—figures that are substantially the same. The left atrium was entered in 25 of our 46 cases, but the pressure was measured in only 18 of these. There was no difference as between the children and adults except that the left atrium was entered more often in adults.

Changes Found on Recatheterization

The occasion to repeat catheterization in the same patient does not often arise, but there are five cases where, for various reasons, this was done. In the first, a boy aged 5, the right ventricular pressure five years later had fallen from 34/11 to 22/1 mm.; the only conclusion to be drawn is that a small rise does not always mean that it will be progressive. The second patient had a very large shunt when she was 47 and was verging on congestive failure, but was not much worse seven years later; her right ventricular pressure had risen from 33/5 to 56/5 mm. without any change in the large left-to-right shunt. Both these patients were acyanotic and in both the arterial oxygen saturation was over 95%. The third patient, aged 44, with congestive failure and slight cyanosis (arterial oxygen saturation 91%), had a P.A.P. of 59/25 mm., and two years later it had risen to 68/26 mm. without any great change in her general condition. The fourth, aged 34, had congestive failure and gross tricuspid incompetence, and during the next year her pressure rose from 95/30 to 110/45 mm., but she was still acyanotic and still had a large left-to-right shunt. The fifth patient had reached a later stage with a right-to-left shunt and an arterial oxygen saturation of 86% when she was first catheterized at the age of 33; four years later she was more disabled, more persistently cyanotic, and the left-to-right shunt had fallen from 3.5 litres to under 1 litre per minute, but the pulmonary pressure was unchanged (100/36 mm.).

Summary and Conclusions

We have discussed the physical signs and radiology of 100 patients with atrial septal defect, in two-thirds of whom the diagnosis was proved by catheterization or necropsy. We have tried to assess the course and prognosis from their history and from the progress of those who have been observed for several years.

After infancy has been passed, the first two decades are a good period when the patients lead a life that is nearly normal but generally without active games. We think that 95% are still doing well when they are 20, and 85% when they are 30 years of age. The prognosis in the fourth and fifth decades is much less good, and only about half of those seen at hospital are still well at 40 and less than a quarter at 50 years. The children are, we think, a representative sample, but adults are less likely to be seen unless they have symptoms, so the real prognosis is better; this is supported by the chance finding of older patients with atrial septal defect at mass radiography and elsewhere.

Usually in early childhood the electrocardiogram already shows the rSR' pattern; the QRS is widened to more than 0.10 sec. in only about half, and a

quarter do not show real primary and secondary R waves, though often these show some notching of the R wave. Usually the heart is large, often with a cardio-thoracic ratio between 55 and 65%—a size that would generally indicate a poor prognosis—but nearly all patients who survive the first year or so do well without the heart becoming any larger till 25, and more often 35, years of age. Then in an increasing number, but not in all, the strain of the large right ventricular output produces increasing dyspnoea, sometimes made worse by the onset of auricular fibrillation, and ultimately right-sided heart failure. This may happen while the pulmonary arterial pressure is still normal in spite of the large pulmonary flow. In others, however, though rarely before 30, the pressure gradually rises, sometimes high enough to reverse the shunt and produce central cyanosis. Such patients have a higher incidence of pulmonary arterial thrombosis, which may be extensive; it may be the cause of the rising pressure rather than the consequence.

Nearly always for 25 years, and sometimes for 50 years, the shunt through the atrial septal defect remains large, so that the pulmonary flow is between 10 and 16 litres with a normal systemic flow of 4 or 5 litres a minute. In the smaller number where the pulmonary arterial pressure rises to about systemic level, the left-to-right shunt may gradually be mixed with a smaller right-to-left shunt and may in the end become quite small.

About one-tenth of patients with an atrial septal defect have some pulmonary veins from the right lung draining into the right atrium or large veins. Nearly the same proportion have some degree of pulmonary valvular stenosis as well as the atrial septal defect, still with a large left-to-right shunt and its characteristic features. In some of these reversal of the shunt seems likely, though we have not seen this happening.

We have not discussed the surgical treatment of atrial septal defect; at present several methods are in use and a standard perfected method is still being developed. In general, although there is no risk of bacterial endocarditis, the disability and the course and prognosis are not very different from, but rather worse than, those of persistent ductus arteriosus. Surgical treatment is, therefore, likely to become a routine procedure.

BRAIN-STEM ENCEPHALITIS* FURTHER OBSERVATIONS ON A GRAVE SYNDROME WITH BENIGN PROGNOSIS

BY

EDWIN R. BICKERSTAFF, M.D., M.R.C.P.
Consultant Neurologist, Birmingham Regional Hospital
Board; Consultant Neurologist, Midland
Centre for Neurosurgery

[WITH SPECIAL PLATE]

In 1951, in collaboration with Professor P. C. P. Cloake and under the title "Mesencephalitis and Rhombencephalitis," I published three examples of a syndrome the exact counterpart of which I had failed to find previously described. In these cases, after a prodromal period of general malaise and mild pyrexia, there developed gradually signs of mid-brain disturbance, followed by a progression suggesting downward extension of the disease until, in two cases, there was almost total suppression of all functions having brain-stem innervation, but no respiratory or cardiac embarrassment. After a stationary period, in which two of the cases appeared moribund, there was a gradual recovery, the patients finally attaining total and absolute normality. The condition was thought to be a virus encephalitis, but without any pathological support for this view. From correspondence in the press, personal communications, and discussions following this paper it became apparent that other physicians and neurologists had seen rare isolated cases almost exactly similar, and having had an equally favourable outcome so that no pathological studies have become available. Two of the cases described by Espir and Spalding (1956) and given the diagnosis of encephalitis lethargica were very comparable at one stage, but their subsequent course differed.

In the last three years I have seen four further examples of this clinical syndrome, and have kindly been allowed to refer to another under the care of Dr. William Gooddy and Dr. J. Hamilton Paterson (Paterson, 1953). My last patient died at the height of the attack and pathological study was possible. Though no claim to be describing a specific disease entity is made, it seems justifiable to group together cases of such great clinical similarity and to draw attention again to this grave condition, from which total recovery is possible.

Reports of Cases

In order to give a complete picture of the group as a whole, the clinical histories already published *in extenso* are briefly summarized as Cases 1 to 3.

Case 1

Female aged 24. In January, 1949, two weeks of headache and muscular pains were followed by drowsiness, ptosis, left facial paralysis, and ataxia developing over one week, and succeeded by diplopia, dysarthria, dysphagia, and numbness down the left side of the body. The patient was easy to rouse, but dozed on cessation of stimulation. Conjugate eye movements were impaired, with coarse nystagmus; masseters and facial muscles were weak; hearing was impaired; there were left hemihypalgesia, a left extensor plantar response, and left cerebellar ataxia. Cerebrospinal fluid (C.S.F.) contained 26 lymphocytes per c.mm. and gave a paretic Lange reaction. For four weeks the signs extended

*Based on a paper read in the Section of Neurology and Neurosurgery at the Annual Meeting of the British Medical Association, Brighton, 1956

until there was complete ptosis and total bilateral ophthalmoplegia, with total paralysis of jaw muscles and facial muscles, gross deafness, total aphagia, aphonia, and inability to lift the head or move the tongue. The remainder of the body was unchanged.

After three weeks a recovery began which was rapid at first, but later typical Parkinsonism of the head and limbs developed and lasted two months. This, in common with all other signs, totally and completely recovered, so that in ten months the patient was normal in all respects and has remained so for eight years.

Case 2

Male aged 36. In March, 1950, one week of malaise and headache was followed by drowsiness, ptosis, diplopia, and ataxia. Four days later bilateral ptosis, fixed dilated pupils, and weakness of eye movements developed. He was drowsy but easily roused, rapidly dozing again. In another three days there were gross bilateral ptosis, total palsy of all but downward eye movements, bilateral ataxia of limbs, and absent reflexes. One week later total right and partial left facial palsy developed. The C.S.F. contained 77 mg. protein per 100 ml. and showed a mildly paretic Lange reaction. Recovery began three days later, and was total and complete in two months. The patient has remained entirely normal for seven years.

Case 3

Female aged 24. Admitted in June, 1950, for ovarian cystectomy. Had headache for one week, followed by transient loss of consciousness; operation then performed, but patient remained drowsy afterwards with mild pyrexia and developed diplopia and dysarthria. Drowsiness increased for one week, then a major convulsion occurred. C.S.F. contained 153 mononuclear cells per c.mm. and gave a paretic Lange reaction. Gradual deterioration over three weeks to severe drowsiness, bilateral ptosis, total bilateral ophthalmoplegia, bilateral paralysis of jaw muscles, palate, pharynx, and tongue. There were slight deafness and slight ataxia in arms and legs. Recovery began after one week and continued over two months, accompanied by a maniacal psychosis. This last feature and all other signs completely recovered, and the patient has been entirely normal for seven years.

Case 4

(Under the care of Dr. William Gooddy and Dr. J. Hamilton Paterson)

A female aged 47 developed numbness of the left side of the body, followed three days later by vertigo, vomiting, ataxia, and weakness of the left side. After a stationary period of approximately three weeks, vomiting recurred, blurred vision developed, and left-sided ataxia increased. A week later there was further deterioration, and over the space of two weeks she progressed to a state in which she was very drowsy, there was total bilateral ophthalmoplegia, her jaw and facial muscles were paralysed, she was unable to speak or swallow, and there was a gross flaccid weakness of all limbs. The C.S.F. was normal throughout the illness.

After one week in this state she began to move her eyes and monosyllabic speech returned; two weeks later speech, swallowing, and eye movements were normal, but tremor of the head and a myoclonic tremor of the palate had developed. She then made a steady recovery except for some emotional lability, and twelve weeks after admission was able to return home. She remained entirely well, and on examination by Dr. Gooddy four years later the only abnormality found was a dubious plantar response on the left side.

Case 5

A boy aged 11 had mumps in the spring of 1954, and on getting up was giddy and unsteady for a few days. He recovered from this and throughout the summer was well except for some emotional lability. In November, 1954, he complained of headache and general malaise, which persisted for four days, when he became drowsy and confused.

One day later the drowsiness increased and gross slurring of speech and marked weakness of facial muscles developed. For three further days his condition deteriorated, and when seen at the height of the illness he was drowsy but easily rousable; there was gross paralysis of conjugate ocular movement in all but a downward direction; the jaw muscles were paralysed and there was a bilateral facial paralysis. He was unable to swallow or speak, but the tongue movement appeared little affected. There was a flaccid weakness—but not paralysis—of all movements of arms and legs, with absent tendon reflexes, equivocal plantar responses, and bilateral ataxia of limbs. His C.S.F., at normal pressure, contained 12 mononuclear cells per c.mm. and 80 mg. protein per 100 ml.

He remained in this state for about five days. Speech then began to return, followed by swallowing and later—over a period of about two weeks—by normal ocular movements. Three months after the onset there was only very slight ataxia of the legs as a residual physical sign, but there had been considerable emotional lability, and during the next year he showed marked impairment of learning capacity and had several bouts of aggressive and violent behaviour. Examination in November, 1955, a year after the onset, showed a very slight ataxia of the legs, but no other abnormal sign, and he is known to have remained physically normal for two and a half years.

Case 6

In November, 1954, a boy of 10 developed slight general malaise, which lasted for three weeks and was followed by headache and, after two days, by fever, photophobia, and vomiting. He was found then to have a mild pyrexia, minimal neck stiffness, but no abnormal neurological signs. His C.S.F. contained 28 lymphocytes per c.mm.; biochemistry normal. There was apparent improvement for six days, and then over a period of 24 hours he became drowsy, developed paralysis of facial muscles on both sides, and was apparently unable to swallow or speak or to sit up. This state of affairs persisted for four days, when he became less drowsy, facial movements, swallowing, and speech began to return, and the rigidity of arms and legs decreased. *Pari passu* with this, however, there developed a Parkinsonian tremor of the right hand and arm and slight tremor of the head, which persisted in diminishing degree for two weeks. By the beginning of February, 1955, he was entirely normal, and has remained so for two and a half years.

Case 7

In early November, 1954, a boy of 10 developed frontal headache and general malaise, which persisted for two weeks and was accompanied by some abdominal pain. He then began vomiting, his headache increased, and he became drowsy and suffered intermittent delirium. Three days later the drowsiness increased, diplopia developed, the eyelids drooped, and he had difficulty in swallowing. His C.S.F. at this stage contained 65 leucocytes per c.mm. (mainly polymorphonuclear) and 60 mg. protein per 100 ml. Over the next three days there was general deterioration, the eye movements became more restricted, the speech slurred, facial muscles weak, and swallowing more affected. Examined after a further 24 hours, he was very drowsy but easily roused, dozing off again when stimulation ceased. There was bilateral ptosis, and almost total ophthalmoplegia in all but a downward direction. The jaw muscles were very weak, the facial muscles weak on both sides, and the palate and pharynx weak. Speech was grossly slurred, and there was generalized hypotonia with absent tendon reflexes and bilateral extensor plantar responses.

Two days later total ophthalmoplegia, total facial, palatal, and pharyngeal paralysis, and complete aphonia had developed. After two further days he improved; swallowing and ocular movements returned, and speech became intelligible. Over the next two weeks there was steady recovery, and by the end of December he was neurologically entirely normal. He showed at this time, and for

some weeks afterwards, undue lability of emotions and some impairment of intellectual capacity. The former has persisted, but otherwise he has been entirely normal for two and a half years.

Case 8

In early March, 1956, a boy of 14 developed vague muscle pains and general malaise and became drowsy; three days later he complained of headache, some abdominal pain, and vomiting. The next day the headache increased and the drowsiness became profound; he had periods of restlessness and confusion and was incontinent of urine. The C.S.F. at this time contained 70 mg. protein per 100 ml., but showed no other abnormality. His condition slowly deteriorated over the next two days, his conscious level fluctuating according to the degree of stimulation; there were slight weakness of facial muscles, gross slurring of speech, difficulty in swallowing, and ataxia of the arms and legs with marked reduction of tendon reflexes. The C.S.F. contained 10 mononuclear cells per c.mm. and 70 mg. of protein per 100 ml.

At this stage he developed an extrapyramidal tremor of the head, neck, and right arm, which disappeared as further deterioration occurred in the next 24 hours; by then he was drowsy but could easily be roused, and there was bilateral ptosis and almost total bilateral ophthalmoplegia. Jaw muscles were paralysed on both sides, and there were bilateral deafness and marked paralysis of palate, pharynx, and tongue. He was unable to speak, to swallow, or to raise his head. There was abolition of tendon reflexes, but it was impossible to get sufficient co-operation to test other functions of the nervous system. Twenty-four hours after this examination he had a sudden fit, which was said to consist of extreme rigid extension of all four limbs, and in this he died.

Necropsy was carried out next day by Dr. E. W. N. Trounson. The brain was removed and fixed. No abnormality was seen with the naked eye in the brain or any other organ. The brain and portions of liver, kidney, spleen, and suprarenals were examined histologically by Dr. A. L. Woolf, who reported as follows.

In the liver there were marked periportal accumulations of lymphocytes (Special Plate, Fig. 1) with some pyknosis of adjacent liver cells. The spleen, kidneys, and suprarenals were normal.

Abnormalities in the brain were remarkably scanty. In the brain-stem there was widespread swelling and ballooning of the myelin sheaths in the less compact fibre tracts as is seen in cerebral oedema; these are illustrated in Special Plate, Fig. 2, taken from the ventral tegmental decussation through which pass the oculomotor fibres. Also in the brain-stem there was astrocytic hyperplasia (Plate, Fig. 3), the astrocytes showing "twinning" and bulkiness of cytoplasm—also seen in cerebral oedema. The nerve cells were not strikingly affected in any part of the brain, but an occasional nerve cell in the third-nerve nucleus showed a wrinkling of the nuclear membrane and commencing cytolysis. In the cerebellum there was a diffuse but slight loss of Purkinje cells, though some folia were completely devoid of these cells. The blood vessels were distended in all areas, but in the frontal lobes, around some of the vessels, there were eccentrically placed perivascular aggregations of lymphocytes.

The Clinical Syndrome

Geographical Distribution.—The number of cases is too small to attach any real importance to this, but the 1949–50 cases all occurred in Birmingham, and Cases 5, 6, and 7 all in the same month of 1954 in closely neighbouring districts of Shropshire and Herefordshire at a time when various presumed systemic virus infections were abundant amongst the local children.

Age.—One patient, with the longest course, was 47, and another 36, but all the remaining patients were below 25 years of age.

Sex.—There were five males and three females.

Prodromal Symptoms.—There was a period of from one to three weeks of general malaise and headache in all cases, and of muscular aching in some.

Onset of Central Nervous Involvement.—This was gradual in each case, and in six cases drowsiness was the first symptom. Vomiting and ataxia were presenting symptoms in the remaining two.

Early Symptoms and Signs.—Headache, present in all cases, was mild, but drowsiness was marked. Six cases had double vision and six vomiting, while five complained of unsteadiness of gait. Drowsiness was present in all cases. The patients appeared to be asleep, but were easily roused to full co-operation, though if stimulation was relaxed they would quickly slip back into sleep again. Ptosis and defective conjugate eye movements were present in all cases, while attempts at lateral or upward eye movement resulted in a coarse large-amplitude nystagmus. Downward movement was usually normal. Dysarthria was marked in six cases. Seven cases ran a low-grade pyrexia.

Period of Progression.—The time from the earliest signs to maximal disability varied: it was one week in two cases, two weeks in two cases, three to four weeks in three cases, and eight weeks in one case. In all except one the progression was slow and unremitting, and in none was it abrupt.

Signs of Maximal Disability.—In seven of the eight cases there was a total or almost total ophthalmoplegia, and in the eighth a partial ophthalmoplegia. If any eye movement remained, it was in a downward direction. Six cases had total bilateral paralysis of the motor supply of the fifth nerve, and all had total bilateral facial paralysis at some stage. Deafness was present in six; six had a total or gross paralysis of the ninth, tenth, eleventh, and twelfth nerves, and six had complete anarthria. There was loss of tendon reflexes in five cases, but with extensor plantar responses. Long-tract sensory signs were present in four.

It was striking that in no case was cardiac or respiratory distress present; muscle tenderness and signs of meningeal irritation were found only to a minimal degree in one.

Period from Maximal Disability to Total Recovery.—Excluding the fatal case, this lasted one month in three cases, three months in one, ten months in two, and seventeen months in one.

New Signs During Recovery.—Five patients developed an extrapyramidal type of rigidity and four a typical Parkinsonian tremor. In all except one case these developed during the stage of return of neurological function, but in the fatal case the signs were apparent just preceding maximal disability. Six cases, during recovery, showed emotional lability, particularly the tendency to spontaneous, inappropriate laughing and giggling. Two showed aggressive and violent behaviour.

Sequelae.—It is notable that neurological recovery has been total in six cases, the seventh having a minimal ataxia. Any extrapyramidal or Parkinsonian features have also totally disappeared. In two cases there has been some intellectual deficit, which was severe enough to interfere with education in one.

Laboratory Investigations.—These gave comparatively little information. Negative findings are not listed, but all available agglutination tests were carried out in all except one patient, with no positive result. The C.S.F. pressure was normal in all cases; there was a pleocytosis, predominantly lymphocytic, of 10–153 cells per c.mm. in five cases; the protein content was over 60 mg. per 100 ml. in four cases, the maximum being 80 mg. Three showed a paretic Lange reaction, but no abnormality in the level of sugar or chlorides was found. A blood leucocytosis of 12,000 to 16,000 cells per c.mm. was present in four cases.

Electroencephalography was performed in two cases only (Cases 1 and 3); this showed widespread delta and theta abnormality in all leads, appearing in bursts, and in the first case predominantly in right temporal leads.

Discussion

The outstanding feature of these cases has been the sub-acute development of disturbed brain-stem function so gross that at some stage in all except one case survival for even a few days seemed impossible. It is difficult in a scientific communication to convey the gravity of the patients' condition when at its worst and the drama of the degree of recovery possible.

In our original communication (Bickerstaff and Cloake, 1951) we employed the term "mesencephalitis and rhombencephalitis" in default of anything which better indicated the part of the central nervous system bearing the main brunt of the abnormality. The disease process, however, is probably widespread throughout the brain, the clinical manifestations of brain-stem involvement being so much more dramatic than other features tend to be obscured. We discussed previously the differential diagnosis and the reasons for excluding many well-known conditions capable of producing transient brain-stem disturbance. These reasons have not changed and they will not be repeated.

The pathological process must be one capable of producing suppression of function without destruction of tissue—for recovery has taken place so rapidly and so completely. It is therefore not very surprising that histological examination of the fatal case has shown so little demonstrable abnormality. It seems probable that the loss of Purkinje cells was an anoxic, terminal manifestation. The vascular distension was certainly referable to the fit in which the boy died. However, the beading and swelling of the myelin sheaths and the "twinning" and swelling of the astrocytes are of greater significance, for if such a process of oedema were widespread throughout the stem function could be suppressed, but not destroyed, and could remain in abeyance until such time as the oedema receded, when rapid recovery would be possible.

Whether or not a process of brain-stem oedema is responsible for the neurological manifestations in this condition, the fundamental cause of the syndrome remains obscure. It has always been attractive to incriminate some unknown neurotropic virus, and the similarity to some cases of encephalitis lethargica has been mentioned several times since our original paper, but the pathological details available now, though scanty, give little direct support for this view and reveal practically none of the perivascular cuffing considered so typical of virus infections of cerebral tissue. An alternative possibility is that the cerebral changes may be a secondary effect—perhaps allergic in nature—to some systemic disease. No overt clinical evidence of generalized disease was manifest to support this in these cases, but the marked periportal round-cell infiltration in the liver of the fatal case was at least suggestive of virus infection.

Taking the clinical pattern of this syndrome as a whole, there are certain similarities to the course of the so-called infective polyneuritis—the mode of onset and progression, the stationary state at maximal disability, and the rapid recovery of gross paralysis with slower final extinction of all abnormality. Indeed, several patients had lost all tendon reflexes even at a time when neither hypotonia nor paralysis of the limbs was marked. There is growing support for the view that infective polyneuritis results from an allergy or hypersensitivity to some agent or variety of agents, as yet undetermined, and the cases considered here may equally well be the clinical end-result of a variety of causal factors rather than a specific disease caused by a specific organism. This fact does not minimize the importance of recognizing the syndrome, for in view of its potentially benign outcome no effort should be spared to maintain the patient's general condition, to control fits, and to prevent inhalational bronchopneumonia, even at a stage when it appears that death must inevitably follow within a matter of hours.

The burden of care will fall upon the nursing staff. Their efforts will be even further stimulated if they realize the probability of a favourable outcome, and for the parents and relatives of the patient the hope sustained by the

medical attendants during the intensely distressing period of maximal disability is invaluable. Once deterioration appears to be checked a reasonably confident prognosis can be given—though a warning should be issued of the possibility of personality changes during the convalescence and the rather more remote danger of permanent impairment of intellectual capacity.

Summary

A description is given of eight examples of a clinical syndrome of gradual onset in which develops almost total paralysis of all motor function, originating first in the mid-brain and later in the whole brain-stem, accompanied by only mild pyramidal or long-tract sensory disturbance, and no cardiac or respiratory abnormality.

From a stationary stage of extreme gravity, dramatic total recovery has occurred in seven cases, with no neurological sequelae.

The pathology of the fatal case is described, and a state of transient cerebral oedema, possibly related to a systemic virus infection, is suggested as the basic cause.

I wish to express my thanks to Dr. William Goody and Dr. J. Hamilton Paterson for allowing me to refer to Case 4; to Drs. Hugh Fisher, J. Macaulay, and A. C. Kendall, consultant paediatricians, for referring to me Cases 5–8; and to Dr. A. L. Woolf and Dr. E. W. N. Trounson for the pathological studies on Case 8.

[WITH SPECIAL PLATE]

This paper describes four patients with a similar and unusual syndrome of a widespread papular and nodular eruption and multiple arthritis. Circumscribed areas of destruction in bone were present, and in two cases this progressed to a "concertina" deformity of the fingers. Tendon-sheath swellings and patches of xanthelasma palpebrarum occurred in two of the cases. Histological examination of all involved tissue in every case showed the same type of giant cells, the cytoplasm of which appeared granular and in places finely "foamy." An unusual type of lipid has been demonstrated in these cells. Two patients died, and in both, apart from widespread infiltration of tissues by the giant cells, a fibrinous pericarditis was present.

Twelve cases showing a similar clinical picture and histology have been described in the literature under various headings, and are summarized in the Table.

Personal Cases

Case I

Mrs. E. P., a housewife. Apart from a hysterectomy for fibroids when aged 40 she had not had any previous illnesses of note. No relevant condition had occurred in the family, and her only brother and sister were alive and well. The patient had been married for 25 years, but was childless. In December, 1949, at the age of 49, she developed painful swelling of the finger, shoulder, and knee joints. At the same time an eruption appeared on the fingers, elbows, both pinnae, the radial aspects of both forearms, and over the manubrium sterni. She came under our observation in July, 1950, and was seen at regular intervals until she died in 1952. When she was first seen there was a widespread papulo-nodular eruption, sheets of yellow-brown papules 0.2–2 cm. in diameter and associated with erythema being present over the forehead, ears, neck, naso-labial furrows, outer aspects of forearms and upper arms, the nail folds, the sacral region, and the anterior aspects of the thighs and lower legs. At the periphery of the involved patch of skin they were occasionally in linear distribution. The larger nodules were present on the scalp, both pinnae, bridge of nose, chin, elbows, dorsum of most fingers, sacral area, and knees. These tended to be purplish in colour. They were well raised from the skin surface and some were confluent (Fig. A). Local heat and pressure did not increase or decrease the number or size of the nodules. The teeth were healthy, but a few papules were present on the lips and gingival margins (Fig. B), the fraenum and posterior part of the tongue, and extending into the tonsillar recesses. There was widespread involvement of the joints associated with moderate pain and often considerable swelling and limitation of movement. Shoulders, elbows, wrists, finger-joints, knees, and ankles were involved. The axillary and inguinal lymph nodes were slightly enlarged. Blood pressure 180/100 mm. Hg.

FIG. A.—Case I. Nodules and papules on ear.

Clinical Course.—Many of the larger nodules remained unchanged, but a few new ones appeared. At times the sheets of papules became less prominent and the erythema faded, but for periods of a few weeks they were more marked and itching occurred. Seven months after the onset four or five large, typical xanthelasma palpebrarum patches were observed. In 1951 an irregular swelling developed in front of the wrists and appeared to be arising from the tendon

FIG. B.—Case I. Papules on upper lip.

sheaths; it remained for six months. The joints became worse and new ones were involved, including the hip, shoulder, sacro-iliac, vertebral, and temporo-mandibular joints. The finger and toe joints became unstable and the fingers shorter, causing wrinkling of the skin. A general kyphosis developed. The patient lost 3 stones (19.1 kg.) in weight, chiefly during the first year of the illness. There were long periods of intermittent moderate pyrexia usually coinciding with the exacerbations of the joint and skin lesions. The general condition steadily deteriorated, and in December, 1952, she developed fever and a cough and died after a few days.

Treatment did not appear to have any effect, and included A.C.T.H. (12.5 mg. twice daily for three weeks) and a low-fat diet over a period of two months. X-ray treatment (a single dose of 400 r at 85 kV) had no effect on the cutaneous nodules.

Investigations.—Blood Wassermann and Kahn reactions negative. Erythrocyte sedimentation rate (Westergren) varied from 5 to 41 mm. in one hour. Blood cholesterol 125–180 mg. per 100 ml. Serum calcium and plasma protein levels, blood counts, glucose tolerance curve, and liver function tests were within normal limits. The bone marrow showed an unusually high number of monocytes, of which a few contained a slightly foamy cytoplasm. The electrocardiograph showed a low T_2 and inverted T_3 . Mantoux reaction: 1 in 1,000 negative; 1 in 100 positive. Analysis of an excised nodule showed 8% total ether-soluble lipids.

X-ray Examination.—On chest radiography calcified lesions were present in the right apex and some pleural adhesions in the right costophrenic angle. At the first

examination of the bones (August, 1950) a generalized osteoporosis was apparent, with numerous small marginal zones of subcortical destruction of bone adjoining the interphalangeal and midcarpal joints. These small zones of bone destruction gradually increased in size; new ones appeared, and by December, 1950, the hands, wrists, shoulders (Special Plate, Fig. 1), knees, and hips were extensively involved. Zones of bone destruction were also present in the posterior articular facets of the spine, the costo-transverse joints, the greater and lesser trochanters of the femora, the ischial tuberosities, and by May, 1951, in the anterior angles of the vertebral bodies. The skull showed no change.

Post-mortem Findings and Histology.—The body fat in general was reduced in amount and deep yellow-brown in colour. Submucous nodules were present on the posterior third of the tongue and in the larynx. The thyroid appeared normal. There were recent small bilateral pleural effusions. The lungs were congested, with collapse of the left lower lobe. A fibrinous pericarditis was present with an accumulation of some 300 ml. of heavily blood-stained exudate. The heart was enlarged, with dilated chambers and a soft, flabby myocardium. Valves and coronary arteries showed only moderate atheroma. Scattered peritoneal adhesions were present, including some recent ones over the anterior surface of the liver and enveloping the spleen. The liver, of normal size, showed on section a typical "nutmeg" appearance. The gall-bladder, kidneys, suprarenals, stomach, intestines, and right ovary were normal; the uterus and left ovary had been previously removed. There was widespread destruction of the articular cartilages; areas of firm granulation tissue extended into the underlying cancellous bone.

Details of Twelve Similar Cases Recorded in the Literature

Serial No.	Authors	Title Given	Sex and Age	Joints Affected	Skin Lesions	Other Clinical Findings	Course	Comments
1	Targett (1897)	—	F 65	"Rheumatic and gouty habit"	Small tumours on fingers	—	—	—
2	Parkes Weber and Freudenthal (1937); Parkes Weber (1943, 1944, 1948, 1955)	Non-diabetic cutaneous xanthomatosis with hypercholesterolaemia and atypical histological features	M 35	Knees and other joints	Widespread, chiefly on hands, face, elbows, and buttocks	Loss of weight and intermittent fever. Tendon-sheath tumours on back of wrists	Gradual improvement over period of 10 years; many nodules disappeared	Blood cholesterol 350 mg.% (one occasion). Improvement followed fat-poor diet
3	Portugal et al. (1944)	Histiocytomatosis gigantocitaria generalizada	M 44	Widespread joint involvement	Widespread papules and nodules	Tendon-sheath tumours	Some papules and nodules disappeared	—
4	Graham and Stansfield (1946)	A case of hitherto undescribed lipoidosis simulating rheumatoid arthritis	M 20	Widespread joint involvement of rheumatoid arthritis pattern	Nodules and papules on scalp, face, elbows, wrists, fingers, and back	Kyphosis and depression of sternum	A sarcoma developed in the axilla, from which the patient died	At necropsy giant-cell infiltration found in muscle, periosteum, synovial membrane, and bone
5	Caro and Senear (1952)	Reticulohistiocytoma	M 50	Hands, feet, spine, and jaws	Papules and nodules on hands, elbows, face, and ears	—	Some papules and nodules disappeared, but new ones developed	—
6	Caro and Senear (1952)	Reticulohistiocytoma; but prefer the term "reticuloendothelial granuloma"	F 36	Hands, wrists, and knees	Papules and nodules on face, ears, neck, forearms, and fingers	—	After 4 years skin lesions were smaller	—
7	Montgomery (1952; in discussion following presentation of Cases 5 and 6)	Reticulohistiocytoma	M 30	Nil	Papules on face, arms, and trunk	—	Papules later disappeared	—
8	Montgomery (1952; in discussion following presentation of Cases 5 and 6)	Reticulohistiocytoma	F 24	Fingers and other joints swollen	Papules on scalp, forehead, nose, neck, and arms	—	—	—
9	Allington (1950; and in discussion following presentation of Cases 5 and 6)	Reticulohistiocytoma	F 66	Chronic rheumatoid arthritis	Nodules on face, ears, forearms, and ankles	Thyroid adenoma	After 4 years most nodules had disappeared and joints had improved	Improvement followed thyroidectomy
10	Laymon (1952); also Goltz and Laymon (1954)	Reticulohistiocytoma and multicentric reticulohistiocytosis of skin and synovia	M 52	Back, fingers, knees, and shoulders	Papules over fingers, hands, ears; nodules over knuckles	Tendon-sheath tumours of wrists	Skin cleared after 6 months; died one month later of carcinoma of colon	Condition began 4 months after resection of adenocarcinoma of colon
11	Goltz and Laymon (1954)	Multicentric reticulohistiocytosis of skin and synovia	F 40	Neck and limb joints	Papules over forehead, scalp, shoulders, chest, and on fingers	Tuberculous lymph node in axilla	—	—
12	Davies and Wood (1955)	Reticulohistiocytoma	F 47	Rheumatoid type of arthritis affecting hands, knees, and other joints	Papules over fingers, neck, ears, and scalp	—	In 3½ years joints became worse, but papules retrogressed and became minimal	This is Case 1 of these authors; their Case 2 is of a solitary nodule and not included here

The changes were most prominent in the knee and shoulder joints.

Histologically, the epidermis was normal. The nodules situated in the upper half of the dermis consisted of an aggregation of large rounded or oval multinucleate cells enveloped in a scanty fibrillary stroma. The cells varied in size up to 50 μ in diameter, and contained from one to twenty or more nuclei, small, compact, and irregularly disposed within the cell. The abundant cytoplasm was eosinophilic, and in most of the cells of homogeneous texture; a faint granularity was discerned in some, and in a few there was a very fine foamy appearance. The submucous laryngeal nodule showed the same appearance. In contrast with the nodules, the xanthelasma palpebrarum lesions showed typical lipid cells, coarsely vacuolated and staining readily with Scharlach R. The granulation tissue from the eroded areas of bone consisted of large, sometimes multinucleate, cells with abundant eosinophilic slightly granular cytoplasm, closely packed in a scanty stroma which was free from inflammatory cells (Special Plate, Fig. 2). The cells were essentially similar to those found in the skin lesions. In some areas distant from the giant-cell accumulation, connective-tissue cells were swollen and interspersed with larger rounded cells similar to those constituting the main bulk of the "tumour." Transitional forms were seen, suggesting that the giant-cell aggregations were derivatives of the synovial fibrocyte. Apart from the skin nodules and joints, the same large cells were found scattered through the dermis and subcutaneous tissues, in bronchial lymph nodes and endocardium. No similar change was demonstrated in kidney, ovary, or spleen.

Histochemical Investigations.—Examination of frozen sections of skin and a subcutaneous nodule with the usual series of Sudan stains failed to demonstrate any lipid except for a faintly positive result with the periodic-acid-Schiff (P.A.S.) technique. The Sudan dyes (chiefly Sudan IV) were originally used, either as a saturated solution in 70% ethanol or in Herxheimer's fluid. Later it was found that a more complete dye transfer from solvent to lipid phase of the section was obtained by the use of the dye as a saturated solution in pyridine (50%) solvent. With this technique, sudanophilic material (S.M.) was found in considerable quantities, mainly in regions of compact collagen fibres, either related to groups of the giant cells or lying free between the fibres. In addition it was present in fibrocytes deeply placed in sheets of apparently normal capsular collagen fibres and in certain chondrocytes. The intracellular and extracellular globules of S.M. were of fairly uniform size (0.7–1.6 μ); they showed birefringency of a low order, and notably in synovial cells and chondrocytes were circumferential.

Further histochemical investigations were made on serial frozen sections to detect any sudanophilic lipid which might be "masked" by virtue of chemical combination with proteins, polypeptides, or mucopolysaccharides. No proteolytic dissociation was demonstrated after incubating sections in a solution of papain for one hour at 37° C. No change was noted after alkaline hydrolysis, but acid hydrolysis with 10% acetic acid for one hour at 37° C. or N/1 hydrochloric acid for eight minutes at 56° C. gave a moderate increase in the amount of both intra- and extracellular S.M. There was no increase in S.M. after incubating sections in hyaluronidase solution for 19 hours at 37° C., although certain structures formerly P.A.S.-positive became P.A.S.-negative. Prolonged attempts at defatting sections (ether, chloroform, xylol, di- and tri-chlorethylene) for periods up to five days reduced only slightly the fine diffuse pinkish sudanophilia of the cytoplasm of the aggregated giant cells, but completely eliminated the larger intra- and extracellular globules of S.M. and the neutral fat of tissue lipocytes.

The results of these investigations did not reveal the presence of lipid in combination with either protein or mucopolysaccharide. The moderate increase in S.M. after weak acid hydrolysis may indicate the presence of some polypeptide-lipoid complex which was mainly intracellular

in site. Furthermore, the results obtained would suggest that the intra- and extracellular S.M. was probably chemically similar.

Case II

Mrs. F. M. G., a housewife. There had been no previous significant illness and there was nothing relevant in the family history. In September, 1947, when aged 50, the patient noticed some yellowish marks on the left upper eyelid, and in March, 1949, slightly itching papules appeared on the face, ears, and arms. She came under our observation in September, 1949, when examination revealed sheets of closely set, shiny reddish-brown papules, varying in diameter from 1 to 3 mm., over the pinnae, behind the ears, in the eyebrows, on both cheeks, the sides and bridge of the nose, the extensor

Fig. C.—Case II. Papular eruption on forearms.

surfaces of both arms (Fig. C), and over both shins. The areas so affected were slightly erythematous. Five or six xanthelasma palpebrarum lesions of 0.5–1 cm. diameter were present on both upper eyelids. No lesions were apparent on the buccal mucous membrane.

Clinical Course.—By March, 1950, the papules round the ears and on the cheeks had almost disappeared and those on the forearms had become flatter; the xanthomatous plaques on the upper eyelids were less noticeable. However, by September, 1951, the nodules had again become more prominent and then involved the V of the neck. Only one of the xanthelasma palpebrarum lesions remained. In October, 1952, she complained of pain in both knees, and later in the shoulders and ankle-joints. From 1952 to 1954 the sheets of papules cleared in some areas, but fresh lesions appeared, usually at the edge of the fading patches.

When seen again in 1956 the eruption was widespread, with clear areas of skin on the points of the elbows and knees, in the axillae, behind the knees, and on thighs and buttocks. In many places these clear areas were ringed by a continuous edge of fused papules. Papules were also present on the lips. Certain areas where nodules had been noted previously were now clear, but had an atrophic wrinkled appearance. There was no sign of the xanthelasma palpebrarum patches. A tendon-sheath swelling was present on the front of the left wrist. She complained that the joints had gradually become stiffer, being worse in the hot weather. The spleen and liver were easily palpable. Enlarged lymph nodes were present in the right axilla.

Investigations.—Wassermann and Kahn reactions negative. Blood cholesterol 130–250 mg. per 100 ml. Plasma protein level, blood count, glucose tolerance curve and liver function tests within normal limits.

X-ray Examination.—A progressive change was noted starting in June, 1952, with small areas of decalcification in one phalanx, the left os magnum and scaphoid. Further erosions developed on the phalangeal margins in both hands and feet, and on the right scapula at the site of insertion of the supraspinatus tendon. By January, 1956, new areas of bone destruction were demonstrated in the right scaphoid and os magnum.

Histology.—Sections from a skin nodule showed essentially the same picture as in Case I. In addition some smaller elongated cells with similar cytoplasm appeared to represent transitional forms between the stroma fibrocytes and the fully developed giant cells.

Case III

Mrs. J. L., a housewife. In 1950, when aged 48, she had complained of itching, followed three months later by pain in the joints and shining brown papules on the hands. Papules then gradually developed on nail folds, backs of fingers, hands, arms, face, neck, buttocks, thighs, and lower legs. Larger nodules appeared over elbows and knees. Papules were present on the tongue and mucous membranes of the mouth and pharynx down to the level of the thyroid cartilage. The joints became more swollen and stiffer until the patient was almost immobile. Her general condition gradually deteriorated; she lost weight, and finally died in April, 1954.

X-ray Examination.—Sharply defined and rounded areas of osteoporosis without evidence of bone reaction were present in outer ends of clavicles, bones of hands and fingers, and to a less extent in legs, feet, and upper part of right radius.

Post-mortem Findings and Histology.—Dr. R. B. T. Baldwin has kindly furnished us with the necropsy report and material for histological examination.

A diffuse thickening was present round the vocal cords, with pea-sized nodules on the right side. The lungs showed a purulent bronchitis and a small infarct at the right base. There was an acute fibrino-purulent pericarditis. The heart chambers were dilated and the muscle was soft and pale. The bronchial and hilar lymph nodes were enlarged; there was a severe cardiac cirrhosis of the liver and the spleen was moderately enlarged.

Histologically, the skin nodules showed essentially the same appearances as in Case I. The giant cells were particularly large, being up to 100 μ in diameter (Special Plate, Fig. 3). The bronchial lymph nodes showed large aggregations of the same type of giant cell as seen in the skin nodules. An incidental and unexpected finding was infiltration of the hilar lymph nodes by carcinoma suggestive of a bronchial origin, although no primary growth was discovered in the lungs or elsewhere.

Case IV

Mrs. E. H., a housewife. In October, 1944, when aged 25, she complained of itching over the abdomen, and a month later had pain, swelling, and stiffness in the wrists, fingers, ankles, and shoulders. She was given a course of intramuscular injections of gold in January, 1945, and during this treatment papules developed on the ankles, face, eyelids, external auditory meati, and central upper back. The condition gradually progressed, and in May, 1945, she was admitted to the Radcliffe Infirmary, Oxford, under the care of Dr. A. B. Carleton; and in 1947 to the Leeds General Infirmary under Dr. J. T. Ingram, where she was seen by one of us (R. P. W.). At this time the eruption was chiefly present over the outer upper arms, front and outer aspects of the thighs, lower abdomen, ears, neck, cheeks, and forehead. It consisted of dusky brown-red shining papules, often follicular and in some areas linear in distribution. The mouth and tongue were clear. She was unable to walk, and the fingers showed concertina type of deformity.

Investigations.—Blood total cholesterol 98-190 mg., free cholesterol 63 mg., and cholesterol esters 127 mg. per 100 ml. Serum calcium plasma protein, blood Wassermann and Kahn reactions, and E.S.R. all normal; Mantoux reaction positive to 1 in 10,000.

X-ray Examination.—Punched-out defects involving carpal bones and terminal phalanges of both thumbs and fingers were reported in 1945. By April, 1948 (Dr. G. H. Illingworth), there was extensive destruction of the proximal and distal interphalangeal and metacarpo-phalangeal joints, and of the wrist joints, leading to telescoping of the fingers (Special Plate, Fig. 4). There were similar changes in the metatarso-phalangeal, tarsal, ankle, and elbow joints. Areas of decalcification were also present in the shafts of the radius and ulna on both sides. A chest skiagram in April, 1957, showed diffuse mottling throughout both lungs.

Histology (Professor D. H. Collins).—In the corium were ill-defined cell groups containing giant cells with up to a score of nuclei and an abundant slightly "foamy" cytoplasm. A few histiocytes, lymphocytes, neutrophils, and eosinophils were also present. Scharlach R stained a small amount of lipid in the giant cells a rusty colour. The appearances were essentially similar to those of the section from Case I.

Discussion

Clinical Features

The average age of onset was 42, with extremes of 20 and 66 years. There were ten females and six males. One patient had a sister with widespread joint disease, but apart from this there was no family history of similar complaints, nor was there any significant past history. In eight cases the onset of the eruption and the joint symptoms coincided. In five cases the joint symptoms preceded the eruption, respectively by two months, six months, one year, four years, and several years. In Case II the rash developed two years before the involvement of joints. The papules and nodules were from 0.2 to 2 cm. in size. The smaller ones, shining and yellow-brown in colour, were chiefly in patches to one or two areas, but in some became widespread. The commonest areas involved were the backs of the hands and fingers, outer aspect of the forearms and upper arms, forehead, margin of the nose, ears, and on the fronts and sides of the neck, including the V. The larger nodules were more purple and present over bony prominences, including the elbows, knees, scalp, bridge of nose, chin, sacral area, and prominent and occasionally disappeared. Papules were present on mucous membrane in four cases. All cases except No. 7 (see Table), about which very few clinical details are available, had pain and often swelling of numerous joints, often involved, and the clinical picture was that of rheumatoid arthritis with in some cases severe crippling. Tendon-developed plaques of xanthelasma palpebrarum, which after a period of one to two years gradually faded. Two cases had enlarged lymph nodes, and in one of these the spleen and liver became palpable. Bouts of pyrexia occurred and there was considerable loss of weight in Case I.

Of 11 cases where the clinical course is known, the eruption retrogressed in seven and completely disappeared in two of these. The joint condition gradually progressed in three of these cases, but in one it improved and in one other, after a period of seven years, the active process appeared quiescent. Four patients died 4 years, 11 months, 3½ years, and 3 years after the onset, the cause of death being malignant neoplasm in the first three and undetermined in Case I. Case II improved following a fat-poor diet. Other cases improved after a similar period without such a diet, and in Case I two months on a low-fat diet while in hospital had no apparent effect.

Pathological Features

Case II had a raised blood cholesterol level (350 mg. per 100 ml.) and Cases II and III each on one occasion had readings of 250 to 235 mg. per 100 ml. respectively. The histological picture of all the material examined was dominated by the presence of a varying number of the same type of unusual large cell. Apart from the aggregations in the skin and synovia, similar isolated cells were demonstrated in the marrow, lymph nodes, endocardium, voluntary muscle, perimorphological grounds it seems likely that these abnormal cells were neoplastic. Transitional cells between fibrocytes and the giant cells suggest that the latter were derived from the fibrocytes of the skin, synovial membrane, and elsewhere. The cytoplasm of the giant cells did not show the usual staining reactions of lipid, and it is suggested that the material may be a polypeptide-lipoid complex. The fact that this material was shown to be present in small

amounts in cells in a relatively isolated position argues strongly in favour of an intracellular origin rather than histiocytic phagocytosis.

Radiological Features

The radiological appearances show many features resembling rheumatoid arthritis, but differ in a number of ways: the bone is destroyed rapidly, whereas the destruction of articular cartilage proceeds more slowly; involvement of the terminal interphalangeal joints is extensive; some unusual joints, such as the posterior articulations of the lumbar spine and the costotransverse joints, are affected; some bony sites other than joints are involved—for example, the connective-tissue attachments on the femoral trochanters, ischial tuberosities, anterior angles of vertebral bodies, and the shafts of long bones such as the radius and ulna.

Relationship to Allied Conditions

Although cases similar to those here presented cannot be found in the literature of the xanthomatous disorders, certain features, notably the multiple xanthelasma palpebrarum and presence of giant cells laden with sudanophilic material, indicate a connexion. There is a histological resemblance to the giant-cell synovioma of tendons and joints, and, although clinically the conditions are not clearly related, it is to be noted that five of the cases in the series developed tendon sheath tumours. Granular-cell myoblastoma also has a similar histological appearance. Such tumours are usually solitary, although a few cases of multiple myoblastomata have been described (Bloom and Ginzler, 1947; Powell, 1946). None of these has a close clinical resemblance to the cases included here, and no similar bone and joint changes are described. It is interesting that Pearce (1950) has shown that the cytoplasm of the granular-cell myoblastoma contains a lipid probably in combination with protein and sugars or amino-alcohols. Subcutaneous nodules in rheumatoid arthritis may be widespread, but never approach the dissemination and the papular appearance of the cases described here, nor is the histology similar. Fletcher (1946) reported a case of severe rheumatoid arthritis in which after 4½ years extensive subcutaneous nodules developed. These showed an appearance more like the necrobiotic nodule of rheumatoid arthritis, but numerous "foam cells" and many multinucleated giant cells were present. Presumably this case is closely related to the series under discussion.

It is suggested that the condition is due to an abnormality in connective-tissue metabolism probably akin to that which occurs in rheumatoid arthritis. However, in the series of cases now described the histochemistry of this change and the resulting histology are different.

Recently cases of this condition have been reported under the heading of reticulohistiocytoma or reticulohistiocytosis. This title does not seem adequate to describe the clinical condition or the underlying disordered connective-tissue cell biochemistry. The term "lipoid dermatitis" is preferred.

Summary

Four patients having an unusual eruption and arthritis are described. Twelve cases with a similar clinical and histological picture have been recorded in the literature under various titles. The eruption consists of sheets of yellow-brown papules over the backs of the hands and fingers, the face, forearms, and other areas, being widespread in some cases. Purple nodules are also present. Xanthelasma palpebrarum and tendon-sheath swellings may occur. The joint condition resembles a severe rheumatoid arthritis, with a number of minor differences and marked bone destruction. The histology of all involved tissue shows the same type of giant cell with an abundant granular cytoplasm which probably contains a lipid-polypeptide complex.

We should like to thank the numerous clinicians, pathologists, and radiologists who have been concerned in the management

of these cases. In particular we would like to thank Dr. J. T. Ingram and Dr. E. Ritter for permission to include Case III, and Dr. J. T. Ingram to include Case IV. Professor C. B. Perry has very kindly given us helpful advice in the preparation of the paper. Our thanks are also due to Mr. J. E. Hancock for the photomicrographs.

EXFOLIATIVE CYTOLOGY OF THE
COLON AND RECTUMPRELIMINARY REPORT ON THE RECTAL
WASHING TECHNIQUE

BY

D. J. OAKLAND, M.B., Ch.B., F.R.C.S.

(From the Surgical Research Laboratories, Queen Elizabeth Hospital, Birmingham)

[WITH SPECIAL PLATE]

Earlier reports on the cellular content of rectal discharges were made by those concerned with the diagnosis of specific inflammatory disease of the colon—that is, bacterial and amoebic dysentery (Dutcher, 1903; Jurgens, 1907; Anderson, 1921; Callender, 1925). Their interest was necessarily confined to the bacterial and parasitic content of the rectum and colon. In recent years there have been several papers in the American literature on the cytological content of the rectum and colon and the recognition of exfoliated malignant cells in cases of neoplastic disease of the large bowel. One of the problems for the cytologist working in this field is the difficulty of obtaining suitable specimens from such a large organ as the colon. A variety of techniques have been described, but none is entirely satisfactory, particularly where the lesion is situated in the proximal colon.

Previous Investigations

Bercovitz (1941) examined the cellular content of bowel discharges in a very large number of patients with normal and diseased large bowel and described the cellular flora, but did not report the presence of malignant cells in his cases of large-bowel tumour. In 1947 Wiseman *et al.* made a brief report on the diagnosis of carcinoma of the colon at various locations from the splenic flexure down to the rectum by the examination of smears prepared from the rectal contents obtained during proctoscopy. Wiseman *et al.* (1949) later reported their experiences with smears taken during sigmoidoscopy as well as proctoscopy with reference to the diagnosis of malignant epithelial tumours. The accuracy of cytological diagnosis of malignancy in the latter series was 76%, as compared with 79% by x-ray examination and 67% by sigmoidoscopic examination. Ayre (1950) described one case in which carcinoma of the rectum had been successfully diagnosed by cytology with a smear

technique. Blank and Steinberg (1951), also using the smear technique, examined a series of patients, including 45 with malignant disease of the rectum and sigmoid colon. They found malignant cells in 65% of cases when the smear was taken from the surface of the growth, but in only one out of 19 cases when it was taken from the bowel wall below the site of the lesion. They concluded that cytological examination of rectal and sigmoidal discharges had no advantage over the classic methods of investigation and diagnosis of carcinoma of the rectum and sigmoid colon.

Loeb and Scapier (1951) described a new method of obtaining specimens of exfoliated cells from the rectum and colon during sigmoidoscopy. Bader and Papanicolaou (1952), using Loeb's rectal washing apparatus, studied a series of 200 cases with symptoms suggestive of malignant disease of the lower alimentary tract. Of these cases 19 were proved to be malignant by surgery and biopsy, and 18 of these had positive or suspicious smears. Rubin *et al.* (1953) reviewed the value of cytology in gastroenterological diagnosis. They examined 33 patients with proved malignant disease of the colon by collecting the returned fluid after an enema of Ringer's solution, and found malignant cells in 27 cases. Of this same group, a radiological diagnosis of carcinoma had been established in only 18 cases.

Most recently Galambos and Klayman (1956) reported a series of 68 patients, 26 of whom had malignant lesions confirmed at operation. The correct diagnosis was established in 16 of these cases by exfoliative cytology. They concluded that colonic exfoliative cytology in experienced hands was a valuable technique in the diagnosis of colonic lesions.

Present Investigation

The purpose of this report is to describe my experience and findings with exfoliative cytology of the colon and rectum at the Surgical Research Laboratories, Queen Elizabeth Hospital, Birmingham. The 86 patients examined were composed of three groups: (A) patients with normal lower alimentary tracts; (B) patients with known carcinoma of the rectum; and (C) patients with suspected malignant disease of the colon. The rectal washing technique of Loeb and Scapier (1951) was used to obtain specimens in all cases.

Technique

In the series of patients without disease of the alimentary tract (Group A) the apparatus described by Loeb and Scapier (1951) was used, sigmoidoscopy being performed in the theatre just before or after the induction of anaesthesia. All patients in this series had an enema the day before sigmoidoscopy. Rectal washings from the patients with known carcinoma of the rectum (Group B) and suspected carcinoma of the colon (Group C) were collected by means of a modification of Loeb and Scapier's apparatus. This consisted of a similar long double-lumen brass tube, the proximal ends of which were led through and soldered to small metal disks which fitted beneath the screw-on caps of small glass specimen jars, a watertight joint being ensured by a rubber washer. Two further brass elbows were soldered to the metal disks, the atomizer bulb being attached to the one and the pump to the other. This apparatus (illustrated herewith) proved more rigid and easier to handle during sigmoidoscopy.

About 20 ml. of normal saline was used to wash the bowel wall, and an equal quantity of 90% alcohol was added to the aspirated specimen to delay autolysis of the cellular content. This fluid (together with a few drops of

Modified rectal washing apparatus.

Meyer's egg albumen) was then centrifuged at 2,000 r.p.m. for ten minutes. Smears were prepared from the deposit, fixed in an ether-alcohol mixture, and stained with the Papanicolaou stain EA 65. The smears were scanned on a moving stage of a microscope, using the high-power objective. Groups of cells of interest were marked with a diamond object-marker, and the position was further noted by reference to the Vernier scale of the moving stage.

Group A

Rectal washings were obtained from 50 patients admitted to hospital for surgical treatment of a condition unrelated to the large bowel. So far as could be ascertained by clinical examination none of them had malignant disease of the alimentary tract; however, x-ray studies were not performed to confirm this. Of the 50 cases, 34 had a non-malignant condition unrelated to the alimentary tract, such as thyroid adenoma or varicose veins; 11 had malignant disease other than in the alimentary tract, and most of these cases were of carcinoma of the breast; and a small group of five cases had chronic peptic ulcer. One washing was taken in each case either just before or just after the induction of anaesthesia.

Results.—Of the 50 smears prepared in this series, three were acellular, but the remainder contained a small variety of cells which varied in number, but were uniform in appearance throughout the series.

Squamous cells were seen in 64% of cases; they were the largest cell observed and had an average diameter of 32 μ . The nuclei were small and pyknotic in some of these cells, and in others they were larger and well defined. The cytoplasm, which was always plentiful, was occasionally laminated, and clear rings or halos were observed around some of the nuclei (Special Plate, Fig. 1).

Columnar epithelial cells and goblet-shaped mucous cells originating from the mucous membrane lining the large bowel were seen in 24% of cases. Clumps of columnar epithelial cells had a typical palisade appearance, but more often these cells were seen end on as a mosaic of regular round cells with centrally placed nucleus (Special Plate, Figs. 2 and 3).

Degenerate and unidentifiable cells were seen in 26% of cases. Many of these cells had the appearance of distended columnar epithelial cells and the nucleus was undergoing karyorrhexis (Special Plate, Fig. 4).

Macrophages were present occasionally, usually containing numerous dark-staining droplets. Polymorphonuclear leucocytes were seen in only 12% of cases, and in only one smear were they present in any number. Red blood cells were never seen, probably owing to the occurrence of haemolysis when alcohol was added to the aspirated specimen.

There appear to be three types of exfoliated cell in the normal colon and rectum: (1) Squamous cells; (2) columnar epithelial cells and mucous cells; and (3) degenerate cells of unknown origin. White blood cells and macrophages are also seen occasionally.

Group B

Rectal washings were taken from 19 patients with carcinoma of the rectum, the diagnosis being confirmed by either biopsy or operation. The object in including this series was to gain experience in the recognition of exfoliated malignant cells and compare them with the individual cells of the actual carcinoma after removal or biopsy. All the washings were taken from a point immediately below the growth.

Results.—Exfoliated malignant cells were observed in 79% of the smears. The cellular content of the smears varied considerably, and some normal cells were seen in all of them. Squamous cells formed the majority of the normal cells in this series, and polymorphonuclear leucocytes were always present but varied greatly in numbers. The exfoliated malignant cells were quite different in appearance from any cell seen in Group A. They had large,

dark-staining nuclei with thickened nuclear membranes and scanty cytoplasm which was difficult to see and stain. There was great variation in size and shape of the nuclei, which had two or more nucleoli (Special Plate, Figs. 5 and 6). The appearance was similar to that of the individual tumour cells.

Group C

Rectal washings were collected from 27 patients with signs and symptoms suggestive of malignant disease of the large bowel. In 12 cases in this series the diagnosis of carcinoma of the colon was confirmed at operation. In two further cases the diagnosis could not be established even after laparotomy and biopsy, one of these having a fixed mass in the ileo-caecal region and the other carcinomatous peritonei. Of those 12 patients with proved carcinoma of the colon, two had carcinoma of the caecum, two carcinoma of the transverse colon, and eight carcinoma of the sigmoid colon.

Results (see Table).—The correct diagnosis was established in nine of the cases by cytological examination, and in one further case malignant cells were identified, but, although laparotomy revealed a fixed mass in the ileo-caecal

Analysis of Cytological and Radiological Findings in Suspect Cases of Carcinoma of the Colon

	No. of Cases	No. of Cases
Total suspected of having carcinoma of colon examined	27	
Diagnosis of carcinoma confirmed	12	
Correct cytological diagnosis	9 (75%)	
Site of lesion:		
Caecum	2	
Transverse colon	2	
Sigmoid	8	
False positive cytological diagnosis	1	
Unconfirmed diagnosis of carcinoma of colon	2	
False positive cytological diagnosis	1	
Barium enema studies performed	9	
Correct radiological diagnosis	7 (78%)	
False negative radiological diagnosis	2	

region with the macroscopic features of carcinoma, biopsy did not confirm the diagnosis. In one case a false diagnosis was made, malignant cells being identified in the smears, but two barium enemas, sigmoidoscopy, and examination under an anaesthetic revealed procto-sigmoiditis with no evidence of malignant disease. In the nine cases where the cytological diagnosis was correct the lesion was in the caecum in one, splenic flexure in one, and sigmoid colon in seven cases.

Barium enema studies were carried out in nine of the 12 patients with proved carcinoma of the colon, giving a correct diagnosis in seven cases (see Table). A diagnosis of carcinoma was queried by the radiologist in three further cases, but in two of these laparotomy refuted the diagnosis, and in one, in which an ileo-caecal mass was present, the diagnosis was not proved. In three cases the results of the barium enema studies of the colon were reported as normal, but laparotomy revealed carcinoma of the sigmoid in two and carcinomatous abdomini in the other.

In this series carcinoma of the colon was successfully diagnosed by cytology alone in one case, and the history is reported below.

Case Report.—Female aged 70 with one month's history of bleeding per rectum but no alteration in bowel habit. No abnormalities detected on clinical examination. Sigmoidoscopy showed a mild degree of granular proctitis and a small adenoma of the rectum. At 7 in. (18 cm.) from the anus there was an area of stenosis through which the sigmoidoscope could not be passed. A rectal washing was collected at this site and a specimen taken for biopsy. Two smears were prepared from the rectal washings; several groups of malignant cells were seen in both of them. The biopsy material was reported as showing chronic inflammatory changes with no evidence of malignancy. Barium enema investigation showed many diverticula in the sigmoid colon with a narrowed segment at the junction of the descending and sigmoid segments, but no characteristic features of malignancy were seen radiologically. Laparotomy revealed a carcinoma at the junction of the sigmoid and descending colons, and the pathologist reported adenocarcinoma of the colon with no invasion of the regional lymph nodes.

In this series abnormal columnar epithelial cells were frequently seen, particularly in those patients with proctitis,

colitis, or diverticulitis. The columnar epithelial cells had enlarged nuclei with an increase in chromatin content, and the amount of cytoplasm was decreased (Special Plate, Fig. 7). These changes are similar to those reported by Boddington and Truelove (1956) in ulcerative colitis. In one patient cells of this type were interpreted as malignant cells, but subsequent investigation by barium enema, contrast enema, and sigmoidoscopy under anaesthesia revealed only proctitis. This patient is being carefully followed up, but up to now, after ten months, has had no further symptoms.

Conclusions

The apparatus for collecting rectal washings was found to be satisfactory in use and good specimens were obtained by this technique. It was found that adequate cleansing of the bowel was important, since any excess of faecal material in the aspirated specimen resulted in a smear too thick to interpret microscopically. Cleansing was effected by soap enema, and purgatives were not given by mouth. Although in this investigation malignant cells were observed in one case of carcinoma of the caecum, the saline enema technique described by Rubin *et al.* (1953) and Galambos, Massey, Klayman, and Kirsner (1956) is more likely to collect cells exfoliated from lesions in the right side of the colon.

The mucosa of the large bowel is lined by columnar epithelium with many goblet-shaped mucous cells. Only two types of cell can be exfoliated from this surface which, together with the squames of uncertain origin and degenerate cells, form a constant cytological content of the normal rectum and colon. The findings in the patients with normal alimentary tracts were in accord with those of Bader and Papanicolaou (1952) and of Wiseman *et al.* (1949). However, Bercovitz (1941), examining 2,158 specimens obtained from 1,123 patients with normal alimentary tracts, found cells in only 11 cases, most of them polymorphonuclear leucocytes. He claimed that the discharges from the normal healthy bowel did not contain cells, and that a marked cellular content was one of the earliest evidences of pathological change in the lower bowel.

Carcinoma of the rectum was successfully diagnosed after one washing in 79% of cases. Three of the five false negative results occurred early in the series and were due to gross faecal contamination of the smear, making cellular identification impossible. The cytological diagnosis of malignant lesions within reach of the sigmoidoscope appears to be a practical proposition, but it is doubtful if this technique has any advantage over biopsy.

Carcinoma of the colon was diagnosed correctly by cytology in 75% of cases. Although the series is small, the results are encouraging, and a larger series of cases are being investigated by both the rectal washing and enema techniques. The one false positive case in the series draws attention to the problem discussed by Galambos and Klayman (1956) and by Boddington and Truelove (1956) of differentiating exfoliated malignant cells from cells exfoliated from an inflamed colonic mucous membrane. In the present series abnormal cells were seen in all the smears prepared from patients with inflammatory disease of the colon. Many of the cells bore some resemblance to exfoliated malignant cells in that the nuclei were enlarged and heavily stained, but they did not show wide variation in contour and the cytoplasm was usually easily recognized.

As McAmmond (1955) points out, cytological investigation requires team-work. The scanning of smears is time-consuming and is not a practical proposition for the clinician. Any cytological service for the diagnosis of malignancy of the colon and rectum would require a trained technician to prepare and scan the smears and a cytologist to give an opinion on the nature of the cells identified.

Summary

In a study of the cytology of the colon and rectum the rectal washing technique of Loeb and Scapier was used on a group of 86 patients, and a modification of

their apparatus is described. The cytological content of the normal lower alimentary tract was found to be constant and composed of three groups of cells: (1) squamous cells; (2) columnar epithelial and mucous cells; and (3) degenerate cells together with occasional white blood cells and macrophages. Exfoliated malignant cells were found in 15 of 19 patients with carcinoma of the rectum, but it is felt that this technique has no diagnostic advantages over biopsy.

Of 27 patients with suspect malignant disease of the colon, a correct diagnosis was obtained cytologically in nine, and 12 were subsequently proved to have carcinoma. The rectal washing technique appears to be most successful in the diagnosis of carcinoma of the descending and sigmoid colons.

I wish to thank Professor F. A. R. Stammers and Mr. B. N. Brooke for advice and encouragement in the preparation of this paper. My thanks are due to Mr. S. H. Sharpe, histology technician, who devised the modification of Loeb and Scapier's rectal washing apparatus and who prepared all the smears and many of the photographs. I am also indebted to Mr. J. F. Dee for some of the photographs, and Mrs. I. Denton for the typescript.

CONGENITAL LOBAR EMPHYSEMA

BY

D. G. COTTOM, M.C., B.M., M.R.C.P.

AND

N. A. MYERS, F.R.C.S., F.R.A.C.S.

From the Thoracic Unit, the Hospital for Sick Children,
Great Ormond Street, London

[WITH SPECIAL PLATE]

Breathlessness in babies may provide much diagnostic difficulty. Frequently it is due to respiratory infection, occasionally to cardiac failure, and rarely to other conditions, one of which is congenital emphysema of the lung. The purpose of this paper is to report six cases and to draw attention to a syndrome which, if recognized, allows of surgical correction. Details of the six cases are set out in the accompanying Table. All the patients were under the age of 4 months, all were dyspnoeic, and, in addition, four had failed to thrive. The left upper lobe was most frequently affected, and in four cases a congenital anomaly of the heart accompanied the pulmonary lesion. Other common symptoms were cough, stridor, and difficulty in feeding due to breathlessness, but cyanosis was observed in only two cases and in neither was it present continuously.

All cases were not of equal severity, and in two the condition became extremely urgent. In the first of these

pulmonary valvotomy had been performed, but 24 hours after operation the baby's condition deteriorated and a chest radiograph (Special Plate, Fig. 1) showed gross emphysema of the left upper lobe with displacement of the mediastinum to the right. A left upper lobectomy was performed, but the baby died shortly after the end of the operation. In the other case a patent ductus arteriosus was ligated in a female baby aged 7 weeks. At this operation the left upper lobe was noticed to be emphysematous, but its removal was not thought to be necessary. Four hours after operation she became extremely dyspnoeic and appeared likely to die. A second thoracotomy was undertaken urgently and the left upper lobe, now grossly emphysematous, was removed. Following this she was much better, and she subsequently made an uneventful recovery. In both of these cases emphysema of the left upper lobe was known to coexist with the congenital heart lesion, and they illustrate the fact that correction of the cardiovascular defect is insufficient to relieve breathlessness in the presence of congenital emphysema.

Clinical Features

All the babies in this series were born at full term after a normal pregnancy, and in only one case was resuscitation difficult. Tachypnoea amounting to dyspnoea is the cardinal symptom, and it is most noticeable when the baby is being fed. A dry cough is often present and stridor is sometimes a prominent feature. Cyanosis is rare and is probably an indication for urgent treatment. Mediastinal displacement is usually present, and over the involved area of lung the chest wall is prominent and relatively immobile. The breath sounds are diminished and typically the percussion note is hyperresonant, but there are no adventitious sounds. Over the rest of the lungs there may be no abnormal physical findings or there may be evidence of collapse or infection.

X-ray Findings

The diagnosis of congenital emphysema may be suspected on clinical grounds, but it can be established only by radiography. The radiograph will show an area of increased translucency with bronchovascular markings still present. There will be downward displacement of the diaphragm on the same side, and there may be a herniation of the over-distended lung across the midline (Special Plate, Fig. 2). The films should be supplemented by screening, and this will show some or all of the following features: (1) relative immobility of some part of the lung fields; (2) lack of variation in the degree of translucency of the emphysematous part; (3) mediastinal displacement with phasic respiratory activity—namely, shift to the affected side with inspiration and the reverse with expiration.

Diagnosis

The possibility of congenital emphysema of the lung should be considered when a previously well infant begins to have attacks of difficulty in breathing. It is primarily necessary to distinguish it from bronchopneumonia or cardiac failure, either of which may coexist with congenital emphysema. In neither of those conditions, although there may be cyanosis together with a raised pulse and respiratory rate, is it likely that the mediastinum will be displaced. The dyspnoea in cardiac failure may be episodic, coming on only with the exertion of feeding; there may be a murmur which directs attention to the heart; and the liver may be enlarged and tender. This last sign, while frequently indicative of cardiac failure, may also occur when the right hemidiaphragm is displaced downwards, and is therefore suggestive but not diagnostic. The presence of altered breath sounds associated with hyperresonance is found in emphysema, while in pneumonia the affected side tends to be dull to percussion.

Bronchospasm severe enough to produce respiratory distress causes bilateral physical signs in the chest, and in the same way it is unusual for fibrocystic disease of the pancreas to lead to difficulty in diagnosis. The aspiration of a foreign body in the first few months of life is a very rare event, and there will usually be a history of the object being taken into the mouth and the sudden onset of dyspnoea.

Four other conditions may, on occasion, cause diagnostic difficulty, and they may be differentiated with the aid of a straight radiograph of the chest. Atelectasis or collapse of lung is most apt to be confused with congenital emphysema, since the diagnosis depends on the comparison of one side with the other. In both conditions one side appears more translucent than the other; in congenital emphysema this is due to pathological overdistension of the lung, whereas in collapse the clarity of one side is purely relative, although in part it may be increased by some compensatory emphysema. With collapse the diaphragm is raised on one side; in congenital emphysema there is no suggestion of elevation of the diaphragm on either side. Reverting to physical signs, it is true that in collapse one side of the chest is duller to percussion than the other, and in emphysema one side is hyperresonant. However, these signs are only of comparative value, and differentiation of the two conditions requires fluoroscopy. With this in emphysema the oesophagus moves towards the clearer side with each inspiration, while in collapse it moves away from the clearer side. In agenesis of the lung there is mediastinal displacement with elevation of the diaphragm on the affected side, but no lung markings can be discerned in that hemithorax unless there is herniation of the opposite lung. Both spontaneous pneumothorax and a large congenital diaphragmatic hernia with abdominal viscera in the chest may be confused with congenital emphysema on clinical examination, but both have characteristic x-ray appearances.

Treatment

The aim of treatment is to remove that portion of the lung which is not functioning and which at the same time is interfering with the function of the remainder of the lungs. Only one therapeutic measure will satisfy this aim, and that is lobectomy. All six cases in this series were treated by removing the affected lobe. In two cases a patent ductus arteriosus was ligated, one at an operation 24 hours before lobectomy (Case 3) and the other at the same time as lobectomy (Case 1).

For the most part, induction of anaesthesia presents no problems, but at this stage the patient must be watched carefully, and, should urgent signs of tension appear, thoracotomy should be performed without delay to allow the obstructed lung to escape from the chest.

At thoracotomy the affected lobe is voluminous and pale. Furthermore, there is no tendency for this lobe to collapse.

when the chest is open, and this is the most striking operative finding. When there is collapse of the other lobes of the ipsilateral lung the recognition of the extent of the disease presents no problem. When more than one lobe is involved, recognition of its extent may be more difficult.

Another problem is the management when the dual condition of emphysema and a cardiac anomaly is present (Special Plate, Fig. 3). Wherever possible both conditions should be treated at the one operation, and if this is impossible it is advisable to treat the congenital emphysema first and then, at a later date, deal with the cardiac lesion.

Discussion

In 1938 Royes reported the case of a man of 28 who was killed in a motor-cycle accident and at necropsy was found to have a localized emphysema of the right middle lobe. Since that time a number of cases of regional emphysema in adults have been reported, but they have usually been discovered incidentally on radiological examination and have been symptomless. Very different is the picture of acute dyspnoea seen in this condition in infancy. Nelson in 1932 was the first to draw attention to the serious nature of emphysema occurring in early infancy when he reported a fatal case in a baby aged 5½ months. This syndrome has been given a variety of names, the best of which is probably "congenital lobar emphysema." That the basic pathology is an overdistension of the alveoli confined to certain segments or lobes is not disputed. Whether the condition is actually congenital or whether it is acquired very early in life is less easy to determine.

It has been suggested that the emphysema may result from over-vigorous attempts at resuscitation, and particularly from the use of oxygen under positive pressure. If this were so, it is difficult to see why it should be localized to one particular lobe, and why it should persist and yet sometimes fail to cause symptoms until the age of 3 months or more. In only one of our cases was there any difficulty in establishing respiration at birth. The possible role of infection is more difficult to assess. That it is not by itself a major factor is clear, since examination of the bronchi and lungs fails to show any evidence of widespread inflammation. On the other hand, it may be an ancillary factor in producing oedema of the bronchial mucosa in the presence of pre-existing abnormalities.

The basic pathology is some form of valvular obstruction which allows the entry of air on inspiration but does not permit it to escape when the baby breathes out. This might be provided by two developmental abnormalities: either by unusually flaccid bronchi, with abnormal or malformed cartilaginous rings, which collapse on expiration, or by flaps of bronchial mucosa which block the return of inspired air. Both these anomalies have been found. Gross and

Lewis (1945) described the findings in a 4-year-old girl who developed emphysema of the right upper lobe with herniation across the mediastinum into the left side of the chest. She was treated by lobectomy, and examination of the specimen showed the bronchial cartilages to be absent. One of the five cases reported by Ferguson and Neuhauser in 1944 was diagnosed by bronchoscopy when it was noted that the bronchoscope entered with exceptional ease, but when it was withdrawn the bronchus collapsed and its lumen became occluded with each expiration. In one case in the present series histological examination revealed gross deficiency of cartilage in all bronchi in the affected lobe (see accompanying photomicrograph).

Photomicrograph of right upper lobe (Case 4), showing large intralobar bronchus with minute islet of cartilage in its wall (centre of picture). Smooth muscle also poorly represented; hypoplasia of bronchus. (x55.)

Robertson and James (1951) described two cases in which the obstruction appeared to be due to redundant folds of bronchial mucosa, and they point out that such folds may not be found when the operative specimen is examined, since it is frequently near the midline and may therefore be included within the divided stump of the bronchus. It is likely that both these forms of valvular obstruction are the result of congenital malformations, and they are often found in association with congenital abnormalities affecting other systems. This close association with other congenital abnormalities, particularly those of the cardiovascular system, is further evidence that the emphysema itself is of developmental origin. Four of our six cases had congenital heart lesions, and it has been suggested (for example, by Sloan in 1953) that intermittent occlusion of the bronchus is brought about by "extrinsic pressure." It is conceivable that a dilated pulmonary artery could act thus, but such a causal relationship could not be substantiated in all our cases. Nevertheless, it is of interest that the congenital heart lesions seen were of the type associated with dilatation of the pulmonary artery—dilatation which either was due to increased pulmonary blood flow or was of the post-stenotic variety. However, since many cases of congenital heart disease have grossly dilated pulmonary arteries without emphysema, it seems probable that there must be an associated abnormality of the bronchus for it to occur.

The condition appears to be most common in the left upper lobe. Apart from the possibility that pressure exerted by an enlarged left pulmonary artery plays some part in the development of the disease, there is no obvious reason for such a distribution. It seems probable, therefore, that in a larger series the distribution would be more equal.

In some instances congenital emphysema may be a benign lesion, and in one of the cases reported by Holzel *et al.* (1956) remission of symptoms occurred. However, this would appear to be unusual, and when the condition is severe enough to produce symptoms, then treatment is essential. Thoracentesis has been advocated when severe intrathoracic tension develops, but it is our belief that urgent thoracotomy is always the treatment of choice, because needling in this condition carries with it a definite risk of

producing a tension pneumothorax. Once recognized, considerable tension exists within the affected area, and therefore lobectomy should never be unduly delayed. In some cases it may be a matter of extreme urgency (Special Plate, Fig. 4), and our experience shows that thoracotomy without lobectomy can be a dangerous procedure when congenital emphysema is present, as there may be a post-operative increase in tension.

Summary

Six cases of congenital lobar emphysema are reported, and their association with congenital heart disease is noted.

The difficulties of diagnosis are considered, and the importance of x-ray examination of the chest in any baby who has respiratory symptoms is stressed.

Treatment of the condition is by the removal of the affected lobe and the consequent relief of intrathoracic tension.

It is a pleasure to record our thanks to Dr. R. E. Bonham-Carter and to Mr. D. J. Waterston for their stimulating help and advice. We also wish to thank the other members of the consultant staff of the Hospital for Sick Children, under whose care some of the cases were admitted to hospital, and Dr. Bodian, who provided the photomicrograph. Finally, we wish to record our indebtedness to Mr. Derek Martin, for the illustrations.

A POSSIBLE METHOD OF FOETAL SEX DETERMINATION

BY

A. M. STEWART, M.B., Ch.B., F.R.C.S.Ed.
D.M.R.D.

Assistant Radiologist, Aberdeen Royal Infirmary

AND

JOHN MCKENZIE, M.B., Ch.B.

Lecturer in Embryology, University of Aberdeen

[WITH SPECIAL PLATE]

The prenatal determination of the sex of the infant has always aroused considerable interest. A number of scientific methods have been suggested without much success, and it is only in recent years that a relatively reliable technique has been evolved (Rosa and Fanard, 1951; Serr *et al.*, 1955; James, 1956; Dewhurst, 1956).

Basis of Method

An unusual form of foetal vertebral body ossification was observed in the course of routine obstetrical radiography during the past year. The variation consisted in a ventral and a dorsal centre of ossification with an intervening oval or linear translucency. It was commonly observed in the lumbar region, involving one vertebra, or more often a number of vertebrae. The two centres were of unequal size, the ventral segment being larger than the dorsal in the antero-posterior diameter, the vertical translucency or cleft being situated nearer the dorsal aspect of the centrum. The translucency cleft may be complete or partially closed by a buttress of ossified tissue bridging the two centres above and/or below. When complete bridging was present the radiological appearances suggested a cavity within the vertebral body. The outlines of the cleft were relatively clearly defined, being

wider in the centre than at the upper and lower margins. Measurement of the ossified centrum of the affected vertebrae showed that, compared with the normal vertebra, there was a definite increase in the antero-posterior diameter. This increase in depth was of some importance when the cleft was almost completely obliterated. It may be the most obvious feature on the radiograph. This cleft must be carefully distinguished from the synchondrosis between the ossified neural arch and the centrum, which lies further dorsally. It was also observed that the translucency corresponding to this synchondrosis was narrower in the cleft vertebrae than in the normal ones, suggesting an advance of ossification posteriorly at the expense of the synchondrosis, and that in fact the bodies of the involved vertebrae are of normal size (Special Plate, Fig. 1).

As this defect lies in the coronal plane it is visualized on the radiograph only when the incident beam passes through the plane of the cleft—that is, when the foetus is in the true lateral position, a posture which is only infrequently seen in the standard postero-anterior and lateral radiographs of the pregnant abdomen. In our experience it is more generally visualized in the prone postero-anterior projection. Radiographs of the highest quality are essential, and by employing momentary compression to the maternal abdomen foetal movement is restricted and the exposure factors are reduced to a minimum.

The term "coronal cleft vertebra" has been employed to distinguish the defect from the more widely recognized one in the sagittal plane. The appearance was observed on ten occasions during 1956, representing 1.3% of all pregnancies referred to the radiology department. In nine instances the defect was present in the lumbar segment only, and in the tenth case the lower two dorsal vertebrae and the first lumbar vertebra were involved (Special Plate, Fig. 2). In two of the foetuses one vertebral body only was affected. Radiography of some of the infants after birth showed that the cleft gradually disappeared but the antero-posterior diameter of the centrum remained larger, at least in infancy. (The results of the long-term follow-up will be the subject of a separate communication at a later date.) The most significant feature of the investigation was that in every instance the child was a male.

Stimulated by the finding of coronal cleft vertebrae on antenatal radiographs, we x-rayed 73 stillborn foetuses of over 28 weeks' gestation and 65 foetuses of less than 28 weeks' maturity. In the first group there was additionally a male infant of about 30–34 weeks' maturity where a solitary lumbar body was involved. In the latter group 21 specimens showed evidence of a ventral and dorsal ossification centre, usually in the lumbar area, but occasionally extending to involve the lower dorsal region. The sex incidence in this group was 13 males to 8 females.

Discussion

The development of the vertebral column proceeds along well-defined lines. Two centres of chondrification of the vertebral body appear at about the seventh week of intrauterine life, and soon fuse with the centres for the arch and costal process to form the cartilaginous model. Ossification of the vertebral arch begins shortly afterwards, and by the tenth week ossification of the centrum has started. Usually there is a solitary centre of ossification in the body, but a paired centre may appear (Arey, 1946). The occurrence of two lateral centres is well recognized (Gray, 1949), but the appearance of a dorsal and a ventral centre is considered unusual. Cohen *et al.* (1956) found that such a variant can occur in 5% of instances. Fusion of the centres with disappearance of the hyaline cartilage cleft takes place at approximately the 16th to 18th week. Rowley (1955) in an analysis of 28 cases of coronal cleft vertebrae found no involvement in either cervical or sacral segments of the spine.

There is some difference of opinion on why this variation in normal development should occur. Two main theories are advanced. In the first the possible persistence

of the notochord, which normally occupies the position of the cartilage cleft, is blamed. However, in no instance have notochordal cells been clearly demonstrated histologically in the cartilage. This is hardly surprising, because during chondrification of the vertebral body the great majority of notochordal cells are displaced into the disk region (Ehrenhaft, 1943). The second, and more plausible, theory is concerned with the invasion of the cartilage body by vessels anteriorly and posteriorly with subsequent ossification in the vicinity of their terminal ramifications. Ventral and dorsal ossification centres rapidly appear with an intervening unossified septum. The persistence of this unusual but quite normal method of ossification beyond the usual time of fusion constitutes the typical coronal cleft vertebra.

The high preponderance of male infants with persistent coronal clefts is as yet inexplicable. Rowley (1955), who first described the radiological appearances in the English literature, also remarked on the high male incidence. Of his 34 cases, only 3 were females, and one of these showed radiological evidence of osteochondrodystrophy. Including our own series, there are now on record examples of coronal cleft vertebrae in 45 viable infants. Thus if the defect is seen on a radiograph of an infant of 28 weeks' gestation or more, there is a 93% probability that the unborn child will be a boy. The percentage will rise proportionately with the advance in maturity, and by 35 weeks the probability reaches 98%.

The proportion of cases exhibiting this anomaly is small. In Rowley's series the incidence on antenatal radiographs was "slightly less than 1%," and in our series 1.3%. This small number of cases can be accounted for in part by the position of the foetus on the radiograph. As has already been pointed out, it is only when the foetus occupies the true lateral position that the cleft is visible. The number of actual cases is probably greater than the above figures would suggest.

The proportion (33%) of double vertebral body centres in foetuses of under 28 weeks' gestation points to a higher incidence of this variant than has already been reported (Cohen *et al.*, 1956). At this stage the sex ratio shows no obvious male bias. Appearance of centres and fusion of epiphyses normally occur at an earlier date in the female, and this tendency holds good in our series of non-viable foetuses where the greater incidence of double centre in the male was at four months and in the female at three months. The increase in antero-posterior diameter of the ossifying centrum may be of importance. This feature, associated with a narrowing of the neurocentral junction, was observed in the prenatal radiographs in three additional instances, where in each case the sex was male. These features were also present in nearly every instance of double centres in our series of non-viable foetuses.

Recent work by Dewhurst (1956) has shown a remarkably high percentage of accuracy in antenatal sex determination by the demonstration of the typical arrangement of chromatin in the cells of a centrifuged specimen of liquor amnii. Obtaining liquor amnii by paracentesis is accompanied by a certain risk of labour induction and damage to the placenta or foetus. Dewhurst considers that the method is unsuitable for general use.

Before the male preponderance in coronal cleft vertebrae in infants after 28 weeks' gestation can be of statistical importance, a study of a larger series than is at present available is required. With this object in view we have considered it important to bring the phenomenon to the notice of obstetricians and paediatricians. A very careful scrutiny of the foetal vertebral column should be made in all radiographs of the pregnant abdomen. It is emphasized that the coronal cleft vertebra is a normal process of ossification and does not indicate a pathological condition.

Summary

The radiological appearance of coronal cleft vertebrae in the foetus *in utero* is described. This was observed

in ten instances representing 1.3% of all pregnancies referred to the radiological department during 1956. The cleft is usually confined to the lumbar region. One further specimen was found in a series of 73 viable stillbirths. In every instance the child was a male. The normal proportion of ventral and dorsal ossification centres in fetuses before the 28th week of gestation is 33%, with no obvious male bias. It is suggested that the presence of the condition, which has no pathological importance, may be used as an aid in determining the sex of the foetus.

We are indebted to Professor D. Baird, Professor R. D. Lockhart, Dr. D. P. Levack, and the staff of Aberdeen Maternity Hospital for permission to publish this article. Our thanks are due to Miss Isobel M. Hunter for the stillbirth radiographs and to Mr. R. Drummond for the illustrations.

RHEUMATOID ARTHRITIS OF THE CRICO-ARYTENOID JOINTS*

BY

W. S. C. COPEMAN, O.B.E., M.D., F.R.C.P.

Physician-in-charge, Department of Rheumatism, West London Hospital; Senior Physician, Arthur Stanley Institute of the Middlesex Hospital

Rheumatoid arthritis has been described affecting almost every diarthrodial joint in the human body. This process must almost certainly sometimes include the crico-arytenoid joints, which although small are extremely mobile and are used not only in phonation but also in normal full respiration. It is strange, therefore, that no article in the English language appears to have been written on this subject, although isolated reports, mostly in European journals, exist, and casual reference to such a condition can be found in some otolaryngological textbooks.

The Crico-arytenoid Joints

The cricoid cartilage is the uppermost ring of the trachea. This, unlike its fellows, has a flat expansion posteriorly which is called the lamina, which makes it similar in shape to a signet ring. On each of the two upper and outer curved edges of the lamina is situated a pyramid-shaped cartilage—the arytenoid—which looks rather like a miniature adrenal gland standing on its kidney. The joints by which these structures are attached to the laminal facets are surrounded by a fibrous capsule with ligamentous reinforcement posteriorly and are lined with a normal synovial membrane.

The vocal cords are attached from the outer side of each of the arytenoid cartilages to a common insertion on the internal surface of the thyroid cartilage where this overlaps the front of the cricoid cartilage. Voluntary variation in the position of the vocal cords is produced by the various

*Abstract of a paper read before the Faculty of Medicine, University of Lisbon, November, 1956.

movements of the crico-arytenoid cartilages. Their repertory includes rotation and gliding movements both forwards and backwards as well as medially towards their fellow. Involuntary widening of the aperture between the cords occurs during full inspiration, and the reverse in expiration.

The muscles which control the movements of the crico-arytenoid joints, and so of the vocal cords, are all innervated by the recurrent laryngeal branch of the vagus nerve. Unilateral paralysis of this, which is not very uncommon from both local and general infections or traumata, leads to hoarseness but not to loss of voice, as the normal cord moves across towards the one affected to compensate. If the nerve on both sides is paralysed, however, the vocal folds remain fixed in the half-way position, causing loss of voice and stridor on deep inspiration. The crico-arytenoid joints, since they are not structurally affected, can generally, in these circumstances, be moved passively with a laryngeal spatula without pain.

Symptomatology

It has been observed that in certain cases of rheumatoid arthritis acute exacerbations of the general joint disease are associated with a period of hoarseness and a feeling of tension in the throat which is often increased by swallowing, speaking, or coughing. Local tenderness on pressure over the larynx between the thyroid and cricoid cartilages, laterally or centrally, is also sometimes present. These attacks pass off when the general activity of the arthritis lessens, and are generally ascribed to intercurrent colds or laryngitis. When in the course of time the disease becomes chronic a permanent huskiness of the voice may remain.

It seems reasonable in retrospect to suspect that there may exist some causal relationship between the variations in the general joint condition and these laryngeal abnormalities.

There appears to be no reason why rheumatoid disease may not affect the crico-arytenoid joints in similar fashion to other larger diarthrodial joints of the body. If this is so we should expect to observe cases which exhibit phases of recurrent acute or subacute inflammatory reaction either confined to these joints or, more probably, as part of a generalized arthritic process. In the later chronic stages of the disease, and usually as the sequel to recurring episodes of this nature, more permanent impairment of movement or even ankylosis of the crico-arytenoid joints might occur.

The following cases of rheumatoid arthritis have been selected as probable examples of these three phases of crico-arytenoid joint involvement.

Case 1

Acute recurrent attacks of hoarseness and slight dysphagia which were associated with recurrent exacerbations of generalized polyarthritis.

The patient was a colonial bishop, aged 60, who spent much time travelling through difficult tropical country under conditions involving considerable privation and great fatigue. Five years previously these periods of exhaustion had become associated with painful swelling of the fingers and wrists, and later considerable pain and stiffness in the cervical spine. All this would at first die down after a few days' rest, but the free intervals between these episodes became progressively shorter. For the last three years permanent changes in the hands, typical of rheumatoid arthritis, had been unmistakable. Associated with these periods of active arthritis for the past two years had been temporary hoarseness of voice, without sore throat, although sometimes with dysphagia, which would get worse towards evening. He would then sometimes lose his speaking voice. He received no special treatment for the arthritis except aspirin in rather large dosage. Penicillin and other antibiotics were administered on several occasions for the "laryngitis," but proved ineffective. On one occasion he developed a mild upper respiratory infection which much exacerbated this condition, and stridor temporarily developed which almost necessitated tracheotomy. These attacks of hoarseness

eventually became very frequent and speaking loudly was painful. It thus became impossible for him to preach, and he returned to England.

When seen he showed unmistakable signs of chronic rheumatoid arthritis of moderate intensity. There was tender fusiform swelling of most of the fingers, early ulnar deviation of the hands and wrists, whilst flexion of the neck produced considerable pain. There was loss of weight, but there were no signs of disease of other systems, and the chest x-ray picture was normal. His haemoglobin was 70%, E.S.R. 50 mm., and all agglutination reactions and the Wassermann reaction were normal. Hoarseness of voice was still present, but not marked in ordinary conversation.

On direct laryngoscopy the left vocal cord was reported as not moving well. A periartritic reaction was seen to be confined to the arytenoid and post-cricoid region with secondary muscle implication. Pain was elicited on the attempt to manipulate the left arytenoid cartilage, but not on the right. The patient's general condition and polyarthritis during the next six weeks responded well to rest, splintage, analgesics, and injections of gold salts; local short-wave diathermy had been applied to the crico-thyroid region. The appearance of the larynx was then reported as normal, no pain being elicited on forced movement of the crico-arytenoid joints on either side.

He wrote nearly two years later stating that no further attacks of hoarseness had occurred although the arthritis of his peripheral joints remained periodically mildly active.

Case 2

Mild attacks of hoarseness in the course of exacerbations of a rheumatoid arthritis of moderate intensity.

The patient, a woman aged 54, had suffered for seven years from rheumatoid arthritis affecting the hands, wrists, feet, knees, and cervical spine. During the last two years she had complained of attacks of hoarseness with slight cough every few months and lasting one to three weeks. On exertion she suffered slight dyspnoea also and sometimes some stridor. These were usually diagnosed as "laryngitis" until she herself noted their association with the periodical increased pain in the affected peripheral joints. An x-ray examination of her chest showed nothing abnormal, and no glandular enlargement or other signs or symptoms of disease of other systems were found. She had not received metallic therapy. Her haemoglobin was 78%, E.S.R. 25 mm., and white-cell count normal.

Laryngological examination during one of the periodical attacks of hoarseness was reported as showing oedema of the pre-arytenoid area. The left vocal cord was fixed in the position of abduction. The crico-arytenoid joint on that side, but less so on the other, was painful on gentle manipulation and probing with a spatula.

Case 3

Probable ankylosis of both crico-arytenoid joints in a patient with long-standing chronic rheumatoid arthritis.

A woman aged 70 had suffered with rheumatoid arthritis of varying intensity over a period of twenty-five years. The arthritic condition had been much exacerbated after a road accident ten years previously in which, however, she had not herself been physically injured. Soon after this, hoarseness of voice developed, at first intermittently and for the last four years permanently. She spoke in a husky whisper, and slept propped up, as inspiratory stridor developed when lying flat. There was occasional pain on swallowing. At first hysteria was suspected, but later, when pain began to be referred behind the ears, she was examined laryngoscopically, the report stating that marked redness but very little swelling was noted in the crico-arytenoid area. The vocal chink was narrowed, and only slightly increased widening, due to bowing of the cords, occurred with full inspiration. The arytenoid cartilages were both fixed, and attempts to move them in any direction were unsuccessful and very painful. The aryepiglottic folds appeared

lengthened, and there was tenderness on lateral pressure over the cricoid space.

Ultimately the patient became bedridden. The condition of the larynx remained unchanged subsequently in spite of considerable temporary improvement in many of the peripheral joints which took place as the result of the administration of cortisone for a few weeks.

Differential Diagnosis

The differential diagnosis in these and similar cases would appear to lie only between rheumatoid arthritis involving the crico-arytenoid joints and paralysis of the recurrent laryngeal nerves in rheumatoid subjects due to some unknown local or general cause of which no evidence can be found. The distinction, which can finally be made only by a laryngologist of experience, remains difficult and perhaps uncertain. Recurrent paralysis of other peripheral nerves in association with exacerbations of rheumatoid arthritis has not, however, been recorded. It seems therefore probable that the local laryngeal signs and symptoms in such cases are evidence of implication of the crico-arytenoid joints in the generalized rheumatoid inflammatory reaction which is affecting other joints in the body.

Summary

It is suggested that in the course of rheumatoid arthritis involvement of the crico-arytenoid joints may sometimes occur as an integral part of the polyarthritic process.

Three cases are quoted which are believed to demonstrate varying stages in this syndrome—namely, acute and subacute recurrent laryngeal episodes, and complete ankylosis of both crico-arytenoid joints in the final stage of rheumatoid disease. Operative procedures did not prove necessary in these cases.

ADDENDUM.—Since the above was written Pearson (1957) has described a case of rheumatoid arthritis of 30 years' duration in a patient who developed increasing huskiness and dyspnoea on exertion. This became worse, and laryngeal obstruction was diagnosed, for which tracheotomy was performed. The patient died later, and necropsy showed changes in the crico-arytenoid joints characteristic of rheumatoid arthritis.

Discussing changing attitudes to the handicapped child, Dr. J. D. KERSHAW (*Public Health*, May, 1957, p. 57) remarks that few individual special schools are big enough to offer training for more than three or four crafts, and he advocates centralization of vocational training in large residential technical schools, where the range of training could be wider. Another point stressed by Dr. Kershaw is that there is still a failure of co-operation between the hospital and school health services over handicapped children. It is the exception to find the hospital physician or surgeon and the school medical officer planning together for the child's future. Often the hospital makes no contact with the school health service until the child's treatment has been completed. By contrast, Dr. Kershaw writes, there are some areas where the hospitals have voluntarily adopted what almost amounts to notification to the school health service of all potentially handicapping defects as soon as they are detected.

LARYNGEAL STRIDOR IN RHEUMATOID ARTHRITIS DUE TO CRICO-ARYTENOID JOINT INVOLVEMENT

BY

O. A. BAKER, M.B., B.S.

AND

E. G. L. BYWATERS, F.R.C.P.

From the Maidenhead Hospital, Maidenhead, Berks, and
the Special Unit for Juvenile Rheumatism, Canadian
Red Cross Memorial Hospital, Taplow, Bucks

The following brief notes record an unusual but
important manifestation of rheumatoid arthritis, with
severe attacks of suffocation.

Case Report

A housewife aged 42, with classical rheumatoid arthritis for four years, showing symmetrical polyarthritis (including finger involvement), bone erosions, subcutaneous and cutaneous nodules, and a positive Rose-Waaler test (1:128), was being treated with salicylates.

On September 1, 1956, she was brought to hospital as an emergency by her general practitioner; she was in marked distress and had great difficulty in getting her breath. "Omnopon" 1/6 gr. (11 mg.) had been given at home. After an hour her breathing was comfortable. For two months before this she had suffered discomfort in the region of her larynx and pain on swallowing, and had lost 10 kg. in weight. She had had no difficulty in breathing before this attack.

By September 7 she had no pain on swallowing and was breathing comfortably. Though still febrile (temperature 100-101° F.—37.8-38.3° C.), she felt much better. Examination with a laryngeal mirror showed localized redness on the posterior aspect of the left arytenoid and oedema of the left aryepiglottic fold. The larynx appeared otherwise normal, and the vocal cords were white and moved equally.

On September 15 (one week later) exertional dyspnoea was present; the oedema was unchanged, but there was some loss of abduction of the left cord. The oedema and redness cleared up during the next 10 days, but the left cord became fixed in a position of adduction and the right cord showed progressive loss of abduction; slight exertion produced inspiratory stridor.

X-ray examination revealed that swallowing was normal and showed no evidence of neoplasm in the chest or neck. Bronchoscopy and oesophagoscopy under a general anaesthetic on September 28 showed no abnormality and the patient made an uneventful recovery from the anaesthetic. The neurologist, Dr. C. H. Edwards, found no evidence of any central or peripheral nerve lesion affecting the larynx. About this time she had three minor attacks and one severe attack of dyspnoea with stridor. A tracheotomy set was kept ready in the ward.

On transfer to the Special Unit for Juvenile Rheumatism on October 19 she appeared thin, anxious, and frightened: some tenderness was noted externally at the mid-point of the right sternomastoid, and her voice was hoarse and her cough "blowing." Exertion of mild degree brought on a severe and frightening attack of dyspnoea and laryngeal stridor, relieved by oxygen (given by B.L.B. mask) in about seven minutes. She was started on delta cortisone at a dosage of 50 mg. a day with an alkaline mixture over the next two weeks, gradually reduced to 15 mg. a day by the seventh week. A dramatic improvement occurred

in her general well-being and in the local condition. Her functional capacity improved to normal and joint movement became painless.

On November 19 indirect laryngoscopy showed marked improvement. Her right arytenoid was mobile, with abduction of her vocal cord up to 60-70% of normal. Her left arytenoid was almost fixed; there was some adduction from the cadaveric position, but no abduction. Her cords approximated well and her voice was strong.

On February 6, 1957, indirect laryngoscopy showed the left arytenoid to be quite immobile and fixed in a slightly anterior plane to the right one. The right arytenoid moved freely but lacked full abduction, the space between her cords on full inspiration being 5-6 mm. She was then able to move freely on her household duties and managed the stairs without dyspnoea on 15 mg. of prednisone a day.

In retrospect, the laryngeal picture resembled that of bilateral abductor paralysis. At no stage was any redness or oedema seen around the right arytenoid and at no stage was oedema observed to cause any direct obstruction to respiration—her difficulty in breathing was essentially due to loss of abduction.

Discussion

The differential diagnosis is fully discussed by Montgomery *et al.* (1955). Although the patient had had a partial thyroidectomy nine years previously, there was evidence neither of neoplastic nor of ischaemic nerve damage, despite evidence elsewhere in this patient of vascular lesions associated with rheumatoid arthritis (nail-fold thrombosis and nail-edge lesions). The presence of a few genuine L.E. cells from time to time, of cold agglutinins, of a leucopenia over 10 weeks of observation (2,150 per c.mm. with 26% polymorphs at the lowest), and of one positive Coombs test out of six, led us to think of systemic lupus erythematosus, in which peripheral nerve palsy sometimes occurs on a vascular basis (Heptinstall and Sowry, 1952), but this appeared to be primarily a local lesion due to crico-arytenoid joint inflammation.

The left crico-arytenoid joint is now ankylosed, but the acute lesion on the right side responded to delta cortisone like the rest of her joints. It is interesting to note that two of the cases recorded by Montgomery *et al.* got worse and developed stridor on cortisone. The lesser salt-retaining properties of the delta analogues compared with cortisone make them potentially more valuable in this situation, and by this means tracheotomy, which would have been necessary otherwise, was avoided.

We are grateful to Dr. Philip Willcox for referring this patient and for the use of his notes.

The second annual meeting of the British Section of the Louis Rapkine Association was held at the Ciba Foundation on Monday, May 6, under the chairmanship of Professor A. V. HILL, F.R.S. The eminent French archaeologist, the Abbé BREUIL, gave a talk on the cave paintings of Rouffignac in the Dordogne, illustrated by slides of the magnificent paintings and rock carvings of mammoths, horses, ibexes, and rhinoceroses found in the caves. The association was founded last year in memory of the French biochemist, Louis Rapkine. Membership is open to British and French doctors and research workers in the biological sciences who have been awarded scholarships or bursaries to enable them to visit the other country and study recent developments in their special subject. Information about the association can be obtained from Dr. G. E. WOLSTEN-HOLME, Ciba Foundation, 41, Portland Place, London, W.1, or Miss A. M. VIDAL-HALL, Scientific Office, French Embassy, 22, Wilton Crescent, London, S.W.1.

CHOLEDOCHUS CYST

BY

S. H. TAYLOR, M.B., Ch.B., B.Sc.

Formerly House-Physician, Department of Medicine,
Queen Elizabeth Hospital, Birmingham

AND

G. SLANEY, M.B., F.R.C.S.

Surgical Registrar, Department of Surgery, Queen
Elizabeth Hospital, Birmingham

Choledochus cyst is a rare cause of jaundice in which a part or the whole of the extrahepatic biliary tract shows gross dilatation, usually of a saccular type. The anatomy of this congenital anomaly was first described by Vater in 1723, and fewer than 200 cases have since been reported (Gross, 1933; Walton, 1939; Shallow, Eger, and Wagner, 1946). Sir James Walton was one of the few authors to describe more than two cases of his own, and he states that these were the only two seen among 23,048 necropsies at the London Hospital in the 32 years prior to 1938. Likewise, Judd and Greene (1928) found only one case of choledochal cyst in 17,381 operations on the biliary tract.

Most authors believe the lesion arises from a congenital weakness of a localized portion of the wall of the common bile or hepatic ducts, this defect probably occurring at the site of a diverticulum or an incompletely developed accessory hepatic duct. Moreover, once the cyst attains a certain size a vicious circle is created, for drainage into the last portion of the common bile duct is further impeded by the pressure of the eccentrically lying cyst.

Pressure of the cyst on surrounding structures, including the extrahepatic biliary system, accounts for much of the symptomatology of the condition. Although the cyst may vary greatly in size, the majority are 10-15 cm. in diameter and usually contain bile, although sometimes the fluid is clear. Gall-stones may be present, and in a case described by Irwin and Morison (1945) a squamous-celled carcinoma was found in the wall of the sac. The dilatation of the common bile duct often extends into the common hepatic duct, but the gall-bladder and cystic duct are usually of normal size. The terminal portion of the common bile duct is often narrowed, and sometimes cannot be found even when obstruction is incomplete (Walton, 1939).

The Clinical Syndrome

The lesion occurs predominantly in females, and symptoms frequently arise between the ages of 5 and 25 years. Shallow, Eger, and Wagner (1943) found that 75% of cases described in the literature were diagnosed before 25 years of age, and Lichtman (1949) reports that 80% of cases have occurred in females. Hertzler and Maguire (1951) state that in 80% of the reported cases congenital cysts of the common duct occur in patients under 25 years of age and 60% of cases occur in children under the age of 10 years. The most usual presenting symptoms are recurrent jaundice, upper abdominal pain which often resembles biliary colic, and a tumour in the right hypochondrium. Pregnancy has often appeared to be a precipitating factor in the onset of these symptoms. In many cases in which the cyst was not palpable the clinical syndrome was identical with that of gall-stone obstruction of the biliary tract, this being the diagnosis most often made. Cholecystectomy has even been performed, the true diagnosis and the presences of the cyst

being missed at laparotomy. Neoplasm is seldom considered on account of the youth of many of the patients.

Demonstration of the cyst directly by cholecystography is usually not possible, but the gall-bladder is often distorted so that it appears comma-like. Calcification may occur in the cyst wall, so that its presence may be confirmed on a plain radiograph of the abdomen, and distortion of the duodenum or colon may on occasion be shown by barium studies.

Few studies have been reported in patients with this condition owing to the infrequency with which the diagnosis was made pre-operatively. The following case is of interest because of the typical features of the clinical syndrome as it presented and the studies that were made possible by the pre-operative diagnosis.

Case Report

A married woman aged 19 had suffered five intermittent attacks of mild jaundice, each lasting a few days, during the two years before admission; these had been unassociated with abdominal pain or any symptoms referable to the alimentary tract. The attack of jaundice which precipitated her admission to a maternity hospital began three months previously, during the sixth month of her first pregnancy. Following a premature delivery at the seventh month, the jaundice largely resolved, but increased again ten days later after the patient had returned home. She was readmitted to hospital deeply icteric and suffering from a mild diarrhoea with three or four pale semi-formed stools daily. A mass in the right hypochondrium, at this time thought to be the liver, was palpable. Cholecystography revealed no abnormality of the gall-bladder, and liver-function tests showed a predominantly obstructive pattern.

She was transferred to the medical unit, Queen Elizabeth Hospital, one week later, on March 4, 1954. She was slightly icteric and rather pale, but there were no abnormal physical signs other than a firm rounded tumour in the right hypochondrium, about 10 cm. in diameter. The liver and spleen were not palpable and a diagnosis of choledochus cyst seemed to be justified. Laboratory investigations showed a normal blood count, but the erythrocyte sedimentation rate was 45 mm. in one hour (Wintrobe corrected). Radiography of the chest and soft abdominal tissues showed nothing abnormal, but barium studies demonstrated a narrowing of the second part of the duodenum with dilatation of its proximal portion. There was a moderate excess of fatty-acid crystals in the stools, and fat-balance studies on a daily intake of 50 g. of fat revealed a moderately severe degree of steatorrhoea with only 72% absorption of ingested fat. Occult blood was not found in the stools. Liver-function tests were normal except for a raised serum bilirubin (5 mg./100 ml.), a raised serum alkaline phosphatase (29 units/100 ml.), and a prothrombin value of 48% by Quick's method. The urine contained urobilin, bilirubin, and bile salts in detectable quantities.

At operation a large ovoid cyst was found arising from the common bile duct. It measured 20 by 10 cm. and contained about one litre of dark green bile. The gall-bladder and cystic duct were normal. The cyst was adherent to many of the surrounding structures, prohibiting its complete resection. It was therefore drained into the jejunum by means of a Roux-en-Y anastomosis.

The patient made a satisfactory post-operative recovery until the 11th post-operative day, when she developed diarrhoea with three to six stools a day. The stools were semi-fluid, pale, rather bulky, and offensive, and fat-balance studies again showed a severe degree of steatorrhoea with only 64% absorption of ingested fat. This fatty diarrhoea continued up to the time of discharge on the 37th day after operation. During the five weeks following operation the biochemical liver-function tests remained normal, and although the serum bilirubin and prothrombin values gradually returned to normal the serum alkaline phosphatase remained persistently elevated at 30-50 units/100 ml.

Intestinal intubation showed the duodenal contents contained normal amounts of pancreatic enzymes, but there was a complete absence of bile from the small intestine as far as the jejunum. It appeared likely, therefore, that the anastomosis between the cyst and the small intestine was not sufficiently proximal to ensure adequate mixing of the pancreatic enzymes and their biliary activators during the processes of digestion. However, before further surgery could be carried out the patient requested discharge, and since that time has refused review. During her stay in hospital the patient showed no significant weight loss, haematological change, or any other clinical manifestations of a general malabsorption syndrome.

Discussion

This patient had many of the clinical features usually associated with this anomaly. She was a young woman with recurrent attacks of mild jaundice and a tumour in the right hypochondrium. The most severe attack of jaundice was associated with pregnancy and resolved following delivery. Laboratory investigations were helpful diagnostically only in so far as they confirmed the presence of an obstructive biliary lesion, and contrast radiography was of value in excluding a tumour of intestinal origin. The treatment of congenital cystic dilatation of the common bile duct is surgical, and there is no doubt that the most satisfactory procedure is choledochojejunostomy using a Roux-en-Y loop. Choledochoduodenostomy has often given satisfactory results initially, but ascending cholangitis and hepatitis have been a frequent sequel to this type of operation.

Of particular interest in the present case was the unexplained steatorrhoea observed before operation, and there is no report in the literature of this abnormality in association with choledochus cyst. A possible explanation is that distension of the upper gastro-intestinal tract with food caused intermittent but complete occlusion of the biliary tract by displacement of the cyst, so that the biliary activators of the pancreatic enzymes were absent at the most crucial phase of digestion in the upper intestine. At other times during the post-absorptive phase, biliary flow was relatively free. A further possibility is that the two conditions are entirely unrelated, the steatorrhoea being due to an idiopathic malabsorption syndrome. Although this latter possibility cannot be entirely ruled out, it is unlikely in view of the normal intestinal mucosal pattern seen on the barium-meal examination and the absence of haematological abnormality.

In spite of the relief of the obstructive element in the syndrome, the steatorrhoea continued unchanged and after operation the patient was excreting 36% of her total ingested fat. The pancreatic secretions were known to be normal in quantity and activity, and it is possible that this malabsorption was due to defective mixing of the food with the pancreatic enzymes and bile.

Summary

A case of choledochus cyst is described. Metabolic studies, with particular reference to fat absorption, were made before and after operation. The pre-operative steatorrhoea persisted after an operation which relieved the biliary obstruction.

We thank Professor W. Melville Arnott and Mr. B. N. Brooke, under whose care this patient was admitted, for their help and encouragement in the preparation of this paper. We also thank Dr. C. F. J. Cropper, of Worcester Royal Infirmary, who referred this case initially, and Mr. Garfield Thomas, who was responsible for the biochemical investigations.

Medical Memoranda

Bilateral Rupture of Rectus Femoris Tendons in Chronic Nephritis

The following case is rare enough to warrant recording, particularly in view of the young age of the patient and the associated general disease. Rupture of both quadriceps tendons has been recorded before, but these cases have been in elderly people (Lloyd, 1949).

CASE REPORT

A man of 34 was admitted to hospital on March 17, 1956, having fallen on to his knees while going down some steps. On attempting to stand his knees gave way. He stated that for some months he had been feeling rather tired and that this came on after a bout of influenza. He had, however, been able to carry on his work.

On examination he was rather pale, with a blood pressure of 160/80 mm. Hg. He was almost completely bald, and this made him appear much older than his years. Both knees were swollen and clinically resembled a haemarthrosis. He was very tender over the upper margin of both patellae, but there was no palpable defect in the extensor apparatus. He was just able to maintain full extension, but this caused him considerable pain. He had sustained an injury to the left ankle which proved to be a first-degree external rotation fracture of the fibula. X-ray examination of the knees showed that both the upper margins of the patellae were tilted forward and there was a calcified plaque in the soft tissues immediately above. It was thought that there was a tear of the rectus femoris tendon alone without involvement of the lateral expansions, and exploration of the knees was advised.

Operation.—The lesion was found to be almost identical on both sides, that on the right being slightly more extensive. A 2-in. (5-cm.) crescent of rectus femoris tendon had been torn off the top of the patella along with a sliver of bone. There was no evidence of calcification in the tendon itself. The lateral expansions were intact, the tear being much less extensive than in the usual quadriceps rupture. The patellae were displaced forward at the site of injury and the rectus femoris tendons tucked in behind. A repair was easily accomplished with silk mattress sutures.

The patient was rather lethargic after operation, but his condition did not cause any concern until the third day, when it became obvious that there had been a sudden serious deterioration in his condition. Investigation showed: blood urea, 312 mg. per 100 ml.; CO₂-combining power, 11.2 mEq/l.; Hb, 50%; serum phosphate, 12.2 mg. per 100 ml. He was passing normal quantities of urine, the specific gravity of which was 1010, with an albumin estimation of 70 mg. per 100 ml. On going into his previous history it was discovered that he had been rejected by the Army during the war because of albuminuria. He was regarded as a case of chronic nephritis, probably in the terminal phase. He shortly developed a pericarditis and died in uraemic convulsions on March 26.

Post-mortem Examination.—Both kidneys were found to be small and sclerotic. Sections of the rectus femoris tendons at the site of rupture showed no evidence of calcification or of degenerative changes.

COMMENT

It is felt that simultaneous rupture of both rectus femoris tendons in so young a patient must be an almost unique occurrence. The severe debility from his renal failure may have been a contributory cause, although there was no evidence of degenerative changes in the tendons. It is interesting to note the very limited extent of the lesion, distinguishing it from the more common form of quadriceps rupture. In the latter injury it is most unusual for the

patient to be able to hold the knee fully extended against gravity, a sign which was absent in this case. The unusual tilt of the patellae therefore proved a useful guide in making the diagnosis.

Fatal Reaction Following the Intravenous Injection of Congo Red

While the Congo-red test for secondary amyloidosis is not now extensively used, it is advised as a helpful diagnostic procedure in primary systemic amyloidosis (Rukavina *et al.*, 1956) and for the detection of amyloidosis in association with rheumatoid arthritis (Fearnley and Lackner, 1955). In view of this, it is considered of importance to record a death following the intravenous injection of Congo red.

CASE REPORT

A 47-year-old man underwent a right pneumonectomy for carcinoma in 1943. This was followed by an empyema which did not finally heal till 1950, during which time several plastic operations were required. Since 1950 he had experienced increasing shortness of breath and progressive reduction in his exercise tolerance. Three weeks before admission to hospital he developed marked swelling of his feet.

On admission he was cyanosed and dyspnoeic at rest. There was no increase of jugular venous pressure. Signs of bronchospasm were present over the left chest. Obvious oedema of the feet was noted. A heavy albuminuria was found without casts or red blood cells. The blood urea was 23 mg. per 100 ml.; plasma protein, 5.3 g. per 100 ml. (albumin 3.4 g.; globulin 1.9 g.); blood cholesterol, 148 mg. per 100 ml. Secondary amyloidosis following the empyema was suspected, and it was decided to perform a Congo red test.

Ten millilitres of a 1% solution of Congo red in normal saline was prepared at the bedside from a sealed ampoule of the powder. This solution was injected intravenously immediately afterwards. About two minutes later the patient complained of severe difficulty in breathing. Respiration ceased within seconds, and unconsciousness with deep cyanosis rapidly ensued. The radial pulse became palpable soon after the loss of consciousness. Approximately five minutes after the loss of consciousness ventilation was started through an endotracheal tube and the chest was opened for cardiac massage. After one hour spontaneous respiration and heart beat were restored, but after a further three-quarters of an hour he collapsed and died without fully regaining consciousness.

At necropsy the empyema was soundly healed. There were approximately 30 oz. (850 ml.) of blood in the left chest, clotted blood in the pericardium, and bruising of the myocardium. No evidence of amyloidosis was found.

COMMENT

Reactions to intravenous Congo red in the form of "chilly sensations" have been described by Keith *et al.* (1915), Strasser (1927) mentioned the occurrence of chills and fevers, and Rossak (1933) noted abdominal pain, flushes, palpitation, and malaise. More recently Discombe (1949) reported severe reactions following its injection—for example, nausea, sweating, headache, and vomiting—and mentioned knowledge of at least one death.

Hallgrims (1939) described a death due to the injection of Congo red. The patient developed symptoms and signs suggestive of damage to the nervous system during the course of the injection and died the same day without regaining consciousness. Selikoff and Bernstein (1946) published an account of six cases with severe systemic reactions following injection. Two of these patients died. These reactions occurred within a few minutes of completing the injection and the manifestations were neurological—that is, intense headache, unconsciousness, and hemiplegia. Congo-red tests had been performed previously in all six patients and none gave a history of allergy.

Macht and Grumbein (1938) showed experimentally that Congo red had a depressant effect on the circulatory and respiratory systems, and this was confirmed by Richardson and Dillon (1939). The latter felt, however, that the dose used in clinical work left a wide margin of safety. There would appear to be four factors, all or one of which may have contributed to the severity of the reaction in the present case.

1. *The Solution was prepared with Normal Saline.*—Richardson and Dillon (1939) found that solutions of Congo red in saline were much more toxic for experimental animals than those prepared in water. Such saline solutions were stable for 24 hours only. This increased toxicity appeared to be due to flocculation which occurred in the saline solution. Somers and Whittet (1956) were able to confirm the greater danger with saline solutions. It is customary to use sterile water in clinical practice, and we were unaware of this increased toxicity at the time.

2. *Incomplete Solution of the Powder.*—The Congo-red powder may not dissolve readily, and incomplete solution is not easily detected. Discombe (1949) claims that reactions following injection of Congo red are due to the presence of particulate material, and Somers and Whittet (1956) found that solutions injected into mice before the powder is completely dissolved were highly toxic. The experience of the latter also suggests that batches of the powder vary as regards solubility. This danger would appear to be a strong argument against the use of freshly prepared solutions, which are usually advised on account of the instability of dissolved Congo red. Incompletely dissolved material could be removed by filtration, and, indeed, Somers and Whittet (1956) have shown how solutions of Congo red may then remain stable for several months—a much longer period than previously accepted. From this it seems that previously prepared filtered and autoclaved solutions may be safer.

3. *Variation in Batches of the Drug.*—Macht *et al.* (1939) found striking differences in toxicity between various batches of the dye, and this was greatly increased by the presence of impurities. A similar experience was reported by Somers and Whittet (1956). It is impossible to say what part this factor played in the reactions in the present case, but it later transpired that the ampoule of powder used had been in the ward for a considerable period of time, and possibly several years.

4. *Anaphylaxis.*—Selikoff and Bernstein (1946) believed that anaphylaxis was the basis of the reactions which occurred in their cases. They suggest that the Congo red, being an azo-dye, combined with the patients' own serum to form an azo-protein to which they became sensitized.

Clinical Pathology Notes (University College Hospital Publication) contains a warning regarding the danger of the Congo-red test in the presence of allergy. In the experience of the authors of this handbook, reactions have occurred where this test has been performed in patients with allergic disease (F. V. Flynn, 1956, personal communication).

The presence of bronchospasm in this patient suggested that he was an allergic subject, and it may well be that the train of events was a manifestation of acute sensitivity to the Congo-red dye.

I am indebted to Mr. G. A. Mason for permission to publish this case.

Reviews

WAR MEDICAL HISTORY

Medical History of the Second World War. The Army Medical Services. By F. A. E. Crew, F.R.S. *Campaigns—Volume I.* 1939–1942. Europe, Battle of Britain, Mediterranean, Middle East, Madagascar. (Pp. 637+xlii; illustrated. 75s.) London: H.M. Stationery Office. 1956.

We are all well accustomed to expect that any publication from the pen of Professor Crew will attain a high literary standard. In this massive volume of 637 pages our expectations are not disappointed. Professor Crew has managed very skilfully to combine a fascinating story of the various campaigns from the outbreak of war in 1939 up to 1942 with a mass of detail regarding the medical and fighting units involved, without spoiling the narrative and yet most cleverly presenting the many and complex problems which faced the medical services "in the field." To keep this volume to a reasonable size it was necessary to curtail the story of the Libyan campaign, which ends at the unfortunate yet glorious retreat of the Eighth Army to Alamein. All students of these histories will look forward with interest to the "continued in our next."

The value to posterity of a war history of this nature lies not so much in the accuracy of the description of the facts of the campaigns as in a correct representation of the lessons learnt. The author has illustrated the difficulties which the medical services had to face when confronted with a highly mobile form of warfare for which their field medical units were hopelessly under-trained and under-equipped, lacking essential transport and thus mobility. These deficiencies, partially overcome by skilful improvisation, demonstrated once again that if the Regular Army field medical units are to be able to take their full place in support of their combatant brethren they must be equipped with every available facility and given an opportunity to train with the fighting forces in peacetime. Graceful acknowledgment is made, however, to the Territorial Army field medical units, which at the outbreak of the Second World War, as in 1914, were the only field medical units with any semblance of field training.

During the Libyan campaign the fantastic distances over which our wounded had to travel by sea, road, and rail to receive definitive treatment in a base hospital are constantly mentioned, but no reference is made to the struggle to persuade the Government to order the R.A.F. to supply air ambulances—a controversy which started in the Middle East before the outbreak of war. Volume I—*Administration of the Medical History of the Second World War* describes the situation. There are numerous sketch maps, many printed with such small lettering that they are difficult to read; it would have helped if reference had been made in the text itself to the particular map of the area being dealt with. The index is perhaps the weakest part of the history, which assuredly will be used as a book of reference, where a comprehensive index with cross-reference to other volumes of the series is of importance.

Campaigns—Volume I combines interesting reading with historical fact, in itself a triumph for any historian to achieve.

J. C. A. DOWSE.

AVIATION MEDICINE

Doctors in the Air. By Wing Commander Robert Maycock, A.F.C. (Pp. 145; illustrated. 15s.) London: George Allen and Unwin Ltd. 1957.

This is not a novel, and should not be associated with any other books bearing a similar title; it is a record of aviation medicine in an "easy-to-read" edition. Wing Commander Maycock was one of the first two R.A.F. medical officers to pass a full wartime pilot's training, and he gives a very impressive account of the doctors who worked and experimented in laboratories, in the field, and

in aircraft. To stimulate the reader's interest he presents a concise and informed review of aerial endeavours from 1500 B.C. to the recent "Berlin airlift." Although it is recorded that a "physician of the Scottish Court" attempted to fly in 1607, it was not until 1912 that Service doctors in the R.N.A.S. and R.F.C. really took to the air and gave serious thought to the physical problems of flying. The records of anoxia, fatigue, and exposure are well illustrated both in the R.A.F. Physiological Laboratory at Farnborough and "on test flight"—the most dramatic story being of the Fortress that flew into the top of a thundercloud at 32,000 feet (9,750 m.), and one doctor, the sole survivor of a crew of eight, was awarded the Air Force Cross. The courage of the research medical officers and the extremes to which they submitted themselves are well illustrated by the experiment of floating in a flying-suit in the sea off the Shetlands in mid-winter; and again when anaesthetized "the doctor" sank in a special water-tank in order that "observers could note how the particular life-jacket behaved on trial and whether it brought the subject to the surface in the correct floating position." There are many interesting records of the R.A.F. Medical Branch in all commands at all levels, with special tribute to the flying personnel medical officers, the parachute medical teams, and air ambulance orderlies. Those readers who served in the R.A.F. during the war should enjoy "spotting" old colleagues in the narrative. I would especially recommend this book to all doctors who contemplate joining the Royal Air Force as a career or for their National Service, in order that they may know, understand, and appreciate what has been done by "some of the few" who did so much for "the Immortal Few" and those that followed.

J. HOPE POOL.

TERRAMYCIN AND AUREOMYCIN

Terramycin (Oxytetracycline). By Merle M. Musselman, M.D., with the collaboration of H. L. Davis, Ph.D., and H. W. McFadden, Jr., M.D. Foreword by Henry Welch, Ph.D., and Felix Marti-Ibanez, M.D. (Pp. 144. 54s.) New York: Medical Encyclopedia, Inc. London: Interscience Publishers Ltd. 1956.

Aureomycin (Chlortetracycline). By Mark H. Lepper, M.D. Foreword by Henry Welch, Ph.D., and Felix Marti-Ibanez, M.D. (Pp. 156. 54s.) New York: Medical Encyclopedia, Inc. London: Interscience Publishers Ltd. 1956.

This series now comprises seven completed and eight projected volumes. To devote a small (though not inexpensive) monograph to each antibiotic has something to be said for it, and this policy has been applied even to the three tetracyclines; that on tetracycline by Dowling has been in print for some time, and here are the other two. On the other hand, very cogent reasons could have been advanced for dealing with them together in a single volume, if anyone could have been persuaded to undertake this task. To deal piecemeal with such closely similar drugs involves repetition, and one would like to read a considered opinion, first of the indications for the group as a whole, and secondly of their relative individual merits. They differ somewhat in antibacterial activity: chlortetracycline is the most active against pneumococci and staphylococci, oxytetracycline against *Pseudomonas pyocyanea*, and tetracycline against *Proteus*. These differences are not made evident by comparing the separate lists of bacterial sensitivities in the two volumes. Indeed, two of the three are actually contradicted by the figures given (for the respective minimum inhibitory concentrations). Nor is it possible by comparing data in the two books to conclude that the blood levels produced by a given dose are higher from oxytetracycline than from chlortetracycline.

Both authors have conscientiously carried out the task of digesting an extensive literature; the respective bibliographies contain 769 and 664 items with titles, and could in themselves be of much value to the seeker after obscure information. Apart from their acknowledged efficacy in many specific infections due to susceptible micro-organisms, chlortetracycline is credited with a curative action in leprosy,

Haemophilus influenzae arthritis, rat-bite fever, and stomatitis, and oxytetracycline in asthma, cat-scratch fever, molluscum contagiosum, and vaginal trichomoniasis. Both books, like the rest of this series, have the titles of the series and of the book itself as page headings, which is unhelpful, since the reader may be presumed to know what book he is reading, and would prefer to be told what section of it the page is in. Musselman's is well subdivided by text headings. Lepper's has none; the 21-page chapter on Gram-negative infections is an expanse of text with no indication of the many subdivisions of this subject. Each of these volumes may be commended as a source of information in its limited sphere, and for the opinions within this of its authors, which must command respect; but it has been left to someone else to survey this group of drugs as a whole, to define their merits in relation to other antibiotics, and to distinguish between the merits of each of them. Anyone adjudicating on this last question might possibly have a hard task in deciding whether it is therapeutically necessary that all three should continue to exist.

L. P. GARROD.

PERSPIRATION

Human Perspiration. By Yas Kuno, M.D. (Pp. 416+xv; illustrated. 72s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1956.

Professor Kuno's previous monograph, *The Physiology of Human Perspiration*, has for long been a standard work, but 23 years have passed since it appeared, and in that time very considerable advances have been made in this field of physiology. The publication of the present volume therefore becomes an event of some importance. In the foreword the author states that it is "an account of the present knowledge of perspiration," but he adds: "Instead of presenting a cumbersome review of the literature we have drawn extensively on personal observation." Some may feel that the conflict of these two aims has led to a certain lack of balance in that, although no important aspect of the subject is neglected, in the presentation of each topic the views and findings of the Japanese school are emphasized. Whether undue weight has been given to these views must remain a matter of opinion—it is perhaps a valuable corrective of the Western tendency to think mainly in terms of work done in the West. Be this as it may, the book does have a serious defect in a work of this nature. On the grounds that the 500 or so references in the previous volume provided an exhaustive bibliography, the present work contains only 37 "selected references," with the result that one finds many references in the text which appear in neither list. One minor blemish may be mentioned. The index, though effective, is somewhat clumsily arranged, and it is marred by a few misspellings. Despite these shortcomings, the book remains worthy of its predecessor—a most important work that every physiologist will wish to read. The book itself matches the importance of its subject-matter: paper, printing, and binding are excellent.

R. K. MACPHERSON.

SURGICAL PATHOLOGY

A Textbook of Surgical Pathology. By Charles F. W. Illingworth, C.B.E., M.D., Ch.M., F.R.C.S.Ed., and Bruce M. Dick, M.B., F.R.C.S.Ed. Seventh edition. (Pp. 730+viii; illustrated. 63s.) London: J. and A. Churchill Ltd. 1956.

A seventh edition of this book, now in its twenty-fifth year, is welcome and indicates its continued popularity. This is well deserved, as we are given not only an authoritative and condensed account of modern surgical pathology in which principles, so important to the student, are emphasized, but a book which is well and clearly printed, appropriately illustrated, and of convenient size to be a working manual. In this latest edition there are new sections dealing with those aspects of water balance and blood chemistry which are important to the surgeon. Such subjects also as hormones and cancer, radioisotopes, hypothermia and refrigeration,

and the crush syndrome are considered concisely and clearly. The illustrations have also been revised, some of the older ones having been replaced while others have been added; many are of specimens in the Museum of the Royal College of Surgeons of Edinburgh. Reproduction has been good and all are admirable. Appropriate references to important contributions to the subject with which each chapter deals are given at the end of it. There is little to criticize, but there is no mention of mycotic aneurysms, which, now that infective endocarditis is controlled with antibiotics, sometimes concern the surgeon. The authors express the hope that the book will continue to prove of value to senior students and those preparing for senior qualifications; there can be little doubt that this hope will be abundantly fulfilled.

LAMBERT ROGERS.

CONGENITAL HEART DISEASE

Cardiopathies Congénitales. By P. Soulié. Preface by Robert Debré. Second edition. (Pp. 448; illustrated. No price.) Paris: Expansion Scientifique Française. 1956.

The second edition of "Congenital Heart Lesions" appears five years after the first. The preface points out that the time is ripe for a new review of the subject, for the surgical technique has made great advances lately; hypothermia and an artificial circulation give possibilities of a bloodless field of operation, and enhance still further the need for medical diagnosis, based on the fullest study of all available data. This book does not claim to be a full treatise on the subject with complete bibliography. There are new sections on electrovectorcardiography, aorto-pulmonary fistulae, aortic stenosis, and pulmonary angiomata. In the first section the account of definite development of the bulbus cordis is very clear. The technique and value of cardiac catheterization and angiocardiology are fully described. The next section describes the various lesions. The tetrad of Fallot occupies the first place, as is logical enough; and then the trilogy. Should not this, more uniformly, be "triad"? Throughout the expression is clear and economical. The illustrations are excellent, particularly the cardiograms and pressure curves. In each instance all the information is well marshalled and co-ordinated in a well-integrated whole. This is a fine work and a mine of practical information. The question of anaesthesia and surgical operation comes rather shortly at the end, but there is a quite adequate account for a physician reader. No fewer than 27 collaborators have produced this book, with a well-blended authority that is a great credit to French cardiology.

TERENCE EAST.

SHAW'S GYNAECOLOGY

Shaw's Textbook of Gynaecology. Revised by John Howkins, M.D., M.S., F.R.C.S., F.R.C.O.G. Seventh edition. (Pp. 704+vii; illustrated. 32s. 6d.) London: J. and A. Churchill Ltd. 1956.

What has long been one of the most popular undergraduate textbooks in this country requires no introduction. Moreover, it requires little more than a glance to understand its popularity. It is a model of clarity and conciseness, well illustrated, and conforming in layout with a long tradition of gynaecological textbooks. Mr. John Howkins is responsible for this new edition, and has succeeded in making a number of improvements without destroying the original author's imprint. He has also had the happy thought of dedicating it to Wilfred Shaw himself. No British gynaecologist is more deserving of posthumous tribute, and none could have wished for better. One can appreciate Mr. Howkins's reluctance to discard too much of the master's work, but Shaw's classification of ovarian tumours would appear to have outlived its usefulness; it is more likely to confuse than help the student of to-day. However, Mr. Howkins will surely not have to wait long for an opportunity to re-examine this matter, for the many other good qualities of this edition promise a quick sell-out.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY JUNE 15 1957

QUARANTINABLE DISEASES

A little more than one hundred years ago the first International Sanitary Conference was held and the first International Sanitary Convention was drafted. The early conferences were concerned with cholera, plague, and yellow fever, and it was not until 1926 that smallpox and louse-borne typhus were added to the list, which was further enlarged in 1951 by the inclusion of louse-borne relapsing fever. Such vast changes have occurred in the incidence of these infections during the last hundred years as a result of advances in epidemiology and methods of control that few people now living under western conditions can appreciate the ravages of widespread pestilential disease in a community. A brief survey of the present position has been made by the World Health Organization,¹ and it is clear that, though all the quarantinable diseases still exist endemically in various parts of the world, their spread from these centres has been controlled by international action and the incidence in them has been reduced by rising standards of living and the introduction of preventive measures.

Cholera, which was pandemic as recently as the early years of this century, is now virtually contained within a limited area. Since the second world war the disease has only once spread outside Asia (to Egypt in 1947), and even within that continent spread has been greatly limited. During the last six years cholera has been confined to its endemic foci and immediately adjacent areas in India and Pakistan with a few cases in Indo-China. The present position of plague differs from that of cholera because it is enzootic in wild rodents in Asia, Africa, and the continent of America, and there is little probability of the eradication of these hosts or of the disease in them. The transmission of plague to man, however, has steadily declined, certain endemic foci have been eliminated, and international spread has virtually ceased. This has resulted from control of the flea vector by modern insecticides and from improved hygiene in towns, ships, and ports. Attack on the domestic rat with new and more efficient poisons is being intensified. Plague can no longer be regarded as a serious menace, and, though outbreaks may con-

¹ Gear, H. S., and Deutschman, Z., *Disease Control and International Travel*, 1956, Geneva.

tinue to occur, they can be rapidly brought under control.

The incidence of louse-borne typhus during the two world wars makes an interesting contrast. Millions of cases occurred during and after the first, but in the second, although serious epidemics occurred, they did not spread and devastate whole communities or countries. The factors responsible for the reduced incidence were improved general hygiene, modern insecticidal control of lice, and possibly typhus vaccine. Even in the endemic areas the incidence of typhus is declining, and there has been no outbreak in the last ten years resulting from international travel. It is unlikely that in future any serious epidemic will occur in times of peace and security: control measures have been so successful that it was suggested that typhus should be omitted from the list of quarantinable diseases, but this was thought to be premature and louse-borne relapsing fever was added to the list. Though widespread and international epidemics of relapsing fever have occurred it has never been a serious problem of international travel, and since it is easily controllable by insecticides it may be classed with typhus as a disease of rapidly decreasing importance.

The incidence of smallpox still remains high in the endemic centres, although it has shown a slight decline in the last five years. Some 55% of all cases were notified from India and Pakistan and a further 23% from other Asian countries. The disease usually appears only in sporadic form in communities in which the bulk of the people are vaccinated. Smallpox, nevertheless, is the disease most commonly reported as infecting ships, and it will remain an international problem until improved health services throughout the world have raised herd immunity by vaccination. As to yellow fever, the main reservoir is now proved to be the monkey population in endemic areas. This reservoir cannot be eliminated, but control of the urban vector, *Aedes aegypti*, has advanced to a point where outbreaks in towns can be rapidly terminated. Sporadic cases continue to occur in human populations living in the forest in the vicinity of infected monkeys. Jungle yellow-fever has extended in Central America and Trinidad, but preventive measures have been applied and human infection has been limited. Until control by vaccination of the human population has been sufficiently widely applied in jungle-yellow-fever areas the threat of spread to receptive countries such as Egypt and India will remain.

The quarantinable diseases now no longer represent the international menace they were fifty years ago, and the threat grows less as the means of control are applied in the countries which still contain endemic

and enzootic reservoirs of infection. As standards of hygiene rise throughout the world and as the poorer countries improve their economy and social services, quarantine as a means of control of the pestilential diseases will become less and less necessary in times of peace and security. The world can now contemplate in the not too distant future the deletion of several of the quarantinable diseases from the list. This does not necessarily mean that all international barriers to the spread of disease will be removed. There may be a demand for the control of spread from their endemic foci of certain diseases which at the present time are widespread in some parts of the world but strictly controlled in others. Malaria might become the subject of international regulations, and, as ability to diagnose poliomyelitis improves and understanding of its epidemiology grows, attempts may be made to limit its introduction into countries with high standards of hygiene from tropical and subtropical countries in which the infection is almost universal. Quarantine as such is likely to disappear, but other measures directed towards preventing the importation of communicable diseases of major importance may be elaborated to replace it.

LEUKAEMIA, ANKYLOSING SPONDYLITIS, AND RADIOTHERAPY

Leukaemia is still an uncommon disease, but its incidence has shown a steady increase in the last twenty years. As R. Bodley Scott¹ pointed out in his Lettsomian Lectures for 1957, although more precise diagnosis may explain part of the increase it does not account for all of it; and L. J. Witts,² in a paper published last month in this *Journal*, emphasized that the search must go on for factors in our greatly changed environment which may have contributed to this increase. Evidence implicating exposure to ionizing radiations was mainly experimental and circumstantial until the reports of increased mortality from leukaemia in Nagasaki and Hiroshima after the atomic bomb explosions of 1945. When an increased incidence of leukaemia was suspected among patients given x-ray treatment for ankylosing spondylitis the Medical Research Council sponsored an investigation, and the results, reported by W. M. Court-Brown and J. D. Abbott,³ confirmed that there was in fact a somewhat increased mortality from leukaemia among these patients. Little evidence was available on the delayed effects of small doses of radiation, and the Medical Research Council therefore initiated an extended survey. This was carried out by W. M. Court-Brown and R. Doll, who investigated the records of patients with ankylosing spondylitis treated with x rays, assessing the death rate among them from

leukaemia and aplastic anaemia, and attempting to determine the relationship between the doses of radiation given and the later incidence of these diseases. The results have now been published⁴; they represent, in the introductory words of the report, "the most substantial contribution to date on the increasingly important subject of the relationship between exposure to radiation and the occurrence of ill effects."

To determine the incidence of leukaemia and aplastic anaemia, Court-Brown and Doll analysed the records of 13,352 patients presumed to have ankylosing spondylitis and given x-ray treatment for this at 81 British radiotherapy centres between 1935 and 1954. On the death certificates of 46 who had died by December, 1954, a diagnosis was recorded of leukaemia, aplastic or hypoplastic anaemia, or myelofibrosis, and in addition three patients still alive were found to have leukaemia. In 28 of the patients death was certified as due to leukaemia and in 12 to aplastic anaemia. The number of deaths from leukaemia which might have been expected in the series, in the absence of any unusual leukaemogenic stimulus, was estimated from the national vital statistics, and the figures up to December 31, 1955, were 2.9 for leukaemia and 0.3 for aplastic anaemia. There was thus a highly significant increase in mortality from leukaemia and aplastic anaemia among the patients in the irradiated series.

For detailed analysis it was necessary to reclassify the patients according to what was later thought to be the most accurate diagnosis, after review of full clinical and pathological data. Of the cases stated to have died from aplastic anaemia, half were probable cases of leukaemia, and of the remainder the diagnosis of aplastic anaemia could be confirmed in only four (only one of which was clearly due to irradiation alone). In addition to the cases of leukaemia occurring in the series, particulars were available of 23 cases of leukaemia and aplastic anaemia occurring in patients with ankylosing spondylitis outside this survey, and 15 of these were known to have been irradiated. Court-Brown and Doll included the data from these cases in their discussion of the latent period and cell type of the leukaemia. The number of cases available to provide information on the latent period was small, since the majority of the patients with leukaemia had received two or more courses of treatment and it was not possible to decide which course was relevant. It seems likely, however, that the latent period for leukaemia after irradiation is seldom less than two years,

¹ Bodley Scott, R., *Lancet*, 1957, 1, 1053.

⁴ Court-Brown, W. M., and Doll, R., "Leukaemia and Aplastic Anaemia in Patients Irradiated for Ankylosing Spondylitis," *Spec. Rep. Ser. med. Res. Coun.* (London), No. 295, 1957, H.M.S.O., London.

⁵ Abbott, J. D., and Lea, A. J., *Lancet*, 1956, 2, 1317.

more often three to five years, and that longer periods are less common. The mortality from leukaemia among patients treated with x rays for ankylosing spondylitis was about ten times greater than the mortality in a normal population of the same age and sex distribution. Could this have been in part due to an association between leukaemia and ankylosing spondylitis itself? The authors thought this unlikely, for three reasons: the differing distribution of cell types among the irradiated and unirradiated cases; the previous findings of J. D. Abbatt and A. J. Lea,⁵ who in a statistical investigation had compared irradiated and unirradiated cases of spondylitis; and the later finding that a relationship exists between the dose of radiation and the incidence of leukaemia.

In their investigation of the relationship between the dose of x rays and the occurrence of leukaemia, Court-Brown and Doll found it impracticable because of the large numbers to calculate for each individual the amount of radiation received, and therefore used a sampling procedure. Details of x-ray dosage were obtained for about one in six of the patients, and the doses were expressed in terms of the dose to the spinal bone marrow (in roentgens) and also in units of whole-body integral dose (megagramme-roentgens). The spinal-marrow dose was estimated in two ways—as the mean dose to the marrow throughout the whole length of the spine, and as the maximum dose at a point in the spinal marrow. The mean spinal-marrow dose was also separately estimated for those patients receiving only spinal irradiation. (Cases used for this particular study included 32 with an established diagnosis of leukaemia, and five probable cases of leukaemia; 18 of the 37 had received only spinal irradiation.) In interpreting their findings, Court-Brown and Doll suggest as a working hypothesis that, for low doses, the incidence of leukaemia bears a simple proportional relationship to the dose of radiation, and that there is no threshold dose for the induction of the disease. Their calculations based on this, and on the figures for cases of leukaemia given only spinal irradiation, show that the dose to the whole marrow which would have doubled the expected incidence of leukaemia may be between 30 and 50 r (for irradiation with x rays of the same average energy as those used in treating ankylosing spondylitis.)

The importance of this report is threefold. It establishes the extent of a therapeutic hazard and thus helps the clinician to determine the treatment needed by his patient. The fact that a hazard has been demonstrated does not necessarily preclude the use of a method of treatment; but the probable benefits from its use have to be weighed against the risks entailed for the individual patient, after considering the possible alternative treatments and the prognosis

if the one method is omitted. Ankylosing spondylitis may be a crippling disorder, and there is no doubt of the benefit in relief of pain and increase of mobility which may be obtained from judiciously applied radiotherapy. As Witts² pointed out, although the death rate of 3 per 1,000 from leukaemia after radiotherapy for spondylitis is ten times as high as the usual incidence of leukaemia in this age group, it is lower than the mortality of 13 per 1,000 for interval partial gastrectomy for peptic ulcer in the best hands. The second point is of more far-reaching importance. The hypothesis that the incidence of leukaemia is proportional to the dose of radiation, and that there is no threshold dose for inducing the disease, would imply that in some cases of leukaemia the disease will have been induced by natural background radiation; and also that any exposure to radiation over and above that from the natural background must increase the risk of the disease developing, so that attention has to be given to the growing use of diagnostic radiology. The increased risk of leukaemia associated with any one x-ray examination in any one patient is very small indeed, but the population undergoing such examinations is very large. Nevertheless it seems unlikely that radiation alone can account for the whole of the increased mortality from leukaemia in the last two decades. Finally, the report is important as a model of the way in which an immense problem of medical research can be handled by a team of workers with varied interests and reduced to manageable proportions. Court-Brown and Doll state that a number of approximations have been necessary to arrive at the estimate of the relationship between radiation dose and the incidence of leukaemia, and that the estimate may be subject to appreciable error. Moreover, their hypothesis that there is no threshold dose, though a reasonable deduction, is not the only one compatible with the data, and they stress that until much more work has been done it will not be possible to decide between the alternative hypotheses.

N.H.S. DRUGS FOR PRIVATE PATIENTS

"All the service, or any part of it, is to be available to everyone in England and Wales. The Bill imposes no limitations on availability—e.g., limitations based on financial means, age, sex, employment or vocation, area of residence, or insurance qualification."

This statement appeared in a White Paper issued by the Labour Government in 1946¹ which described the provisions of the N.H.S. Bill. In 1949 the Conservative Party declared it was their policy to allow private patients to obtain drugs free of charge as one of the benefits available under the N.H.S. With un-

¹ See *British Medical Journal*, 1946, 1, 461.

failing regularity the Representative Body each year passes a resolution in favour of the same thing. Sub-committees are set up to consider the matter. Deputations go to Ministers of Health. Yet nothing happens. There is enough frustration in the medical profession as it is, but this failure on everyone's part to press home promises made to patients by both major parties is baffling in the extreme. Fresh support for the measure now comes in a welcome leading article in *The Times* of June 5: "And even though," the article states, "the doctors wanting the change frankly admit their wish to stimulate fee-paying, it is hard to see why the patient who genuinely wants to pay his doctor should be denied the right to get his drugs through the Health Service."

It is indeed hard to see why—and hard to understand why Governments and political parties will not keep their promises. The profession's representatives must continue to press the Government to do what its predecessors have said they would do. If one of the effects of providing drugs free for private patients were an increase in private practice, so much the better. The B.M.A. is pledged to protect the interests of private practice. Many patients, we believe, would become private patients if secured against the unexpected heavy cost of "life-saving" drugs in a severe illness. Many doctors are temperamentally averse to working in a State service. To attempt to force by one measure or another all into the one State service does more harm than good and goes against the grain of the British character. The more variety there is the better, and a bigger element of private practice would encourage this. Recent correspondence in the *Supplement* is a sign of a growing desire for this. The Minister of Health might have a look at some of the ways of providing drugs to the insured population in other countries. No doubt the profession's representatives would be prepared to consider for private patients the introduction of such modifications as exist in Australia and Norway, for example. This would give the Government the opportunity of an experimental trial of a different system. And the N.H.S. is badly in need of such experiments.

DIFFUSE PULMONARY FIBROSIS

Some 700 deaths are attributed to non-occupational fibrosis of the lungs in England and Wales every year. The figure for occupational fibroses is only slightly greater than this. Within the occupational group the fundamental cause of the fibrosis is rarely in doubt, but, if there is no history of industrial exposure, morbid anatomical studies often reveal no more than the fibrotic

end-result of some indeterminate inflammatory process. The complexities of this problem, particularly in relation to the collagen diseases, were reviewed by a clinician, a pathologist, and a radiologist at the Annual Congress of the British Institute of Radiology in 1955.¹⁻³ From the pathological standpoint most of the collagen diseases may be associated with pulmonary fibrosis, though not necessarily in a characteristic form. Scleroderma may produce irregular masses of scarring or diffuse fibrosis with cyst formation. Lupus erythematosus is ordinarily associated with non-specific changes, such as bronchopneumonia and oedema, but fibrinoid necrosis has been recorded. Polyarteritis nodosa is one of the few diseases within this group which causes identifiable pulmonary changes, but other causes of necrotizing arteritis need to be remembered. Rheumatoid arthritis may yield specific pulmonary nodules in addition to diffuse fibrosis. Despite these seemingly typical changes the diagnosis of individual collagen diseases is almost invariably determined by extrapulmonary features. Indeed, if the lungs alone are affected a firm diagnosis may be impossible, and if proliferation of bronchial epithelium or smooth muscle coexists an entirely different aetiology may be suspected.

To clinicians and radiologists the problem presents in a different way, and the whole range of processes which may give rise to diffuse reticular or nodular pulmonary opacities needs to be considered. Thus, the radiological diagnosis of diffuse fibrosis is by no means easy. Patterns indistinguishable from fibrosis may be produced by such unrelated conditions as carcinomatosis and the vascular congestion of mitral stenosis. Fortunately most of the causes of diffuse pulmonary opacities can be recognized by their associated extrapulmonary manifestations or by special investigations.

The occupational history may give a lead to diagnosis, as may former residence in a particular part of the world (for example, histoplasmosis⁴). High on the list of differential diagnoses come tuberculosis and sarcoidosis, which can usually be identified by laboratory procedures. Less common general disorders include the xanthomata (Hand-Schüller-Christian disease, Letterer-Siwe disease, eosinophilic granuloma) and the mesodermal dysplasias of the tuberous sclerosis group, which radiologically often give a characteristic honeycomb appearance throughout both lungs; their diagnosis is confirmed by extrapulmonary features. The pulmonary changes in the collagen diseases rarely constitute a diagnostic problem; they are more in the nature of curiosities in patients who show obvious signs of the various diseases elsewhere; their radiological patterns are as would be expected from the pathological changes already described.

Diffuse fibrosis having been accounted for in the great majority, a hard core remains in which the nature of the fibrosis remains obscure. Within this group there are many, mostly men between the ages of 40 and 60, who give a history of increasing breathlessness over the previous few months or years, and whose radiographs

¹ Seadding, J. G., *Brit. J. Radiol.*, 1956, 29, 633.

² Gough, J., *ibid.*, 1956, 29, 641.

³ Lodge, T., *ibid.*, 1956, 29, 645.

⁴ Symmers, W. St. C., *British Medical Journal*, 1956, 2, 786.

show a diffuse reticulation in both lungs, particularly in the lower halves. The sputum may be mucoid or purulent, and often the fingers are clubbed. A few respond to steroid therapy, but the majority eventually die from right heart failure. Post-mortem examination reveals a chronic diffuse interstitial fibrosis of undetermined origin. This disease, whatever it may be, is quite common, and appears to be some form of hitherto unidentified infection.

In summary, perhaps clinicians are in the strongest position to determine the cause of an obscure pulmonary fibrosis. They have the advantage of the history, physical examination, and special investigations, and few such cases cannot eventually be classified more or less satisfactorily. Indeed, the thoroughness with which these three methods of investigation are pursued determines to a large extent the chances of success.

PITOCIN DRIP

Since G. W. Theobald advocated the continuous intravenous administration of oxytocin in obstetrics in 1948,¹ the pitocin drip has achieved a prominent place, in hospital practice, in the induction of labour and the treatment of inefficient uterine action. This has been evident from the many reports published since 1950; while in the last 18 months synthetic oxytocin, synthesized by V. du Vigneaud in 1953,² has been found on clinical trial to be no different qualitatively or quantitatively in its action from the natural product.³⁻⁶ Most reviews of the value of the pitocin drip have given prominence to its supposed risks and drawbacks. These are the danger of causing uterine rupture in women who have previously undergone caesarean section, or who are of high parity, or in whom disproportion may be present; the inadvisability of giving it to toxæmic patients; the illogicality of administering it for incoordinate uterine action; and the necessity for the doctor to remain with the patient the whole time the drip is running. In a new account of his own experience, Theobald⁷ protests that the laying down of these limitations, which seriously lessen the usefulness of the pitocin drip, arises from disregard of his fundamental concept of the use of oxytocin "in physiological amounts" and not as a pharmacological substance. Theobald and his colleagues believe that labour occurs as a result of an enormous increase in the sensitivity of the myometrium to oxytocin, an increase normally effected over days or hours at or near term but possibly taking place any time during pregnancy. They advise that the pitocin drip should be started in a concentration of 1:10,000 or at most 1:5,000, and that

the strength should never exceed 1:2,500, because the sensitivity of the uterine muscle may increase during the administration. This is an important statement, for the dilution of pitocin most commonly reported as used is 1:1,000, while in the fatality reported by M. Lesser and G. A. Eason⁸ the concentration was much higher. Theobald and colleagues find that the obstetrician is required to be present only for the initial half-hour in order to observe any untoward alteration in the rate or rhythm of the foetal heart. Thereafter the foetal heart is recorded at frequent intervals.

The body of this latest paper reports the results of Theobald and his colleagues in the induction of labour and in the management of inertia.⁷ For the former purpose the first step is to sweep the membranes widely and then rupture them, allowing as much liquor as possible to escape. For this procedure the cervix must be soft and taken up and the os admit at least one finger. If, as happens in only 20% of cases, labour has not started within 24 hours, a 1:5,000 pitocin drip is set up. If labour then begins, the drip is continued until the end of the third stage of labour in order to minimize post-partum haemorrhage. If labour does not follow, a solution of 1:2,500 is substituted, and if this proves ineffectual the drip is taken down but started again the next day. The standard rate of infusion is about 40 drops per minute, and if at any time contractions are too frequent or prolonged Theobald prefers to change to a weaker solution rather than reduce the drip rate. Of 1,030 women induced in 1952-4, 222 required a pitocin drip. There were 7 avoidable foetal deaths among these cases, but only one was ascribed to the pitocin. Twenty of the 222 patients were delivered by caesarean section, mostly because of disproportion or severe toxæmia. Toxæmia was not regarded as a contraindication to intravenous pitocin, but when oedema was considerable a dilution of 1:2,500 was used at less than 20 drops per minute and for not more than a few hours. It was found a rewarding routine to give all patients 500,000 units of penicillin intramuscularly 8-hourly from the time of rupture of the membranes until delivery was completed.

In 600 cases of uterine inertia, including an unstated number with incoordinate uterine action, Theobald and colleagues employed wide sweeping and low rupture of the membranes followed by deep sedation, usually with morphine and scopolamine. In about 60% of cases labour was well established thereafter. In the remainder, 216 of the 600, a pitocin drip was necessary to reinforce these procedures, with some increase in the forceps rate (35%), a low section rate (4%, and almost all for disproportion), and an avoidable foetal mortality of 3%. Theobald holds that irregularity of the foetal heart in inertia is usually due to incoordinate uterine action, and that both are best countered by deep sedation rather than resort to caesarean section. This is because he regards incoordinate action as due to activity superimposed on the normal contractions following the excessive liberation of noradrenaline at uterine motor nerve endings. Once this superimposed activity has been obviated by adequate sedation, the pitocin drip can be

used to advantage. Theobald sums up by claiming that the procedures he advocates are effective; that they reduce the caesarean section rate; that they involve no serious hazard to the mother; and that the associated foetal mortality is not unreasonable. His views, set out in his usual forthright manner, may not command universal acceptance, but his arguments and his results merit close study by all obstetricians.

SUDDEN DEATH IN INFANCY

Detecting the cause of an infant's death can be surprisingly difficult, as several contributors to our columns have pointed out in the last few months. In any series of cases a residue commonly remains in which the cause of death is a matter of speculation. J. B. Arey and J. Sotos¹ have reviewed the records of 103 children who were either dead on reaching hospital or who died within 24 hours. The series included cases in which a severe disease or congenital anomaly was known to have existed for some time, cases of rapid deterioration superimposed on an apparently minor infection, and cases in which death suddenly overtook an apparently healthy infant. This last group included deaths similar to those recently discussed in this *Journal* by J. L. Emery and E. M. Crowley²—namely, babies unexpectedly found dead in their cots. The histories of 50 cases referred from a coroner's office to a hospital showed that 49 had had an immediately antecedent illness.

Cot deaths are a worry to the paediatrician and forensic pathologist alike. The old diagnosis of "status lymphaticus" is no longer tenable. "Accidental suffocation" does sometimes occur—for example, when a baby is caught in a twisted pram-harness or is left lying with his feeding-bottle in his mouth—and it may occur more easily in babies who are already ill or mentally defective. But suffocation is unconvincing as the main diagnosis unless the circumstantial evidence is strong. In recent years the theory has gained support that cot deaths are usually due to infection, and the work of Emery and Crowley is in accord with this view. The search for the evidence of infection has produced contradictory results. Many pathologists³⁻⁵ have found a low-grade pneumonia or pneumonitis with a mononuclear reaction. This change is seldom severe and is not in itself sufficient to have caused death, but it may possibly represent a site from which some virulent organism, so far unidentified and almost certainly not bacterial, may have gained entry to the body. On the other hand Arey and Sotos found that six of their ten cases of sudden death had septicaemia due to virulent bacteria. A. M. Barrett⁶ analysed twenty-eight cases of unexpected death after a short,

mild illness, and 23 cases of cot death. He attributed seven cases in the first group to respiratory disorders, five to cardiac disorders, five to inhaled food or vomit, four to "convulsions," three to gastro-enteritis, and one to meningococcal septicaemia, leaving three unclassified. Seventeen of the cot deaths were of uncertain cause.

Among 150 necropsies performed in 1955 in a British hospital,⁷ 66 were on children who died within 24 hours of admission. Fifty-six of the 66 were under 1 year old. Twenty-one of the 66 were babies less than a week old, in whom death was due to prenatal or perinatal factors. Of the remaining 45, 31 had shown some sign of illness for more than 24 hours before death, leaving 14 in whom death occurred within 24 hours of the onset of symptoms. None of these were cot deaths. The causes of death were as follows: septicaemia (with Waterhouse-Friderichsen syndrome), two; volvulus, two; miliary tuberculosis, one; intracranial haemorrhage, one; bronchopneumonia, one. In seven cases no exact cause of death was established. Of these last seven cases, one had a septicaemia without obvious foci, one showed "toxæmia," and the others showed histologically minor infection in lung or bowel. So far, then, it appears that most pathologists can at least find common ground in agreeing that sudden death in infancy is usually the result of infection.

The clinician would probably support this view. He remembers fulminating cases of gastro-enteritis, meningococcal septicaemia, and even "streptococcal pneumonia." Many an apparently mildly infected child has died suddenly in hospital without being suffocated. The infant with "viral bronchiolitis" sometimes shows nothing but severe apnoeic attacks for 48 hours before the chest signs appear. Cot deaths reach a peak at the age of 3 or 4 months, and if they had been due to suffocation the peak might be expected to come earlier. P. V. Woolley⁸ has shown that babies are more comfortable when covered entirely by blankets than might be thought. Remembering these points, the physician must often have thought that had a particular child not died in hospital it would have been classed as a cot death. It is interesting therefore to find that Barrett, after comparing the pathology in known cases of suffocation with that found in his 23 cases of cot death, concluded that the pathological features of deaths "of uncertain cause" were at least consistent with those of suffocation.

The main cause of cot deaths is still undetermined. The reasons for this are several. First, the material studied by the hospital pathologist differs from that studied by the forensic pathologist. Secondly, the pathological differences between asphyxia, infection, and non-specific agonal changes in the lungs are not always clear-cut. Thirdly, evidence of infection is not necessarily proof of the cause of death. The full explanation of these deaths may have to wait, as E. S. Duthie and R. A. Goodbody have said,⁹ "until new methods of examination for virus infections become available to the routine pathologist." Meanwhile there is evidently need for close collaboration between the pathologists and clinicians if all sides of these puzzling cases are to be studied.

FAR EAST INFLUENZA

BY

C. E. GORDON SMITH, M.D.

L. H. TURNER, M.D.

Institute for Medical Research, Kuala Lumpur

AND

C. J. V. HELLIWELL, M.B., B.S.

General Practitioner, Kuala Lumpur

The current influenza epidemic in the Far East has received world-wide and sometimes alarmist newspaper publicity. No account of the Hong Kong epidemic, from which the Malayan one presumably derived, has yet appeared in any of the medical journals to reach us. The following outline of the main aspects of the epidemic in the Federation of Malaya is therefore presented for the information of the medical profession in countries to which it may spread.

Peak Being Reached

Influenza was made a notifiable disease in the Federation on May 4 as soon as news of the epidemic in Singapore was received. The first notification in Kuala Lumpur was on May 6, and virus isolated from this patient was dispatched, after preliminary identification, to London and Washington on May 17. Although there are various defects in the figures, the notifications demonstrate the main features of the spread of the disease. By May 10 notifications were being received from most of the large towns; but the rural areas were not widely affected until about two weeks later and in many the peak is only now being reached. In each town the incidence has risen sharply during the first four or five days and has then been maintained for about three weeks. The spread in town and country is illustrated in the Table, which shows the notifications in the Perak North District, which contains one large town, Taiping, and a heavily populated rural area.

In Kuala Lumpur the majority of patients early in the epidemic were poorer people living in the most crowded and least healthy environments. Since then the disease has progressively affected those living in better circumstances, so that in the fourth and fifth weeks of the epidemic more and more patients from the upper class of Asians and among the Europeans have been seen. Asian military units have so far been much more heavily affected than the British, although in one small mixed unit the difference in rate was not marked. The apparent racial difference in incidence seems therefore more likely to be due to differences in degree of exposure and general environment and health than to immunity; influenza, after all, is not uncommon in Malaya and A-prime virus was isolated during an outbreak around Kuala Lumpur as recently as 1953.

Clinical Features

The clinical severity of the disease has varied widely, but a typical attack has the following course. Especially in children, the first complaint is usually of thirst followed in

6-12 hours by a very sore throat. On examination, a bright red velvety inflammation is characteristically confined to the posterior pharyngeal wall. About this time the temperature is around 102° F. (38.9° C.) and the pulse about 120 per minute. A generalized headache develops 3-6 hours later and in adults and adolescents is often accompanied by aching, particularly in the lower chest and lower back. Aches are uncommon in children, whose main discomforts are the sore throat and a "floating," "bloated" headache. Tonsillar enlargement without suppuration may occur during the next 24 hours, usually in patients with chronic tonsillitis. Dry cough is common at this stage, but no crepitations have been detected in the lungs of uncomplicated cases. By the third day the cough is brassy and associated with tracheitis. During the second 24 hours the fever is maintained, but the sore throat disappears and the headache and muscular aches diminish. Recovery is usual by the fourth day, and most patients return to work after about five days' absence. Vomiting has not been marked except in those intolerant of salicylates or given solid food during the first 24 hours.

Although the incidence of influenza has been very high the number of deaths attributable to it has been very small. Most patients have been able to go to clinics for treatment, but some have been too weak to stand—about 10% in a children's clinic—and several fainted while awaiting treatment. Several young children have shown meningism, and this has been noted in three fatal cases,* which had terminal convulsions and coma. These cases were not proved virologically.

About 10% of patients return to the clinic after the third or fourth day with secondary bronchitis, tonsillitis, etc. A few patients have had a short recurrence of fever about the seventh or eighth day.

Symptomatic treatment with salicylates has been very effective when combined with strict bed rest for two to three days, a bland diet, and copious fluids. Intramuscular chloramphenicol has been given to a number of severe cases with apparent benefit, but controlled evaluation of this observation has not been possible.

Virus Strains

Several strains of virus have been isolated in this Institute by us and by the United States Army Medical Research Unit working here. Four of them have so far been sent to the World Influenza Centres in London and Washington for detailed study. Haemagglutinin-inhibition tests with the first three strains isolated at once showed that they were unrelated to strains for which antisera were available to us (i.e., A: PR8; A-prime: FM-1, FW/1/50, FLW/1/52; B: LEE, IB-1, B/Malaya/5/55). Subsequently, A/Nederlands/56 antiserum and virus were received from Dr. C. H. Andrews (World Influenza Centre, London) and our new isolates were shown to be unrelated to it. A complement-fixation test with a representative strain has shown that the new isolates belong to type A. Paired sera (acute and convalescent phases) of patients from several parts of the Federation were tested by haemagglutinin-inhibition against the newly isolated strains and against the reference strains listed above, and significant rises in the antibody titre were found only against the new strains.

*Reported by Dr. Saraswathy, General Hospital, Kuala Lumpur.

PRESENT KNOWLEDGE OF
THE CIRCULATION

HARVEY TERCENTENARY CONGRESS

Having at its first session reviewed the knowledge of the circulation in earlier centuries (see our last issue, p. 1357), the Harvey Tercentenary Congress then turned to the present.

Role of the Heart

For the afternoon of Monday, June 3, Professor G. W. PICKERING (Oxford) took the chair.

Dr. L. N. KATZ (Chicago) spoke on the regulation of the heart. The function of the heart was to pump blood and to adjust the amount to the need. He went on to describe a new type of intact heart-lung preparation which permitted the measurement of coronary flow and other parameters. When heart rate or work was made to increase, after a time there was a sudden drop in oxygen consumption and a decrease in the coronary arterio-venous oxygen difference—that is, the heart's efficiency increased. It was as if the heart had suddenly shifted into a higher gear.

Professor K. MATTHES (Heidelberg) said that the function and structure of the right and left ventricles differed in certain important respects. The pressure and the vascular resistance were relatively steady in the pulmonary compared with the systemic circulation, and this was reflected in the different anatomical features of the two ventricles. The pressure/volume elasticity ratio was different on the two sides, the right ventricle being more distensible than the left. Hence with an equal inflow the filling pressure was lower on the right than on the left. The central and pulmonary venous pressures belonged to a low pressure system regulated by renal mechanisms and the intra- and extra-cellular fluid.

Dr. S. WEIDMANN (Berne) described the electrical events underlying cardiac contraction. The use of a glass electrode 0.2 μ in diameter made it possible to record the changes in electrical potential in a single cardiac muscle fibre. Recordings showed a monophasic action potential. The changes in potential difference were probably produced by ion migration: during depolarization sodium entered the fibre and during repolarization potassium left it. The concentration of ^{42}K in the coronary outflow increased greatly at the time of the action potential.

Dr. PAUL WOOD (London) showed a film on the jugular venous pulse. The normal venous pulse was described and the genesis of its two peaks and two troughs—*a* and *v*, *x* and *y*—were explained. A giant *a* wave was found in tricuspid stenosis and in right ventricular hypertension. Arrhythmias gave distinctive changes in the venous pulse. "cannon" waves occurring in heart block, whilst in atrial fibrillation the *a* wave and *x* descent were absent. With tricuspid incompetence a giant *v* wave was found and in constrictive pericarditis a sharp *y* descent was typical but not pathognomonic, since it occurred also in any form of congestive failure. Tricuspid stenosis was characterized by a slow *y* descent and absent *y* trough.

Haemodynamics

On Tuesday morning Professor ROBERT PLATT, P.R.C.P., took the chair. Professor C. HEYMANS (Ghent) discussed the role of the aortic and carotid sinus baroreceptors. These baroreceptors were connected to the vasomotor centre in the brain and thus reflexly controlled heart rate and output, arterial and venous tone, and adrenal medullary secretion. They thus maintained a set level of blood pressure. It was possible experimentally, however, to increase the tension in the wall of the carotid sinus by local noradrenaline and so "reset" the baroreceptor, with a consequent fall of systemic pressure. Professor Heymans suggested that "resetting" of the baroreceptor threshold in the opposite direction might be a component of hypertension in man.

Professor G. NYLIN (Stockholm) then described his studies of blood flow, made with the aid of red cells labelled with

either ^{32}P or thorium B. Dilution curves reflected both circulation time and cardiac volume, and were therefore an indication of heart size. Professor Nylin had found the minute volume of the heart to be 6-7 litres, and the thoracic pool volume to be 2 litres in 32 normal subjects. In 62 patients with heart disease, the thoracic volume was increased: 3.3-4 litres, reflecting the degree of cardiac enlargement. The same technique was now being used for the study of cerebral blood flow, which had been found to be 1-1.3 litres a minute, with a cerebral pool of 130-150 ml.

Dr. G. S. DAWES (Oxford) discussed the changes in the circulation at birth. Although the foramen ovale was usually considered to lie between the atria, he had shown that functionally it lay between the inferior vena cava and left atrium. Consequently most of the venous return from the foetal inferior vena cava passed to the left atrium. At birth, cessation of umbilical blood flow reduced the venous pressure, whereas the increased pulmonary flow raised left atrial pressure and the valvular foramen was thus closed. Cessation of umbilical blood flow also reduced the foetal cardiac output by half, with a consequent rise of systemic resistance. The onset of ventilation produced a fourfold increase in pulmonary blood flow with a fall in pulmonary vascular resistance. Thus the foetal flow of blood through the ductus arteriosus was reversed and a left to right shunt ensued. Constriction of the ductus began immediately, but closure took seven to ten days in man.

Coronary Circulation

Dr. CLAUDE S. BECK (Cleveland, Ohio) chaired the symposium on Tuesday afternoon.

Dr. DONALD E. GREGG (Washington, D.C.) described the experimental work which he has carried out over the last 20 years on coronary flow. He has shown that, contrary to earlier views, coronary sinus blood is mainly derived from the left coronary artery. If the heart was arrested by vagal stimulation, there was an increase of blood flow in the left coronary artery and in the coronary sinus, thus demonstrating that the contracting myocardium impairs the blood flow during systole.

Dr. Gregg pointed out that the retrograde flow in a ligatured coronary artery was quite considerable, although it could not maintain function. In the dog it only required to be doubled to maintain viability. The collateral circulation restored the flow to normal levels in about four weeks. The problem was how to make these anastomoses develop in man in the absence of obstruction.

Dr. CLAUDE S. BECK (Cleveland, Ohio) described his work on the role of oxygen differentials in causing ventricular fibrillation. The well-oxygenated heart, or the completely cyanotic heart, was in a state of electrical stability and would not fibrillate. If in an oxygenated heart coronary branches were ligated so that an area became anoxic, ventricular fibrillation ensued. The same phenomenon was seen in a cyanotic heart, if one arterial branch was perfused with oxygenated blood so that one area was not cyanosed. Thus the even distribution of blood within the heart was more important than the total coronary flow. After a coronary occlusion the patient's fate depended on the amount of blood available for the ischaemic heart beyond the occlusion; and this could be augmented by operation. The operation, consisting in partial ligation of the coronary sinus, abrasion of the pericardium, and powdering it with asbestos, was then shown in a beautifully produced and highly convincing film. Dr. Beck has now operated on 172 patients, with only two deaths.

Mr. G. A. MASON (Newcastle upon Tyne) had concentrated on operations which would produce an anastomosis with extracardiac vascular tissues. Lung or muscle could be grafted on to the heart, or the Vineberg operation of implanting the internal mammary artery in the myocardium could be used. He had operated on 30 severe cases between 1937 and 1950. There was a 30% mortality, but good results were obtained in 50%. Since 1951, however, he had used the original Beck operation of aorto-coronary sinus shunt in 15 patients. There were two deaths in the first months

after operation, and three patients were no better, but 10 had gained appreciable benefit. He thought external collaterals were more important than intercoronary anastomoses.

Pulmonary Circulation

Professor J. McMICAHEL, F.R.S., took the chair for the Wednesday morning session.

Dr. ANDRÉ Cournand (New York) discussed the role of mechanical and vasomotor factors in the control of the pulmonary circulation in normal man. By means of simultaneous bronchspirometry and cardiac catheterization the effects of unilateral hypoxia had been studied. Resistance to flow usually increased if the alveolar oxygen tension was less than 35 mm. Hg, but infusion of acetylcholine caused a fall in the resulting pulmonary hypertension. Although mechanical factors such as the pulmonary blood flow and the left atrial pressure played the dominant role in controlling the pressures in the pulmonary vessels under normal conditions, changes in vascular tone were also important. The studies with acetylcholine had shown that the pulmonary vessels could vary their tone independently of sympathetic activity.

Professor C. V. HARRISON (London) described the post-mortem findings in pulmonary hypertension. In mitral stenosis the pulmonary artery and its main branches were usually dilated, while the segmental branches were of normal size or dilated in the upper zones and narrowed in the lower zones, sometimes showing local constrictions. Histologically, muscular hypertrophy was found in the narrowed vessels, but was always much more pronounced in the lower zones; the areas of local constriction were due to deposits of fatty material in the vessel wall. In congenital heart disease with a left to right shunt the main pulmonary arteries and all vessels down to the smaller segmental branches were dilated, but the finer branches were narrowed and histologically showed moderate muscular hypertrophy, without the zonal difference seen in mitral stenosis. He concluded that the vascular narrowing in the pulmonary vessels in the majority of cases of mitral stenosis was spastic and reversible. The zonal differences were probably due to the effect of gravity.

Dr. STIG RADNER (Lund) described a new method of obtaining the pressures in the aorta, pulmonary artery, and left atrium by the technique of suprasternal puncture. This procedure had been carried out in 232 cases, with one death from cardiac tamponade, but he regarded it as simple and safe. From pressure pulses obtained in this way he described the mechanical events in the normal left heart cycle. In mitral incompetence he thought that retrograde propagation of the left atrial *v* wave occurred, causing a late systolic hump in the pulmonary arterial pressure curve. A high amplitude *v* wave indicated mobility of the mitral valve, whereas equality of *c* and *v* was evidence of a rigid valve.

Results of Cardiac Surgery

In the afternoon Sir CLEMENT PRICE THOMAS presided at a session made memorable by a most successful experiment in transatlantic communication. A panel of experts present at the American Medical Association's meeting in the Carnegie Hall, New York, joined in the discussions, their voices being transmitted by the new transatlantic cable. The voices were heard as clearly as those of the panel in the Great Hall of the College of Surgeons. Large photographs of the panel members were displayed in the hall, and as each spoke a red light was seen beneath his portrait. Dr. MICHAEL DE BAKEY (Houston, Texas), chairman of the panel in New York, opened the discussion by reading a message of greeting from the President of the United States to the A.M.A. meeting and the Harvey Tercentenary Congress. The members of the American panel were: Dr. ALFRED BLALOCK (Baltimore), Dr. FRANK GERBODE (San Francisco), Dr. JOHN H. GIBBON, Jun. (Jefferson Medical College), and Dr. GEORGE E. BURCH (Louisiana).

Earlier, a series of papers on the results of cardiac surgery were given. Professor G. D'ALLAINES (Paris) reported the results in 551 cases of mitral stenosis submitted to operation. The mortality was 6.9%. He used instrumental valvotomy in 57% of cases. Cases with mild regurgitation mostly did well, but all cases of severe regurgitation were unchanged or worse. Seventy-one patients had been followed for from 1-6 years. A good functional result was found in 70%, and pulmonary hypertension was greatly reduced in 90%. The functional result was unaffected by the presence of calcification or slight regurgitation, but the result was not so good in patients with atrial fibrillation. The most important factor was a good valvotomy.

Professor A. G. BROM (Leiden) spoke on 119 cases of atrial septal defect treated by direct suture under hypothermia. He attached great importance to the maintenance of alkalosis by hyperventilation. He thought electrocardiographic evidence of anticlockwise rotation good evidence of a septum primum defect. The ostium primum could be closed only by using an extracorporeal circulation and inserting a prosthesis. He advised operation if there was an ostium secundum with a pulmonary flow twice the systemic flow and a pulmonary systolic pressure less than 70 mm. Hg. There were 11 operative deaths, but only one in the last 70 cases. Of 29 patients who had been recatheterized, 26 had no shunt, but a small defect was present in three as a result of the use of interrupted sutures.

The treatment of pulmonary stenosis was discussed by Sir RUSSELL BROCK (London). He reviewed 436 cases, which included 268 cases of Fallot's tetralogy and 128 cases of pure pulmonary valve stenosis. In pulmonary valve stenosis, although open operation under hypothermia was better in principle, the end result was not necessarily better than in a closed operation. In 19 open valvotomies there had been only one death. With Fallot's tetralogy he found the late mortality twice as high after the Blalock operation as after pulmonary valvotomy, and twice as many required reoperation. There was also a high rate of cerebral complications after the Blalock operation.

Dr. MAURICE CAMPBELL (London) reviewed 130 cases of aortic coarctation. Under the age of 30 the treatment was surgical, but older patients needed careful review, as secondary changes might prevent any benefit. Of 56 cases operated on, three had not improved. The blood pressure fell but not quite to normal, and this was probably due to a renal factor. In pulmonary stenosis, even if the pressure change at operation was not satisfactory, it often became so later. He thought the anastomosis operations compared well with direct operations for Fallot's tetralogy because the operative mortality was lower. In the long run the late deaths might be the same in both groups.

Transatlantic Hook-up

In the two-way transatlantic discussion afterwards Dr. BLALOCK said that the cases of Fallot's tetralogy which Taussig had followed showed similar results from anastomosis or closed resection. Dr. GERBODE thought that mitral valvotomy should be used in pregnancy, whereas Professor D'ALLAINES preferred to wait till after delivery. Dr. GERBODE did not advise carotid occlusion during mitral valvotomy. He favoured instrumentation by the ventricular route. Dr. GIBBON used an extracorporeal circulation for all cases of atrial septal defect. It allowed more time, which was useful for complicated defects. Dr. BURCH thought older cases of coarctation could now be operated on with greater success. Sir CLEMENT PRICE THOMAS asked what was the optimum age for operation on coarctations. Dr. BLALOCK thought 8-12 years. Dr. GERBODE emphasized the high death rate from untreated coarctation in infants. Sir RUSSELL BROCK thought 4-5 years the optimum age.

Dr. GIBBON asked what was the best route for operating on aortic stenosis. Professor P. R. ALLISON (Oxford) thought that the aortic route under direct vision was the best since one could divide the three commissures, and this should give good results even in calcified valves.

Sir RUSSELL BROCK favoured open operation for non-calcified valves, but the closed ventricular route for calcified valves.

Cerebral Circulation

Dr. MACDONALD CRITCHLEY took the chair on Thursday morning. Dr. SEYMOUR S. KEY (Bethesda) said that studies over the past 10 years failed to support the doctrine of Monro (1783) that rigid enclosure of the brain prevents any variation in cerebral circulation, or that all the changes in the cerebral circulation were secondary to changes in the general circulation, as Hill (1896) believed. It would appear that, although arterial and venous pressures played important roles, the greater control was exerted by such factors as intracranial pressure, blood viscosity, and the humoral and neurogenic control of the vessels themselves. In normal man the cerebral circulation accounted for about 16% of the resting cardiac output, and the oxygen consumption of the brain represented 20% of the total basal metabolism. Pharmacological studies in man indicated that carbon dioxide was a most potent vasodilator in the brain and might be the most important physiological regulator of the cerebral circulation.

Professor T. ALAJOUANINE (Paris), in collaboration with Dr. P. CASTAGNE and Dr. F. LHERMITTE described a study of cerebral vascular occlusion by post-mortem arteriography of the carotid and vertebral vessels. This not infrequently revealed obstruction of one or more of these arteries. The arterial supply had also been studied by injecting the cerebral vessels (after removal of the brain) with coloured radio-opaque substances. By these methods it had been possible to demonstrate an arterial obstruction in every case of cerebral infarction.

Dr. E. H. BOTTERELL (Toronto) emphasized the importance in cases of subarachnoid haemorrhage of cerebral injury by intracerebral clot, subdural haematoma, infarction, and hydrocephalus. He then described his results using hypothermia, advocating arteriography as soon as possible after the bleed and early surgery.

Splanchnic Circulation

The afternoon session was under the chairmanship of Sir JAMES LEARMONTH.

Dr. STANLEY BRADLEY (New York) said that direct measurements of the splanchnic blood flow in animals had confirmed the validity of the indirect bromsulphthalein technique which is applicable to man. Variation in the splanchnic volume was an important factor in circulatory homeostasis. Following haemorrhage in the dog decrease of splanchnic volume served to maintain cardiac output, but the reduction in flow through the splanchnic bed was not so marked as through the kidney, where the ischaemia could be sufficient to produce tissue damage.

Dr. SHEILA SHERLOCK (London) discussed the measurement of the portal pressure. At the present time determination of the pressure in the splenic pulp or occluded hepatic vein appeared the most reliable, both correlating well with results obtained by direct measurement in the portal vein. Comparison of the results of splenic venography with those of splenic pressure measurement had shown that portal hypertension could occasionally exist without demonstrable portal-systemic collaterals. A large collateral circulation could also exist without portal hypertension, which suggested that the collateral vessels might be effective in relieving the increased pressure.

Professor R. MILNES WALKER (Bristol) said that the serious consequence of portal hypertension was haemorrhage from varices, although encephalopathy might arise from a large portal-systemic shunt and occasionally "hyper-splenism." There was no direct relation between the amount of fibrosis in the liver and the degree of portal hypertension it caused by intrahepatic obstruction. The most effective treatment for portal hypertension was the production of an efficient shunt, preferably by portacaval anastomosis. There was no evidence that deviation of the portal blood from the liver impaired its function. A satisfactory portacaval anastomosis would practically guarantee freedom from fur-

ther haemorrhage and in selected patients usually resulted in return to a normal existence. Approximately 15% of his patients showed some sign of portal-systemic encephalopathy post-operatively.

Peripheral Circulation

On Friday morning Professor A. KEKWICK was chairman.

Professor HENRY BARCROFT (London) described recent British work on the limb circulation. The introduction of adrenaline by iontophoresis into the skin of the forearm produced a "physiological skinning" by vasoconstriction. Heating the subject then caused no increase in the limb blood flow, showing that the increase which normally occurs takes place in the skin. The usual vasodilatation had been shown to be an active one mediated by cholinergic fibres. Salivary glands were known to produce an enzyme which breaks down protein to produce bradykinin, which causes vasodilatation. Bradykinin had been found in sweat, and in increased amounts in the tissues around sweat glands after heating of the body. The forearm blood flow also increased in a recumbent subject on raising the legs. This had been shown to be mediated by the sympathetic and took place in the muscles. It was due to variation in vasoconstrictor tone.

Professor W. D. M. PATON (London) discussed ganglion-blocking agents and their effects on the blood vessels. They reduced autonomic activity and caused little change in blood flow. In contrast, in shock and haemorrhage, there was sympathetic overactivity, capillary damage, and a diminution in blood flow, leading to irreversible shock. The autonomic reactions in shock could be harmful, and ganglion-blocking agents conferred protection against them. He had also found that the idea of sympathetotonic and parasympathetotonic individuals was a myth. Studying various manifestations of activity in both systems in students, he had found that each person had his own highly specific autonomic pattern—an "autonomic fingerprint." This explained the variability of response of hypertensive patients to ganglion-blocking agents.

Professor J. H. DIBLE (London) dealt with the pathology of obliteration of peripheral vessels. Peripheral ischaemia causing gangrene was rare—the trouble was usually due to atherosclerotic narrowing of the main vessels. Professor Duguid had revived Rokitansky's idea that thrombotic encrustation of vessel walls led to infiltration of the thrombus with lipid, and Professor Dible thought this was often the case.

Professor C. G. ROB (London) discussed the surgery of occlusive vascular disease. He thought surgery was useful only in the minority of cases in which local manifestations were predominant. He had performed direct vascular operations in 38% of diseased aortic and iliac vessels and 15% of femoral vessels. One feature demanding treatment in aortic occlusions was hypertension, which might be due to partial occlusion of a renal artery and could be cured by surgical treatment of the diseased vessel. In some cases aortic or iliac occlusion involved only a small segment—these were very suitable for operation. Gangrene was a strong indication for surgical treatment of the diseased vessel. He gave long-term anticoagulant therapy to all these patients post-operatively. Of 145 cases involving the lower limb, 30 had undergone reconstructive operations and 20 of these were successful. He had also operated on 26 cases of internal carotid occlusion, with 2 deaths. Six were now asymptomatic, and in 13 a good flow had been established.

Concluding Address

The concluding address was given by Sir RUSSELL BRAIN (London). He discussed Harvey as a scientific philosopher, and demonstrated with quotations from his works how much Harvey's thought was ahead of his time, so that contemporary terminology had been inadequate for him. Sir Russell Brain analysed Harvey's profound conception that the microcosm mirrors the macrocosm, explaining that his use of analogy was a current method of reasoning in his time. Finally he compared Harvey with Sherrington. *The Integra-*

ive Action of the Nervous System had close affinities with *De Motu*, and so had *Man on His Nature* with *De Generatione*. Sherrington was a poet, and, although Harvey had not written poetry, nevertheless he still had a poet's delight in words.

During the Congress there were a number of excellent demonstrations on colour television. In the first the uses of dye dilution curves in circulatory studies were shown. The other two dealt respectively with respiratory techniques for investigating the pulmonary circulation, and with the heart-lung machine and cardiac arrest.

Preparations and Appliances

A FOETAL DOLL FOR OBSTETRIC TEACHING

Dr. F. E. HYTEN, Obstetric Medicine Research Unit (Medical Research Council), Midwifery Department, University of Aberdeen, writes: There is a need in obstetric teaching for a realistic foetal doll; ideally, it should look and feel like a real foetus and be capable of no more than the normal

range of body and limb movements. The doll here illustrated has been developed by the Chad Valley Co. to these requirements, in association with this Unit. The basic mould was made in plaster-of-Paris of an anatomically normal 6½-lb. (3,000-g.) stillborn infant. The doll is cast in a firm foam latex and incorporates a metal skeleton and a hard composition skull. Only normal joint movements are possible; for example, the knee cannot be overextended, and manipulative procedures can be accurately demonstrated.

The doll weighs about 1½ lb. (700 g.), and a prototype which has been used extensively for the past six months shows little signs of wear.

The dolls are manufactured by the Chad Valley Co. Ltd., Wellington, Shropshire, price £10 10s. each, or £5 5s. without the metal skeleton.

Nova et Vetera

CENTENARY OF LEPRO HOSPITAL IN BERGEN

The old leper hospital in Bergen having been burnt down on Christmas Eve, 1853, its place was taken by the present building, which opened its doors to its first patient on June 12, 1857. Housing some 270 lepers at a time, and a total of 2,031 in the past hundred years, the number of its inmates is now reduced to 5. Its present chief, Dr. R. Melsom,¹ has celebrated this centenary in a publication in which he has traced the history of his hospital. The two men, Dr. D. C. Danielssen and Dr. Gerhard Henrik Armauer Hansen, who did much for its high reputation were outstanding, forceful personalities. Danielssen, the senior, acquired horrified awe in the minds of his patients by his passion for post-mortem examinations. He was inquisitive also about his patients' reactions in their lifetime, and on several occasions he tried to inoculate himself and members of his staff with leprosy material—always with negative results according to Professor T. M. Vogelsang.² To which Danielssen presumably remarked: "I told you so!" For he regarded leprosy as a non-infectious disease—"hereditary dyscrasia sanguinis." This diagnosis hinged on much laborious pathological and anatomical research, and on quantitative analyses of the albumin and globulin content of the blood of lepers. When Rudolf Virchow visited Bergen in 1859, Danielssen demonstrated the brown nodules which he had learnt to regard as characteristic of leprosy, and which are now known to be conglomerations of leprosy bacilli. Virchow pooch-pooched the notion of some causal relationship, dismissing these nodules as mere clumps of degenerated fat. To his dying day Danielssen fretted over having meekly deferred to the great Virchow on this occasion.

Hansen spotted the unstained bacillus of leprosy in 1873, reporting his discovery at a medical meeting in Oslo in 1874. It was some time later that this bacillus was successfully stained for the first time. Danielssen might well have been forgiven had he resented the refutation of his pet theory by his junior, but as a matter of fact he was furious with Hansen for not having pushed his claim to his discovery with sufficient energy. Hansen also was addicted to incursions into the field of experimental pathology. In 1879, several years after his discovery of the bacillus of leprosy, he attempted to inoculate the eye of a patient suffering from the smooth form of leprosy with material taken from a patient suffering from the nodular form of the disease. The inoculation proved negative as such, but the patient's mental reaction was "markedly emotional." The storm which now blew up was so violent that Hansen was relieved of his appointment as chief of the hospital. But a grateful country refused to dismiss him as the chief medical officer for leprosy for the whole of Norway, and his brief lapse from good taste in the matter of vivisection was well-nigh forgotten when he died in 1912, the acknowledged discoverer for the first time of the microbic origin of a chronic disease.

The Gemmological Society of Great Britain has dedicated a library to the memory of Sir James Walton, F.R.C.S. The library contains some 1,000 volumes on gemstones and minerals; some of the books were previously part of Sir James's library. Sir James Walton, besides being a vice-president of the Royal College of Surgeons, was also an expert on the lattice-structure of minerals and a well-known collector of gemstones.

Correspondence

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

Vaccine Against Poliomyelitis

SIR,—Your issue of June 1 may be kept in gilded covers, for in it the report of the Poliomyelitis Vaccines Committee of the Medical Research Council is published (p. 1271), and, with the cool objectivity of a scientific survey of this nature, the dawn is announced of the day which will see new epidemics of paralytic poliomyelitis no more. Among the 148,684 children from 1 to 9 years of age who received two injections of the British-prepared (Glaxo) vaccine within less than three weeks 2.7 per 100,000 suffered from paralytic poliomyelitis, whereas among the non-vaccinated over 14 per 100,000 were affected.

These figures from the well-planned trial may be compared with those included in the report on the 1956 poliomyelitis outbreak in Chicago¹ submitted by the Chicago Board of Health. Both the British and the Chicago analyses show that no paralytic poliomyelitis occurring in vaccinated children had any connexion with the vaccination, as paralysis did not occur in the inoculated limb. From June 28 to October 4, 1956, Chicago had 1,111 cases of confirmed poliomyelitis of which 835 were paralytic. During the spreading of the epidemic vaccination was intensified, and by the first week of October, of the 1,150,000 children in Chicago up to 19½ years of age, 125,000 had had no inoculations of Salk vaccine, 125,000 had received but one inoculation, 600,000 had had two inoculations, and 300,000 children had received three inoculations. It is impressively convincing of the effectiveness of the vaccine that in the non-vaccinated group of children the paralysis attack rate per 100,000 population was 358.4, in the children who had had one inoculation 154.4, in those who had received two inoculations 14.2, and in the children who had obtained the full course of three injections 0. Even though if not absolutely certain it also appears that the intensive inoculation during the epidemic contributed to the unexpected short duration of the outbreak.

On the basis of these two experiences we seem to be well on the way, given sufficient vaccine, to eradicate the outbreak of the most severe, extensive, and expensive of the crippling diseases. But a serious effort must be made at the present to rescue as many as possible of those who, like the hero in Remarque's famous novel *All Quiet on the Western Front*, may be struck the day the war ended.

As you well said in your leading article of May 25 (p. 1229), until our production of vaccine is sufficient to cover all the urgent requirements, there is certainly a strong argument for importing the best brands of American vaccine if that is possible. If such vaccine was available in sufficient quantity—and I am told that it is—only an unsound financial reason may prevent its importation, but this should not deter the authorities, as if this year we were to have, say, 5,000 paralytic cases without vaccine and only 1,000 after appropriate inoculation, the reduction in expenditure for hospital bed occupation, treatment, and instrumentation will be a profitable investment, as many of these patients cost the taxpayer more than £1,000 each year until they are—if they ever are—beyond the responsibility of the Health Service. After nearly 100,000,000 inoculations without mishap in America and Canada of the Salk vaccine since the Cutter incident, no one could object as to the safety of the American vaccine as prepared by the best drug firms. I do not see any other reason which could be adduced against the immediate use of the American Salk vaccine, as in matters such as these national pride is not involved, the virus being an international aggressor and the vaccine being prepared with the same virus. The only thing which here would be national would be the victims.

Being in daily contact with the present ravages of the disease I have had my grandchildren vaccinated with three inoculations of the American (Parke, Davis) vaccine sent to me by a kind American colleague. It would be dishonest that we, the medical men who know, protected our families and that the bulk of the population was left waiting until enough vaccine is produced in our laboratories. If that was to occur the National Health Service would not be a service but a liability.—I am, etc.,

Oxford.

J. TRUETA.

Choledochoduodenostomy

SIR,—The paper on this subject by Mr. J. P. Hosford (*Journal*, May 25, p. 1202) will be of considerable interest to all those who have to carry out bile duct surgery. It may not be inappropriate, therefore, to consider the history of this operation, and previous experiences of its results. This may serve to emphasize some of the points raised in the paper.

Riedel was probably the first to do the operation (1890). Finsterer¹⁻⁴ in 1952 reported 233 cases where the operation had been carried out, largely for a suppurative cholangitis, or where white bile was present. His immediate mortality was 8%. No ascending infection was observed in any of his cases when followed up from 5 to 25 years. Three were reported not cured and eight had continued "slight" symptoms. In two of the three cases which were not cured, the stoma had become closed. He insisted that troubles arising after this operation were due to a small stoma, which must be bigger than 2 cm. Plenk⁵ reported on 95 cases he had treated privately, with one post-operative death. Seventy-one of these cases had a frankly purulent cholangitis. He also described 293 hospital cases and he states that no case of ascending cholangitis had been encountered in any of these. He said that purulent cholangitis would be cured if the stoma was large enough, as the most important thing was drainage. Becker,⁶ in reporting a number of other cases, put forward the theory that purulent cholangitis is not an ascending infection, but descending, and that all such cases were rapidly improved when the bile could escape freely into the duodenal lumen. Waltman Walters⁷ states that in choledochoduodenal anastomosis cholangitis is not the result of duodenal reflux into the biliary tract. Recurring pain, with or without jaundice, chills, or fever are the result of varying degrees of obstruction at the anastomosis. Kjaergaard⁸ carried out the operation for 12 cases of the "post-cholecystectomy syndrome," where severe colic, in the absence of common duct stone, occurred after cholecystectomy. Six of them were much improved, and none had any complications from the operation.

Professor Milnes Walker first called my attention to the possibilities of this operation in 1947, since when I have carried it out in 31 cases. I have followed up another 19 cases, with the kind permission of surgeons in this area. The only case where there has been evidence of cholangitis is one where a stoma of 1 cm. in size was made. Apart from this case, all have a patent stoma as shown by barium meal, or by gas in the biliary tree. In some cases considerable pressure has to be exerted in order to get the barium up the duct. Three cases have persisted with what appears to be biliary pain, and in one of these a small filling defect can be seen on the skiagram—presumably a stone just above the ampulla of Vater. The patient does not wish any further surgery to be done, as the attacks of pain are infrequent and do not seriously inconvenience her.

I have found the results following this operation to be better than those after dilatation of the ampulla, or of transduodenal section of the sphincter—i.e., internal choledochoduodenostomy. The anastomosis should never be done unless the common bile duct is obviously dilated, and the best results will occur where the wall is thickened and white in colour. It has been my practice to fold back the duodenum covering the common bile duct until pancreatic tissue is

reached, in order to divide the common bile duct as low as possible. The stoma should be at least an inch (2.5 cm.) in size, and so far I have not had any biliary leak. The gallbladder, of course, must always be removed. The pressure in the common bile duct even after cholecystectomy is much higher than that in the duodenum, and it is probable that there is no reflux of food through the stoma under ordinary conditions. This is in contradistinction to a cholecysto-gastrostomy, where pieces of food debris have not infrequently been found in the gallbladder at a later operation. A small but definite percentage of these biliary cases have an achlorhydria,¹⁰ so it must not be presumed that the duodenal contents are necessarily sterile. One of my cases developed a severe infective hepatitis; it is problematical whether this was due to the degree of ascending infection or was merely fortuitous.

In any biliary operation it is impossible to draw firm conclusions until many years have passed, but from my observations it does appear that the operation may be of real value in cases of common duct stones, especially if a purulent cholangitis or any degree of stenosis is present, or if the pancreas is harder than normal. The convalescence in these cases is surprisingly rapid. I must thank a number of surgeons in this area who have permitted me to review their cases.—I am, etc.,

Bristol.

SIR,—Mr. John Hosford (*Journal*, May 25, p. 1202) advocates this operation for stones in the common bile duct under certain circumstances, and records his experience in 21 cases. Some years ago I took a similar view, and I expressed it in a Hunterian lecture at the Royal College of Surgeons in 1940, by which time I had carried out the operation 17 times. I also thought that the regurgitation of duodenal contents into the biliary tree, which could be demonstrated by x-ray examination, was a matter of no importance in the presence of free drainage through the choledochoduodenostomy. As time went on I began to see these patients returning with attacks of fever, rigors, and transient jaundice, and I came to the conclusion that recurrent cholangitis occurred too frequently to make the operation one to carry out except under very exceptional circumstances. I also think that a widespread adoption of this procedure would result in an increased operative mortality, although the rate is low in Mr. Hosford's capable hands. If the operation is to be done I agree that the opening should be reasonably large, and to achieve this I made an oblique opening in the duct.

In the last five years I have performed this operation only once, and I have relied on careful exploration, washing out the duct, and drainage as a routine for stones whether multiple, recurrent, or associated with infection.—I am, etc.,

Leeds.

DIGBY CHAMBERLAIN.

Examination of Immigrants

SIR,—I regret that my work often entails delayed contact with the *Journal*. In "Medical Notes in Parliament" (*Journal*, April 6, p. 826) under the heading "Tuberculosis Among Immigrants," it is reported that Mr. T. Iremonger (Ilford, North) asked what examination of immigrants into the United Kingdom was made to determine whether they were suffering from tuberculosis or other communicable diseases. I was astonished at the reply as reported in the paragraph.

Mr. J. K. Vaughan-Morgan, Parliamentary Secretary, replied (I quote the *Journal*) that "any alien immigrant might be subjected to a general medical examination before

he was permitted to land. Where tuberculosis was suspected in any person, British or alien, coming to this country the port medical officer notified the medical officer of health of the district to which the person was proceeding, so that he might be brought under observation. The port medical officer had power to examine any person if he had reason to think he was suffering from any other infectious disease, apart from venereal disease."

It is impossible to accept such a reply, for, although each statement may be theoretically true, it has no relation whatever to actual practice. The port medical officer receives from the ship surgeon a notification of all readily diagnosable infectious diseases, and an occasional doubtful one, but when it is considered that the ship surgeon sees only a small proportion of the passengers, and the port health officer none at all (other than those above drawn to his attention), there can be no reason for suspicion, and indeed no chance of it. As a surgeon for more than eight years on ships bringing to one of our largest ports thousands of passengers annually, I have, to the best of my recollection, called attention to one case only, that of an Indian woman who had phthisis, and knew it. The surgeon, and through him the port officer, were the last persons she would wish to see but that she became afraid of continued and serious haemoptysis. One crew member also had a haemoptysis, and was sent home at the beginning of the voyage. In effect, as I have seen it, there is no check whatever.

Many countries, including Commonwealth countries, insist that, for certain types of immigrant at least, there must be produced a chest x-ray film and report before they will be at all considered as immigrants. There can be no doubt that, while we are attempting to stamp out the disease, we are allowing into the country fresh centres of infection; we have been informed also that in certain parts of the country, probably due to immigration, there has been a remarkable increase in venereal diseases.

All this tempts one to a comment on a broader situation with which every ship surgeon of experience will be familiar. A considerable number of visitors, often from countries better off financially than our own, and however welcome, "save up" operations, chronic ailments, dentures, appliances, etc., for payment, in whole or in part, by the British taxpayer. This same taxpayer is informed on high authority that he cannot afford luxuries; he can see also for himself that he can scarcely afford the present, even underpaid, Health Service. In the light of this it might be well to consider that, while liberality is a fine quality, a man whose family is on the verge of want deserves no credit for scattering largesse on the broad highway.—I am, etc.,

Sutton, Surrey.

JNO. CRAWFORD.

Thrombocytopenic Purpura Following Quinidine

SIR,—The report of a case of thrombocytopenia due to quinidine by Drs. Stanford Bourne and Denis J. O'Sullivan (*Journal*, May 4, p. 1046) prompts us to place on record a further case.

A man of 55 had been suffering for many years from occasional attacks of paroxysmal auricular fibrillation. He had taken quinidine intermittently for six years. An attack developed on April 8, 1957, and clinically he appeared to have auricular fibrillation. He was given phenobarbitone 1 gr. (65 mg.) that night and the attack had subsided by morning. He was advised to take regular prophylactic quinidine, and on April 10 he took quinidine hydrochloride 3 gr. (0.2 g.) at 9 a.m. Later that morning he went by car to Cambridge, where he became ill with nausea and shivering. At 1 p.m. his temperature was 101° F. (38.3° C.) and he was admitted to hospital. No abnormal physical signs were found. His temperature was normal the next day and he was discharged. It was considered possible that this attack was due to quinidine, and he took no further dose until April 15, when he was given ½ gr. (32 mg.). He took the same dose the next morning with no ill effect. He took nothing on April 17, but on April 18 took 1 gr. (65 mg.). He was well in the morning and played golf but developed

shivering and nausea in the afternoon and his temperature rose to 102° F. (38.9° C.). He sweated that night, and, because of headache, took 7½ gr. (0.5 g.) of aspirin. The next morning he awoke to find blood in his mouth and a rash on his body. On examination there were large haemorrhagic vesicles on the tongue and palate and numerous petechial spots on the trunk and limbs. He was afebrile.

He was admitted to the West Suffolk General Hospital. His blood count was normal, but the platelets numbered 140,000 per c.mm.; bleeding-time 21 minutes (Ivy); clotting-time 14 minutes (modified Lee and White). The following day the platelet count had fallen to 52,000, but no fresh lesions had appeared and the oral lesions were resolving. The purpura gradually cleared without specific treatment. On the fourth day the platelets numbered 51,000, and the next day had risen to 112,000. By the seventh day the platelet count was normal, 276,000 per c.mm. Clinically, he appeared to have made a complete recovery and he was discharged from hospital.

This case is of interest because the patient had taken quinidine intermittently for six years before becoming sensitized to the drug, and because of the extremely small dose, 1 gr. (65 mg.), which precipitated thrombocytopenic purpura.—We are, etc.,

R. ARDEN JONES.

K. M. MACKENZIE.

Bury St. Edmunds, Suffolk.

Women's Footwear

SIR,—I could not agree more with Mr. Reginald T. Payne's letter (*Journal*, May 18, p. 1180) on women's footwear and its appalling effects. Why we should have to give these wretched sufferers free treatment for their feet in the future I cannot see. I suggest that the B.M.A. draw the attention of Her Majesty's Government to the position forthwith. We should be able to save much more than the cost of one requested increase in pay by so doing.—I am, etc.,

London, N.1.

MARGARET O. THORPE.

SIR,—The trouble with women's shoes is twofold: (1) the high heel; (2) the short, narrow toe, with the point opposite the third toe, resembling a gothic arch, and so cut that there is not room enough between the sole and the upper. The consequences are that the body weight falls on the metatarsal heads, normal movements of the knee, ankle, and foot are abolished, and the foot slides on a more or less steep slope down into the toe of the shoe; the anterior arch spreads and becomes convex downwards, the great toe is pushed into the valgus position and the smaller toes are crowded together into an ungainly heap, and all the extensor tendons become contracted. Furthermore, though a woman would not be surprised at her waist measurement increasing as years go by, few in my experience change the size they buy in shoes. It is quite common to find that if you run a pencil round the stockinged foot you can stand the shoe inside the outline. It is quite true that it is difficult to buy shoes for women which do not grossly deform the foot, but the blame for that does not lie wholly with the makers—the customer must bear her share.—I am, etc.,

Hove.

C. M. OTTLEY.

Myringoplast

SIR,—With the advent of tympano-plastic procedures, the treatment of chronic suppurative conditions of the ear has entered on a new and exciting era. New instruments for these procedures are being designed. The myringoplast designed by Dr. R. France Rohan (*Journal*, May 25, p. 1240) is one of these. It is an ingenious device for putting a patch on the drumhead for testing purposes. Perhaps it would have been more comfortable to use if the trigger were below, rather than above, the shaft. Dr. Rohan is correct in his criticism of the acoustic probe. It is uncomfortable for the patient, takes up too much time, and the results have to be very carefully assessed.

A plaque of moistened cotton-wool applied to the drum-head to close the perforation will quickly demonstrate the improvement in hearing. In cases where the drum is completely destroyed, the effect of baffling the round window is easily tested by occluding the round window niche with a small ball of moist cotton-wool. A thin sheet of moistened wool placed to cover the whole middle ear and the baffle already in position in contact with the remains of the malleus, or in contact with the head of the stapes, will imitate the operative methods that are used. If the hearing improvement is definite and clear cut, operation and the operative procedure are demonstrated.—I am, etc.,

Liverpool.

G. A. MOULDEN.

The H-bomb

SIR,—The views expressed by Mr. Norman Capener (*Journal*, May 25, p. 1246) deserve the utmost support. Despite the number of important leading articles and annotations in the *B.M.J.* and *Lancet* underlining the hazards arising from the continued testing of nuclear weapons, the medical profession has been slow to take action on this issue. This may in part be due, as he suggests, to a certain reluctance to adopt an attitude in opposition to official Government policy. Nevertheless the possibility that disease may be caused by radioactive fall-out is surely a matter of very proper concern to doctors. For those of us who take leave to differ from Lord Cherwell's assumption that war becomes less likely when the great powers are brandishing H-bombs at one another, our responsibility is clear: we must do all we can to prevent further tests by any Government in any part of the world.—I am, etc.,

Bristol.

ALLAN HULME.

Slippery Hospital Floors

SIR,—As one who has recently become dependent on walking-sticks, I have come to realize how slippery are most hospital floors. The polished linoleum in the wards forms quite the most treacherous walking surface which one normally encounters. I trust hospital furnishers will bear this in mind.—I am, etc.,

Cambridge.

R. A. SPALDING.

Acute Immediate Reactions to Penicillin

SIR,—Having read Dr. M. O. Raven's letter (*Journal*, June 1, p. 1305) I should like to say that I entirely agree with his remarks on the subcutaneous injection of crystalline penicillin. I have used his method for the past 6½ years, and so far have not seen any reaction. I employ a No. 1 hypodermic needle for injecting into and withdrawing from the vial, and then change to a No. 18 for the actual injection, which is done so quickly that the patient barely notices it.—I am, etc.,

Broadstairs.

CASSIE E. WILLIAMS.

Allergic Response to Hyaluronidase

SIR,—The letters from your correspondents Dr. P. J. Joubert (*Journal*, January 5, p. 46) and Dr. Kathleen Barber (*Journal*, January 19, p. 166), reporting allergic reactions to hyaluronidase injection in two patients, have prompted me to review the toxic effects observed following 4,800 injections of this substance given to out-patients at Guy's Hospital over the past three years. These injections were given for a variety of skeleto-muscular disorders by intra- and per-articular, intramuscular, and subcutaneous injections; in each case 1,000 units of hyaluronidase were combined with either hydrocortisone, 2% procaine, or normal saline. The incidence of side-effects was remarkably low apart from the occurrence of local sepsis, with which hyaluronidase cannot be implicated. There were three cases of urticaria, one case of purpura, and one of bronchospasm associated with itching of the scalp and oedema of the eyelids. This latter appears

similar to the event reported by Dr. Joubert, but the symptoms were of far less severity than in his case.

Holborow and Keech¹ showed that, although hypersensitivity developed rapidly in their patients subjected to repeated hyaluronidase administration, this sensitivity could probably be ascribed to the protein impurities in the enzyme preparations used by them. Certainly, many hundreds of cases in the present series have been subjected to repeated injection with a very pure preparation of hyaluronidase and this hypersensitivity has not been observed. Is it not possible in such combined injections that the active agent introduced with the hyaluronidase has had an antigenic effect? Seifter,² after repeatedly administering doses of 200,000 times the maximum therapeutic dose of hyaluronidase, observed no signs of local or systemic injury and concluded that it was a non-toxic material.

While I agree with Dr. Barber that there is possibly a danger of severe reaction from this agent, and this must be constantly borne in mind, it would seem that the incidence of 0.09% of allergic side-effects seen in this series is so small that it should not be regarded as a deterrent to the use of so valuable a therapeutic agent.—I am, etc.,

P. HUME KENDALL.

London, S.E.1.

Myeloblastic Anaemia Following Chloramphenicol

SIR,—We have read with interest the medical memorandum by Dr. P. S. Mukherji (*Journal*, June 1, p. 1286) in which it is suggested that an acute myeloblastic leukaemia was caused by chloramphenicol therapy. In our opinion this is another example of the tendency to incriminate chloramphenicol as a toxic agent on the flimsiest of circumstantial evidence.

The case report shows that the patient's haemoglobin level fell from 94% in September, 1953, to 74% in August, 1954, before chloramphenicol had ever been given. Surely this is of some significance in the absence of demonstrable haemorrhage? Further, there is no record of a full blood examination having been made in October, 1954, when the haemoglobin was 72% pre-operatively. The marked drop in the haemoglobin level post-operatively was presumably largely the result of haemorrhage. The reasons for administering chloramphenicol post-operatively are not given. We would prefer to assume that this patient was suffering from some form of blood disorder for at least one year prior to the operation, which merely precipitated his inevitable end. In any case, it would seem unwise to administer chloramphenicol to a patient already suffering from an undiagnosed anaemia. Should this anaemia worsen following chloramphenicol therapy, it is still unjustifiable to attribute the ultimate diagnosis of acute myeloblastic leukaemia to this therapy.

On the author's own admission, the possibility of the condition existing prior to the administration of chloramphenicol cannot be excluded. In British justice, any element of doubt regarding the guilt of a criminal compels a verdict of "Not guilty," which we feel should apply in this case.—We are, etc.,

J. MCC. MURDOCH.
A. H. IOANNIDIS.

Edinburgh, 3.

Pseudomonas pyocyanea in Cetrimide

SIR,—With regard to Dr. G. L. Robinson's letter (*Journal*, May 25, p. 1242) the difficulty is easily resolved. Some 30 years ago I began to use 1% acriflavine (now proflavine) in substitution for tincture of iodine (the solubility is not quite so great but near enough). I have never found this "irritating." The water in this area is apt to be very hard at times. A few years ago, finding the flavine solution did not "run" into the skin, I mixed it in equal parts from a bottle of 1% cetrimide ("cetavlon") near by. This makes a very elegant preparation of low viscosity, very agreeable to the skin, and presumably it would be very disagreeable

to the *Pseudomonas*. It will also clear up a pyoderma and is very useful in prophylaxis and treatment of varicose veins of the leg liable to phlebitis. I have found cetrimide cream 1% very good for the gravitational ulcer itself.—I am, etc.,

Dagenham, Essex.

M. MELGRAVE.

Hospital Confinement

SIR,—Some people may find it a little difficult to decide from Mr. F. E. Stabler's admirably terse letter (*Journal*, May 18, p. 1182) whether or not he is in favour of continuing with some measure of domiciliary confinement. Aware of the immense success of the Newcastle experiment begun about 20 years ago, and since embodied in what later became known throughout the country as the "obstetric flying squad," it may be presumed that he is still lending the weight of his authority as a teacher and examiner in favour of its continuation. I doubt if Dr. J. P. O'Dwyer (*Journal*, April 20, p. 947) will be able, readily, to produce the facts on which his comparatively innocuous statement was made, though with much effort he might be able to present "irrefutable statistical evidence," nowadays almost synonymous with facts.

Conditioned by many years of propaganda from various sources, if for no other reasons, the parturient now seems to favour hospital confinement. In the Liverpool region the percentage of these confinements to total births varies from 60% to 90%. Clearly this is a matter that must to some extent be permitted to sort itself out. It can scarcely be doubted that the next generation of obstetricians, both practitioner and consultant, will have come to regard a fully institutionalized maternity service as a commonplace.—I am, etc.,

Liverpool, 1.

H. VINCENT CORBETT.

Fish in Wards

SIR,—I should like to support Dr. Alexander Watt (*Journal*, May 18, p. 1182) in his rejection of budgerigars as ward pets. Their noise may be a "cheerful chatter" to the fit, but it can be a "non-stop, nerve-fraying racket" to a sick person. A well-set-up and efficiently lighted tropical aquarium is the best type of ward pet, being colourful and decorative to the women patients, and interesting to the men, most of whom have tried keeping fish at some time or other. Regular servicing is, however, necessary to keep a tropical aquarium at its best, and if the hospital finance committee will not pass the necessary sum to pay a professional retainer, then the secretary of the local aquatic society should be contacted. Usually such a society will be only too pleased to arrange a rota of "expert" amateurs who will call in and attend to the aquarium and who will replace any casualties with their own surplus fish.—I am, etc.,

London, W.C.1.

C. V. WESTON.
Assistant Secretary,
The Tail-walkers' Club (Great Britain) Ltd.

Range of Movement of Testicle

SIR,—Mr. Denis Browne (*Journal*, May 18, p. 1165) is, I suggest, a little hard on the professors of anatomy who have not incorporated all his ideas into their teaching. When so many dissenting voices were raised in answer to his views¹ anatomists might be permitted to consider the matter themselves, and, like Mr. Browne's surgical colleagues, make up their own minds on a controversial matter.

Although I would agree with Mr. Browne that the normal adult testis will rarely, if ever, pass through the normal external inguinal ring, I would not agree with him in the case of the pre-pubertal testis. I have passed histologically normal testes through the external ring quite easily at necropsy and also at operation. In the correspondence following Mr. Browne's paper Mr. John Hosford² stated that the testis can be drawn into the inguinal canal and shown to be there at operation, a fact that Mr. Browne admitted in

certain cases. It is not sufficient therefore merely to say that "the normal testicle is far too big to go into the normal external ring at any age," implying that it goes instead into the "superficial inguinal pouch" in all cases of physiological retraction.

We know, therefore, that in some cases the pre-pubertal testis will pass from the scrotum into the inguinal canal, and there is no reason to doubt (as Mr. Browne does) that this is due to the activity of the cremaster muscles. If the cremaster muscles can carry the testis into the "superficial inguinal pouch" with the power suggested in Mr. Baty's paper,³ and with which Mr. Browne seems in full agreement, I see no reason why these muscles (in view of their morphology) should not be even more effective at bringing the testis at least to the external ring, if not through it. The medial and lateral cremasters of man do not run down directly to the testis as in ungulates, but encircle the testis, ending in a dorsal raphe much as they do in rodents. In rodents the cremasters can be shown to squeeze the testis into the inguinal canal, and the mechanism seems to be basically the same in man, though the human muscles are less powerful. Needless to say, the cremasters are often too weak to do this in man, especially when the medial cremaster is absent.

The question of withdrawal of the testis during sexual excitement is well enough known. Seiler⁴ described it and considered it in relation to the cremaster muscles in his work on the descent of the testis. It is probably simply a manifestation of testicular withdrawal during emotional stress—e.g., fright, or a doctor's cold hands.

If the testis will not pass through the external inguinal ring, it does come to lie outside the external oblique aponeurosis in the position indicated by Mr. Browne and called by him the "superficial inguinal pouch." The attachment of Scarpa's fascia to the external inguinal ring is firm except in the supero-lateral quadrant, where it is loose. Naturally, as this fascial laxity is in the line of the ascending testis, the testis tends to bulge into this loose fascia and to give the impression of a pouch. But Scarpa's fascia is attached to the margins of the ring, so that the "pouch" has no mouth and its extent would be very difficult to delineate. It would be much more accurate to avoid the term "pouch" and to describe a region of loose attachment of Scarpa's fascia to the external inguinal ring.—I am, etc.,

London, W.C.2.

Prevention of Recurrences of Rheumatic Fever

SIR,—In their article "Prevention of Recurrences of Rheumatic Fever" (*Journal*, May 25, p. 1234), Dr. E. G. L. Bywaters and his colleagues draw attention to the comparative cost of the daily administration of a number of penicillin and sulphonamide preparations. Crystalline penicillin G in a dosage of 200,000 units twice daily is compared with phenoxymethyl penicillin (penicillin V) 120 mg., twice daily. It has been demonstrated by a number of investigators who have contributed to the extensive literature on penicillin V that considerably higher blood levels result from its use than from an equivalent dose of penicillin G by mouth. These findings are supported by cumulative urinary excretion levels. I do not wish to occupy your space by quoting a lengthy bibliography, but there is much evidence to show that 120 mg. of penicillin V may be expected to give blood and urinary excretion levels approximately double those following the administration of 200,000 units of penicillin G by mouth.—I am, etc.,

London, S.W.3.

C. N. BROWN.

Gonadal Dysgenesis

SIR,—I am greatly interested by the paper of Drs. R. Hoffenberg and W. P. U. Jackson (*Journal*, June 1, p. 1281) in which they describe a female patient with gonadal dysgenesis resembling in many ways the two patients I reported in 1955,¹ and in which they comment on my description of these two patients as "male pseudohermaphrodites" of a

"hitherto undescribed form." I find their conclusion that my patients were also examples—albeit unusual variants—of the gonadal dysgenesis syndrome entirely reasonable; though perhaps I might be pardoned for feeling that the tone of their paper is just a little hypercritical. Moreover, I think that their genetic hypothesis to account for the syndrome and for male pseudohermaphroditism is a very valuable suggestion.

It might well be argued that the matter of terminology is not one of great importance, since male pseudohermaphrodites of the classical varieties and male examples of the gonadal dysgenesis syndrome are all varieties of intersex males. Furthermore, in their genetic scheme, Hoffenberg and Jackson regard the type of patient which they and I described as due to gene "1" (the gene for intrauterine hypogonadism) acting alone, and male pseudohermaphroditism as due to the same genetic situation. By their own scheme, therefore, they class male pseudohermaphrodites and this variety of the gonadal dysgenesis syndrome together—though obviously this is true only for the male patients in the latter group.

The description of genetic females with the same features as those of the genetic males which I reported undoubtedly makes a term which will include both more desirable than one which is applicable to one sex only. And if only the histology of the gonads of my patients were known, it might indeed leave no alternative but to regard them as belonging to the gonadal dysgenesis group. Therefore, while I feel I do not need to apologize for having described my patients as male pseudohermaphrodites, I am entirely willing to concede the point of view expressed by Drs. Hoffenberg and Jackson in their excellent paper.—I am, etc.,

London, W.C.1.

Intestinal Lipodystrophy

SIR,—In your annotation (*Journal*, April 27, p. 998) on Whipple's disease (intestinal lipodystrophy) you direct attention to the possible susceptibility of this condition to steroids and you stress the role of mesenteric node biopsy in diagnosis. The presence of characteristic lesions in extra-abdominal nodes has been reported by several writers since Korsch first described them in 1938.¹ Writing in 1955 Puite and Tesluk² confirmed the presence of Schiff-positive macrophages in peripheral nodes in three cases of the disorder. It is of further interest that this paper suggests a possible familial element in the aetiology, with an apparent predilection for males.—I am, etc.,

Detroit, Michigan, U.S.A.

William Harvey

SIR,—I feel this is a fitting time to write regarding my investigations into the paternal ancestry of Dr. William Harvey whose tricentenary celebrations are now taking place. There is little doubt his family originated in the county of Lincoln. Although universally accepted as belonging to an old Kentish race, no evidence has ever been produced supporting this theory. From my personal researches during the past twelve years it would appear his father, Thomas Harvey, was a son of a certain William Harvey or Harby, yeoman at Thurlby, near Bourne, Co. Lincs. This family was descended from Sir Bryan de Hardeby of Evedon, who married Avicia, daughter and heiress of Sir Hugo de Sancto Vedasto, feudal Lord of Evedon in 1283. Sir Hugo was of pure Norman noble descent. Dr. William would probably inherit his olivaster complexion through this ancestry. As my investigations are still continuing, I would appreciate any help from others interested in Dr. William Harvey.—I am, etc.,

Rutherglen, Glasgow.

ARTHUR JAMIESON.

Obituary

G. F. BUCHAN, M.D., F.R.C.P., D.P.H.

Dr. G. F. Buchan, formerly medical officer of health for the Borough of Willesden, died at his home there on June 3 at the age of 78. He was for many years one of the most prominent workers in the public health service.

George Frederick Buchan was born at Kilmaurs, near Kilmarnock, on November 18, 1878, the son of Dr. George Buchan. As a student at Glasgow University he had a brilliant career, gathering award after award, including the first prize in natural philosophy, the prize in mathematics, the junior Arnott prize, the Alexander Donaldson scholarship, the James A. Paterson bursary, the Joseph Black medal in chemistry, and the William Hunter medal in medical jurisprudence and public health. He graduated M.B., Ch.B. in 1901, with distinctions in several subjects, including clinical medicine. With a career in preventive medicine in view, he took the Cambridge D.P.H. in 1902, and then worked for a time in infectious diseases hospitals in London under the old Metropolitan Asylums Board. Moving to Birmingham, he was appointed assistant medical officer of health under Sir John Robertson, and later he held a similar post under the Essex County Council. In 1909 he was appointed medical officer of health and school medical officer of Heston and Isleworth.

Buchan began his career at Willesden in 1912, when he became medical officer of health there, and he held the post for the long period of thirty-five years. During that time he was the inspiration behind many new developments in the work of the public health department, and his fame as a leading worker in the field of preventive medicine attracted foreign visitors to Willesden to find out at first hand how he put his methods into practice. He was an excellent teacher, and lectured on public health at Guy's Hospital and St. Mary's Hospital medical schools and at the London School of Hygiene and Tropical Medicine. Many who took the D.P.H. at that school will remember George Buchan's enthusiastic demonstrations of field work in Willesden. He himself examined for the D.P.H. of the London Conjoint Board and in State medicine and in hygiene and forensic medicine for London University. Elected a Member of the Royal College of Physicians of London in 1927, he became a Fellow of the College six years later.

The Society of Medical Officers of Health owed a great deal to Buchan, who became a member in 1908. Within four years he was elected honorary secretary of the Home Counties branch and to the council of the society. He was honorary treasurer of the society from 1919 to 1946, except for the session 1925-6 when he was president, and in 1946 he became the first chairman of the council. To him must go a great deal of the credit for the great increase in the membership of the society during the years he was treasurer. He took a leading part in the campaign for adequate salaries for medical officers of health, and he did much to bring about the Askwith agreement of 1929. The society's memorandum on local government areas, adopted by the society in 1932, was largely a product of his brain. He received the honorary fellowship of the society in 1947: he was also an honorary fellow of both the American and

(Elliott & Fry)

Canadian Public Health Associations. A vice-president of the Royal Sanitary Institute (now the Royal Society for Health), he had served on its council, of which for a time he was chairman.

A member of the British Medical Association for over forty-five years, Buchan was a member of the Council from 1924 to 1930 and a representative at the Annual Representative Meetings from 1942 to 1951. For varying periods since 1919 he had served on a remarkably large number of committees, including the maternity and child welfare subcommittee (1919-39); the public health committee (1924-50); the special committee on Poor Law reform (1925-9); the advisory committee on the salaries of whole-time public health medical officers (1932-40); the nutrition committees (1933-4 and 1947-51); the negotiating committee (1944-9); and the compensation and superannuation committee (1944-52). He was a prominent member of the Medical Planning Commission, which issued an interim report in 1942. When the Association held its Annual Meeting at Edinburgh in 1927 he served as a vice-president of the Section of Preventive Medicine, and he was president of the same Section at Cambridge in 1948. In the days before the second world war he was a member of the Advisory Committee on Nutrition, and in more recent years he was chairman of the Central Middlesex Group Hospital Management Committee.

Dr. George Buchan is survived by his wife and daughter, and by his brother, Dr. John J. Buchan, formerly medical officer of health of the city of Bradford.

Dr. F. HALL writes: When a great and loved headmaster dies, his passing gives a feeling of personal loss to all who have benefited from his administration. It is in this sense that the public health service and especially the Society of Medical Officers of Health mourns the death of George Frederick Buchan. In the service to which he devoted his professional career he was an outstanding figure, and "Buchan of Willesden" was long recognized as an authority on all matters pertaining to the public health, for in this field of work he attained a national eminence noted for his practical knowledge and discerning judgment. Valuable as his services have been to Willesden and indirectly to the nation, it is as a member of the Society of Medical Officers of Health that his memory will be long preserved. For many years he was a trusted leader, and both as president and as chairman of council guided the policy of the Society and at all times maintained its prestige and authority. Of commanding presence and forceful in debate, he brought to bear the critical powers of a brilliant intellect on an immense number of subjects which came before that body, and by his detailed work in the various committees was the main author of numerous memoranda which were submitted to the Ministry of Health and other Government departments.

What honours the Society could confer were gladly bestowed on George Buchan, for all who worked with him recognized that no personal considerations prevented him from stating, forcibly, what he believed to be in the interests of the public health and of the Society, which to him existed only for the promotion of the public health. Older members of the Society will remember him in this character of a strong yet courteous personality, winnowing the wheat from the chaff of verbiage in documents official and unofficial, and presenting the results in clear and practical terms. He will also be remembered for his qualities of friendship; he was a fine character, a man good to know, and the Society has lost one of its most famous members.

Sir COURTENAY MANIFOLD, K.C.B., C.M.G.
M.B., C.M.

Sir Courtenay Manifold, who had had a distinguished career in the Indian Medical Service, both in the field and as an administrator, died at Kyrenia, Cyprus, on June 7. He was 93 years of age.

Courtenay Clarke Manifold was born at Sitapur, India, on April 3, 1864, the second son of Surgeon-General M. F.

JUNE 15, 1957

OBITUARY

BRITISH
MEDICAL JOURNAL 1423

Manifold, who died in 1897, and was educated at Clifton College and at Edinburgh University, where he graduated M.B., C.M. in 1886. He entered the Indian Medical Service in the following year and was attached to the Central India Horse until 1893. During the subsequent six years he was in charge of the medical administration of Rampur State, except for an interval in 1897, when he was on active service in the Tirah campaign. For his work in the campaign he was mentioned in dispatches and awarded the medal and clasp. In 1899 he was sent on a mission to Western China and for his services received the thanks of the Commander-in-Chief in India. He was again on active service as a member of the headquarters staff at the relief of Peking in 1900, being mentioned in dispatches and receiving the medal and clasp, as well as special promotion to the rank of lieutenant-colonel. Another mission into Central and Western China in 1900-1 earned him the thanks of Lord Kitchener. In 1903 he was awarded the MacGregor silver memorial medal, being the only medical officer up to that time to receive the distinction, which was given annually for good work in exploration. In 1904-5 he was in command of a special mission to Tsu-chuan and again he received official thanks for his work. Papers describing the results of his explorations in China were published by the Royal Geographical Society.

From 1910 to 1915 Manifold was Inspector-General of Civil Hospitals in the United Provinces and a member of the Legislative Council. He was appointed C.B. in the 1914 Birthday Honours. During the first world war he was Director of Medical Services of the 1st Australian and New Zealand Army Corps, and was appointed C.M.G. in 1917 for services rendered in connexion with military operations in the field. In 1918 he became Director of Medical Services at Anzac headquarters in France. In the same year he was appointed Honorary Physician to the King, and had the Belgian Croix de Guerre conferred upon him for distinguished service during the campaign. During the war he was also twice mentioned in dispatches. He retired from the I.M.S. in 1923 with the rank of major-general, having been promoted K.C.B. in the previous year. The Secretary of State for India approved the grant to him of a Good Service Medal in 1930.

After retirement Manifold lived at various places abroad until he settled at Kyrenia, in Cyprus, in 1935. A member of the British Medical Association since 1891, he was president of the Cyprus Branch in 1936-7. During the second world war he served as deputy commissioner for Cyprus for the War Organization of the British Red Cross and the Order of St. John. He was twice married: first, in 1904, to Miss Josephine B. Montagu, who died in 1941, and, secondly, in 1944, to Miss Christine F. Scott.

ARTHUR ZANKER, M.D.

Dr. Arthur Zanker, who died suddenly at his Croydon home on April 30 at the age of 66, was the physician in charge of the Croydon child guidance clinic and a medical officer at Warlingham Park Hospital, the parent hospital of the unit.

Arthur Zanker was born at Bohumin in Czechoslovakia (at that time part of Austria) on July 22, 1890, and studied medicine in Vienna, where he graduated M.D. in 1914. Almost at once he was called into the Austrian Army Medical Service and in 1915 was captured by the Russians. Then followed three years of captivity, during which he was moved from one camp to another before he was finally sent to a typhus-fever camp in Siberia. Throughout his imprisonment he continued his medical work, and with the aid of the Swedish Red Cross he was able to get away from the Russians, taking with him the invalid soldiers under his care.

In Vienna, after the war, Dr. Zanker turned to paediatrics and by 1923 was established as a specialist, with an appointment at the Mutterberatungsstelle (child welfare

centre). He was now a pupil of Alfred Adler and worked voluntarily at the *Erziehungsberatungsstelle*, a clinic devoted to the guidance of maladjusted children. He contributed two chapters to Adler's book, *Guiding the Child*, in addition to contributions to the medical press. In 1938 he was forbidden by the Nazis to practise in Austria, and his appointments were terminated. He was able to come to England with his wife and daughter in 1939 through the intervention of an acquaintance living in Croydon and then settled in the borough with his family.

As soon as he was given permission to resume his medical work Dr. Zanker became attached to the Warlingham Park Hospital. His skill with children was quickly recognized and gradually his duties became more and more in the child guidance clinic, although he never discontinued his work with adult patients, in particular with the elderly. He was a pioneer of music therapy for the mentally ill, publishing many papers on that subject, as well as on psychiatric problems of old age and those associated with spastic children. He formed the social club for elderly ex-patients and conducted the patients' choir and instigated its orchestra. Outside the hospital his interests included music and poetry. He was an accomplished performer on the violin and viola and had been a member of the Croydon Philharmonic Orchestra. He also translated the works of Keats and Shakespeare into his native language, and collected anthologies of his own verse have been published in Austria, where even now one volume is in print.

He was a skilled child psychiatrist, a musician of some standing, and a poet of far more than usual talent, and yet it will not be chiefly for these qualities that he will be remembered by his friends, colleagues, and patients. Everyone who came into contact with him was touched by his overwhelming kindness. He was surely a man who would "turn the other cheek" whatever hardship he endured, he never bore malice nor spoke a cross word, and his modesty and quite unassuming goodness were outstanding characteristics in one who had endured so much and lost so much. He would often talk to his friends about his native land and of his early life, but always he saw the good in life and tried to minimize or excuse the bad. Of his capture by the Russians he used to describe the confiscation of his own fine chestnut horse and remarked on how well the Russians looked after it. In an appreciation broadcast by the Austrian programme of the B.B.C. on May 3 the author quoted Zanker's own prophetic words from one of his writings many years ago. "As a young doctor," he wrote, "I was always struck, on leaving the hospital at night, how abrupt could be the meeting of life and death." He married in 1923, and his wife survives him with their only daughter.

Medical Notes in Parliament

NUCLEAR FALL-OUT

A short statement by the PRIME MINISTER about the British nuclear explosion in the Pacific on May 31 set off another disturbance in the Commons on June 4. Mr. MACMILLAN said (as he had done of the first explosion) that the fall-out was insignificant. Mr. H. GAITSKELL, Leader of the Opposition, directed attention to the reported protest of 2,000 U.S. scientists as showing the real concern felt in informed quarters about the danger of the continuation of these tests. Mr. MACMILLAN replied that the reports did not show that the scientists' appeal was supported by any new evidence. The Government, he said, had made proposals for a method by which these tests could be limited or controlled, and they were also ready and anxious to discuss from the most favourable point of view any other proposals that might develop during the deliberations of the Disarmament Subcommittee.

Mr. ANEURIN BEVAN (Ebbw Vale, Lab.) provoked the Prime Minister's resentment by an interjection, "Don't be

so bloodthirsty," which he threw at Conservative members who voiced their dissent from his assertion that there was universal agreement that some deaths would be caused by these tests. Mr. MACMILLAN dismissed as "unlikely" and "impossible" the hypothesis that new nations would embark on tests before the British series was finished; and Mr. BEVAN in turn derided this as nonsense.

Mr. J. STRACHEY (Dundee, West, Lab.) took up the point about there being no new evidence in the U.S. scientists' appeal, and asked, "Is the Prime Minister really telling us that new evidence is necessary before we even support the all-round abolition of tests by all countries?" Mr. MACMILLAN: "I think that new evidence is necessary before I altogether overthrow the evidence given to me by the greatest experts in the country, who serve all Governments in turn."

M.R.C. Assurance

Rejecting two other suggestions that the effect of radioactive fall-out on health and genetics should be investigated by a royal commission or a select committee, Mr. MACMILLAN said that the Medical Research Council was the best instrument at the Government's command. Mr. GAITSKELL asked when the House might expect a further report from the council. Mr. MACMILLAN repeated his previous statements that he was considering that. He pointed out that the council had a number of standing committees which advised it on particular parts of the subject. Every item of new evidence that came to hand was considered by the committees and by individual experts advising the council, as well as by the council's officers. He was informed that the result of this continuous process of review was to make the council confident that there was as yet no new evidence that would lead to a modification in any respect of the conclusions in their published report. The council had, however, assured him that if and when important new evidence became available it would make immediate arrangements for calling the whole council and making a similar review as was made before.

Test of Samples

Mr. F. ALLAUN (Salford, East, Lab.) asked on June 5 for tests to be made by the Medical Research Council of the degree of rate of fall-out of strontium-90 in Lancashire, because of the heavy rainfall and the density of population there. Mr. DUNCAN SANDYS, Minister of Defence, replying for the Prime Minister, stated that the Medical Research Council was obtaining samples of soil, vegetation, milk, and bone from widely distributed parts of the country; and their content of radio-strontium was being analysed. The choice of the particular sites was a matter for expert decision, and would be designed to give a representative indication of levels in the United Kingdom. The results would be published.

Influenza in Asia

Sir FRANK MEDLICOTT (Norfolk, Central, Nat. Lib. and Con.) asked the Minister of Health on June 5 what steps were being taken to deal with the possibility that the new form of influenza raging in the Far East might spread to Europe and reach Great Britain. Mr. D. VOSPER stated that the outbreaks of influenza in the East were being caused by a new variant of the virus, but all reports were that the illness was clinically mild in character. There were standing arrangements for information to be supplied about outbreaks of influenza in this country through general practitioners, industrial medical officers, and others, and port medical officers reported epidemic influenza among persons arriving in this country. As a precaution, practitioners were being reminded of these arrangements. The characteristics of this new strain of virus were being investigated at the World Influenza Centre and in other research departments.

Tuberculosis in Hong Kong

Mr. S. AWBERY (Bristol, Central, Lab.) was informed by Mr. J. PROFUMO, Under Secretary for the Colonies, that 12,000 cases of tuberculosis were notified in Hong Kong in 1956, and it was believed that rather more than this number were treated privately without official notification. Examinations of employed adults showed that roughly 2% had the disease actively. Treatment of cases during 1956 included 456,000 attendances at Government clinics. With the opening of a new hospital on June 6 there would be 1,440 beds for tubercular patients; 29,000 persons received B.C.G. vaccination in 1956; 131,000 persons were rehoused in 1956, and it was estimated that nearly 110,000 more would be rehoused this year.

Leprosy

Dr. BARNET STROSS (Stoke-on-Trent, Central, Lab.) asked the Minister of Health on June 3 for a statement on the work conducted by the World Health Organization towards the eradication of leprosy. Mr. J. K. VAUGHAN-MORGAN, Parliamentary Secretary, stated that the Organization's programme and regular budgets for 1957 and 1958 provided for assistance to leprosy control in several countries. The Director-General had recently reported on improved prospects for control with the use of sulphone drugs, but had pointed out that many technical problems remained. The money available to the Organization, and its general activities, were determined by member countries at the World Health Assembly.

Dr. STROSS asked what would be the approximate cost of sulphone drugs required for the treatment of a case of leprosy for a period of two years. Mr. VAUGHAN-MORGAN said that, if given in tablet form, it would be about 12s. If given by injection the cost would be at least 50% more. Dr. STROSS commented that the Government should, as in the past, set an example to other member countries and find as much finance as possible so that everyone would be able to get treatment. Mr. VAUGHAN-MORGAN pointed out that there were other diseases with which the World Health Organization had to deal. They should leave it to the Organization to work out the priorities.

Nerve Gas Antidote

Mr. PHILIP NOEL-BAKER (Derby, South, Lab.) asked the Minister of Supply whether his department had found an antidote to the group of poison gases known as nerve gases or "tabun." Mr. AUBREY JONES stated that an antidote was available to protect against moderate doses of nerve gases. Considerable progress had been made towards finding an antidote which was effective against more severe doses.

Local Co-operation

Sir KEITH JOSEPH (Leeds, North-east, Con.) asked whether the Minister of Health would consider asking the Central Health Services Council to review the subject of co-operation between hospital, local authority, and general practitioner services, on which they reported to him in 1952, in the light of subsequent developments. Mr. VOSPER replied that a number of committees had studied the subject since 1952, notably the Guillebaud Committee, which reported last year. Although he had this subject very much in mind, he was reluctant to ask the Central Health Services Council to make yet another review. Sir KEITH JOSEPH asked if the Minister was satisfied that co-operation between the various bodies gave the best service conceivable to the public. Mr. VOSPER said he was by no means satisfied that the highest possible degree of co-operation had been reached. He thought it was more a matter of the attitude of mind of those concerned than a need for new machinery.

Prescription Costs Inquiry

The committee to investigate prescription costs has been established. The chairman is Sir HENRY HINCHLIFFE, a

governor of Manchester University and a member of the management committee of St. Mary's Hospital, Manchester. He is a former president of the Association of British Chambers of Commerce, and was a member of the Advisory Council of the Department of Scientific and Industrial Research from 1949 to 1954. The other members are:

Dr. WILLIAM BROCKBANK, honorary physician, Manchester Royal Infirmary; dean of clinical studies and lecturer in medicine, Manchester University. Dr. K. E. CAPPER, editor, *British Pharmaceutical Codex*; joint secretary, National Formulary Committee. Dr. H. C. FAULKNER, member of General Medical Services Committee of B.M.A.; assistant M.O.H., London County Council. Dr. F. E. GOULD, member of G.M.S. Committee; secretary, Birmingham Local Medical Committee. Dr. D. V. HUBBLE, physician, Derby Royal Infirmary. Professor C. A. KEELE, professor of pharmacology and therapeutics, London University. Professor M. G. KENDALL, professor of statistics, London University. Dr. A. M. MAIDEN, a rural practitioner; member of G.M.S. Committee; honorary secretary, Lincolnshire (Lindsey) Local Medical Committee. Dr. A. D. STOKER, a rural practitioner; member of G.M.S. Committee; secretary, Derby Local Medical Committee. Professor A. P. THOMSON, dean of faculty of medicine, professor of therapeutics, Birmingham University. One appointment is outstanding, and will be filled by another general practitioner, probably from Wales.

The Minister of Health, announcing these names on June 7, stated also the terms of reference, which are: "Having regard to the increased cost of prescriptions in the National Health Service, to investigate the factors contributing to this cost, and to make recommendations."

Rehabilitation and Re-employment

The House of Commons, before adjourning for Whitsun, discussed briefly the training and resettlement of disabled persons, and multiple sclerosis.

Sir KEITH JOSEPH (Leeds, North-east, Con.), dealing with the first of these subjects, drew attention to the large gap between the ability of a man to return to work after rehabilitation and the availability of work for him.

Mr. ROBERT CARR, Parliamentary Secretary, Ministry of Labour and National Service (Mitcham, Con.), said the Government welcomed the report of the Percy Committee on this subject and intended to press on wherever possible with the implementation of their recommendations. The Minister of Health would shortly be sending out advice to the hospital authorities on these matters, and would be asking them to consider the committee's recommendation for a rehabilitation committee to be set up by each hospital board to further the suggestions the report made. Another recommendation that would be taken up would be the setting up in every major hospital of a resettlement clinic to review difficult cases of disablement. The Government proposed to accept a recommendation suggesting that the minimum age for industrial rehabilitation should be reduced from 16 to school-leaving age. The committee's recommendations about district rehabilitation officers had also been accepted, and plans were being worked out for a longer initial training period, which it was hoped would be a substantial increase over the present period. The Government regarded the Percy Committee's report as an important and valuable one, and, subject to the needs of economy, they intended to maintain the progress already made in the six months since its publication.

Multiple Sclerosis

Mr. D. KEENAN (Nottingham, South, Con.) raised the subject of multiple sclerosis. Mr. J. K. VAUGHAN-MORGAN, Parliamentary Secretary, Ministry of Health, who replied on this, said there were about 1,500 deaths a year due to either multiple sclerosis or its complications, but so far the cause of the disease was entirely unknown. Much was being done under the auspices of the Medical Research Council and otherwise to try to find the cause. Social and geographical studies had suggested there was a variance in the incidence of the disease, but the reason was not known. Fortunately

there was no change in the incidence in recent years; it was not increasing, but it was not diminishing. The main effort was being concentrated on fundamental work in shedding more light on the nature and causes of the form of degeneration of the nervous system which led to the appearance of symptoms in this disease. The need for further research was fully realized, but the intractable nature of the problem rather than the lack of funds hampered progress at present; it was lack of bright ideas, and not cash, which was holding back progress.

Health Records.—The statistical branch of the Ministry of Health has been increased, and is carrying out an extensive review and reorganization of records and returns with a view to providing a speedier and fuller service.

Electricity Accidents.—There were 39 fatal electrical accidents in 1955, and 55 in 1956.

Ionizing Radiations.—A Code of Practice for the protection of all hospital workers exposed to ionizing radiations has been prepared by the Radioactive Substances Advisory Committee and will be published shortly.

Vital Statistics

Week Ending June 1

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 691, whooping-cough 1,807, diphtheria 1, measles 21,613, acute pneumonia 320, acute poliomyelitis 67, dysentery 740, paratyphoid fever 9, and typhoid fever 6.

Infectious Diseases

The largest variations in the notifications of infectious diseases in England and Wales during the week ending May 25 were increases of 2,848 for measles, from 16,665 to 19,513, and 23 for dysentery, from 750 to 773, and decreases of 239 for whooping-cough, from 2,258 to 2,019, 63 for food-poisoning, from 226 to 163, and 46 for scarlet fever, from 664 to 618.

52 cases of acute poliomyelitis were notified during the week, and these were 18 fewer for paralytic and 4 more for non-paralytic cases than in the preceding week. The largest returns were Essex 10 (Lexden and Winstree R.D. 4, Colchester M.B. 3), London 9 (Wandsworth 3), and Gloucestershire 7 (Bristol C.B. 7).

Increases in the number of notifications of measles of 100 or more were reported from 17 counties; the largest rise was 371 in Warwickshire, from 1,352 to 1,723. Towns with large rises in the notifications of measles included 267 in Birmingham C.B., from 694 to 961, 116 in Swindon M.B., from 69 to 185, 114 in Bristol C.B., from 263 to 377, 114 in Sheffield C.B., from 324 to 438, and 92 in Woolwich, from 51 to 143; the largest falls in the towns were 135 in Leeds C.B., from 328 to 193, and 81 in Birkenhead C.B., from 111 to 30. Only small variations were recorded in the local trends of scarlet fever. The largest falls in the incidence of whooping-cough were 42 in Glamorganshire, from 71 to 29, 33 in Hertfordshire, from 90 to 57, and 33 in Lancashire, from 213 to 180. 3 cases of diphtheria were notified, 1 fewer than in the preceding week, and 2 of these cases were notified in Liverpool C.B.

The chief centres of dysentery were Lancashire 153 (Fylde R.D. 49, Manchester C.B. 21, Blackburn C.B. 13, Blackpool C.B. 13, Liverpool C.B. 10), Yorkshire West Riding 141 (Bradford C.B. 25, Leeds C.B. 23, Sheffield C.B. 21, York C.B. 16), London 77 (Bethnal Green 42), Yorkshire East Riding 47 (Kingston upon Hull C.B. 33), Cheshire 41 (Dukinfield M.B. 13), Northumberland 36 (Newcastle upon Tyne C.B. 17), Durham 33 (South Shields C.B. 13, Warwickshire 29 (Birmingham C.B. 17), Nottinghamshire 25 (Nottingham C.B. 18), Bedfordshire 22 (Bedford M.B. 17), and Shropshire 20 (Oswestry R.D. 14).

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1948-56 are shown thus -----, the figures for 1957 -----. Except for the curves showing notifications in 1957, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

INFECTIOUS DISEASES AND VITAL STATISTICS
Summary for British Isles for week ending May 25 (No. 21) and corresponding week 1956.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenza pneumonia.
§ Includes puerperal pyrexia.

Medical News

Harvey Congress Banquet.—Sir HENRY DALE, O.M., proposed the toast "The Harvey Tercentenary Congress" at the banquet held last week. He congratulated the organizers on the brilliant success of the occasion. Harvey, said Sir Henry, had early become a member of what was then the fully international community of science. This was the third tercentenary commemoration of Harvey and his work to be held in his, Sir Henry's, lifetime. The first, when he was 3 years old, was in 1878, at Folkestone, when Sir Richard Owen unveiled the statue of Harvey in that town: to celebrate the three hundredth anniversary of his birth. At that time there still seemed to be a wide breach between the experimental and practical aspects of medicine which had only just begun to show signs of closing at the end of the nineteenth century when he, Sir Henry, as a student entered the wards of St. Bartholomew's Hospital. When the Royal College of Physicians commemorated the tercentenary of *De Motu Cordis*, there were already signs of a notable change. "And now in this present, third commemorative congress, we find ourselves faced with what I suppose we imagine to be a pretty full development of the scientific age of both medicine and surgery." Physicians and surgeons were using the latest resources of experimental science to make their work ever more certain and effective, to the very great benefit of their patients. After the President of the Congress, Mr. A. DICKSON WRIGHT, had responded, Professor ROBERT PLATT, president of the Royal College of Physicians, proposed the health of the visitors, and the LORD CHANCELLOR replied.

Harvey Congress at Folkestone.—On Saturday and Sunday the Harvey Tercentenary Congress moved to Folkestone. William Harvey's birthplace, for the conclusion of its commemorations. On the Saturday morning Sir GEOFFREY KEYNES presided over a symposium in the Leas Cliff Hall at which seven speakers discoursed on Harvey's birthplace, Harvey at Cambridge and Padua, Harvey's influence on French medicine, and "Harvey the Scientist." In the afternoon there was a special service at Canterbury Cathedral, at which the address was given by the headmaster of the King's School, Canterbury. In the evening, by courtesy of the civic authorities and Messrs. Pfizer Ltd., a banquet in Elizabethan style was held at the Hotel Metropole. Royal sturgeon and swab pie were the chief dishes, and madrigals or "chaunts" were sung by the Pfizer singers. Sir GEOFFREY KEYNES proposed the toast of "Folkestone," the Mayor, Councillor L. VICTOR FOWLER, responding. Professor D. M. DUNLOP had the task of proposing "William Harvey" and Mr. A. DICKSON WRIGHT, the Congress president, replied. On the Sunday, Matins was held at Folkestone parish church and afterwards there was a civic procession to Harvey's statue.

Harveian Society of London.—The Harveian Society of London welcomed many guests from Britain and abroad at the Buckston Browne-Gray Hill reception held on June 6 in Gray's Inn Hall. Mr. and Mrs. A. DICKSON WRIGHT received the guests, who enjoyed the privilege of being entertained in the stately and beautiful sixteenth-century hall, now restored after being nearly destroyed by bombs. Music played during the reception was by sixteenth- and seventeenth-century composers.

B.E.L.R.A.—The annual meeting of the British Empire Leprosy Relief Association was held at the Colonial Office on June 4, and was followed immediately by an extraordinary general meeting at which it was resolved to drop the word "Empire" from the association's title. After Sir ALAN BURNS, the chairman, had moved the adoption of the annual report, the association's new medical secretary, Dr. J. ROSS INNES, spoke of his experiences in the field, "An idea has grown up," he said, "that the leprosarium should

be abolished, and that we should turn our backs on it and put all our efforts into out-patient and home segregation work. I wish to state from my experience abroad that this is nonsense." It was a mistake to rely too much on the sulphone drugs, Dr. Innes continued; all public health measures, from leprosarium to teaching and propaganda, were needed to conquer leprosy. More full-time doctors, nurses, laboratory workers, and others were still wanted. Last year, according to the report, B.E.L.R.A. had 29 overseas workers, who included one doctor and seven nurses, and for the first time the association's income exceeded £100,000. The main fields of the association's activity were Nigeria, Tanganyika, and Uganda.

Berkeley Castle Portrait.—Above, by kind permission of the owner, Captain R. G. BERKELEY, we reproduce the portrait of William Harvey from Berkeley Castle. The portrait was brought to light recently by Dr. STUART W. HINDS, of the London School of Hygiene and Tropical Medicine, and was shown publicly for the first time at the Harvey Tercentenary Congress in London last week (see this *Journal*, June 8, p. 1358). As yet the authenticity of the portrait remains to be established. It bears the inscription "Doctor Harvey famous phisition that found out ye circulation of the blood." Dr. Hinds, with the collaboration of Dr. J. R. BROWN of the London School of Hygiene and Tropical Medicine, is submitting the picture to scientific examination and making other inquiries about it. When these investigations are complete they hope to publish their findings.

Storage of Poliomyelitis Vaccine.—Messrs. Glaxo Laboratories Ltd. now state that their poliomyelitis vaccine ("poli-virin") will remain potent for six months if stored properly. The previous limit was four months. Although storage in a refrigerator is necessary, the range of temperature in a properly regulated domestic refrigerator (2-10° C.—36-50° F.) has been found satisfactory for the purpose. Exposure to higher temperature for a few hours during an immunization session or during transit is not harmful, though temperatures over 20° C. (68° F.) should be avoided, as also should exposure to sunlight.

Lord Adrian Elected.—On June 8, Lord ADRIAN, O.M., Master of Trinity College, was elected Vice-chancellor of Cambridge University for the academic year 1957-8.

B.M.A. Film Index.—The catalogue of the Association's film library is now available in the form of a card index. It comprises 166 cards, with guide cards. Each card gives a brief synopsis of a film, an appraisal, and an indication of the type of audience for which the film is suitable. In addition, the titles of 153 other films still available from the film library are listed. As new films are added to the Library, supplementary cards, up to twenty in number, will be issued free of charge to all holders of the index. The price of the index is 15s. (post free), and a cardboard container for it is available at 4s. The index and container are obtainable on application to the Secretary of the Association, B.M.A. House.

United Hospitals Choir.—This choir, previously known as the United Hospitals' Festival Choir, is pursuing a new policy. Most of the large teaching hospitals have formed their own music societies, so the choir now intends to provide mainly for those medical and hospital personnel in London with no facilities of this sort—for example, those working in the smaller hospitals and general medical and dental practitioners and their staffs. A good proportion of the choir's membership continues to be drawn, however, from among the students and nurses of the big hospitals. Musically it has been decided not to concentrate so exclusively on a small handful of over-exploited favourites. A recent performance of Mozart's Requiem Mass has encouraged the choir to prepare choral and orchestral works by Purcell, Britten, Schubert, and Handel. The first concert will take place in October. The choir rehearses on Thursday evenings from 7.30 to 10 p.m. at a school in Soho. Further details may be obtained from the secretary, Miss J. MAGRATH, 18, West Side, Clapham Common, London, S.W.4.

Index Ophthalmologicus.—A new edition of the *Index Ophthalmologicus*, which includes a world list of ophthalmologists, will be issued on the occasion of the Eighteenth International Congress of Ophthalmology in Brussels next year. Any ophthalmologist in Great Britain or Northern Ireland who is not a member of the Faculty of Ophthalmologists or of the Ophthalmological Society of the United Kingdom, and who wishes to have his name included in the list, is asked to communicate with the hon. secretary, Ophthalmological Society of the United Kingdom, 45, Lincoln's Inn Fields, London, W.C.2, before July 31.

M.R.C.O.G.—At a council meeting of the Royal College of Obstetricians and Gynaecologists on May 25 the following were admitted members: D. C. Aird, G. B. Batchelor, R. A. T. Boland, G. D. D. Cable, M. I. Cassimjee, J. S. W. Chambers, P. K. Choudhuri, C. A. B. Clemetson, K. I. Digwood, A. Freier, W. J. Garrett, W. Gault, W. Gavin, L. Goldman, C. J. Goosen, B. Kirsch, M. A. Lakeman, E. W. Lillie, H. H. McCrostie, J. G. Markus, A. E. B. Matthews, T. T. E. Michael, A. B. Miller, A. K. Mitra, J. M. B. Muirhead, A. C. C. Pinion, L. J. Rice, R. Richards, T. J. Ryan, G. J. W. Stump, S. M. Thanevela, K. F. G. Wilson, and R. Yule.

London University.—At the Foundation Day ceremony on November 22 Sir CHARLES LOVATT EVANS, F.R.S., formerly Jodrell professor of physiology at University College, London, and now an emeritus professor of the University, is to receive the honorary degree of Doctor of Laws. The title of university reader in histochemistry has been conferred on Dr. A. G. E. PEARSE in respect of his post at the Postgraduate Medical School of London.

Aviation Medicine Award.—Colonel J. P. STAPP, a physician of the U.S. Army Air Force, has received the first Liljencrantz Medal, an annual award for outstanding research into medical aspects of acceleration and high altitude flight. The medal, presented by the Pfizer Laboratories, was awarded by the U.S. Aero Medical Association. Colonel Stapp rode a rocket-powered sled in which he decelerated from 632 m.p.h. to a full stop in 1.4 seconds, thus subjecting himself to a force 40 times greater than the pull of gravity.

COMING EVENTS

Symposium on Mucoproteins.—Joint meeting of the Association of Clinical Biochemists and the Biochemical Society, June 29, 11 a.m., Royal Victoria Infirmary, Newcastle upon Tyne.

Institute of Dermatology.—Course for general practitioners, particularly for those working in dermatological clinics, September 16 to 20. Apply before July 8 to the dean, Institute of Dermatology, St. John's Hospital, Lisle Street, London, W.C.2.

Autoradiographic Techniques.—Short courses for biologists at the Atomic Energy Research Establishment, Harwell, July 22–26. Details from the Isotope School, Atomic Energy Research Establishment, Harwell, near Didcot, Berks. Fee £10 (excluding accommodation).

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, June 17

● INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—3 p.m., Professor W. C. W. Nixon: Disordered Uterine Action. 4.30 p.m., Professor J. Walker: Foetal Anoxia.
LIVERPOOL UNIVERSITY: FACULTY OF MEDICINE.—At Surgery Theatre, Old Medical School, 5.15 p.m., Professor E. Sachs (Washington): Sir Victor Horsley—Pioneer of Neurosurgery.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Dr. William Evans: Pulmonary Heart Disease.

Tuesday, June 18

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. H. T. H. Wilson: Erythroderma.
SOUTH-WEST LONDON MEDICAL SOCIETY.—At Bolinebroke Hospital, Wandsworth Common, S.W., 8.30 p.m., Dr. J. C. McI. Matheson: Prisons.

Wednesday, June 19

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. A. Tickner: Epidermal Proteins.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. R. V. Gibson: Pulmonary Heart Disease.

Thursday, June 20

HYPNOTHERAPY GROUP.—At Royal Society of Medicine, 8 p.m., Brains Trust. Question Master, Mr. E. E. Wookey, L.D.S.; Members, Drs. George Newbold, Denys Kelsey, Gordon Davies, and Gordon Ambrose.
INSTITUTE OF NEUROLOGY.—5.30 p.m., Professor Kendall B. Corbin (U.S.A.): Analysis of 100 Cases of Protruded Cervical Disks with Compression of a Single Root.

LONDON JEWISH HOSPITAL MEDICAL SOCIETY.—At Medical Society of Aspects of Treatment of Rheumatoid Arthritis.
NORTH-EAST LONDON CLINICAL SOCIETY.—At Prince of Wales's General Hospital, Tottenham, N., 2.30 p.m., summer meeting.

NUFFIELD ORTHOPAEDIC CENTRE.—At Wingfield-Morris Orthopaedic Hospital, 8.30 p.m., Mr. H. Jackson Burrows: West Indian Orthopaedics from the Touchline.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.—7.30 p.m., annual general meeting. Talk by Dr. A. J. Haddow: Work of the Virus Research Institute at Entebbe.

Friday, June 21

● INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. F. R. Bettley: clinical demonstration.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. Philip Ellman: clinical demonstration.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—10 a.m., Mr. G. H. MacNab: Intestinal Obstruction in the Neonatal Period. 4 p.m., Dr. M. Thompson: Principles and Practice in the Management of Rheumatoid Disease.

ROYAL SOCIETY OF HEALTH.—At Guildhall, Cambridge, 10.30 a.m., Dr. A. G. Kitchell, Ph.D.: Nature of the Agents which Attack Food: With Special Reference to Meat; Mr. W. M. Whiteman, M.A.: Caravan Users and Their Needs.
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Institute Theatre, 5 p.m., Sir Heneage Ogilvie: Shock.

BIRTHS, MARRIAGES, AND DEATHS

DEATHS

Bulleid.—On May 26, 1957, at Guy's Hospital, London, S.E., Arthur Bulleid, M.R.C.S., L.R.C.P., F.D.S.
Gaffney.—On May 24, 1957, at his home, Ashleworth, Gloucester, Edward James Gaffney, M.R.C.S., L.R.C.P., L.D.S., late of Streatham, London, S.W., aged 80.
James.—On May 26, 1957, at South Perth, Western Australia, Geoffrey Alfred James, M.D., D.C.H., aged 37.
Jones.—On May 27, 1957, at Wrexham War Memorial Hospital, Gladys Mary Thurlow Jones, M.R.C.S., L.R.C.P., of Glanrhyd, Llanelli, Dolgellay, Merionethshire.
Mulligan.—On May 22, 1957, at Golden Acre, Wvndham Road, Walford, Hants, Ulrick John Gordon Mulligan, M.B., B.Ch.
Ponton.—On May 25, 1957, John Alfred William Ponton, M.D., of "Sunnymede," Bude, Cornwall.
Rossiter.—On May 27, 1957, at "The Hawthorns," Sea View Road, Sunderland, Co. Durham, Charles Benjamin Rossiter, M.D., F.R.C.S. Ed., late of Auckland, New Zealand.
Routledge.—On May 25, 1957, at Huddersfield, Yorks, Agnes Petrina Routledge, M.B., Ch.B., of Port William, Wigtownshire, aged 61.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Do Corpses Sink or Float?

Q.—What determines whether a body floats or sinks after drowning? Is it true that it generally sinks, but comes to the surface again after about a week?

A.—The specific gravity of the human body approximates to that of fresh water. Water itself forms almost 75% by weight of the human body. Fat is the lightest constituent and bone the heaviest. A living person can float in fresh water with his lungs expanded but will sink on expiration; in sea-water, which has a specific gravity of 1026, the same person will float irrespective of the state of the lungs. The balance between floating and sinking is obviously delicate, and the amount of air trapped into the voluminous clothing of a fat woman has been known to keep her afloat in sea-water, though dead, for 45 minutes.

Persons dying from shock of immersion where the lungs are not waterlogged will tend to float immediately. It is generally true, however, that drowned bodies tend to sink after a few minutes owing to the displacement of the air in the lungs by water. The development of gases of decomposition cause the body to rise again. The time taken for a body to float after submersion depends on the speed of putrefaction. This in turn will depend on a variety of causes, e.g., temperature of the water, purity of the water, post-mortem injuries by passing craft, etc. The temperature of the water varies with the time of the year and the tide, if any. The purity of the water will depend on whether it is stagnant (a rarity) or contaminated by sewage or effluent from factories. Such contamination is particularly marked in estuaries such as the Thames below Teddington. Post-mortem injuries from the propellers of passing craft or from barges settling down at low tide will generally accelerate decomposition. The time taken for a body to float in sea-water is difficult to assess, since such bodies are generally washed ashore. In the brackish waters of estuaries in summer weather bodies will often come to the surface in two or three days, but in winter it is more usual for them to remain submerged for two or three weeks. In the purer water of rivers, lakes, and gravel pits bodies commonly remain submerged for a week in hot weather, but may remain below the surface as long as six weeks in the depth of winter.

Timing of Intravenous Ergometrine

Q.—Should intravenous ergometrine be given before or after the expulsion of the placenta? If before, precisely when?

A.—If ergometrine is given before the delivery of the placenta it is best given intravenously in a dose of 0.5 mg. either as the head is crowned and about to be delivered, or with the delivery of the anterior shoulder. In the writer's view, the former is better. The delivery of the trunk should then not be hurried, the theoretical idea being that strong retraction of the uterus separates the placenta, which passes into the lower segment and through the cervix, following the foetal buttocks so closely that it is not trapped by the contracting cervix. Once the baby is born and the cord divided, the placenta is then immediately delivered by cord traction aided by suprapubic (rather than fundal) pressure. Sometimes it is better to lift the fundus upwards off the placenta rather than to press downwards with the abdominal hand. The effect of ergometrine given intravenously is short-lived, so once the placenta is delivered a further 0.5 mg. should be given intramuscularly to avoid delayed post-partum haemorrhage.

By this technique the incidence of third-stage and post-partum haemorrhage is reduced to one-tenth of that which is unavoidable if an oxytocic is given only after the delivery of the placenta. Many obstetricians, however, do not adopt the new method because they fear that the placenta may be imprisoned within the uterus. This fear is misplaced; at least no reported controlled series of cases shows that the giving of ergometrine increases the need for manual removal of the placenta. Nevertheless, if the technique is to work well, it does need accurate timing, and this means that, in addition to the accoucheur, there must be present someone who can give an intravenous injection. It is a method which is not suitable for the single-handed obstetrician.

Opinion and practice still vary a good deal, but even those obstetricians who do not give ergometrine as a routine at the end of the second stage of labour agree that it should be used in those cases in which the patient is delivered under general anaesthesia, and in those in which there is some other reason for believing that the occurrence of third-stage or post-partum haemorrhage is more likely than usual. It may be added that those obstetricians who work without an expert assistant sometimes resort to giving ergometrine (with or without hyaluronidase) intramuscularly at the end of the second stage of labour. This is not so efficient as giving it intravenously.

Treatment of Lichen Planus

Q.—What is currently regarded as the most useful treatment for lichen planus? Have there been any recent advances in our understanding of this condition?

A.—Until recently most dermatologists gave arsenic or mercury by the mouth in the treatment of lichen planus. However, the recent work of P. D. Samman¹ has cast considerable doubt on the efficacy of this treatment. He followed cases of lichen planus over a long period and was unable to show any difference between those that were treated with these drugs and those that received no internal treatment. For this reason many dermatologists are now inclined to give no internal treatment for this condition.

It is generally agreed that local treatment makes little difference except for the relief of irritation. For this purpose anti-pruritic creams or lotions are prescribed if irritation is troublesome. They probably have no curative effect.

In the worst cases, systemic treatment with steroids may be given.² A short course of ten or fourteen days will often completely remove the eruption and relapse is not usual. This treatment is reserved for the worst cases, since it usually requires admission to hospital and is of course subject to the usual reservations attendant upon steroid therapy in general.

Our understanding of lichen planus has not improved.

Reliability of Paul-Bunnell Test

Q.—Under what circumstances may the Paul-Bunnell test prove misleading? Is it possible to get a false positive in leukaemia or other conditions if the serum is absorbed by guinea-pig kidney and ox red cells?

A.—Although it is generally held that, in the absence of serum sickness, the presence of agglutinins for sheep red cells to a titre of 1 in 200 or over is diagnostic of infectious mononucleosis, much confusion can be avoided if the Paul-Bunnell¹ reaction is only regarded as positive if confirmed by the ox red cell and guinea-pig kidney differential absorption test developed by Davidsohn.² If this is always done, not only will the antibodies for sheep red cells that occur in most normal human sera and those arising during the course of serum sickness be easily identified, but it will often be possible to diagnose infectious mononucleosis with confidence when the Paul-Bunnell reaction itself has not reached the arbitrary level of 1 in 200.

There is no evidence, at present, that antibodies characteristic of infectious mononucleosis ever arise during the course of any other disease.³ In fact, if the differential absorption test is always performed the possibility of a false positive result will be limited to those very rare occasions when antibodies persisting from a previously undiagnosed attack of infectious mononucleosis are found for the first time during the investigation of some other condition.

Tumour Differentiation and Infiltration

Q.—Why should an undifferentiated tumour exhibit a greater capacity for infiltration than one that is better differentiated?

A.—The power to infiltrate is related to the average rate of growth of the cells of a tumour—that is, the average number of mitotic divisions which take place in these cells in unit time. If this rate is high there will be no time for the average cell to grow in size and to differentiate between mitoses—that is, the growth rate is inversely proportional to the degree of differentiation observed, and rapid growth is associated with the formation of small cells, all of which are spherical in shape.

A slowly growing tumour tends to be compact, and as it expands it exerts steady, uniform, and increasing pressure on the capillaries and cells of the connective tissue immediately surrounding it. The cells and fibre of this connective tissue die. The connective tissue further away and not subjected to this pressure reacts to the products of autolysis produced in the zone of cell death and a mild inflammatory response is produced. The inflammatory zone is replaced by the formation of granulation tissue in which fibroblasts proliferate and are responsible for the deposition of collagenous connective tissue which eventually forms a capsule. If, however, mitosis is unusually rapid the cell mass is no longer compact and can exert no sustained expansile pressure on the surrounding connective tissue. The protection of a capsule is lost and groups of tumour daughter cells insinuate themselves between the normal cells of the tissue of origin.

Thrombophlebitis Migrans

Q.—What is the modern treatment and prognosis of thrombophlebitis migrans? My patient has the condition in a superficial vein in his thigh.

A.—It is necessary to distinguish between primary idiopathic thrombophlebitis of a single vein and thrombophlebitis migrans, which is essentially recurrent and multiple in distribution. In the first type, which fits the description of the case in question, the prognosis is good, particularly if the vein involved is a superficial one. The treatment is local immobilization by strapping the vein with a strip of elastic adhesive bandage laid along its course, together with ambulation to discourage stasis and thrombosis in deep veins.

In true thrombophlebitis migrans the prognosis is not so good. The limb or life of the patient may be endangered in the severe cases with extensive recurrent involvement of superficial and deep veins. The pathology of the venous lesions is the same as that found in thromboangiitis obliterans, of which it may occasionally be the precursor. Severe cases require treatment in hospital with full anticoagulant treatment under laboratory control. Less severe cases may be treated by support to the limb by elastic stockings or bandages together with anticoagulant treatment of a less intensive kind.

A compromise must be reached between the difficulties of regular laboratory control of blood coagulability and the possibility of reaching dangerously low levels of blood coagulability without it. For this purpose the drug phenylindanedione is useful to maintain a stable reduction in prothrombin percentage over prolonged periods of time. Initiation of treatment with daily doses of 100–150 mg. under laboratory control is best, with later maintenance

on 50–75 mg. daily according to the response. For short periods of intensive therapy a prothrombin percentage of the order of 25% is necessary, but for prolonged treatment somewhat higher levels may have to be accepted.

Garlic in Hypertension

Q.—Does garlic contain any hypotensive substance? I have twice come across patients on the Continent who have reacted favourably to "garlic therapy" for hypertension.

A.—Extracts of garlic are reputed to owe their action to volatile oils containing organic sulphides and allyl aldehyde. These substances in fairly large doses are toxic. With reasonable doses no action leading one to suspect a possible usefulness in hypertension has been described. The use of garlic dates back at least to Culpeper, who described it as "the poor man's treacle, it being a remedy for all diseases and hurts (except those which it does breed)." A feeble fungistatic and bacteriostatic effect by garlic preparations has been demonstrated in recent years. Although it is difficult to exclude some mild hypotensive action, it would be necessary with a disease like hypertension to ensure that evidence for the effectiveness of garlic was carefully controlled by the use of some other inert but equally odoriferous principle.

Sensitivity to Penicillin in Congenital Syphilis

Q.—What course of treatment is advised for a congenitally syphilitic child (now aged 6) who is sensitive to penicillin?

A.—The questioner gives no indication as to symptoms, treatment already administered, or the results of laboratory investigations. Antibiotics other than penicillin have been used successfully in the treatment of syphilis: chlortetracycline, oxytetracycline, chloramphenicol, and erythromycin, for instance, are all effective antisyphilitic agents. A course of oxytetracycline in doses of 60 mg. per kilogramme of body weight daily for ten days is suggested. This should be followed by a ten weeks' course of intramuscular injections of bismuth (injection bismuthi B.P., 1 ml., once a week).

Serological follow-up is essential, and failure of the titre to decrease demands an examination of the cerebrospinal fluid.

Gastric Analysis in Suspected Cancer

Q.—Is the presence or absence of free acid in the gastric juice of any value in the diagnosis of cancer of the stomach?

A.—In established cancer of the stomach x-ray examination, supplemented if necessary by gastroscopy, is so exact as to make other investigations superfluous. In early cancer the findings of gastric analysis are so variable as to be positively misleading. As a diagnostic measure, whether for cancer or other digestive disorders, the test meal technique is quite obsolete and even such modifications as the augmented histamine test have only a limited application.

Correction.—Dr. H. Grundmann, in his letter on acute immediate reactions to penicillin (*Journal*, June 8, p. 1363), in the paragraph referring to experimental salvarsan sensitization, mentions intradermal injection of 1 ml. of a 1:100 solution of a primary non-toxic salvarsan derivative—e.g., myosalvarsan. He should have written 0.1 ml. of a 1:100 solution.

CLAUDE BERNARD AND THE DISCOVERY OF GLYCOGEN

A CENTURY OF RETROSPECT*

BY

F. G. YOUNG, D.Sc., Ph.D., F.R.S.

Department of Biochemistry, University of Cambridge

On March 21, 1857, Claude Bernard communicated to the Société de Biologie in Paris a description of the isolation of glycogen from liver tissue and of the chemical and physical properties of the isolated substance. Two days later he delivered a communication on the same subject to the Académie des Sciences in Paris (Bernard, 1857).

Almost exactly a hundred years afterwards, I believe that it is appropriate to consider once again the significance of Bernard's discovery and to review briefly what has been learned about glycogen since that time. I propose also to outline the observations which led to the discovery of glycogen and the glycogenic function of the liver. I shall recall the heated controversy between Pavy and Bernard, since we can undoubtedly often learn something to-day from the mistakes of the past.

In his excellent biography of Claude Bernard the late Professor J. M. D. Olmsted (1939) states that, according to Bernard's views, carbohydrate is stored as glycogen in the liver (p. 202). This statement is not entirely correct, as I shall hope to show; and because misstatements have been made from time to time about Bernard's views on the significance of liver glycogen I shall quote in a number of instances what Bernard actually wrote. The translations from the French are my own.

When Bernard began his researches on the metabolism of carbohydrate almost nothing was known about the fate of dietary sugar in the animal body. The excretion of glucose in the urine in the disease diabetes mellitus had long been recognized, while in 1826 Tiedemann and Gmelin had found that fermentable sugar is formed from starch during the course of alimentary digestion. But what happened to this sugar was unknown. In agreement with the dominating views put forward by Dumas and others, according to which green plants alone form complex substances while animals always break them down, it was tacitly assumed that sugar was broken down to smaller molecules by the animal body.

Glycogenic Function of the Liver

In his thesis for the Doctorate of Medicine Bernard (1843) describes how cane sugar which is injected into the veins of an animal is eliminated in the urine, whereas preliminary treatment with digestive juices renders

*Based on a lecture given in the University of Cambridge on March 7, 1957.

this sugar capable of complete assimilation in the animal body when it is introduced by this route. This important observation made him decide to find out what happened to the sugar which was absorbed into the blood stream during the normal course of digestion. As he said many years later, he decided to follow the metabolic fate of all absorbed foodstuffs step by step and to study the various transformations which these substances underwent. "I proposed," he wrote, "to apply these methods successively to different substances—the proteins, sugars, and fats. I began with the sugars because their study seemed to me to be the most simple. But this plan of investigation was too big; to-day, after 30 years of research which has not been wholly sterile, I am still engaged in studying the metabolism of the sugars" (Bernard, 1879, pp. 40–41). There are few engaged in original investigation who have not experienced Bernard's feeling that any research problem is too big to be completely solved.

In his thesis for the Doctorate of Science, published in 1853, Bernard wrote: "My aim was to follow closely the sugar, which was absorbed from the food, in its passage along the blood stream first to the liver, then to the lungs, and finally to all the other tissues of the body. I wanted to know if the sugar was destroyed in traversing the liver, which is the first organ through which it passes after being absorbed into the tributaries of the portal vein. For this purpose a dog which had been fed on carbohydrate food for seven days was killed during the digestion of a meal, by section of the spinal bulb. As quickly as possible I opened the thorax and abdomen in order to discover if sugar was present in the blood which had passed through the liver. Now it was easy to show quite clearly that the blood of the hepatic veins, where they joined the inferior vena cava, contained a large amount of glucose" (Bernard, 1853, pp. 10–11). This experiment seemed to indicate that the liver did not absorb or destroy the sugar passing to it in the blood flowing from the gut, but Bernard did not draw this conclusion without further experiment. He decided that he must ascertain whether or not the sugar present in the blood of the hepatic veins was similar to that absorbed from the gut. For this purpose he performed a similar experiment on a dog fed on a diet which consisted of meat only, and which was therefore apparently free from carbohydrate. To his surprise he again found that the blood of the hepatic veins

contained a large amount of sugar, although he was quite unable to detect sugar in the contents of the stomach and intestines. Moreover, he found that the blood of the portal vein contained no sugar before it entered the liver, whereas the blood leaving the liver in the hepatic veins contained much glucose. He therefore concluded that the liver possesses the power to produce sugar. He repeated this type of experiment under all sorts of different conditions but always with the same result—namely, the blood of the hepatic veins was always found to contain an abundance of sugar while that of the portal vein contained none unless the animal had received sugar in its diet.

He found, moreover, that when an animal which had fed on meat alone for two weeks was killed, an aqueous extract made of the liver tissue contained much sugar, although none could be detected in similar extracts made from other organs. By fermentation with yeast, and by means of other tests, the sugar in the extract of the liver was identified as glucose. It was clear, therefore, that sugar could be present in the body when no carbohydrate food was being absorbed and that this sugar was formed by the liver. When, as he wrote in 1853, "sugar is manufactured in the liver, which must therefore be considered as an organ which produces or secretes sugar" (Bernard, 1853, p. 54), he was introducing an important new idea—namely, that substances may be secreted directly into the blood stream. Moreover, the ideas of Dumas, Boussingault, and others that animals always destroy or decompose complex substances had to be modified, since the liver was capable of producing a substance as complex as sugar when this substance was not present in the diet.

Having discovered that glucose could be produced in the body, Bernard abandoned his original intention to investigate the site of destruction of the sugar absorbed as food from the intestine. He set out to discover the origin of the sugar newly formed in the liver.

Discovery of Glycogen

At this time Bernard's estimations of the sugar content of extract of liver tissue were made in duplicate by titration with the copper reagent of Barreswil, a modified Fehling's solution. He relates (Bernard, 1865, pp. 291–295) how one day he was pressed for time and was unable to make his duplicate determinations simultaneously. He made one estimation immediately after the death of an animal and postponed the other until the following day. The second estimation gave a value very much higher than the first, and the difference was so great that Bernard investigated the reason for this discrepancy. Hitherto he had not ascribed significance to the length of time which elapsed between the death of an animal and the determination of the sugar content of the liver tissue. He now found that time was of great importance. Immediately after the death of an animal the liver was found to contain very little sugar, but within only a few minutes the amount of sugar had substantially increased, and at the end of two hours a large quantity had usually made its appearance. By forcibly injecting a current of water through the blood vessels of a freshly excised liver he was able to free the tissues from sugar. When such a washed, sugar-free liver was allowed to remain at a moderate temperature for a few hours large quantities of sugar appeared (Bernard, 1855b). This conclusively showed that the sugar was formed, not from substances in the blood as had previously seemed possible, but from materials in the liver tissue itself.

A cold aqueous extract rapidly made from liver tissue immediately after the death of the animal contained no detectable reducing sugar, but after two days at room tem-

perature much sugar had appeared. If, however, the fresh extract were boiled no sugar subsequently made its appearance. These results and many other similar ones showed that the liver contained an extractable substance which did not give the ordinary tests for reducing sugar but which could give rise to reducing sugar by the action of a "ferment" in the liver (Bernard, 1855a).

The fact that the liver could produce sugar from a substance within itself was published in 1855 by Claude Bernard, but it was not until 1857 that he was able to describe the isolation of the sugar-forming substance, or "la matière glycogène" as he named it.

After Bernard's announcement in 1855 of the ability of the liver to produce sugar, many investigators attempted to isolate the precursor, and it has been claimed that Hensen independently isolated glycogen. Many years later Pflüger repeated Hensen's observations, and concluded that Hensen had in fact obtained a mixture of protein and glycogen, and not pure glycogen. Nevertheless Hensen must be given some credit for his work, although Bernard makes no reference to it in his own writings.

Criticisms of Bernard's Early Experiments

For many years Bernard insisted, in spite of contradiction, that the blood of the portal vein of a dog fed on meat contained no sugar. Among those who disagreed, Figuier was so insistent that a special committee of the Académie des Sciences was set up to report on this important matter of controversy. The committee's report completely vindicated Bernard, agreeing with him that no trace of fermentable sugar was present in the blood of the portal vein of an animal fed on meat. Figuier was unconvinced, however, and he was later joined in his contentions by Chauvau, Pavy, and others. Although in 1859 Bernard was still insisting on his mistaken assertion, I have been unable to find any mention of this point thereafter until he admitted in 1877 that his earlier findings in this respect were incorrect (see Young, 1937).

The young English doctor, Frederick William Pavy, criticized Bernard's experiments on much wider grounds. In 1852 Pavy worked for a year in Bernard's laboratory in Paris, returning to become lecturer in physiology at Guy's Hospital and assistant physician. Pavy was apparently uncertain that in the experiments which he had seen performed in Bernard's laboratory the withdrawal of blood from the dying dog provided material that was characteristic of the conditions in the living animal. When he returned to England he therefore passed a catheter down the jugular vein of the living unanaesthetized dog and withdrew blood from the right heart (Pavy, 1854–5, 1860). His original intention was to investigate the disappearance of the sugar from this blood when it was perfused through the lungs of another animal. He was astonished to find, however, that there was almost no sugar at all present in the blood of the right heart obtained in this manner. He found, however, that if the animal was killed and the blood then collected from the right heart, much sugar was present therein, although sugar could not be detected in the blood obtained from a heart which had been rapidly removed from the living animal. Pavy then began to suspect that the production of sugar by the liver might be a post-mortem phenomenon, and was led to conclude that inferences about the ante-mortem state that had been drawn from post-mortem investigations of this sort must be abandoned.

In 1860 Pavy consolidated his position as a critic of Claude Bernard's views. He stressed that, on the whole, his experimental results did not disagree with those of Bernard, although in two important respects they did. First, Pavy agreed with Figuier and others in finding that portal vein blood did contain sugar. Pavy said that the amount present was indistinguishable from that found in other parts of the circulating blood of the living animal. Second, he did not agree with Bernard that blood removed from the right heart of the living animal is strongly reducing. Far from accepting the view that the liver secreted

sugar, Pavy believed that it absorbed it and stored it as glycogen in a sort of detoxication process. Only under pathological conditions did the sugar escape from the liver into the circulation, where it could produce undesirable effects, such as those found in diabetes mellitus. After death, or in the diabetic condition, the liver lost its power to form or hold glycogen and the organism was flooded with sugar. Bernard's gibe, that if Pavy considered the production of sugar by the liver to be a post-mortem phenomenon he must consider "a diabetic person to be a walking corpse—a very queer idea" (Bernard, 1877, p. 349), was really irrelevant.

In 1860 Pavy described his finding that restlessness or struggling of an unanaesthetized animal in which a catheter had been introduced into the jugular vein resulted in a substantial increase in the sugar content of the blood. He further observed that "obstruction of the breathing determines an unnatural increase of sugar in the circulation and a strongly diabetic state of the urine may be induced in this way" (Pavy, 1860). Pavy is not usually credited with these early observations of emotional hyperglycaemia and of asphyxial hyperglycaemia and glycosuria. Pavy was also aware many years before Bernard that glucose rapidly disappears from blood after it is shed (Pavy, 1854–5) and, finding that the blood became acid as the glucose vanished, made the pertinent suggestion that the disappearing sugar had been converted to lactic acid.

Although Pavy's criticisms of Bernard's investigations met with some support, the prestige of the discoverer of glycogen was such that they were comparatively ineffective. In 1877 Pavy again returned to the problem with a vigorous criticism of the methods used by Bernard for the estimation of blood sugar, at the same time describing a new method of his own. The application of his own method, he believed, demonstrated that there was no significant difference between the sugar contents of arterial and venous bloods. In his book *The Physiology of the Carbohydrates*, published in 1894,* Pavy presents evidence to show that the "blood of the general circulation contains a standard or definite amount of sugar which, under natural and ordinary conditions, may be stated to range from about 0.6 to 1.0 or a little over 1.0 per 1,000 and which presents no evidence of any essential variation in the different parts of the system spoken of," although after the ingestion of carbohydrate food the portal vein blood sugar was considerably greater than that of the hepatic veins, showing that the liver was absorbing the sugar and presumably converting it to glycogen. After a long and fruitful life, Pavy died in 1911 at the age of 82, still convinced that Claude Bernard was wrong in his belief that the liver normally secretes sugar.

Surgical removal of the liver obviously provided a crucial experiment by which a choice could be made between the views of Bernard and Pavy, and although Minkowski in 1886 and Seegen in 1890 removed the liver from geese, in which the vascular arrangement permits this without undue difficulty, Pavy (1894) had no difficulty in rejecting the relevance of this evidence to the mammal. It was indeed not until 1922, when F. C. Mann and T. B. Magath (1922) accomplished hepatectomy in the dog and observed that the blood sugar then rapidly falls, that Bernard was finally proved to be right, and Pavy wrong.

Fate and Origin of Sugar in the Liver

Bernard's early belief about the fate of the sugar liberated by the liver was that it diffuses over the entire organism by way of the circulation, the amount of sugar steadily diminishing the further the blood flows from the liver, which is the origin of the sugar (Bernard, 1885a, p. 470). By 1877 he had found, in confirmation of Chauvau and others, that arterial blood generally contains more sugar than venous blood. At the same time he corrected his previous mistaken belief that no sugar was present in the blood of the portal vein. Nevertheless, he reaffirmed, there is normally more sugar in the blood leaving the liver than in the blood entering that organ.

*The criticism, and its trenchant attempted rebuttal, evoked by Pavy's book, I have discussed elsewhere (Young, 1937).

Soon after Bernard's discovery of glycogen in the liver, Sanson found that muscular tissue also contains glycogen, while, later, Nasse and Weiss and others showed that this glycogen diminishes in amount during muscular contraction. Bernard thought it possible that this glycogen in the muscles might be transported to them from the liver by the way of the blood. He found that the glycogen in the muscles never gave rise to glucose. "Muscle glycogen always undergoes a lactic acid fermentation, and this is the only change that muscle glycogen ever undergoes, either in the living animal or after death" (Bernard, 1877, p. 428). Taking into account the fact that the muscles continuously absorb glucose from the blood, Bernard concluded that in the living animal sugar is destroyed in the muscles, and not formed there. These ideas provided the basis of what is generally known as Claude Bernard's theory of the glycogenic function of the liver, although Bernard does not define it precisely as such. According to this theory, production of sugar by the liver is closely related to the rate of utilization of sugar by the tissues in general, the glycogen in the liver being the immediate source of the secreted sugar.

According to Bernard's views, liver glycogen is formed largely from nitrogenous material in the food. He could find no evidence that the glycogen content of the liver rose after the administration of fat to an animal. The question of whether liver glycogen is ever directly formed from carbohydrate in the food was a tricky one. Although Bernard contradicts himself a number of times on this point, his view, on the whole, appears to be that the glucose which arrives at the liver from the gut is not directly converted into glycogen. Let me quote his words from *Leçons sur le Diabète* (1877, pp. 321–322). "Is the large amount of glycogen formed in the liver after the ingestion of carbohydrate, the result of a direct conversion, a recession of sugar to glycogen, or does the sugar play only the role of a powerful nutritive stimulant which increases the glycogenic function to a marked degree? I have attempted to test the hypothesis that cane sugar is directly converted to liver glycogen. If this conversion really occurs, if it has as its end the preservation of the substance until such time as it is to be utilized, it is reasonable to suppose that when this time comes the substance will resume its previous form, that is it will undergo the converse of those changes to which it had previously been subjected, and that invert sugar will be re-formed from glycogen."

Bernard found that the glycogen formed in the livers of rabbits which had been fed on sucrose did not give a laevorotatory sugar on hydrolysis. In fact, he records that the sugar formed seemed to be more dextrorotatory than glucose. As the result of these experiments Bernard wrote: "The indisputable fact is that the administration of cane sugar considerably increases the liver glycogen content; but how does the sugar act in this case—as a nutritive stimulator or as a substance which is directly converted to glycogen? I am inclined to believe, I must confess, that the first suggestion is the more correct" (Bernard, 1877, pp. 322–323). When he fed a dog on starch the liver was found to contain less glycogen than the liver of a dog fed on fibrin. "This result seems to indicate," he wrote, "that the animal body cannot form glycogen with a ternary body alone, but that it can with a more complex substance such as fibrin" (Bernard, 1877, p. 542). Apparently Bernard regarded the secretion of glycogen by the liver as a complicated process and considered that it would therefore require a complex substance for its stimulation. Since starch contains only three elements—carbon, hydrogen, and oxygen—it was not suitable, but fibrin, being the more complex substance altogether, was able to stimulate the process of sugar formation. It is clear, therefore, that the statement which is so often made to-day about Bernard's work is wrong. He did not believe that the liver absorbed sugar from the blood and converted it directly into glycogen. He was uncertain (see Young, 1937), but inclined to the view that the glycogen which appears in the liver during the absorption of carbohydrate food is not derived from exogenous sugar but secreted, newly formed, by the tissues of that organ.

Bernard's Measurement of Blood Sugar

It is of interest to know how it was that Bernard failed to detect sugar in blood—for instance, in that of the portal vein—at a time when other workers using similar methods succeeded. One reason is clear. In many of his early experiments he did not test the blood until some time after its removal from the body and so much of the sugar in the blood was lost by glycolysis. In one of his earlier publications he describes a method for the detection of sugar in "old blood." Pavy, who had worked in Bernard's laboratory, suggested that another cause of failure arose from the fact that Bernard did not allow his test mixture (Fehling or Barreswil solution plus protein-free blood filtrate) to stand for a sufficient length of time after boiling. The detection of sugar by the relatively insensitive method of fermentation was in any case not very satisfactory.

In his early experiments, carried out on a dying or dead animal, Bernard must have stimulated the breakdown of glycogen in the liver to a very substantial extent, so that the blood of the hepatic veins contained abnormally large amounts of sugar, amounts which Bernard could easily detect even with his inadequate methods. If, like Pavy, he had carried out his experiments under physiological conditions so that a stimulation of the breakdown of liver glycogen was not induced, it seems extremely probable that he would have been unable to detect sugar in the blood of the hepatic veins at all. For we know to-day that in the post-absorptive state the blood of the hepatic veins contains only about 20 mg. per 100 ml. more sugar than that of the portal vein. Since Bernard was unable, in his early experiments, to detect any sugar at all in the blood of the portal vein, the blood of the hepatic veins would almost certainly, under physiological conditions, have yielded negative results. Pavy was nearer to the truth in his statement that the blood of the portal vein and hepatic veins contained indistinguishable amounts of sugar than was Bernard in his assertion that portal vein blood contained no sugar while the blood of the hepatic veins contained an abundance. The curious paradox therefore arises that if Bernard had been more careful with his experimental conditions he might never have discovered glycogen and the glycogenic function of the liver, while if Pavy had been a little less rigid in his determination to use strictly physiological conditions he might not have been led to an incorrect theory of carbohydrate metabolism, based on very carefully determined experimental results.

Although Bernard's experimental findings were occasionally at fault and at times influenced by preconceptions, such as the importance of nervous control of secretion of sugar by the liver (see Young, 1951), his strength appears to lie in his ability to discard a theory once its experimental basis had been undermined. Even though he was apt not to state frankly that he had been wrong, he nevertheless did change his ideas. This ability Pavy did not share to such a marked degree.

Formation of Liver Glycogen from Carbohydrate

This problem, which Bernard never definitely solved, was examined critically by J. Otto, a pupil of C. Voit. On the basis of experiments by Bernard and others, Otto decided that liver glycogen could not be formed from fat. Therefore, he argued, if the glycogen content of the tissues of a sugar-fed animal rises it follows that the glycogen has been formed either from protein in the body of the animal or from ingested sugar. From the weight of the nitrogen excreted during a given time, the weight of protein carbon metabolized during this period could be calculated. If this weight of carbon from protein was less than the weight of carbon in the glycogen deposited then some part of the glycogen must have been formed from the ingested sugar. The results of experiments on these lines were published in 1891 after the early death of Otto (Otto and Voit, 1891) and demonstrated that liver glycogen could indeed be formed from ingested glucose and fructose and from any di- and poly-saccharide which could be hydrolysed in the alimentary

tract to form these sugars. Once the direct conversion of ingested sugar to liver glycogen was admitted, the process of sugar secretion by the liver lost its former significance. The secretion of sugar by the liver could indicate that exogenous sugar, which had been temporarily stored as liver glycogen, was being liberated for use in other parts of the body and not that sugar was being manufactured from other sources.

In the early years of the twentieth century Pflüger denied the validity of all the evidence which had accumulated up to that time that protein could be converted to sugar in the body. He was justified in his criticism that in experiments designed to prove this the preliminary period of fasting had been too short, so that a considerable but unknown amount of glycogen was present in the body when the feeding of protein began. Nevertheless, his continued declaration that any increase in the amount of glycogen in the body which had been found as a result of feeding protein food was within the experimental error of the investigation appears to be too sweeping. Indeed, he was quite frank in his statement that his investigations on carbohydrate metabolism were begun with a prejudice. As Pflüger wrote (1907, p. 377), "My aim has been to find the origin of sugar in sugar itself and not in any other substance."

Pflüger (1905) was apparently impressed by the fact that the ingestion of certain sugars—for example, pentoses—did not result in a rise in the amount of glycogen in the liver. He considered that "as the liver cells are unable to form glycogen from such carbohydrates, it would be an extraordinary thing if they were able to do so from substances whose constitution is quite different from those of sugars," and with this argument supported his view that proteins are not converted to sugar in the body. This reasoning led him to believe that glycogen might be formed from fat, particularly since the formation of carbohydrate from fat had been rigorously proved to take place in the plant world; for instance, in the germinating castor-oil seed. Pflüger had shown experimentally that sugar could be converted to neutral fats in the animal body. Therefore, he argued, the reverse process was most likely to occur—that is, that neutral fats could give rise to sugar and so to glycogen (see Young, 1937).

Most of the evidence put forward by Pflüger to support the belief that fat is converted to sugar in the animal body was not of a positive type. It consisted mainly of arguments designed to demonstrate the improbability of the belief that sugar came from sources other than fat, and in particular that it could not be produced from protein. In his old age, however, Pflüger did become convinced that liver glycogen could arise from protein (Pflüger and Junkersdorf, 1910). The amount of glycogen in the liver and muscles of a fasting dog was reduced to a low level by the administration of phlorrhizin. The feeding of codfish to such a dog led to a substantial increase in the amount of glycogen, both in the liver and in the muscles. Since the codfish contained only a very small amount of glycogen and no appreciable amount of protein-bound carbohydrate, and since under these conditions the feeding of fat did not increase the glycogen content, Pflüger at last accepted the conclusion that liver glycogen could be formed from protein. The acceptance of this conclusion meant that most of Pflüger's work on carbohydrate metabolism had to be reinterpreted. The result of this was the general rejection of Pflüger's belief that sugar could be formed from fat; but because of all the confusion that had been brought about by the promulgation of Pflüger's ideas, Bernard's views about the formation of liver glycogen had been obscured. What is said about them to-day is often coloured by Pflüger's belief that carbohydrate must itself be the main source of liver glycogen.

Glycogen Since the Time of Pflüger**(a) The Cori Cycle**

The important researches of Meyerhof and others into the role of glycogen breakdown in muscle and in yeast carried out during the inter-war period cannot be discussed

here. But what came to be known as the "Cori cycle" during the late 1920's is of particular relevance. Carl and Gerty Cori showed that lactic acid liberated by the muscles of a mammal was largely re-converted into glycogen, not in the muscles but in the liver (see Cori, 1931). Thus glucose could pass through a cyclical process in being successively converted from liver glycogen to blood sugar, to muscle glycogen, to lactic acid, and back to liver glycogen. In this process, energy was released in the muscles and absorbed in the liver.

(b) The Chemical Structure of Glycogen

That on complete hydrolysis, glycogen yields glucose alone was established by Claude Bernard. Although this finding has been challenged from time to time, its validity has never been generally doubted. The fact that maltose is formed by the hydrolysis of glycogen under the influence of amylases was demonstrated by Claude Bernard. Maltose possesses a 1:4- α -glucosidic linkage (Haworth, 1929), and if one postulates a repetition of such a linkage one can imagine a straight chain of n glucose molecules joined with 1:4- α -glucosidic linkages—an amylose structure, as it is called. In such a molecule, if n is large then the empirical formula for glycogen of $(C_6H_{10}O_5)_n$, first established by Kekulé in 1858, is applicable. But this applies only if n is more than about 30, since in the formation of glycogen from a straight chain of n molecules of glucose only $n-1$ molecules of water are abstracted. The formula for glycogen will therefore be $(C_6H_{10}O_5)_n - (n-1) H_2O$, which approximates to $(C_6H_{10}O_5)_n$ only when n is large. The fact that glycogen is a non-reducing polysaccharide agrees with the view that n is large.

In 1932 Haworth and Percival showed that n was only 12 for the preparations of liver glycogen then examined, this figure being deduced from the amount of 2:3:4:6-tetramethyl glucose liberated when fully methylated glycogen was hydrolysed. This tetramethyl glucose represented the non-reducing end of the chain and therefore provided a measure of chain length. Other workers subsequently assessed n at figures between 12 and 18 for glycogen, and a figure of 14 and 15 may be regarded as representing the average (see Cori and Lerner, 1951). The upper limit for glycogen may be taken as 17, a continuous series ranging between $n=12$ and $n=17$ (Cori, 1954). When n is greater than 17 the substance is not glycogen but amylopectin, the branched polysaccharide which constitutes about 80% of most natural starches. Since, for reasons we have already considered, n for the whole molecule is probably larger than

Structure of glycogen. The segment of glycogen pictured has a molecular weight of 38,000. The open circles represent the glucose units in α -1:4 linkage, the black ones those in α -1:6 linkage. Reproduced, by permission, from Gerty T. Cori's "Glycogen Structure and Enzyme Deficiencies in Glycogen Storage Disease." (The Harvey Lectures, 1952-3, 48, 146. Academic Press, Inc., New York.)

this, it was likely that these short chains must be joined by lateral linkages (See Diagram).

In their investigations on glycogen, Haworth and Percival found that fully methylated glycogen had a minimum molecular weight in molten camphor corresponding to that of a dodecasaccharide—that is, about 2,400. This indicated that any bonds joining the units of methylated dodecasaccharide were easily broken when the substance was dissolved in molten camphor, and were therefore unlikely to be co-valent bonds. I was unable myself at this time to reproduce this observation of the solubility of methylated glycogen in molten camphor, and Oakley and I (Oakley and Young, 1936) found from measurements of osmotic pressure that the molecular weight of both glycogen and fully methylated glycogen was of the order of 1,000,000.

As the result of their investigations, Haworth and his colleagues put forward a laminated structure for the molecule of glycogen, while, on the basis of physical measurements, Staudinger (1937) suggested a "comb" structure, and Meyer and Bernfeld (1940) a "tree" structure. In the early investigations the nature of the linkages between the chains of 12-17 glucose units was not specified. In 1937 D. J. Bell (1937) isolated dimethyl glucose from the products of hydrolysis of fully methylated muscle glycogen in an amount about twice that of the tetramethyl glucose found. Subsequently, Barker, Hirst, and Young (1941) identified 2:3-dimethyl glucose among the hydrolytic products of fully methylated starch. This suggested the possibility that the inter-chain link was attached to the 6 position of certain glucose residues, and since the link could easily be hydrolysed it was very likely a 1:6 linkage. With the isolation of isomaltose or brachiose (6-[α -D-glucopyranosyl]-D-glucose), which is a disaccharide with an α -1:6 linkage between two glucose units, from the products of the acid hydrolysis of glycogen by Wolf from and O'Neill (1949) and with the isolation of the same disaccharide from the products of enzymic hydrolysis of starch by Montgomery *et al.* (1949), it seemed very probable indeed that the links between the chains would be 1:6 α -glucosidic bonds. Further evidence that this was so came from studies with enzymes, although the existence of other types of linkage has not been completely excluded.

(c) Enzymic Breakdown of Glycogen

In 1936 it was shown (Cori and Cori, 1936; Cori, Colowick, and Cori, 1937) that glucose-1-phosphate was the product of the breakdown of glycogen by an enzyme, present in mammalian muscle and acting in the presence of inorganic phosphate, which they named "phosphorylase." Later, they were able to demonstrate (Cori, Cori, and Schmidt, 1939) that the action of phosphorylase on glucose-1-phosphate *in vitro* could, under suitable conditions, produce a polysaccharide which resembled glycogen in many respects, though it yielded a blue colour with iodine (like starch) and not a brownish-red colour as glycogen does. Independently, in this country, Hanes (1940) showed that potato-phosphorylase would produce a starch-like polysaccharide from glucose-1-phosphate *in vitro*. Much of the subsequent enzyme researches were carried out in parallel on glycogen by Cori and Cori, and on starch by Hirst, Peat, Bourne, and others. I must confine my attention to glycogen.

In 1943 Cori and Cori showed that highly purified crystalline muscle phosphorylase gave, with glucose-1-phosphate *in vitro* under suitable conditions, only a straight chain polysaccharide (amylose) of a greater chain length than that of glycogen. But they also found that muscle extract contained another enzyme, branching enzyme, which could convert the straight-chain polysaccharide into a branched one.

Swanson (1948), in Cori's laboratory, showed that the colour with iodine yielded by these glucose polysaccharides varied with the mean chain length. With 8-12 glucose units in a chain the colour developed with iodine was red. With 30-35 it was blue. Intermediate chain lengths gave intermediate colours. I should like to recall here what Claude Bernard recorded (1877, p. 553): "I have found that if the

muscles of a rabbit are paralysed and thus forced to rest, the glycogen content rises. I have observed in this case that the glycogen gives a blue colour with iodine, just like that with starch." Presumably the outer chains of the molecule grow as the glycogen content of the muscles increases under these conditions.

In 1951 Cori and Larner showed that the complete degradation of glycogen in animal tissues required two enzymes: (a) phosphorylase, for the breaking of 1:4 linkages by the introduction of phosphoric acid (phosphorylation) with the production of glucose-1-phosphate; and (b) debranching enzyme (or amylo-1:6 glucosidase) for the hydrolytic fission of the 1:6 linkages, with the production of free glucose. This enzyme appeared to be specific for α -1:6-glucosidic linkages. The ratio of free glucose to free + phosphorylated glucose formed when both enzymes acted upon glycogen was a measure of the degree of branching. In all instances it was found for glycogen that the outer chains of glucose residues ("the peripheral tier") was longer than the inner branches (see Cori, 1954). In a typical glycogen with a mean chain length (n) of 15, the length of the outer chains is 8 or 9 glucose units, with 3-5 glucose residues in the inner branches—that is, between branching points.

In their experiments Cori and Larner (1951) found that, as might be expected from the action of debranching enzyme, the stimulation of muscle results in the release of small amounts of free glucose, as well as of lactic acid. Thus, Bernard's belief that glycogen in muscle always undergoes a lactic acid fermentation was not quite correct. According to the present formulation of glycogen, about 6% of the glucose residues can yield free glucose, and about 94% lactic acid or other molecules, when glycogen is broken down in muscle.

By applying enzymic methods of molecular analysis to the glycogen in the liver and muscles of patients with glycogen-storage disease, Illingworth and Cori (1952) and Illingworth, Cori, and Cori (1956) have distinguished several types of this disease. In the liver-kidney type, first described by von Gierke, other organs are not affected and the specific lesion appears to be a deficiency of glucose-6-phosphatase in liver and kidney cortex. In generalized glycogenosis, some cases possess glycogen with abnormally short outer chains and a deficiency of debranching enzyme (amylo-1:6-glucosidase), and their disease can be attributed to the deficiency of this enzyme; others do not exhibit these abnormalities, and the aetiology of their condition is still obscure.

Cori (1954) has observed that the nutritional state has a marked effect on the degree of branching of the glycogen molecule. Glycogen deposited in the liver when glucose or fructose is fed to fasting rabbits is less branched than the liver glycogen from well-fed rabbits. Glycogen from the livers of embryonic guinea-pigs is more branched than the glycogen obtained from the livers of newly born or adult animals (Cori, 1954). As Cori has pointed out, the length of the outer chains is very important in the characterization of glycogen. It varies more than the length of the inner chains and largely determines the average chain length of the entire molecule.

(d) Enzymic Synthesis of Glycogen

The debranching enzyme (amylo-1:6 glucosidase) is apparently purely a hydrolytic enzyme and almost certainly plays no part in the synthesis of glycogen from glucose-1-phosphate. The presence of a branching enzyme in muscle was revealed by the researches of Cori and Cori (1943), as has already been pointed out. Larner (1953), in Cori's laboratory, has observed that when this enzyme acts upon glycogen containing radioactive labelled glucose in its outer chains 1:6 linkages are formed between radioactive glucose units previously linked by 1:4 bonds. This enzyme has been described as amylo-(1:4→1:6) transglucosidase. The enzyme from the liver needs an outer chain length of more than 6 glucose units before it will induce branching. The reverse process—that is, the formation of 1:4 linkages at the expense of 1:6 linkages—has not been demonstrated.

(e) Formation of Glycogen in vivo

The enzymes that together can catalyse the conversion of glucose to glycogen are, in accordance with the studies we have considered above and other relevant investigations, hexokinase (glucose to glucose-6-phosphate), phosphoglucomutase (glucose-6-phosphate to glucose-1-phosphate), phosphorylase (glucose-1-phosphate to amylose), and branching enzyme (amylo-(1:4→1:6)-transglucosidase) (amylose to glycogen). Although these enzymes exist in liver and muscle tissues and can together catalyse the transformation of glucose to glycogen, it is not certain that the pathway thus made possible—glucose → glucose-6-phosphate → glucose-1-phosphate → glycogen—is the main one followed in intact tissue. Beloff-Chain *et al.* (1955) believe that oligosaccharides may be involved in the formation of glycogen from glucose in diaphragm muscle.

It is true that in liver tissue the increase in phosphorylase activity associated with the action of glucagon or adrenaline is always associated with a greater breakdown of glycogen and not with increased formation of this substance. But, of course, the conditions prevailing in the cell when phosphorylase activity rises under the influence of adrenaline and glucagon may be specifically appropriate for the lytic action of phosphorylase, as opposed to the reverse effect. Be that as it may, the direct conversion of glucose to glycogen in the liver, about which, as we have seen, Claude Bernard had some doubts, has been clearly demonstrated within recent years with the aid of isotopes. Using deuterium as a labelling isotope, Stetten and Boxer (1944) found that dietary glucose can indeed be converted directly to liver glycogen, although their studies showed that only a small proportion was so directly transformed, the major part of the liver glycogen being formed from smaller molecules, perhaps lactate in part, when glucose was fed to a rat.

According to Stetten and Boxer only about 3% of the dietary glucose is converted to glycogen, about 30% being transformed to fat. The rest is presumably oxidized through other routes. De Duve and his colleagues (Berthet *et al.*, 1956), using radiocarbon-labelled glucose, have recently also demonstrated the direct conversion of glucose to liver glycogen, as well as to muscle glycogen, this process being stimulated by insulin.

Stetten and Stetten (1954, 1955) have found that when glucose labelled with radiocarbon is given to normal rats, and the structure of the liver and carcass glycogens analysed by the enzymic method, the administered glucose is found first to enter the peripheral chains of glycogen and then move down the molecule. The process of the inward movement of the radioactive glucose in the molecule of glycogen is more rapid with glycogen in the liver than with muscle glycogen. Subsequent studies (Stetten, Katzen, and Stetten, 1956) have shown that the radioactive glucose preferentially enters the glycogen molecules of smaller size than average in the liver, and of larger size than average in the muscles. These observations, and the earlier ones of Cori and Cori, emphasize the metabolic inhomogeneity of the glycogen molecule.

During the past ten years the use of isotopes has confirmed that carbon atoms from certain amino-acids, contained in protein, can be transferred to liver glycogen. Although it has also been demonstrated in a similar manner that carbon can be transferred from fatty acids to liver glycogen, it is still doubtful whether a net synthesis of glycogen can occur at the expense of the breakdown of fatty acids.

Conclusion

During its first century of recognition glycogen has passed from a starch-like material of unknown constitution, the immediate precursor of the sugar secreted by the liver, to a substance whose molecule can be enzymically dissected, much as Claude Bernard dissected an animal. Already this power to effect such molecular analysis of glycogen by means of enzymes has differen-

tiated glycogen-storage disease into a number of different types, and has revealed that the peripheral part of the glycogen molecule can undergo metabolic change independently of the central part. What light these new observations will throw on medicine will become clear early in the second century of glycogen. I believe that we can confidently assume that Claude Bernard would have given his interested approval to the many investigations into the structure and biosynthesis of glycogen which have taken place during the last twenty-five years of the first century of this substance.

Courses for the training of matrons and assistant matrons for old people's homes are organized regularly by the National Old People's Welfare Council (in association with the National Council of Social Service). Each course lasts fourteen weeks. The next course will begin on September 9; there will be another early next spring. Applicants, who should be women of over 30 years of age, need have no special qualifications, although a practical knowledge of nursing and housekeeping is an advantage. Intending students may apply through their local education authorities for grants towards their training from the King George VI Social Service Scheme (Old People). Further details may be obtained from the secretary, National Old People's Welfare Council, 26, Bedford Square, London, W.C.1. There are over 1,400 homes for old people, provided either by voluntary organizations or by statutory authorities, and competent staff are constantly required.

TREATMENT OF ULCERATIVE COLITIS WITH LOCAL HYDROCORTISONE HEMISUCCINATE SODIUM

BY

S. C. TRUELOVE, M.D., M.R.C.P.

Nuffield Department of Clinical Medicine
University of Oxford

(From the Radcliffe Infirmary, Oxford)

A previous article (Truelove, 1956) dealt with the treatment of mild and moderate cases of ulcerative colitis by means of a rectal drip of hydrocortisone. The result of 21 treatments was complete symptomatic relief within a few days in 14 instances, and it was concluded that this method was a useful addition to therapy. However, although clinical remission was accompanied by much-improved sigmoidoscopic appearances, it was found that the histological appearances of biopsy specimens of the colonic mucosa did not in general show a corresponding improvement.

Various possibilities which might have accounted for this discrepancy were considered. One was that the actual preparation of hydrocortisone used was not entirely harmless to the inflamed mucosa. Hydrocortisone in the form of its free alcohol is only slightly soluble in water, and it was therefore supplied by the manufacturers in solution in 50% ethyl alcohol. This concentrated solution was diluted 10 times in normal saline for actual instillation into the rectum, but nevertheless it seemed possible that even a 5% solution of ethyl alcohol might damage, or at least prevent from healing, a mucosa which was already diseased. This possible source of failure to induce mucosal healing can be eliminated if one uses a form of hydrocortisone which is freely soluble in water. Such a substance—hydrocortisone hemisuccinate sodium—has recently been synthesized, and Glaxo Laboratories kindly made supplies of it available for clinical trial.

Hydrocortisone Hemisuccinate Sodium

This is a white crystalline powder highly soluble in water, with which it forms a clear, colourless solution. There are as yet only scanty references in the literature to its use in man. The first account appears to be that of Orr *et al.* (1955), who used it intramuscularly to treat conditions such as disseminated lupus erythematosus, acute bronchial asthma, and the crisis of Addison's disease, and for replacement therapy after bilateral adrenalectomy; the results were comparable to those obtained by corresponding doses of hydrocortisone. The same authors also studied the effect of injecting it intravenously into a human being without adrenals and found evidence of an exponential decay curve characterized by a half-life of four to five hours, which agrees well with data obtained for hydrocortisone itself by Hellman *et al.* (1954), making use of a preparation labelled with radioactive carbon. These and other facts suggest that the two compounds are metabolized by the liver and excreted by the kidney in a closely similar fashion. Orr *et al.* suggested that the hemisuccinate would be valuable in the treatment of severe emergencies in which a "shock-like" state occurs, by virtue of its

high solubility in water, so that the equivalent of 100 mg. of hydrocortisone can be given in a volume of 2 ml. by simple intravenous injection from a syringe without the use of infusion apparatus. This use has also been suggested by the Council on Pharmacy and Chemistry (1956) in a brief account of the substance.

Its use for local application to the skin has been described by Robinson *et al.* (1956), who found it valuable in the treatment of those skin diseases, such as atopic dermatitis, contact dermatitis, seborrhoeic dermatitis, and pruritus ani, which are improved by local treatment with ordinary hydrocortisone. The hemisuccinate appeared to be efficient in a lower concentration than the preparations of less soluble hydrocortisone. Coste *et al.* (1955) have studied the action of hydrocortisone hemisuccinate sodium when injected into inflamed joints, and find that symptomatic relief is obtained comparable to that experienced with other preparations of hydrocortisone.

So far as is known, therefore, the biological actions of hydrocortisone hemisuccinate sodium are identical with those of hydrocortisone itself except in so far as they may be modified by the much greater water solubility of the hemisuccinate.

Present Investigation

Hydrocortisone hemisuccinate sodium was supplied for trial by Glaxo Laboratories in bottles containing the molecular equivalent of 100 mg. of hydrocortisone. For therapeutic use the contents of one of these bottles was transferred to a standard blood-transfusion bottle and dissolved in 120 ml. of normal saline. (The volume of 120 ml. was selected purely because bottles of sterile normal saline of this size are prepared in this hospital for routine use and could therefore be supplied to the patients without the need of special arrangements. Any volume of saline up to about 250 ml. would appear to be suitable.) The solution of hydrocortisone hemisuccinate sodium must be prepared shortly before its use because slow hydrolysis of the hemisuccinate occurs with standing in solution, and the resulting free hydrocortisone goes out of solution.

The patients treated were all in a stage of mild or moderate symptoms. As in the previous study, patients severely ill with the disease have been excluded from this study and have been treated as in-patients along conventional lines. No other treatment was employed while the local hydrocortisone was in use. The patients carried out treatment entirely in their own homes, with the exception of two who were already in hospital and who began treatment as in-patients, going home after three days to complete it there. No difficulty has been experienced by the patients in carrying out the treatment.

The treatment is carried out nightly when the patient would normally be going to bed. The solution of hydrocortisone is prepared in the infusion bottle. The giving apparatus with its attached rubber catheter is plugged into the infusion bottle, which is then hung up close to the patient's bed. The patient lies in bed, inserts the catheter well into the rectum, turns on the screw-clip to start the solution running and adjusts the rate to 1-2 drops a second. As was found in the previous study, this slow rate prevents the instillation acting as an ordinary enema and causing defaecation. When the solution has run in, the catheter is removed and allowed to drop down into a bowl or basin beside the bed, where it is left until the next day. Thus the patient is able to settle down to his night's sleep as soon as the instillation is completed.

Treatment consisted at first of 10 nightly treatments, but later this was increased to 14 as the supplies of hydrocortisone hemisuccinate sodium increased.

Assessment of the Therapy

All patients were seen on the day on which treatment was to begin at night. Sigmoidoscopy was carried out and the appearances were recorded. In all cases a biopsy specimen was taken from the lower colon, between 15 and 20 cm. from the anal margin, by means of an improved version of a special colonic biopsy instrument (Truelove *et al.*, 1955). Specimens were taken for cytological examination by the Papanicolaou technique by means of a special instrument described previously (Boddington and Truelove, 1956).

The patients were examined again on the day after their last night of treatment and corresponding observations were made.

Results

Eighteen courses of treatment have been given to 15 patients, three of them having received two separate courses. The response to treatment of the individual patients is given in Table I, together with brief details of their previous history and their subsequent progress.

The clinical response to treatment was as follows: rapid remission, 11; improved, 1; no change, 6. This corresponds with what was found in the previous study, using ordinary hydrocortisone, when there were 14 remissions out of 21 treatments. Clinical remission was almost always very rapid in those patients who showed a favourable response, usually occurring in the first few days of the beginning of treatment; there was often marked improvement after the first night's treatment. In some patients the effect was dramatic in that the patient became symptom-free after the first instillation. For example, in Treatment No. 17, the patient had suffered from diarrhoea for the previous two weeks with six loose motions a day containing much blood. His haemoglobin value had fallen from 102% to 81% in that period and he felt ill. On the day following the first instillation he passed two formed stools not containing blood, and continued to do so.

Sigmoidoscopic Appearances

The sigmoidoscopic changes corresponded closely to the clinical response, all those patients going into clinical remission showing a marked improvement in the sigmoidoscopic picture. In these patients the abnormal fragility of the colonic mucosa, which manifests itself as "contact bleeding" and is largely or entirely responsible for loss of blood in this disease, was conspicuously absent. This was evident when taking "smears" from the colonic surface for cytological examination, because no obvious blood could be seen on the instrument when this was done and only a small quantity of mucoid material resulted. When the colonic mucosa is inflamed, as it is in an active phase of ulcerative colitis even when symptoms are very slight, the specimen must be taken with delicacy, for otherwise the epithelial cells are deluged by red blood corpuscles and the examination is rendered useless. By contrast, the special "smear-taking" instrument can be used with much more vigour on a normal mucosa without causing bleeding.

In this respect the patients in remission after hydrocortisone hemisuccinate sodium were normal or close to it. The patients who were classified as showing "near-normal" appearances at the end of treatment displayed a particular type of fine granularity of the mucosa as the only abnormal finding. The abnormality revealed itself as the reflection of numerous "pin-heads" of light. It is believed that each point of light arises where the mucosa has a tiny bulge on its surface due to the presence of a large lymphoid follicle in the substance of the mucosa itself. Lumb and Protheroe (1955) described the frequent occurrence of these big follicles in the mucosa of ulcerative colitis as occurring during a phase of healing, a view from which I have no reason to dissent. In any event, large lymphoid follicles were commonly found in the biopsy specimens taken from patients who showed this special form of granularity.

TABLE I.—Summary of Clinical History and the Response to Treatment with Local Hydrocortisone Hemisuccinate Sodium. (The length of treatment was 10 days for the first three patients and 14 days for the remainder)

Treatment No.	Previous History	Immediately Before Treatment	Response to Treatment	Subsequent Progress
1. Female aged 46	Attacks of blood and mucus per rectum with diarrhoea since 1944, admitted 4 times, the last occasion being in 1948. During admissions sigmoidoscopy showed inflamed mucosa of rectum and lower colon and barium-enema examination showed appearances of ulcerative colitis affecting rectum and sigmoid colon. After last admission remained comparatively well, although subject to mild attacks of passing blood and mucus for a few days at a time. Two weeks ago suddenly developed abdominal pain and diarrhoea with 4 loose motions a day containing blood. These symptoms persisted and she felt unwell.	<i>Clinical:</i> 4 loose motions a day with much blood and mucus present. Hb 79%. General malaise. <i>Sigmoidoscopic:</i> Hyperaemia and granularity of rectum with increased fragility. These appearances become less severe above the recto-sigmoid junction.	<i>Remission:</i> Immediate response. No diarrhoea after 1 day. No discharge of blood after 2 days. Thereafter passed 2 formed motions a day. Feeling of malaise disappeared. <i>Sigmoidoscopic:</i> Near-normal. Slight granularity only. No increase in fragility, no hyperaemia.	Remained symptom-free (10 months' follow-up)
2. Female aged 31	Developed ulcerative colitis in Feb., 1954. Admitted May, 1954, because symptoms had become worse and 8-10 loose bloody motions a day were passed. Barium enema showed evidence of ulcerative colitis affecting sigmoid colon. Sigmoidoscopy showed sharp inflammation of colonic mucosa. Treated with systemic corticotrophin and made excellent response. After a year became subject to intermittent diarrhoea with occasional gross blood, but was not badly affected until 1956, when attacks became more severe with 7-8 loose stools a day containing blood and with symptoms becoming more or less continuous.	<i>Clinical:</i> 7-8 loose stools a day containing small amounts of blood. Hb 71%. E.S.R. 37 mm. <i>Sigmoidoscopic:</i> Marked hyperaemia and granularity with free bleeding on contact. Much purulent exudate present.	<i>Little change:</i> Some improvement but not symptom-free. Bleeding almost ceased, but still had 4 stools a day, rather loose. Hb 76%. E.S.R. 32 mm. <i>Sigmoidoscopic:</i> Improved, but mild hyperaemia and granularity persisted.	Gradual improvement but mild symptoms persisted.
3. Female aged 34	In 1953 suddenly began to pass blood and mucus in motions and then developed diarrhoea with 4-5 motions a day. These symptoms lasted for 2 months. Thereafter stayed well until June, 1956, when diarrhoea suddenly developed with 5-6 motions a day, loose and with some blood present. Felt ill.	<i>Clinical:</i> 6 loose motions daily with small amounts of blood present. Barium enema showed evidence of ulcerative colitis in descending and sigmoid colon. <i>Sigmoidoscopic:</i> Marked hyperaemia and granularity with greatly increased mucosal fragility. These changes extended as far up as could be seen.	<i>Remission:</i> Immediate response to treatment with one motion not containing blood on day following first rectal drip. <i>Sigmoidoscopic:</i> Much improved. Mild hyperaemia and granularity up to 12 cm. from anal margin, with normal appearances above that.	Remained symptom-free and was sigmoidoscopically normal at end of study. Hb 93%. E.S.R. 14 mm. (9 months' follow-up)
4. Female aged 45	20 years ago had severe attack of ulcerative colitis, in hospital 3 months. Attack lasted for more than a year. Thereafter was entirely symptom-free until 1955, when diarrhoea developed with much blood in stools. Barium enema showed changes of ulcerative colitis in descending and sigmoid colon. Sigmoidoscopy showed evidence of mild ulcerative colitis. Treated with cortisone as out-patient, becoming symptom-free in 3 weeks. Sigmoidoscopic appearances became normal. Thereafter remained in clinical remission, although E.S.R. was raised, until June, 1956, when she again began to pass blood in motions. After 3 weeks of these symptoms local hydrocortisone hemisuccinate started.	<i>Clinical:</i> 2 poorly formed motions a day with blood present. <i>Sigmoidoscopic:</i> Marked hyperaemia and granularity as far as could be seen, with many petechiae and increased mucosal fragility.	<i>Little change:</i> 3 formed motions a day still containing a little blood. <i>Sigmoidoscopic:</i> Little change.	Treated with oral cortisone and rapidly became symptom-free with near-normal sigmoidoscopic appearances (9 months' follow-up)
5. Female aged 30	For past 5 years has had bouts of diarrhoea with as many as 10-12 stools a day which are loose, offensive, and contain blood and mucus. Has felt tired and has lost weight. In May, 1956, admitted to hospital because of a severe attack. At that time had gross bloody diarrhoea. Hb 81%. Barium enema showed changes of ulcerative colitis extending from middle of transverse colon to rectum. Sigmoidoscopy showed evidence of severe ulcerative colitis. Treated with systemic corticotrophin and went into remission. However, soon relapsed and began to get diarrhoea with blood in stools. These symptoms continued and by Aug., 1956, was having gross bloody diarrhoea. Local treatment then begun.	<i>Clinical:</i> Bloody diarrhoea with 7-8 loose stools a day containing moderate or large amounts of blood. <i>Sigmoidoscopic:</i> Marked hyperaemia and granularity. Fragility greatly increased. Purulent exudate present and ulceration. These changes extend up as far as could be seen.	<i>Little change:</i> Noticed slight improvement but nothing marked. <i>Sigmoidoscopic:</i> No change.	Treated with oral cortisone but she became worse and this was stopped. Then treated with "salazopyrin" with slight improvement, but symptoms, though less severe, persisted at end of follow-up.
6. Female aged 39	In Feb., 1955, had sudden attack of diarrhoea with blood, lasting 5 months. Thereafter was fairly well but would often pass blood and mucus per rectum although without diarrhoea. In Sept., 1955, diarrhoea recurred with 5 motions a day containing blood. This settled down to 2 motions a day with blood and mucus. In Oct., 1955, treated with local hydrocortisone and rapidly became symptom-free. Remained symptom-free for 8 months, then suddenly relapsed with diarrhoea and gross blood in stools. After 5 weeks of these symptoms, again treated with local hydrocortisone, becoming symptom-free in a few days. Remained well for 2 months, but then began to pass much blood and mucus per rectum several times a day.	<i>Clinical:</i> Passing much blood and mucus per rectum several times a day. <i>Sigmoidoscopic:</i> Marked inflammation as far up as could be seen.	<i>Remission:</i> Blood stopped after 2 days. Passed some mucus for a few more days and then became entirely normal. <i>Sigmoidoscopic:</i> Near normal.	Remained symptom-free for 3 weeks, then began to pass blood and mucus. After one week of these symptoms she was again treated with local hydrocortisone hemisuccinate (see Treatment No. 10).
7. Male aged 43	In Oct., 1955, first noticed blood in stools, then symptoms gradually became worse. At first had 2-3 motions a day, always with blood present; he gradually worsened, and was admitted to hospital in Sept., 1956, with 4-5 motions a day containing blood. Barium enema showed mild changes of ulcerative colitis.	<i>Clinical:</i> 3-5 motions a day with much mucus and blood present. <i>Sigmoidoscopic:</i> Marked hyperaemia and granularity of mucosa as far up as could be seen. Fragility increased. Purulent exudate present. No gross ulceration seen.	<i>Remission:</i> Immediate response to treatment and was symptom-free in 3 days. <i>Sigmoidoscopic:</i> Much improved. Mild inflammation only.	Remained in clinical remission, but sigmoidoscopically showed some relapse after one month. At end of study was still symptom-free, but sigmoidoscopy showed definite inflammation. Hb 97%. E.S.R. 5 mm. (7 months' follow-up)

[continued overleaf]

TABLE I.—Continued

Treatment No.	Previous History	Immediately Before Treatment	Response to Treatment	Subsequent Progress
8. Male aged 35	In March, 1955, gradual onset of diarrhoea with 5-10 motions a day, occasionally containing blood. In Oct., 1955, was treated with local hydrocortisone, with rapid remission. Remained symptom-free regarding bowel action for 11 months, although 2 months after end of treatment ischio-rectal abscess developed; this was treated by surgical drainage and healed well. After 11 months bowel symptoms returned and after one week hydrocortisone hemisuccinate was given	<i>Clinical:</i> 6 unformed motions a day containing small amounts of blood <i>Sigmoidoscopic:</i> Well-marked hyperaemia and granularity extending as far as could be seen	<i>Remission:</i> Became symptom-free in 1 week <i>Sigmoidoscopic:</i> Much improved. Mucosa still rather hyperaemic but no increased fragility	Remained symptom-free for 2 months, then symptoms recurred with 6 loose motions containing gross blood and with fall of Hb from 102% to 81%. Treated again with hydrocortisone hemisuccinate (see Treatment No. 17)
9. Male aged 47	In Oct., 1955, had dull abdominal pain with fever and sweating for about a week. He then passed 2 stools a day, watery with much mucus and occasional blood. Barium enema showed evidence of ulcerative colitis in rectum and sigmoid colon. Sigmoidoscopy showed ulcerative colitis of marked severity. In Jan., 1956, had local hydrocortisone, with rapid remission. Remained symptom-free for 3 months, then relapsed and was again treated with local hydrocortisone with excellent response, becoming symptom-free after first instillation. Remained well for 3 months, then began to pass 3 loose stools a day containing much mucus. At this stage local hydrocortisone hemisuccinate given	<i>Clinical:</i> 2 liquid motions a day with much mucus present <i>Sigmoidoscopic:</i> Marked hyperaemia and granularity stretching up as far as could be seen. Fragility increased	<i>Remission:</i> Immediate response to treatment with 1 formed normal motion a day after the first instillation <i>Sigmoidoscopic:</i> Very mild hyperaemia only. No increase in fragility	Remained symptom-free for 2 weeks and then again developed very loose motions with much mucus and small amounts of blood present and was again treated with hydrocortisone hemisuccinate (see Treatment No. 14)
10. Female aged 39	See Treatment No. 6	<i>Clinical:</i> Passing blood and mucus per rectum several times a day <i>Sigmoidoscopic:</i> Severe inflammation up to 15 cm. from anal margin, mucosa becoming normal above this. Rectal mucosa very hyperaemic and granular, with mucopus present. Mucosa oozes blood with slight trauma	<i>Remission:</i> Bleeding stopped after first night. Normal motions after second night. Thereafter symptom-free <i>Sigmoidoscopic:</i> Near normal	Remained symptom-free with normal haemoglobin and E.S.R. (6 months' follow-up)
11. Female aged 44	In 1953 developed bouts of diarrhoea lasting 2-3 weeks. In 1955 had severe attack of diarrhoea with 8-12 liquid motions a day containing much blood and mucus. Lost 5 kg. in weight and was anaemic. Barium enema showed changes of ulcerative colitis throughout almost whole colon. Sigmoidoscopy showed typical changes of ulcerative colitis. Treated in hospital with cortisone and general medical measures. Treatment complicated by deep vein thrombosis, first of right leg and later of left, for which anticoagulant therapy given. However, colitis responded and she was in clinical remission on discharge. After 2 months' remission colitis recurred, and as an out-patient she was given oral cortisone; again went into remission. On stopping cortisone diarrhoea recurred with 6 loose motions a day though with very little blood. Further course of oral cortisone as out-patient brought improvement without her being entirely symptom-free. Reasonably well until Oct., 1956, when diarrhoea returned with 10-12 liquid motions a day containing small amounts of blood. At this stage local treatment given	<i>Clinical:</i> 10-12 liquid motions a day with small amounts of blood present. Much abdominal pain <i>Sigmoidoscopic:</i> Severe inflammation. Fragility greatly increased. Exudate present. Ulceration	<i>Little change:</i> 10 unformed motions a day, although with no blood present, and with abdominal pain <i>Sigmoidoscopic:</i> Improved. Fragility normal but still hyperaemic	Treated with salazopyrin; response being excellent. One normal formed motion a day after 4 days' treatment (6 months' follow-up)
12. Male aged 31	In 1950 developed diarrhoea, with bowels usually open 3-5 times daily; occasionally more severe bouts, when bowels were opened 8-10 times daily. Small amounts of blood and mucus present. Symptoms were continuous. In 1954 admitted to hospital without much benefit. In 1955 readmitted with 8 motions a day containing blood. Barium enema showed evidence of mucosal damage throughout whole of colon and terminal ileum. Sigmoidoscopy showed appearances of ulcerative colitis. Moderately anaemic. Treated with oral cortisone with much improvement. Thereafter continued on cortisone as out-patient but still had moderate diarrhoea. In Nov., 1956, symptoms became worse while still on cortisone, with 6-8 loose motions a day but without blood. At this stage local treatment given	<i>Clinical:</i> 6-8 loose motions a day not containing blood <i>Sigmoidoscopic:</i> Moderate inflammation stretching up as far as could be seen	<i>No change</i> <i>Sigmoidoscopic:</i> No change	Treated with oral cortisone combined with salazopyrin with gradual improvement
*13. Female aged 40	In Aug., 1956, developed diarrhoea with up to 10 loose motions a day containing blood and mucus. In Oct., 1956, seen as out-patient at Radcliffe Infirmary by colleague. Hb 92%. Barium enema showed changes suggesting ulceration in rectum only. Following barium enema had exacerbation of symptoms with 18 or more loose stools a day containing blood, with generalized abdominal pain. Hb fell to 79%. At this stage transferred to me and local treatment started	<i>Clinical:</i> 18 or more loose motions a day with blood and mucus present. Hb 79%. Generalized abdominal pain <i>Sigmoidoscopic:</i> Severe inflammation extending as far up as could be seen	<i>Remission:</i> Immediate improvement, but had mild symptoms for 18 days, when she became entirely symptom-free with 1 formed stool a day; no abdominal pain and feeling well. Hb had risen to 91% <i>Sigmoidoscopic:</i> Slight hyperaemia and granularity affecting rectum only. Normal appearances above 5 in. (12.5 cm.) from anal margin. Mucosal fragility not increased	Remained symptom-free with normal sigmoidoscopic appearances (6 months' follow-up)

* This patient immediately showed marked improvement, but she still had mild symptoms at the end of 14 days' treatment. Treatment was therefore continued for a further seven days, in the course of which she became entirely symptom-free.

TABLE I.—Continued

Treatment No.	Previous History	Immediately Before Treatment	Response to Treatment	Subsequent Progress
14. Male aged 46	See Treatment No. 9	<i>Clinical:</i> 2 very loose motions a day with small amounts of blood and much mucus present <i>Sigmoidoscopic:</i> Severe inflammation extending as far as could be seen, with much increased mucosal fragility causing free bleeding on contact	<i>Remission:</i> 1 normal stool a day after 3 days' treatment <i>Sigmoidoscopic:</i> Mild hyperaemia and slightly increased fragility of mucosa	Remaining symptom-free (6 months' follow-up)
15. Male aged 28	In 1949 had left pleural effusion followed by iridocyclitis. In 1951 tuberculous pulmonary lesion of left upper lobe found on x-ray examination. Treated in sanatorium. June, 1951, early tuberculous caries of spine. Thereafter well until Jan., 1956, he had short episodes of diarrhoea with blood and mucus. In Aug. developed severe bloody diarrhoea with constitutional disturbance. Attack became very severe. Treated with systemic corticotrophin, salazopyrin, and antituberculous drugs. On this regime improved but developed toxic anaemia with Heinz bodies. By Dec., 1956, was improved but still getting 6-7 motions in 24 hours, loose and sometimes liquid but without gross blood. At this stage given local treatment	<i>Clinical:</i> 6-7 loose or liquid motions a day with mucus present but no gross blood <i>Sigmoidoscopic:</i> Well-marked hyperaemia and granularity extending up as far as could be seen. No gross ulceration. Fragility moderately increased. Mild polypoid changes at 15 cm. from anal margin	<i>Slight improvement:</i> 5 partly formed motions a day not containing blood or mucus. Gaining weight <i>Sigmoidoscopic:</i> Improved, but still hyperaemic and slightly granular	Gradual improvement and became symptom-free (6 months' follow-up)
16. Male aged 23	In 1954 began to pass bright red blood per rectum and much mucus. Bowel action usually regular but occasional diarrhoea. Barium enema normal, but following this had diarrhoea with 6 unformed stools a day containing blood. Transferred to me for treatment, by which time diarrhoea was easing off with 2 loose stools a day containing blood and mucus	<i>Clinical:</i> 2 loose stools a day containing blood and mucus <i>Sigmoidoscopic:</i> Marked hyperaemia and granularity with much increased mucosal fragility. These changes extended up to 17 cm. from anal margin and had become mild	<i>Remission:</i> Symptom-free after 4 days <i>Sigmoidoscopic:</i> Mild hyperaemia and granularity in lower half of rectum only. Within normal limits above	Remaining symptom-free (4 months' follow-up)
17. Male aged 34	See Treatment No. 8	<i>Clinical:</i> For past 2 weeks had had 6 loose motions a day with gross blood present. Hb 81%, having previously been 102%. General malaise <i>Sigmoidoscopic:</i> Mild hyperaemia and granularity, with increased mucosal fragility stretching up as far as could be seen	<i>Remission:</i> Immediate response to treatment with 2 formed stools a day not containing blood. Feeling well <i>Sigmoidoscopic:</i> Very slight hyperaemia and fine granularity. Appearances near normal. Mucosal fragility not increased	Remaining symptom-free (4 months' follow-up)
18. Male aged 26	In 1955 began to pass blood with motions. Few small haemorrhoids injected but trouble continued. Seen by me in July, 1956, when sigmoidoscopy showed hyperaemia, oedema, and petechiae of rectum with the mucosa gradually becoming normal above 6 in. (15 cm.) from anal margin. Treated with "i-so-gel," symptoms became negligible. In Dec., 1956, symptoms recurred. Blood passed every day and much mucus, but motions firm	<i>Clinical:</i> 2 formed stools a day but with blood and much mucus <i>Sigmoidoscopic:</i> Marked inflammation up to 15 cm. from anal margin, thereafter fading off and becoming normal about 17 cm. from anus	<i>Little change</i> <i>Sigmoidoscopic:</i> Marked inflammation from anal margin up to 12 cm., thereafter fading off and becoming normal about 17 cm. from anus	Treated with salazopyrin, became symptom-free in 3 weeks (4 months' follow-up)

The close agreement between the clinical and sigmoidoscopic findings in the present study can be seen if the data are arranged in the form of a simple contingency table (Table II).

TABLE II.—Correlation Between the Clinical Response to Treatment and the Sigmoidoscopic Findings

Clinical Response to Treatment	Sigmoidoscopic Findings at End of Treatment		
	Normal or Very Mild	Improved, but Definite Inflammation	Unchanged
Remission	11	1	
Improved		2	4
No change or slight improvement only			

Histological Findings

Biopsy specimens were taken from all patients on the day on which treatment was begun, and all showed evidence of severe or moderate inflammation, using the criteria employed by my pathologist colleague, Dr. W. C. D. Richards, in a previous joint study (Truelove and Richards, 1956). On the day following the last night of treatment another specimen was taken from all patients except one. Thus there are 17 pairs of specimens for comparison.

The histological response showed a close agreement with the clinical response, as can be seen from Table III. In some of the specimens classed as showing improvement there was

TABLE III.—Correlation Between Clinical and Histological Response to Treatment

Clinical Response to Treatment	Histological Response to Treatment	
	Improved	No Change
Remission	9	1
Not in remission	1	6

little or no inflammation in the specimen taken at the end of treatment, although the glands might be stunted and reduced in number and large lymphoid follicles were often present in the lamina propria. In the other specimens classed as showing improvement there were still some inflammatory changes remaining at the end of treatment, but they were clearly less marked than at the beginning. An example of a good histological response is shown in Figs. 1 and 2.

Cytological Findings

In a previous study (Boddington and Truelove, 1956) it was found that the colonic epithelial cells are frequently abnormal in ulcerative colitis. Compared with normal colonic epithelial cells, many of those seen in active ulcerative colitis are much enlarged, with big nuclei having nucleoli and a disturbed chromatin pattern. Similar findings have been reported independently by Galambos *et al.* (1956). In view of the fact that a correlation was found to exist between the clinical and sigmoidoscopic evidence of active disease on the one hand and the degree of abnormality

FIG. 1.—Histological appearances before treatment, showing heavy infiltration of the mucosa with inflammatory cells. (H. and E. $\times 150$.)

FIG. 2.—Histological appearances in the same patient after 10 days' treatment with local hydrocortisone hemisuccinate sodium. (H. and E. $\times 150$.)

shown by the epithelial cells on the other, it is probably valid to regard the state of the epithelial cells before and after treatment as an index of tissue response.

Making use of this index, it has been found that clinical remission with local hydrocortisone hemisuccinate sodium is accompanied by a change in the colonic epithelial cells towards normal appearances. The close correlation that exists is shown in Table IV, which has been constructed from data supplied by my cytologist colleague, Mr. M. M. Boddington, who has classified the cells as showing improvement, no change, or deterioration. Some patients are not included, for in them the specimens taken before or after treatment were not sufficiently rich in epithelial cells to permit him to form a satisfactory judgment of any changes that had occurred.

By contrast with this finding, the number of pus cells present in the colonic smears does not show any positive correlation with clinical response, as is shown in Table V. Although based on a somewhat rough-and-ready estimate, the complete discrepancy between clinical response and

TABLE IV.—Correlation Between Clinical Response and Changes in the Colonic Epithelial Cells

Clinical Response to Treatment	Appearance of Colonic Epithelial Cells after Treatment Compared with Appearance Before Treatment	
	Improved	No Change or Worse
Remission	5	1
Not in remission	1	4

diminution in pus cells should not be ignored, especially as we know that smears made from a healthy colon show either a complete absence of pus cells or only very occasional ones. This finding raises the possibility that infection is playing a part in many cases of ulcerative colitis and that such infection is not improved by local treatment with hydrocortisone. Nor would one expect it to be, for it is generally accepted that hydrocortisone encourages the spread of infections. It was indeed this possibility which caused me to exclude from this and the previous study those patients who were severely ill with ulcerative colitis, because of the risk that local hydrocortisone might cause extensive spread of a secondary, pyogenic infection.

Not in remission	3	5

Discussion

The main interest of the present study has been the evidence of histological improvement in the colonic mucosa of those patients who pass into clinical remission with local treatment. In terms of clinical response, there is nothing to choose between the hemisuccinate sodium and ordinary hydrocortisone. We may therefore deduce with a reasonable degree of confidence that the improvement in histological response obtained by the use of hemisuccinate is to be attributed solely to its being freely soluble in water and thus able to be used without the disturbing presence of ethyl alcohol in the diluent. Nevertheless, on general principles it seems wise to prefer an agent with which the actual diseased tissue shows improvement, and therefore the hemisuccinate is recommended for future local use in the colon.

Taken in conjunction with the previous study (Truelove, 1956) the present findings constitute a *prima facie* case for regarding local hydrocortisone as a useful form of treatment in ulcerative colitis, at any rate in a proportion of the patients with the disease. This opinion is reinforced by the finding that a patient who has once responded to local hydrocortisone is likely to do so again if symptoms recur. There is now a small group of patients who have repeatedly responded swiftly to local treatment, one patient having been treated twice, one patient three times, and two patients four times. So far only a single patient has failed to respond to a second course of treatment after going into remission with the first. In view of the episodic nature of the disease in many patients, an occasional exception of this sort need not be taken as invalidating the general principle that one successful treatment means that future treatments will also be successful.

However, the view that local hydrocortisone is a useful treatment is based only on a personal judgment that rapid remission would not occur in as many as two out of every three instances unless the treatment was having some positive effect. In view of the variable course of ulcerative colitis, and especially in view of a widely held opinion that the disease is a psychosomatic disorder, it would be unwise to pay too much attention to clinical impressions. It is therefore essential that new forms of treatment should be the subject of comparative study. Perhaps the wisest view is to regard the present findings as encouraging enough to justify the initiation of controlled trials.

If we assume for the moment that the hydrocortisone was indeed responsible for the rapid remissions experienced by the patients who did well with this form of treatment, there are various practical and theoretical issues which arise. One concerns the fact that patients either respond swiftly to the treatment or show little or no change: in this respect the

findings resemble what has been found for skin diseases (Sulzberger and Witten, 1954). However, it may have some bearing on the aetiology of ulcerative colitis. Numerous theories have been put forward to account for this condition, such as that it is an expression of allergy, dietary deficiency, damage from bacterial dysentery, overproduction of lysozyme, parasympathetic overactivity, or emotional stress.

Some workers regard "ulcerative colitis" as no more than a non-specific response of the colon to one or more of these factors (Brooke, 1954). Others seek, so far in vain, to explain the condition on the basis of a single causal mechanism and regard other apparently provoking factors as irrelevant. Yet others regard it as a specific response of the colon but conceive that any one of a number of factors may act as a "trigger" and fire off the disease in its overt form. Presumably a consistent difference of response to a local treatment such as hydrocortisone might indicate that different mechanisms are responsible for ulcerative colitis in different patients. In other words, such a variable response from one patient to the next might imply that in ulcerative colitis we are dealing not with a single disease but with a family of diseases.

However, there is another possible explanation of the failure of some patients to respond to treatment. Although students of the disease are now almost unanimous in regarding it as not being primarily an infective condition, secondary infection undoubtedly plays a dominant part in many of its complications. In view of the contents of the colon, it would be surprising if the mucosa, once being abnormal, were not liable to infection. The cytological findings of the present study lend some support to this idea. The situation may therefore be analogous to what occurs when an atopic dermatitis becomes secondarily infected. It is then commonly found that local treatment with hydrocortisone is useless, because hydrocortisone encourages the spread of most infective processes. It has been shown that in these circumstances a combination of hydrocortisone with an appropriate antibiotic will bring about healing, for there is no mutual interference, either chemical or biological, between hydrocortisone and antibiotics (Robinson *et al.*, 1956). It therefore seems important to test the effect of combining hydrocortisone with antibiotics for local use in ulcerative colitis. So far I have not used this combination, as it was considered essential to assess first the direct action of hydrocortisone alone.

Problems also arise in connexion with the exact details of treatment in those patients who show a beneficial response to local hydrocortisone. One way of using this agent is to give a short course of treatment whenever symptoms recur and hope that a reasonably long remission will follow each course; this is the approach which has been made so far. However, it is possible that patients should have a much longer course than has been used in the present study in the hope that a longer period of remission will follow. Another possibility is that treatment carried out once or twice a week might hold a patient in permanent remission. These are issues which will require further study under controlled conditions.

Summary

In a previous study it was found that about two out of every three patients with mild or moderate attacks of ulcerative colitis went into rapid remission when treated with a slow rectal drip of hydrocortisone dissolved in 5% ethyl alcohol. However, it was found that biopsy specimens of the colonic mucosa did not show a corresponding improvement.

A substance soluble in water—hydrocortisone hemisuccinate sodium—has now been used in place of hydrocortisone itself to determine whether the previous failure to obtain mucosal response was due to the weakly alcoholic solution which acted as a vehicle for the ordinary hydrocortisone.

Local treatment with hydrocortisone hemisuccinate sodium brought about rapid remission of symptoms in 11 out of 18 courses of treatment. The clinical response was therefore closely comparable to what was previously found for hydrocortisone itself.

The sigmoidoscopic appearances in those patients going into remission showed marked improvement and were only slightly abnormal at the end of 10–14 days.

The histological appearances of small biopsy specimens of the colonic mucosa in general showed improvement corresponding with the clinical and sigmoidoscopic appearances. It seems likely that the lack of histological improvement in the previous study was due to the presence of 5% ethyl alcohol in the rectal infusion.

Cytological study of colonic smears before and after treatment revealed a close correlation between clinical remission and a change of colonic epithelial cells towards a normal appearance. However, numerous pus cells were still present after treatment, even in those patients in remission, and suggest the possibility that an infective element is often present, which, as would be expected, is not improved by hydrocortisone.

The theoretical and practical implication of the findings are discussed with special reference to the issues which need to be settled by further studies. In particular, it is suggested that the present results are sufficiently encouraging to justify controlled trials.

I am grateful to Glaxo Laboratories for making a gift of the hydrocortisone hemisuccinate sodium; to Miss Shirley Thomas, who assisted at the sigmoidoscopic examinations and also prepared the histological sections; to my colleague, Mr. M. M. Boddington, for permitting me to use the cytological findings which are part of a study we are jointly making; to Mrs. B. Humphreys for keeping the records of the patients; and to Dr. Jean Grant for supplying me with blood transfusion sets already modified to carry a soft rubber catheter instead of an intravenous needle. I am indebted to the Medical Research Council for a personal grant in support of this and other studies into ulcerative colitis. It is fitting to pay a tribute to the patients themselves and especially to the way in which they have submitted to repeated sigmoidoscopic examinations even when symptom-free.

The *West African Journal of Biological Chemistry*, a new quarterly covering microbiological chemistry, chemical pathology, chemotherapy, pharmacy, pharmacology, and agricultural research, is intended to keep West African scientists in touch with one another and with contemporary biochemical work. It is edited by Dr. O. Bassir, University College, Ibadan, Nigeria, and published by J.M.P. Publishing Services, Effingham House, Arundel Street, London, W.C.2, price 21s. per annum.

TOXIC EFFECT OF STREPTOMYCIN UPON BALANCE AND HEARING

BY

TERENCE CAWTHORNE, F.R.C.S.

AND

DOUGLAS RANGER, F.R.C.S.

From the National Hospital for Nervous Diseases,
Queen Square, London

The curious and damaging affinity of streptomycin for the eighth-nerve system was recognized by Hinshaw and Feldman (1945) soon after its introduction into clinical practice. They found that the earlier compounds, the calcium and sulphate salts, affected mainly the vestibular part of the eighth-nerve system, causing a disturbance of balance, though it was noted that sometimes deafness also followed prolonged use of the drug owing to intoxication of the cochlear system as well.

The disturbance of balance caused by intoxication of the vestibular system was often so inconvenient and disabling that a search was made for a compound of streptomycin without these undesirable toxic effects. This led to the introduction of dihydrostreptomycin. Unfortunately this compound proved to have a selective and destructive action upon the cochlear system, causing deafness, though in large enough doses it also affected the vestibular system. It was soon found that deafness was even more inconvenient than giddiness from loss of vestibular sense, and in consequence there has been a retreat from the cochleo-toxic dihydrostreptomycin in favour of the vestibulo-toxic sulphate preparation of streptomycin, though some prefer to use a mixture of the two in what is believed to be subtoxic doses. Nevertheless, instances of disturbed equilibrium and of deafness have been reported after using the mixture.

As we have seen a number of patients crippled by streptomycin therapy, some after small doses, we feel that the time has come to reconsider the toxic properties of streptomycin, with special reference to its effect upon the vestibular system, particularly as many of our patients have been middle-aged or elderly, when the effect of a disordered vestibular system is not easily overcome.

Eighth-nerve System and Streptomycin

The eighth-nerve system consists of two sensory receptors—one for balance and the other for hearing—both of which are housed in the labyrinthine spaces of the internal ear in each temporal bone. The nerve fibres from each set of end-organs are collected within the temporal bone into two nerves—the cochlear, on which lies the spiral ganglion, and the vestibular, on which lies the ganglion of Scarpa. These two nerves leave the temporal bone together as the eighth cranial nerve and after a short course enter the brain stem, where again they separate, the vestibular fibres going to nuclei in the brain stem and cerebellum on the same side, and the cochlear to nuclei on both sides. Thence each is relayed to appropriate motor nuclei in the brain stem and spinal cord, and to higher centres in the temporal lobe.

There has been much discussion about which part of the eighth-nerve system is affected by streptomycin. Earlier workers, Hinshaw and Feldman (1945), Fowler and Glorig (1947), and Winston *et al.* (1948), favoured the nuclei in the brain stem, but more recently it has been held that the end-organs or peripheral ganglia bear the brunt of the toxic effect. Causse (1949), Ruedi *et al.* (1951), and Hawkins and Lurie (1954) believe that the drug acts peripherally. If

sufficient streptomycin is given both central and peripheral parts of the system can be affected.

Effect of Loss of Vestibular Function

At this stage it will be convenient to consider the effect of loss of vestibular function, as this is the part of the eighth-nerve system usually affected, and the effect and process of compensation are not always fully appreciated.

Balance is governed by impulses received from the vestibular end-organs in the labyrinth. These are aided by visual impressions which often give advance information about a change in balance (for example, uphill, downhill, steps, uneven ground, etc.), while kinaesthetic impressions from the skin, muscle, and joints also aid balance. In fact, man, accustomed as he is to walking with his feet firmly on the ground and in daylight or well-lighted surroundings, is able to do much of his balancing with his eyes and his skin-muscle-joint sense, being quite unaware, except when something goes wrong with it, that he is possessed of a special balancing sense.

The effect of losing vestibular function is governed by the suddenness and degree of the failure. In its acutest form the vertigo, nystagmus, and vomiting can reduce the sufferer to a state of helpless misery. As central control is gradually established these symptoms and signs subside in the course of about three weeks, leaving a residual difficulty in balancing when up and about, and a tendency to momentary dizziness with sudden head movements. Balancing at first is not easy, and even the most adept will walk with a wide base and will need a stick for some time and will have to turn slowly. They will also have to go cautiously on uneven ground or up and down stairs and will have to avoid walking in the dark. Furthermore, they will find that all movements must be planned beforehand and executed deliberately, otherwise they will tend to overbalance. The rate of recovery depends upon the age and also upon temperament. The young make a quick recovery and can adapt themselves well to the loss of the vestibular sense, though they cannot manage if deprived of either of the other aids to balance. On the other hand, patients over 40 usually find it difficult to walk unaided after losing the vestibular sense, and some may be positively crippled. Much, however, depends upon temperament and training, and the following case record shows what a good recovery can very occasionally take place.

Mrs. A. S., aged 58, had 2 g. of streptomycin sulphate daily for 10 days for bronchiectasis. After this each vestibular labyrinth remained unresponsive to caloric stimulation, but the patient was a woman of great determination who had fought against chronic ill-health for many years; and within two months she was able to resume her household duties and go out shopping unaided.

When the loss of vestibular function is less sudden and incomplete the clinical picture is less dramatic and less obvious. Nevertheless, if it is not recognized as such it can be disabling, and we have always found that demonstrating a definite organic cause for the symptoms is the first stage in the management of disturbed vestibular function. Patients are encouraged to walk and balance, using the special head and balancing exercises devised at King's College Hospital by Cawthorne (1946) and Cooksey (1946). Most patients are able to get about again within a few weeks, though the older among them have to use one or even two sticks. The young are usually able to adapt themselves to altered conditions of balance sufficiently well to be able to get about unaided and to do most forms of work. Older patients, however, find it very difficult to readjust. If their plight is not appreciated and vigorous measures are not undertaken to get them moving again, they may well remain in bed or at any rate be chair-ridden.

For these reasons we feel that loss of vestibular function can be a serious disability and that all who use streptomycin should be fully aware of its potentially disabling properties even, at times, after a dose as small as 3 g. given in three days.

JUNE 22, 1957

Sometimes the vestibular disturbance seems to be more than usually disabling, as the following case record shows.

Mrs. S. M., aged 26, lost vestibular function on one side only after 29 g. of streptomycin sulphate given over a month for tuberculous salpingitis. With one normally acting labyrinth she was in the same state as those patients who have one labyrinth destroyed on account of Ménière's disease. Such patients invariably respond well to balancing exercises and are able to return to an active life after a month. However, despite the fact that she was young, of a cheerful disposition, and keen to recover, she was unable to walk unaided after six weeks of balancing exercises. This we feel may well be due to damage to the central vestibular system in the brain stem as well possibly to the labyrinth. In such an event it is likely that the normal compensating processes which are believed to be due to the tonic action of the vestibular nuclei are interfered with, thus delaying recovery.

Properties of Streptomycin

Streptomycin is prepared from *Streptomyces griseus* and is second after penicillin in the antibiotic hierarchy. It is available as the sulphate or dihydro salt and is usually given by intramuscular injection, though it can be used in addition intrathecally, injected into the pleural or peritoneal cavity, or given by inhalation. Orally it is effective only within the gastro-intestinal tract, and locally on the skin or in wounds it is apt to cause local reaction. Like penicillin it is bacteriostatic and in large doses is bactericidal, and is particularly useful in combating infections caused by *Mycobacterium tuberculosis*, *Escherichia coli*, *Pseudomonas pyocyanea*, *Proteus vulgaris*, and certain other Gram-negative organisms as well as many of the Gram-positive. It is used for tuberculous infections and, because of its action on Gram-negative organisms, for infections of the gastro-intestinal tract and the genito-urinary tract. It is also used for certain infections by Gram-positive bacteria which are resistant to penicillin, and sometimes it is given in combination with penicillin.

Unlike penicillin, which is excreted by the renal tubules, it is excreted by glomerular filtration. With each antibiotic the serum level cannot normally reach more than a certain height despite the dosage, owing to the filtering-off action of the kidney. If renal excretion is impaired then the level of the antibiotic in the serum may reach a higher level than in the normal subject. This is one reason why some cases of toxic manifestations following even a small dose of streptomycin have been reported; and is illustrated by the following cases.

Mrs. A. H., aged 65, who was suffering from pyelonephritis in her only functioning kidney, lost all vestibular function after a total dose of 3 g. of streptomycin sulphate, 1 g. being given on each of three successive days.

Mr. B. S., aged 25, had pyelitis in his only kidney, the other having been removed five years previously. He was given only 0.5 g. of streptomycin sulphate daily for one month, and at the end of this time he had lost all vestibular function.

Thus streptomycin should be given only in small doses and with great caution to patients with renal dysfunction.

It is generally believed that as much as 1 g. a day of streptomycin is well tolerated for several weeks, and the toxic effects are usually noticed only when more than 1 g. a day is given for at least a fortnight.

Glorig (1950), however, has found that intoxication is by no means uncommon with smaller doses than 1 g. a day, and this has also been our experience, as the following case shows.

Mrs. R. G., aged 72, who was suffering from recurrent bronchitis following coronary thrombosis, was given a course of injections of streptomycin sulphate, 1 g. each day. After three days she noticed some dizziness, and as this seemed to get worse the streptomycin was discontinued after five days, when 5 g. in all had been given. Despite this she was so disabled by a disturbance of balance that she could not leave her bed for over three months and then she could walk only a short way with a companion, and with the aid of a stick after a further two months. Examination revealed a severe impairment but not complete loss of response to caloric stimulation of the vestibular labyrinths, and this defect has remained unchanged for one year.

Generally the toxic effect of streptomycin on the eighth-nerve system is irreversible; though in a fortunate few some recovery of function takes place if the drug is withdrawn soon after symptoms have appeared, as the following example shows.

Mrs. T. K., aged 63, was given 1 g. of streptomycin sulphate daily for four days following resection for carcinoma of the rectum. She became very giddy and gave no response to caloric stimulation of each labyrinth. When tested four years later the right labyrinth responded normally to caloric stimulation though the left was still unresponsive.

No doubt the ability to compensate in part for loss of vestibular function has led to the belief that return of function after the drug has been stopped happens much more often than is really the case.

On the other hand, it has been suggested that vestibular function can continue to deteriorate after the withdrawal of the drug, though we do not believe that such an unfortunate state of affairs can be very common.

Progressive loss of hearing after the withdrawal of dihydrostreptomycin is also reported, and the following case shows how disturbing this can be.

A professional man aged 39 received daily 1.5 g. of dihydrostreptomycin by intramuscular injection, and 0.1 g. intrathecally for six weeks, because of tuberculous meningitis. He recovered from the infection, but lost the function of one vestibular labyrinth and some of the hearing in each ear. After the drug had been stopped the hearing continued to deteriorate for three months. A hearing-aid gave him but little assistance, and despite great efforts he was unable to keep up his profession. He became more and more depressed and finally took his own life.

Another effect of streptomycin which can be distressing, though fortunately it is reversible, is upon the skin. Skin reactions may vary from a mild dermatitis to a severe and extensive exfoliative dermatitis, and the following case is an example of this and of vestibular destruction.

P. M., a boy aged 13, developed an aching left ear after a head cold, and two days later the ear began to drip clear fluid at the rate of half a teacupful in three hours. He was admitted to hospital and given systemic penicillin pending further investigations. Two days later the ear discharge became purulent and signs of meningitis appeared. Pus from the ear grew *Ps. pyocyanea*. He was given streptomycin, 0.9 g. daily intramuscularly and 0.1 g. daily intrathecally. After 10 days the left mastoid was opened and two days later the streptomycin was stopped because of generalized exfoliative dermatitis. Within a week the dermatitis had almost entirely cleared and the cerebrospinal fluid was normal. The boy made a complete recovery except for loss of vestibular function. He soon adjusted to this, and when last seen, eight years after his illness, he had been in employment as a tractor driver for three years. Despite absence of vestibular function his disability was noticeable only when he tried to walk with his eyes closed, and he volunteered the information that he was unable to swim and in fact was afraid of the water, this of course being due to loss of visual and kinaesthetic aids upon which he had to rely for maintaining balance.

Ménière's Disease

It has been suggested that the toxic effect of streptomycin upon the vestibular system should be turned to advantage in the treatment of Ménière's disease, where the disordered vestibular system can be ablated without any harm to the hearing.

Unfortunately, streptomycin can act equally upon each vestibular system whether diseased or not, so that when Ménière's disease is unilateral and the patient is over 40, to abolish both sides of the vestibular system may well end up by the cure being worse than the disease, as the following case record shows.

Mr. W. W., aged 56, had been troubled with bouts of severe vertigo and vomiting for three years. Before each attack the slight but persistent noise in his left ear increased and the hearing in that ear was also affected. In between attacks, however, he was quite well and the hearing in the left ear was only slightly affected. A caloric test of vestibular function revealed a moderate impairment of response on the left side only. Nothing influenced the frequency and severity of the attacks, so, in view

of the good hearing on the left side, it was decided to try the effect of a course of injection of streptomycin. He was given 2 g. daily for four weeks, after which there was no evidence of any remaining vestibular function on either side. When we first saw the patient a year later he was still unable to walk at all. After a course of special balancing exercises he was just able to get about with the help of a companion and a stick, but it was an effort both for him and for his companion and he could not venture up or down stairs or beyond his own small garden; he was quite definite that if he could he would change back to his attacks and good balancing between-whiles.

There are, however, occasions when the deliberate intoxication of the vestibular system in cases of bilateral Ménière's disease is justified.

The two cases just described illustrate very well how much more disabling loss of vestibular function is in older as compared with younger persons such as the boy P. M. Ruedi (1951) and others have hoped that in Ménière's disease function in the affected labyrinth is more readily destroyed than that in the healthy labyrinth. This has not been our experience, though this is not to say that the toxic effect is always bilateral and symmetrical, and we have seen several patients in whom only one side was affected. The case of one of these, Mrs. S. M., has already been described.

Increased Incidence of Vestibular Damage

We seem to have seen more patients recently with absence of or disordered vestibular function following the administration of comparatively small quantities of streptomycin; and the Table includes all those patients listed in years since 1951 who have shown symptoms and signs of intoxication after a total dose of less than 20 g. of streptomycin.

Patients Exhibiting Toxic Effects of Streptomycin Where the Total Dose has been Less than 20 g., 1951-6

Name	Age	Daily Dose (g.)	Total Amount (g.)	Condition for which Given	Hearing	Vestibular Function
1951: Mrs. M. B. Mr. P. D.	48 62	2 1	10 11.5	Cystitis Fistula in ano	Unaffected "	R. lost L. lost, R. impaired
1952: Mrs. T. K. Mrs. H.	63 50	1 2	4 9	Resection of colon Nephrectomy	" Slight high tone loss. Both	Both lost Both slightly impaired
Mrs. L.	44	1	16	Tuberculosis in solitary kidney	Severe deafness. Both	Normal
1953: Mrs. S. M. Mr. C. W.	50 66	1 2	5 8	Renal calculi Retention of urine	Unaffected "	Both impaired L. lost, R. impaired
1954: Mr. L. D. Mr. B. S.	68 25	1 0.5	12 15	Pulmonary tuberculosis Pyelitisolitary kidney	" "	Both lost " "
1955: Mrs. P. Mrs. F. P. Mr. S. H.	63 50 41	2 1 1	11 16 12	Resection of colon Pulmonary tuberculosis Bazin's disease	" " Moderate deafness. Both	L. lost Both impaired Normal
Mrs. A. H.	65	1	10	Pyelitis	Unaffected	Both lost

Mrs. G. G.	47	1	14	Pulmonary tuberculosis	"	" "
Mrs. M. P.	63	2	16	Broncho-pneumonia	"	" "
Mrs. A. K. Mrs. F. S.	42 50	1 1.5	3 15	Laparotomy Perianal abscess	" "	R. impaired Both lost
Mrs. R. G.	72	1	5	Bronchitis	"	Both impaired
Mrs. J. A.	40	2	10	Nephrolithotomy	"	R. lost

We think that this increasing incidence may be due to a more general adoption of the custom of carrying out tests of sensitivity to different antibiotics on infected material. Streptomycin is usually one of the antibiotics tested, and if the infection is found to be more susceptible to streptomycin than to any other antibiotic, the clinician may decide to use it in preference to the others. Although he may be aware of the toxic effect of streptomycin upon the eighth-nerve system, we have the impression that a dose of 1 g. a day for two weeks is generally regarded as being a safe dose. Many of the infections tested for antibiotic sensitivity are particularly sensitive to streptomycin, and this applies especially to infections of the lower respiratory, the lower digestive, and the urinary tracts.

It may well be that the incidence of vestibular damage when the dosage of streptomycin does not exceed 1 g. a day for two weeks is low; but it is there, and we are finding it to be on the increase. For these reasons we believe that all clinicians should be aware of the possible consequences of the use of streptomycin even in small doses over a short period of time.

Reports that the pantothenate salts of streptomycin reduce ototoxicity have not been confirmed, but work is still continuing on the development of other preparations of the drug. Thus it seems that there is some hope that a less toxic form of streptomycin may soon appear.

For the present, however, until we are sure of this it behoves all who use streptomycin to do so as sparingly as the infection will allow, and to be prepared to withdraw it at the first symptom of ototoxicity.

Finally, if the daily dose does not exceed 0.5 g. toxic symptoms are unlikely to occur, except when there is renal insufficiency, and in such an event streptomycin should, if possible, be avoided. It is, of course, appreciated that to control certain serious infections such as tuberculosis a daily dose of 1 g. may be necessary.

Summary

The ototoxicity of streptomycin is discussed and the effect of intoxication of the vestibular part of the eighth-nerve system is described.

Though it is generally believed that toxic symptoms are unlikely to appear so long as the daily dose does not exceed 1 g., several instances are given in which intoxication occurred even though this dosage was not exceeded.

The number of cases of intoxication is on the increase, and this may be due to a wider use of streptomycin as the result of sensitivity tests.

Renal insufficiency, by permitting a high concentration of streptomycin in the blood, renders a patient unduly susceptible to the drug.

It is concluded that symptoms of intoxication are unlikely to occur so long as the daily dose of streptomycin does not exceed 0.5 g.; though it is appreciated that in serious tuberculous infections as much as 1 g. a day may be needed.

We would like to thank all our colleagues at the National Hospital for Nervous Diseases, Queen Square, the Middlesex Hospital, King's College Hospital, the London Chest Hospital, and elsewhere for referring their patients to us, and to Dr. H. M. Walker for the help he has given.

MYXOMA OF THE LEFT ATRIUM SUCCESSFUL SURGICAL REMOVAL UNDER HYPOTHERMIA

BY

E. F. CHIN, F.R.C.S.

AND

D. N. ROSS, F.R.C.S.

Thoracic Unit, Southampton Chest Hospital

Myxoma of the atrium generally occurs as a polypoid tumour attached to the left side of the atrial septum in the region of the fossa ovalis. Pathologically it is smooth and shiny, with a soft, gelatinous consistency, and microscopically is seen as a structureless matrix with scanty scattered cells, usually lying singly. The histology of the tumour removed from our case showed the following characteristics. It was composed of a mucoid matrix containing much old and recent haemorrhage and areas of structureless fibrin. Lying in groups and strands, and especially in association with thin-walled blood vessels, were "lepidic," stellate, and fusiform cells of a myxoma. This contained much intracytoplasmic foamy material giving the histochemical reactions of a mucin. The tumour weighed 60 g.

Myxomata may arise as a result of myxomatous degeneration in a thrombus, or they may represent true new growths. A review of recent observations on their pathology and varying clinical picture has been published by Brewin (1948).

It is inevitable that a significant number of myxomata will be encountered in the course of the many hundreds of mitral valvotomies performed yearly, and it is important that the surgeon should have a precise knowledge of the problems and steps involved in their successful removal. At the same time, every effort should be made to diagnose these cases pre-operatively, when a planned operation for removal of the myxoma can be carried out with reduced hazard of dissemination of tumour emboli.

Case Record

A man aged 25 was admitted to hospital under the care of Dr. R. O'Meara, in August, 1956. He then had a right-sided hemiplegia. This cleared quickly. Though auricular fibrillation was not present it was felt that an embolus was responsible.

Examination at that time showed a thrill and a short, rather sharp apical systolic murmur, and a split-second sound was audible at the apex; a diastolic murmur was heard with difficulty only after the patient had been exercised. Screening showed moderate enlargement of the left atrium, and the heart shape suggested mitral stenosis. He was referred to the cardiac clinic of Southampton Chest Hospital for an opinion regarding surgery and, indeed, whether this was a case of mitral stenosis at all.

When seen in October, 1956, by Dr. W. Somerville, he had signs which suggested mitral stenosis. A diastolic murmur with pre-systolic accentuation was present. The mitral first sound was classified as grade III. An opening snap was evident. A short systolic murmur was heard. He was in regular rhythm. Serial x-ray films showed that the cardio-thoracic ratio had increased from 52% to 57% over the course of a year. In view of these findings and the history of an embolus, cardiomyopathy was advised.

At operation, on December 4, the lungs had the appearance and the feel of typical "mitral lungs." The carotid vessels were taped and the pericardium was opened, reveal-

ing pericardial fluid in excess. The atrial appendage was opened without clamps. Exploration of the mitral valve showed it to be perfectly normal, but in the region of the medial commissure a plunging soft tumour was felt. It was thought to arise from the atrial septum, but no detailed assessment was attempted for fear of dislodging some tumour or clot. The atrium was closed and the patient was returned to the ward. Heparin was given immediately in an attempt to prevent a clot embolus, though it was realized that this would in no way prevent a tumour embolus. Heparin was continued for three days, and then was changed to phenindione ("dindevan").

Open cardiac surgery, under hypothermia, was planned for December 15. This time interval was decided upon to allow the patient to recover as fully as possible from the previous cardiomyopathy, and to have an operative field not too obliterated by adhesions. The patient was well until the ninth post-operative day, when he suddenly developed a left facial paresis. At this time his prothrombin index was 37%. It was felt that this was a tumour embolus, but of course dislodged clot was also a possibility. It must have been very small, as the paresis had gone by the following day.

The second operation was undertaken, as planned, on December 15. The temperature was brought down to 83.3° F. (28.5° C.) by surface cooling (Dr. E. S. Machell). The patient was placed in the supine position and a bilateral approach was used through the bed of the fourth rib on both sides, with transection of the sternum. The right innominate and the left common carotid vessels were encircled with rubber slings for compression when the circulation was restored at the conclusion of operation. The superior and inferior venae cavae were occluded, and after 30 seconds a clamp was placed across the transverse sinus, occluding the aorta and pulmonary artery. The right atrium was opened widely.

With the right atrium open, the septum was seen to be bulging to the right. It was obvious that this was due to the tumour mass. Entry into the left atrium was effected by stabbing through the fossa ovalis, then cutting down to its lower margin and extending this incision upwards just beyond its rim. The finger was then slipped in and the incision extended upwards.

The tumour, having a gelatinous consistency, flowed through the defect. Portions of the tumour which presented at the septum were sucked away. It was found that a sucker was the most effective way of picking up the tumour. A finger was then slipped through the septum around the pedicle of the myxoma. At this stage it was too big to deliver itself into the right atrium, but when the presenting portion of the tumour had been removed it slipped through into the right atrium, and the pedicle could be held between the fingers. The pedicle, with a small surrounding portion of the septum, was excised. The left atrium was sucked out, and one additional large fragment of the tumour was obtained. It was then explored with the finger and no remaining tumour or clot could be felt. The cavity was flushed out with saline and this was aspirated. There appeared to be no remaining particles of tumour or clot, and the septal closure was completed under saline to exclude air.

On completion of the septal closure a clamp was applied across the atrial incision and the superior vena-caval sling was removed. The carotids were occluded and the transverse sinus clamp was removed. The inferior vena-caval sling was then released, after which carotid occlusion was maintained for 20 seconds. The total occlusion time had been nine minutes, at a temperature of 83.3° F. (28.5° C.).

During the closure of the septum marked bradycardia was present, but the rhythm was regular. Just as the atrial closure was being completed, ventricular fibrillation supervened. Cardiac massage was instituted immediately and adrenaline was injected into the left atrium. When the heart was pink it was defibrillated, but for the next hour it had to be assisted by massage almost continuously. In spite of repeated electrical defibrillation and injection of adrenaline, calcium

chloride, methylamphetamine hydrochloride, and atropine, cardiac rhythm was not permanently restored until the temperature had reached 86° F. (30° C.), as a result of continuous irrigation of the pleural cavities with warm saline. At this level the E.C.G. showed sinus rhythm. The pericardium was then closed and the heart was observed for a further 40 minutes. During this time the rhythm remained regular, and this was confirmed by the E.C.G. Two hours later the patient was fully conscious and co-operative, with no sign of cerebral damage. The pulses were all present post-operatively.

Discussion

Clinical discussions tend to emphasize a history of multiple peripheral emboli, and although there was only one embolic episode in our case, its presence, in the absence of established atrial fibrillation, should have raised suspicion of a myxoma. The diastolic murmur is not surprising in association with a pedunculated tumour arising from the septum. On the other hand, syncope from obstruction of the mitral orifice, as in ball-valve thrombus, is unlikely, since the tumour is jelly-like and can easily be forced through the mitral orifice.

When a tumour of this nature is encountered during the exploration of the mitral valve it is important, in view of the friable nature of the mass and the hazards of a cerebral embolus, that a minimum of intra-atrial manipulation be

carried out. In addition, it is desirable that the tumour should be removed immediately, since in the cases described by Brock (1956) there was bilateral cerebral embolism by the time of the second operation. In our case a further cerebral embolus occurred on the ninth day in spite of post-operative heparinization. Heparin was used in view of the finding of massive clot adherent to the tumour in Brock's case, and the danger of clot embolus was again confirmed in our case, as patches of clot were intermingled with the tumour (Fig. 1).

The correct approach to the tumour as it lies against the atrial septum is through the right atrial chamber (Brock, 1956): the successful outcome fully justifies the validity of this concept (Fig. 2).

The right atrial chamber lies above and to the right of the left atrium, which is inaccessible

placed between the right atrium and the vertebral column. On the other hand, recent experiences with right atrial surgery in the closure of atrial septal defects has emphasized the safety and ease of approach to the dependent left atrium through an incision in the septum.

Since most cases of mitral stenosis are operated upon in the antero-lateral or lateral position, it is necessary to turn the patient on his back and extend the incision across the sternum along the fourth right rib bed. However, it is reasonable to dissect out and snare the cerebral vessels, which are accessible in the lateral position, in order to avoid a tumour embolus during subsequent surgical manipulations.

The safest approach through the septum is via the fossa ovalis, and this should be opened by plunging the point of the scissors through it. The upward extension of the incision must be done with great care, and before this is completed the fingers should be slipped through the septum to assess how far cephalad it can be carried. If carried too far the transverse sinus will be opened and an uncontrollable haemorrhage will result. The tumour may be too large to deliver through the septal incision, as in our case. If the tumour is hooked with a finger around the pedicle and is made to present, a great deal of it can be sucked away until it is small enough to slip through the defect. In excising the pedicle it seems advisable to lift it up and excise a small portion of the septum with the pedicle. The table should be tilted slightly to the left so that when the left atrium is flushed before closure all the air can escape without being occluded beneath the septum.

Hypothermia is necessary to cover the period of circulatory arrest, and a difficulty arises in the use of surface cooling with an open chest. This means that the wound would generally have to be closed during induction of the cooling unless a blood stream method of cooling is available (Brock and Ross, 1955). This latter method has the great advantage, in this type of case, of permitting cooling to be carried out after the chest has been opened, and it has the additional advantage of facilitating rapid re-warming before closure of the chest. Resuscitation of the heart in our case was greatly hampered by lack of prompt re-warming facilities. Diathermy re-warming is effective in cases with good circulation, but a surface re-warming loses its efficiency when there is circulatory failure.

Summary

Myxoma of the atrium is likely to be encountered in the assessment and surgery of cases diagnosed as mitral stenosis.

In order to avoid the hazard of tumour emboli, the myxoma should be removed with a minimum of manipulation, and the cerebral vessels should be snared before re-establishing the arrested circulation.

It appears to us that the most satisfactory approach is via the right atrium, with an incision in the septum under conditions of hypothermia.

Blood-stream cooling avoids delay in removal of the tumour and postponement of a definitive operation, and re-warming carried out by this method facilitates rapid resuscitation of the heart.

Details of the successful surgical removal of a left atrial myxoma are given.

HAEMOGLOBIN K IN AN EAST INDIAN AND HIS FAMILY

BY

J. A. M. AGER, M.B., B.S.

Lecturer in Clinical Pathology, St. Thomas's Hospital, London

AND

H. LEHMANN, M.D., Ph.D., F.R.I.C.

Senior Lecturer in Chemical Pathology, St. Bartholomew's Hospital, London

The abnormal haemoglobins in East Indians so far described are principally sickle-cell haemoglobin (haemoglobin S) and haemoglobin D, and to a less extent haemoglobin E. Haemoglobin S is found in some aboriginal communities of Southern India, where in the Panyans and in the Irulas the percentage incidence is about 30, and in some tribes in Western India (Lehmann and Cutbush, 1952a, 1952b; Büchi, 1955; Sukumaran, Sanghvi, and Vyas, 1956). The rather high incidence of 55% has been mentioned for the Parjah Kondhs by Foy, Brass, and Kondi (1956). Although some families with the sickling trait have been noticed among Biharis working as labourers in Assam (Dunlop and Mozumder, 1952), sicklers were not detected amongst 23 Karias and 100 Oraons employed as forest labourers on the Andaman Islands (Lehmann and Ikin, unpublished). Shukla and Parande (1956) have observed sickling in a Mahar family. The Mahars are a "scheduled caste" in Maharashtra, and it is noteworthy that the earliest communities of India, including the Veddoids, were either driven by the later arrivals into remote places where they retained their identity or were subjugated and incorporated into what we know to-day as the scheduled castes. Though first reported in isolated instances from America and Europe, haemoglobin D has been found to occur in 3% of Sikhs and in 1% of Gujaratis (Bird and Lehmann, 1956a; Jacob, Lehmann, and Raper, 1956). India would thus appear to be a reservoir for this abnormal haemoglobin. Haemoglobin E was first discovered in a child of mixed Hindu ancestry (Itano, Bergren, and Sturgeon, 1954), but none has been found in many Indian communities investigated since, except for some occasional observations in Bengalis (Bird and Lehmann, 1956b; Chatterjea, Saha, Ray, and Ghosh, 1956; Saha, Dutta, and Ghosh, 1957). The incidence of haemoglobin E is of course high immediately East of Bengal in Burma and in the neighbouring Siam and Malaya.

The "Fast-moving" Abnormal Haemoglobins

The first abnormal haemoglobins to be discovered by electrophoretic technique were all migrating more slowly at alkaline pH than normal adult haemoglobin (haemoglobin A). In the last two years, however, four haemoglobins have been described which move faster than haemoglobin A at alkaline pH: H, I, J, and K. There has been some confusion about the nomenclature, and the following is based on a discussion of this problem at a working party meeting under the chairmanship of Dr. J. V. Neel during the 6th Congress of the International Society of Hematology in Boston in 1956 (see Lehmann, 1957).

Haemoglobin H (Rigas, Koler, and Osgood, 1955) has been found in Chinese, in Filipinos (Motulsky, 1956), in Siamese (No-Nakorn and Minnich, 1956), and in one Malaysian Malay (Lehmann and Singh, 1956). The only observations in non-Mongoloids are in two Greek families (Gouttas, Fessas, Tseveris, and Xefteri, 1955), in a Greek Cypriot

(Ager, unpublished), and in a Jordanian Arab (personal communication by Dr. J. C. White).

Haemoglobin I was seen in an American negro family and in Algiers (Rucknagel, Page, and Jensen, 1955; Cabannes, Sendra, and Dalaut, 1955).

Haemoglobin J was discovered in an American negro family (Thorup, Itano, Wheby, and Leavell, 1956). It was noted in West Africa—at first called "Liberia I" (Robinson, Zuelzer, Neel, Livingstone, and Miller, 1956)—and was found according to Robinson *et al.* (1956) in a French Canadian family by Colonel W. H. Crosby. Huisman, Noordhoek, and da Costa (1957) have found this haemoglobin in an Indonesian family; and Raper (1957) has described an example in a Gujarati Indian.

Haemoglobin K has been described in three Berber families by Cabannes, Buhr, and Sendra (1956), and by Robinson *et al.* (1956) in a survey of Liberians—provisionally named "Liberia II." Edington and Lehmann (unpublished) have seen three examples amongst members of the Dagomba tribe from Northern Ghana. In a man of East Indian origin and in his son we have now seen a haemoglobin which has the electrophoretic properties described for haemoglobin K.

Electrophoretic Properties of Haemoglobin K.—Haemoglobins H and I move at pH 8.6 considerably faster than haemoglobin A and are separated from it about as much as haemoglobin E in the reverse direction. Haemoglobins J and K move more slowly than H and I; haemoglobin K is the slower. While haemoglobin J just faintly separates from haemoglobin A, haemoglobin K tends to appear as a band in front of haemoglobin A but barely separated from it. At pH 6.5 the situation is reversed and the abnormal component is attached to the rear of the haemoglobin A band. There is, however, a discrepancy between the reports on haemoglobin K: Cabannes *et al.* (1956) found a separation between haemoglobins A and K at this acid pH, whereas Robinson *et al.* (1956) found no such separation in their mixture of haemoglobin A and "Liberia II," which latter—subject to a final comparison between the two—is thought to be identical with haemoglobin K.

Findings

The subject of the present investigation, an Indian resident in London, was born in South Africa, where his grandfather had immigrated from India (Madras). Though he married a woman of Scots and West Indian origin there is no evidence in his appearance or from his family history that there has been any admixture of non-East Indian blood amongst his own ancestry. He was 43 years old and was being examined for assessment of Addison's disease and treatment of pulmonary tuberculosis. As he was a non-European he was examined for abnormal haemoglobin. There was no anaemia, and no abnormality was found in the size or appearance of his red cells; the osmotic fragility of these cells was normal. The sickling test was negative, and alkali-resistant haemoglobin (haemoglobin F) was absent. The solubility of the reduced haemoglobin was within normal limits (Itano, 1953).

On paper electrophoresis at alkaline pH the haemoglobin was seen to consist of two components—one resembling haemoglobin A in its electrophoretic properties, and another, amounting to 38%, which was moving faster than haemoglobin A though it was barely separated from it. His haemoglobin mixture was compared with mixtures of haemoglobins A+H and A+J respectively each both at alkaline and at acid pH. The first was obtained from a Greek Cypriot and the second was kindly made available by Dr. A. B. Raper. Furthermore, Dr. H. A. Itano and Dr. T. H. J. Huisman obliged us by comparing the haemoglobin of our patient with mixtures of haemoglobins A+J, and Dr. R. Cabannes by comparing it with a haemoglobin A+K mixture. The outcome of these comparisons was that the abnormal haemoglobin of our patient moved on paper electrophoresis at alkaline pH very much more slowly than haemo-

globin H (or I) and rather more slowly than haemoglobin J, but identically with haemoglobin K (Fig. 1).

As noted above, Cabannes *et al.* (1956) found their haemoglobin A+K mixture to separate into two fractions on paper electrophoresis at pH 6.5, but Robinson *et al.* (1956) failed

FIG. 1.—Paper electrophoresis at pH 8.6, barbiturate buffer. Comparison of haemoglobins A+J with the haemoglobin of the patient (A+K). It will be seen that at pH 6.5 haemoglobin consists of haemoglobin A and of another component migrating faster than haemoglobin A but more slowly than haemoglobin J.

FIG. 2.—Paper electrophoresis at pH 6.5 phosphate buffer. Comparison of haemoglobins A+H with the haemoglobin of the patient (A+K). It will be seen that at pH 6.5 haemoglobin A moves towards the cathode, and haemoglobin H towards the anode, and that the abnormal component of the patient's haemoglobin does not separate from haemoglobin A.

to achieve a separation with their sample at this pH. Our sample behaved like that of Robinson *et al.* (1956) (Fig. 2). Edington and Lehmann's three samples of haemoglobins A+K from Ghana (unpublished) also did not separate on paper electrophoresis at pH 6.5.

On examination of the patient's family one child was found to have the same abnormal haemoglobin as the father (Fig. 3). Its blood picture was normal, foetal haemoglobin was absent, and the osmotic fragility was within normal limits.

Comment

Haemoglobin K has so far been seen in Kabyles, Libyans, and Dagombas, all from Africa. The present example

FIG. 3.—Family of the propositus. White = haemoglobin A; black = haemoglobin K.

be assessed. Haemoglobins C, D, and E have been found to exist at higher frequency in populations other than those in which they were originally described. Although haemoglobin K is "rare" at present, it may well not be considered rare in years to come, when more populations have been examined for abnormal haemoglobins.

Summary

An abnormal haemoglobin was discovered in a South African of Indian extraction living in London. The haemoglobin had the electrophoretic properties of haemoglobin K. One son showed the same abnormality.

We should like to thank Professor F. T. G. Prunty, physician to St. Thomas's Hospital, London, for his permission to examine the propositus, who at the time was a patient under his care. We are grateful to Dr. A. B. Raper for enabling us to use his haemoglobin A+J mixture in this study, to Dr. H. A. Itano and Dr. T. H. J. Huisman for comparing our haemoglobin mixture with known samples of haemoglobins A+J, and to Dr. R. Cabannes for identifying it by a comparison with his original specimen containing haemoglobins A+K.

A European seminar on "The Nurse in Industry" was held in London recently under the joint auspices of the International Labour Office and the World Health Organization. About 50 representatives from 15 countries attended the seminar, and among those who took part were industrial nurses, social workers, industrial medical officers, and medical inspectors of factories. There were discussions on the importance of the nurse as a member of the occupational health team, which might include an industrial medical officer, first-aid attendant, social worker, chemist, and safety officer. Among the suggested duties of the occupational health nurse were the first care of accidents and sickness, occupational and non-occupational, the follow-up of this care, rehabilitation, assisting with the prevention of accidents and physical and mental sickness. She should also assist in the planning and carrying out of the programme of health education for individuals and groups; and she should be responsible for the organization and administration of the nursing services and the training and supervision of first-aid attendants and auxiliary nursing personnel where they are employed. In addition to all this she should be concerned with establishing and maintaining good relationships with employers, employees, foremen, supervisors, and the social services—and she should be independent in relation to the factory management.

ABSORPTION OF FREE ACID, POTASSIUM, AND BENZATHINE PHENOXYMETHYLPENICILLIN AFTER ORAL ADMINISTRATION

BY

J. COLQUHOUN, M.B., Ch.B.

EILEEN C. SCORER, B.Sc.

G. SANDLER, M.B., B.S., M.R.C.P.

AND

G. M. WILSON, M.D., F.R.C.P.

From Department of Bacteriology, Royal Infirmary, Sheffield, and Department of Pharmacology and Therapeutics, University of Sheffield

Phenoxymethylpenicillin (penicillin V) was first prepared in 1947 (Behrens *et al.*, 1948), but was not used as a therapeutic agent until 1953 (Brandl *et al.*, 1953). Since then many reports have demonstrated that it is more reliably absorbed after oral administration than other forms of penicillin (Jones and Finland, 1955; Juncher and Raaschou, 1955; Wright *et al.*, 1955; Heatley, 1956; Welch, 1956; Rinsler and Cunliffe, 1956; Bunn, 1956). It is also therapeutically effective (Martin *et al.*, 1955; Hart *et al.*, 1956; Wood *et al.*, 1956). In the majority of these investigations, phenoxymethylpenicillin free acid has been used, but more recently some attention has been given to phenoxymethylpenicillin salts (Andresen, 1955; Björkman and Löfberg, 1956; Brunner and Giovannini, 1956; Kaipainen and Härkönen, 1956). A knowledge of the blood levels and persistence of effect that can be obtained with different preparations and doses is clearly of importance in planning treatment. This report describes the levels achieved with 60-mg. and 240-mg. doses of phenoxymethylpenicillin free acid, and compares the results from the higher dose of this compound with those from corresponding amounts of potassium and benzathine salts of phenoxymethylpenicillin. The absorption of the benzathine salt has also been studied in patients with treated pernicious anaemia in whom there was complete gastric achlorhydria.

Methods

The subjects comprised volunteers from amongst doctors, medical students, nurses, and convalescent patients not suffering from cardiac, renal, or gastro-intestinal disease. In the first series of observations on 24 people a single dose of 60 mg. of phenoxymethylpenicillin free acid was given half an hour before breakfast. Serum concentrations were measured at $\frac{1}{2}$, 1, 2, 3, 4, 5, and 6 hours after swallowing the tablet. Twenty subjects took part in the second series of observations, in which the serum levels obtained with single doses of 240 mg. of phenoxymethylpenicillin free acid, 266 mg. of potassium phenoxymethylpenicillin, and 320 mg. of benzathine phenoxymethylpenicillin were compared. Equivalent weights of penicillin were present in these three different doses, which were administered in two tablets. The 20 subjects all took the three preparations in successive weeks in a random order. The tablets were taken half to one hour before breakfast. The interval and the type of meal were kept constant for each subject, so that the comparisons were made so far as possible under identical conditions. Finally, to investigate the importance of gastric hydrochloric acid in the absorption of benzathine phenoxymethylpenicillin, this compound was given to 11 patients with treated pernicious anaemia who had agreed to take part

in the trial. The diagnosis had been confirmed by examination of the peripheral blood and bone marrow and the demonstration of a histamine-fast achlorhydria.

The concentration of penicillin in the serum was estimated by dilutions in phenol-red-glucose-serum medium (May *et al.*, 1947), which were inoculated with *Streptococcus pyogenes*. Comparisons were made with similarly inoculated dilutions of benzylpenicillin in the same medium. This technique was used in previous studies from these departments (Wayne *et al.*, 1949).

Results

The serum concentrations obtained with the 60-mg. dose of phenoxymethylpenicillin free acid are shown in Table I. With this dose, high concentrations were not obtained in the blood, but appreciable levels persisted for up to three hours.

The results with 240 mg. of phenoxymethylpenicillin free acid are shown in Table II and the comparison with the two salts in Tables III and IV. There was considerable variation between individuals in the concentrations achieved with each preparation. The most rapid absorption and highest concentrations were achieved with the potassium salt. At the half-hour measurement the potassium salt gives a significantly higher mean level than the benzathine salt. The other comparisons do not show a significant difference. With all three forms the mean persisted for up to four hours

above 0.06 unit per ml., which may be taken as the minimum bacteriostatic level (Wayne *et al.*, 1949).

The benzathine salt was given by mouth to 11 patients with pernicious anaemia (Table V). The mean levels were higher than in the subjects with normal gastric function.

Discussion

The lower (60-mg.) dose of phenoxymethylpenicillin is the amount that might be given in the long-term prevention of infection. The concentrations obtained here with this dose are similar to those reported by Henry and Meynell

(1956). High levels cannot be obtained with this small amount, which will have an effect only on highly sensitive organisms.

The larger dose (240 mg.) of phenoxymethylpenicillin free acid gave much higher serum levels, and effective amounts were present in the blood for up to four hours. The higher concentrations achieved with the potassium salt have also been reported by Kaipainen and Härkönen (1956) and by Björkman and Löfberg (1956). The calcium salt apparently gives levels similar to those afforded by the free acid (Henriksen *et al.*, 1956; Rinsler and Cunliffe, 1956).

Some of the physical and chemical properties of the benzathine salt of phenoxymethylpenicillin have been described by Brunner and Giovannini (1956). The solubility in water of benzathine phenoxymethylpenicillin is 0.08% at 37° C. The pH of the saturated solution is about 5 and the solubility rises with increasing pH values. The minimum solubility is at pH 4.5, but in more acid conditions the solubility of the compound increases sharply. In the group of subjects with normal gastric function, lower levels were attained with the benzathine salt than with the free acid and potassium salt. The results in the patients with pernicious anaemia suggest that in the absence of gastric hydrochloric acid the benzathine salt is more fully absorbed. In tablet form it has no advantages over the other preparations. The lower peak values are not associated with a longer persistence of effective concentrations. However, the low solubility of the salt in water means that oral suspensions are relatively stable and it may be more suitable for administration in syrup form. In adults the potassium salt in tablet form is clearly preferable.

Summary

The serum concentrations achieved after 60-mg. and 240-mg. oral doses of phenoxymethylpenicillin free acid have been investigated.

The levels given by the potassium and benzathine salts in amounts equivalent to the 240-mg. dose of free acid have been compared. The potassium salt was most rapidly absorbed and gave the highest peak values. The benzathine salt gave the lowest values. The persistence of effect was similar in all three substances.

In patients with treated pernicious anaemia the benzathine salt gave higher levels than in the normal subjects.

We thank Dr. D. A. Kent and Dr. G. C. Turner, our house-physicians, for their assistance and Dr. W. P. Kennedy, of the Distillers Co. (Biochemicals) Ltd., and Dr. E. V. B. Morton, of Boots Pure Drug Co. Ltd., for arranging for the supply of the penicillin preparations.

EVAPORATED MILK IN INFANT FEEDING

BY

P. D. MOSS, M.B., M.R.C.P., D.C.H.
 Paediatrician, Blackburn Group of Hospitals

Attention has recently been drawn to eight large outbreaks of food-poisoning which occurred within one month (Anderson and Stone, 1955; *Monthly Bull. Minist. Hlth*, 1955; *Lancet*, 1956). They were all traced to spray-dried milk and found to be due to a staphylococcal enterotoxin. During the preparation the actual organisms had been destroyed, but the toxin, which is relatively heat-stable, had not. It is destroyed by heating to 88° C. (190.4° F.) for one hour. Roller-dried types of dried milk have not been incriminated in similar outbreaks, but they do contain live micro-organisms which can on occasion give rise to gastro-intestinal upsets. A personal experience, for example, was of an infant who developed diarrhoea after the first feed from a newly opened tin. The laboratory reported "a heavy growth of *B. proteus*." The fact that tins are dated indicates a recognition of some degree of danger.

In evaporated milk we have a perfectly safe infant food. The milk is received from the farm and raised to an initial temperature of 212° F. (100° C.) during solids stabilization and, later during final sterilizing (after cans are hermetically sealed), to 240° F. (115.5° C.) for 15 minutes. During this process no milk is retained in any chamber for more than 15 minutes between the heating processes. This is of considerable significance because investigations have shown that 35% of cases of bovine mastitis are caused by the staphylococcus (Malcolm, 1957). Milk may therefore arrive at a factory already contaminated, although untouched by hand. In the investigations referred to above a steady build-up was found in the staphylococcal count in a balancing chamber which was incompletely emptied during a working day. This could not happen in the process of evaporating milk. The final sterilization completely eliminates any live organisms or spores. There only remains the question of heat-stable toxin remaining potent. The factory process of evaporation does not give any opportunity for a build-up of toxin-producing organisms. It would therefore seem impossible for the end-product to contain any, unless perchance the milk already contained a toxin when it arrived at the factory. The staphylococcal enterotoxin is, of course, peculiar in that although it is inactivated by heating to 65° C. for 30 minutes, it may withstand heating to 100° C. for 15 to 30 minutes (Wilson and Miles, 1955). Milk arrives at the factory from many sources, and any toxin which may be contained in a sample is no doubt so diluted in the bulking process that the chances of its causing any gastro-intestinal upset are extremely remote.

Why, then, is it not more widely used in this country as an infant food? The answer appears to be "that uncritical prejudice has been the chief factor in the limitation of its use." This is a quotation from a paper by Marriot and Schoenthal published with reference to their experience in America as far back as 1929. It seems equally true in this country nearly 30 years later.

Experience in Blackburn

Evaporated milk has been in general use in infant feeding in the Blackburn Group of Hospitals for over four

years. It would appear that experience here can be of use to others, and is therefore worth recording.

In the Blackburn Group, the original intention was not specifically to introduce evaporated milk as the basic food for infants. What was desired was some simplification of the routine in the milk kitchen. It was the policy up to that time to continue to use whatever food the infant had been having up to its admission. Many different feeds were therefore being used. This seemed wasteful in time and in money, as tins of various brands of dried milk inevitably were unused through going "out of date." The question to be settled was therefore what food could be used to eliminate these troubles. It has been repeatedly demonstrated, and is within the experience of most of us, that an infant can thrive on almost any of the recognized branded foods and on the national products. Clearly the decision had to rest on factors other than simple nutritional value. After due thought it was felt that in evaporated milk we had a product with a combination of qualities not found collectively in dried foods. It is quite sterile and does not deteriorate on keeping. It mixes easily and the end-product is homogeneous. There are no large particles and the fat does not separate out. There is no tendency to blockage of the holes in the teat and thus no temptation for the attendant to finger the teat. The fat is very finely divided into globules only one micron in diameter. This aids its digestibility by increasing the surface area exposed to digestive enzymes. The heat treatment modifies the protein physically, with the result that a fine soft curd is formed in contrast to the tough curd of untreated milk. This also is reflected in the stool, which resembles that of a breast-fed infant. The altered protein has less allergenic properties. Finally, evaporated milk can be used for infants of all ages, both mature and premature, and also when cereals are added, if desired. It was therefore decided to adopt evaporated milk for general use in infant feeding in this group of hospitals virtually to the exclusion of all other artificial foods.

It must be stressed that the first choice of feed is always breast milk. This applies not only in the maternity departments of this group but also in the children's general wards. Mothers are admitted with the infant whenever possible for breast-feeding. Expressed breast milk is used whenever it can be procured for appropriate cases.

Preparation of Feeds.—The system known as pre-sterilization is adopted in the milk kitchen. Evaporated milk is eminently suitable for this method. Feeds for 12 or 24 hours are prepared in bulk and the bottles filled, cooled rapidly, and placed in a refrigerator. At feed-time the bottle is placed in a container of hot water and brought to the required temperature.

Premature Infants

It has been repeatedly demonstrated that evaporated milk, suitably modified by dilution with water and the addition of sugar, is as good a feed as any spray-dried, roller-dried, or untreated cows' milk (Ford, 1949; Gruber *et al.*, 1949; Sturrock, 1952). Moncrieff (1956) suggested that perhaps unsweetened evaporated milk is the most practical alternative to breast milk. Sauer (1932) had the opportunity of feeding two triplets on an evaporated-milk formula and comparing them with the third, who was breast-fed. He found that the weight gains were similar, and that frequently the stools could not be distinguished.

A basic formula of one part evaporated milk and two parts water with one level teaspoonful sugar per 4-oz. mixture (3 g. per 100 ml.) of evaporated milk used, serves very well as a feed for premature infants. No rigid quantity per pound is used. It varies widely with different infants. Feeds begin between the second and fifth days of age according to size and condition of the infant. There seems nothing to be gained by using dilute feeds at first. Usually bland fluids are given initially, then a small quantity of full-strength milk formula, and this is increased as rapidly as is practicable up to the amount that experience shows the infant will comfortably

take. This may be 4 oz. or more per pound (250 ml. or more per kg.) body weight per day in some cases. Concentrated vitamins are introduced from the end of the first week and an iron preparation is given by mouth after the first month. Artificially fed infants are usually discharged when they weigh $5\frac{1}{2}$ lb. (2.5 kg.). When expressed breast milk has been available a gradual change over to the milk formula is made when 5 lb. (2.3 kg.) is reached. Usually the mother has by this time considerable experience in caring for her infant, as more often than not she is kept in hospital with the baby. In all cases she is shown the preparation of feeds and the care of teats and bottles. She is given a printed guide to subsequent feeding and is seen from time to time in a follow-up clinic. The local authority is notified in advance of her discharge and she is supervised in the home by health visitors.

It was previously our practice to change from expressed breast milk to a half-cream roller-dried milk. It was often noted that the infants' buttocks quickly became red and not infrequently actually became raw. The sisters from time to time suggested that changing to some other brand of milk would prevent this trouble. The brands were accordingly tried, always with disappointing results. Sore buttocks continued to occur. It was with some surprise that we gradually became aware that when evaporated milk was used there were very few sore buttocks in the premature infants and that when they did occur it was usually as a result of antibiotic therapy and due to thrush infection. This was certainly not one of the findings anticipated when the type of feeding was chosen. The reason for the improved results so far as buttocks are concerned is not very clear. It seems unlikely that sterility is the answer, as a good milk-kitchen technique with terminal sterilization had been employed. It seems likely to be associated with the presentation of the fat, but no special experiments have been done to prove this hypothesis. It is interesting, however, to record Lowenburgh (1929), who wrote of evaporated milk: "Complete digestion of the fat is practically assured and the irritating effect of free fatty acids so troublesome with ordinary milk is eliminated."

Another common finding when a change was made from expressed breast milk to a half-cream milk was that the infant put on a great deal of weight very rapidly and became bloated and rather pale. This appearance is not seen when an evaporated milk formula is used. The infants resemble the breast feeders much more closely than when fed with other types of milk.

Full-term Infants in the Maternity Department

Where breast milk cannot be employed all infants are fed with an evaporated milk formula. The same formula as for premature infants can be used. An average infant will take about $2\frac{1}{2}$ to 3 oz. per pound (156-190 ml. per kg.) body weight by the end of the first week. We have had no occasion to use any other feed. Bland fluids are, of course, given for various reasons, but when milk feeds are begun it is evaporated milk which is invariably used in default of breast milk. The mother is given details of how to carry on after discharge and the usual follow-up arrangements are made. No effort is made to influence her choice should she prefer to use some other type of feed. Feeding full-term infants with the evaporated milk formula has proved to be entirely satisfactory and is accepted as such by all concerned in the maternity department. There is no desire to change back to a dried milk. When the method was introduced there was, of course, as much prejudice within the department as elsewhere, but in the light of experience all that has long since disappeared.

Infants in General Wards for Sick Children

Formerly it was our practice to keep the infant on the feed it had been having up to the time of admission. Thus many brands were employed. This meant that a nurse had to spend a lot of time preparing feeds in the milk kitchen and that there was waste on account of tins going out of date. It was to see if these two factors could be eliminated that the question of a standard feed was considered. As

described above, it was decided to give a trial to an evaporated milk formula, and by general consent the trial has extended into accepted routine.

The present practice is to put all infants who are not receiving breast milk on the evaporated milk formula. This is done without regard to the feed used outside hospital. Bland fluids are used as indicated by the medical condition, but when milk is reintroduced into the diet it is the reconstituted evaporated milk which is employed. If a cereal is necessary, it can be added to the formula without any difficulty, just as it can be added to fresh cow's milk. Bottled pasteurized milk is used when the toddler stage is reached.

So far there has been little need for any other milk. Evaporated milk is used for the ordinary run of cases of respiratory infections, feeding difficulties, meningitis, urinary infections, and the like; and also for the more complicated cases, such as coeliac disease, infantile eczema, and other allergic conditions. It has been used in hypercalcaemia and in hyperchloraemic renal acidosis. But there is no fetish in its use. Other feeds have simply not been necessary. In America it seems commonplace for an infant to require a soya-milk feed in treatment of allergy, but we seem to manage quite nicely without it here. Now that calcium-free milks are available we may perhaps get quicker results with the hypercalcaemic infants, and shall certainly use such a milk if necessary. But experience shows that the standard formula used is an excellent general artificial feed and that there is no necessity to stock various types of branded milks. One might anticipate that some other milk could similarly be used quite successfully. We have not put this to the test, as we feel that evaporated milk is essentially safest and is the least trouble to prepare.

If a high-protein feed is required, a more concentrated formula can be prepared by using less water, or protein can be added to the standard formula. Feeds with a lower fat content are very rarely required. This is probably because the fat is so finely divided into globules. Citration is not commonly employed in this unit, but it can easily be done if desired.

In an Isolation Hospital

Isolation hospital units are usually difficult to staff these days; standardization of feeds is therefore especially desirable if it can be achieved. This has proved to be just as possible here as in other departments. Perhaps the most important type of case to consider is that of gastro-enteritis. We follow the usually accepted practice of rehydration, electrolyte balance, and electrolyte repair, and come eventually to the reintroduction of milk feeds. The usual standard formula can again be employed without any difficulty. It is used just as ordinary milk is used in the older child. If the very wasted infant should require high-protein treatment a stronger—less dilute—preparation of evaporated milk is usually well tolerated. A protein preparation can be added to the ordinary formula if desired. Evaporated milk is similarly used in the dysenteric diseases. Lactic acid feeds and the like appear to be quite unnecessary and the results are at least as good as previously.

Evaporated Milk Outside Hospital

There has been no question of "pushing" this type of feeding by doctors and nurses in the hospitals. Its adoption by those in hospitals has had inevitable repercussions outside. Mothers from the maternity departments have continued to use the preparation when they reach home. Other parents have associated the feed given in the hospital with the recovery of their sick child and wish to continue on the feed. Those whose job it is to market evaporated milks have not, of course, been slow to take advantage of the situation thus created. The result is that the milk is now stocked by the welfare clinics, and those concerned with infant feeding are becoming well versed in the use of evaporated milk. Many mothers keep their infants on the formula until the stage of toddler diet and a few even beyond. Others prefer to use some other feed, and from

the hospital end no attempt is made to influence them one way or the other. It is true to say that in this area parents are "getting used" to evaporated milk for infant feeding. The health visitors are also by now quite accustomed to advising on how it should be used.

There are many substandard homes and many ignorant parents in this area. There is a tendency to think that a tin of evaporated milk is dangerous in such circumstances. This is, of course, the reverse of the truth. A baby taking a full bottle uses a whole tin of milk in a day. As both milk and container are sterile there is little danger here. An infant on a 4-oz. (114-ml.) feed uses a tin in two days. Some manufacturers issue a half-size can, which would be used in one day. If the tin is cleaned on top and pierced by two holes and covered with a clean saucer after each portion of milk is withdrawn, there is little likelihood of contamination. If the tin is kept on the mantelpiece over a hot fire, and cleanliness is not a feature of the family, then there may be some risk of contamination, but it is still likely to be much less than if a dried milk is used. There is an appreciable moisture content in so-called dried milk. The tin lasts not one day or two days, but one week or two weeks. It is not sterile to begin with, and the hand of the preparer of the infant feed is put into the package 20 to 40 times each day—say, over 200 times by the time the package is finished. It is not likely to remain uncontaminated.

Some advocate the preparation of a full 24-hours requirement of food at once. This is, of course, quite suitable for hospitals and for the home in which there is a refrigerator. It is satisfactory in winter in any clean home, but in the less clean home it is probably undesirable. Far better to pour the requirement of each feed into the cleansed bottle and add the appropriate amount of boiled water and sugar, and use straightaway. The residue is best kept in the tin. This should be covered and placed in a cool place as indicated above.

A Formula for General Use

Experience shows that one great and common difficulty besets all who would advise on the use of evaporated milk for feeding of infants. How do we carry in our head the data on which to base a formula for any given child? Most doctors and nurses carry in their heads relevant facts on which they can check feeds if a dried-milk preparation is used. This is usually based on a fluid requirement of $2\frac{1}{2}$ oz. per lb. (156 ml. per kg.) of body weight per 24 hours. If the feed is four-hourly and five feeds are given in a day, then half the expected weight in pounds gives the size of the individual feed—namely, a 10-lb. (4.5-kg.) infant requires about five feeds of 5 oz. (140 ml.) each. This can easily be applied to the evaporated milk if the following formula is used:

Evaporated milk, one-third ..	..	This provides
Water, two-thirds ..	..	about 20
Sugar, a level teaspoonful for every	..	calories per
4 oz. (114 ml.) of the mixture ..	..	oz. (28 ml.)

Thus a 12-lb. (5.4-kg.) baby would require approximately a 6-oz. (170-ml.) feed five times a day. The formula is:

Evaporated milk ..	2 oz. (57 ml.)	Calories	100
Water ..	4 oz. (114 ml.)	..	122½
Sugar ..	1½ teaspoonfuls	..	22½
Per day ..	30 oz. (850 ml.)	..	612

This is an approximation, and many infants will take nearer 3 oz. per lb. (190 ml. per kg.) of body weight. It will be seen that this formula conforms to accepted standards of daily calorific requirement. It is sometimes desirable to give some extra water. This can be given as plain water or as a separate drink containing a vitamin-C preparation.

As with dried foods, some evaporated milk is fortified with vitamin D. It is unwise to rely on this alone to substitute for cod-liver oil, as there is then a deficiency of vitamin A. Sturrock (1952) found that infants so fed had significantly more upper respiratory infections than those fed on other milks and supplemented with additional vitamins in the form of cod-liver oil or vitamin concentrates.

Cod-liver oil or its equivalent plus orange juice or its equivalent should always be given.

In this country evaporated milk contains 33 I.U. of vitamin D₃ per undiluted fluid ounce (28 ml.). This means that when reconstituted there are about 500 I.U. per quart (440 I.U. per litre). National dried milk contains 1,400 I.U. per reconstituted quart (1,230 I.U. per litre) and an average figure for other proprietary powdered milks is 1,600 I.U. per reconstituted quart (1,410 I.U. per litre). In view of the suspicion that idiopathic hypercalcaemia of infancy is associated with a high intake of vitamin D, it will be noted that if evaporated milk is used the additional vitamin A can be given without unduly raising the vitamin-D intake—for example, a teaspoonful of cod-liver-oil compound as issued by the infant and child welfare clinics contains about 700 units of vitamin D and 3,500 units of vitamin A, and if given to supplement a daily intake of 20 oz. (570 ml.) of evaporated milk formula, means a total daily intake of about 950 units of vitamin D plus an additional 3,500 units vitamin A. If, on the other hand, 20 oz. (570 ml.) of reconstituted dried milk were given plus a teaspoonful of cod-liver-oil compound, 1,400 to 1,500 units of vitamin D would be taken daily plus the additional 3,500 units of vitamin A.

Cost as Compared with National Dried Milk

The cost of an ounce (28 ml.) of reconstituted evaporated milk is 0.4 pence and of reconstituted National dried milk 0.245 pence. It would seem on first sight, therefore, that it would cost nearly twice as much to feed an infant on evaporated milk as on National dried milk. This, of course, is far from the truth. The Table shows the relative cost to

	4 oz. (114 ml.) National Dried Milk × 5	4 oz. (114 ml.) Evaporated Milk × 5	8 oz. (227 ml.) National Dried Milk × 5	8 oz. (227 ml.) Evaporated Milk × 5
Baby food per day	4-9d.	8-0d.	9-8d.	16-0d.
Fresh milk, 1 pint	8-0d.	4-0d.	8-0d.	4-0d.
Total cost per day	12-9d.	12-0d.	17-8d.	20-0d.

a family which uses 1 pint (570 ml.) of fresh milk and, for the baby, either National dried milk or evaporated milk, bearing in mind that one cannot have both National dried milk and priority cheap milk for the same infant. While baby is small it is cheaper to feed on evaporated milk than on National dried milk, while when he is big it is more expensive. It is clear that the difference in cost is negligible. It is to be noted that no specific formula is being used here, both milks being merely reconstituted to cow's milk standard for fair price comparison.

Summary

Evaporated milk can be used as an infant feed for premature and mature infants in maternity departments where breast milk cannot be used. It can be used as a feed for infants in wards for sick infants, including wards for infectious diseases. It can be used, with very rare exceptions, to the exclusion of all other milk preparations if desired. A simple method of calculating feeds based on the $2\frac{1}{2}$ oz. fluid per pound (156 ml. per kg.) per day is described. This enables doctors and nurses to prescribe the appropriate feeds as easily as for any other food. It is shown that it makes very little difference to a family budget whether evaporated milk or National dried milk is used.

BLOOD CHIMERISM IN A PAIR
OF TWINS

BY

Lister Institute, London

This paper describes some tests on the blood of a brother and sister who are twins: the blood groups show that each twin is living on red cells only some of whose ancestors were directly inherited, the rest having been acquired as grafts *in utero* from the opposite twin; the presence of female "drumstick" nodules on the nuclei of some of the polymorphs of the male twin shows that ancestral white cells too must have been successfully grafted. Mixed blood in dizygotic twins is common in cattle but appears to be extremely rare in man.

In 1916 Lillie demonstrated an anastomosis of blood vessels between the chorions of dissimilar bovine twin embryos. Lillie said that the rapidly elongating embryos "meet and fuse in the small body of the uterus at some time between the 10 mm. and 20 mm. stage. The blood vessels from each side then anastomose in the connecting part of the chorion; a particularly wide arterial anastomosis develops, so that either foetus can be injected from the other." Lillie realized that in this anastomosis was to be found the explanation of the freemartin condition: hormones of the male twin, having crossed the anastomoses, could divert the proper development of the sex apparatus of the female twin. This explanation, so far as we know, has not been superseded.

In 1945 Owen discovered that the red cells of dizygotic twin cattle were antigenically a mixture of two kinds and that this could be explained if primordial red cells, having crossed the anastomoses, could take root and grow in the opposite twin. This discovery was of fundamental importance to the theory of the nature of antibodies (Burnet and Fenner, 1949).

In 1953 a blood donor, Mrs. McK., was found to have two kinds of blood (Dunsford, Bowley, Hutchison, Thompson, Sanger and Race, 1953). Of her red cells 60% were O, *kk*, *Jk^aJk^b* and 40% were A₁, *Kk*, *Jk^bJk^b*. On inquiry Mrs. McK. said she had had a twin brother who died in infancy 25 years before. As Mrs. McK.

Note.—In a letter to the *British Medical Journal* in 1953 Mr. S. Baron, of California, said that he himself must be a chimera because in his R.A.F. days he had been told that he was group "AO." Curiously, the grouping had been done by two of us (B. W. I. and R. R. R.), and reference to our records showed him to be a normal group B. We mention this in the hope that the letter will no more be quoted as another example of a chimera.

secreted H substance but no A substance in her saliva it was assumed that the O cells were her own and that the A cells were descendants of immigrant embryonic cells from her brother. Mrs. McK. is normal in every way and is clearly not a freemartin, for she has now had three children. Certain physical properties of the anti-B of Mrs. McK. showed it to be of the kind found in persons of the genotype A₁O, as opposed to the kind found in persons of the genotype OO (Filitti-Wurmser and Jacquot-Armand, 1956).

Five months after the publication of this human example, mixed blood was reported in a pair of sheep twins (Stormont, Weir, and Lane, 1953); the twins were of different sex, and the female was found to be a freemartin.

In their masterly work "Quantitative Studies on Tissue Immunity," Billingham, Brent, and Medawar (1956) describe the finding that twin chicks are chimeras—probably all of them.

Another example of chimerism in man is reported by Nicholas, Jenkins, and Marsh (1957) in the present issue of this Journal.

Blood Groups of the Family W.

Recently Miss W., aged 21, made her first donation of blood at the North London Blood Transfusion Centre. Her red cells appeared at first to be a very weak form of group A, for when mixed with anti-A or anti-A+B on a slide and looked at through the microscope very small agglutinates were seen which were vastly outnumbered by unagglutinated cells: anti-B caused no agglutination. The serum of Miss W. contained anti-B but no anti-A. The very weak reaction with anti-A led to the testing of the blood of the W. family and the realization that we were dealing with another example of chimerism, this time with the advantage that both twins were alive.

The blood groups of the family of Miss W. are shown in the pedigree (see Fig.). Nothing unusual was found in the groups of her father or her mother or her elder brother. When the twin brother's blood was tested it was easily seen to be a mixture, because he has a much less unequal proportion of the two components than his sister. The two components of the mixed blood possessed by the twins differ in five systems: ABO, MNSS, Rh, Duffy, and Kidd. The grouping of the twin brother's blood is described first.

Blood groups of the W. family. The groups directly under the twin chimeras, II-2 and II-3, are those of their inherited blood; a little to the right are those of their grafted blood. Antisera used: anti-A, -A₁, -B, -A+B, -H; anti-M, -N, -S, -s, -U, -Mia, -Vw; anti-P+P₁, P₁; anti-C, -c, -Cw, -D, -E, -e, -f, -V; anti-Lu^a, -Lu^b; anti-K, -k; anti-Lea, -Leb; anti-Fya; anti-Jka, -Jkb. Arrow = propositus.

Method of Separating O and A₁

The original method used by two of us (R. S. and R. R. R.) to separate the two components, O and A₁, in the blood of Mrs. McK. was used again. The method is simple in principle. Anti-A is added to the mixed blood in a Petri dish. The larger agglutinates of A cells are collected and are then freed from agglutinin by shaking in the presence of dissolved A substance. The remaining mixture of A and O cells is put into a long tube and left to settle; the agglutinated A cells sink more quickly than the free O cells, which are taken from the supernatant fluid.

As the method has not previously been published it may be useful to give some details here—though doubtless improvements could be made to every stage.

The amount of blood required depends on the proportions of the components. For II-2 three Petri dishes were enough, but for II-3 we used ten before we had a really adequate sample of A cells—for only about 1% of her cells were A.

For the separations we used human anti-A and an extract of the seeds of *Dolichos biflorus*—which agglutinates A₁ cells more avidly than does human anti-A (Bird, 1951). We are grateful to Lieutenant-Colonel G. W. G. Bird, who suggested the use of the extract because of its avidity and because, being a simpler substance than human anti-A, it might later be more easily won from the agglutinated A cells by the A substance. This proved indeed to be true.

Probably the more dilute the extract the better, so long as it can still cause enormous agglutinates of A₁ cells on a slide: a crude extract diluted 1 in 5 was found to sensitize A₁ and O cells for antiglobulin serum, so that subsequent tests had to be on saline suspensions of the separated cells. This difficulty was later overcome by using an extract that had been purified by chemical means: it could probably have been overcome by mere dilution of the extract.

1. Into each Petri dish put 2 ml. of diluted *Dolichos biflorus* extract (or 2 ml. of human anti-A diluted 1 in 2) and 0.5 ml. of a 50% suspension of the A₁:O mixture of cells. Rock until the agglutinates do not seem to be getting bigger. (If the A cells are relatively few the agglutinates are very small and difficult to catch; the agglutinates can be made larger by centrifuging the mixture and returning it to the dish.) Pipette the larger agglutinates into a tube marked A. Rock the dishes again and pipette their contents into a tube marked O; the dishes are washed with a few millilitres of saline, which is transferred to tube O.

2. Fill tube A with saline and invert; when the agglutinates have settled (in a few seconds if they are large ones) remove the supernatant saline; wash in this way three more times. To the deposit of agglutinates add 3 ml. of A substance (Knickerbocker) and 3 ml. of saline. Shake hard and leave for about 20 minutes. Look for agglutinates in the supernatant suspension: if they are present add more A substance or perhaps wait longer. Fill the tube with saline, leave it to stand, first on a slope then vertically, for about an hour. Take as much as needed of the supernatant suspension, and wash the cells therein three times: this is the A sample.

3. While 2 is going on centrifuge tube O to bring small agglutinates together, but do not remove the supernatant antibody and saline. Add more saline, if necessary, to fill the tube; invert. Stand, first on a slope then vertically, for about an hour. Remove sufficient supernatant suspension, and wash the cells therein three times: this is the O sample.

Groups of the Twin Brother, II-2

The addition of anti-A caused large agglutinates to appear, but even by the naked eye a pink background could be seen which the microscope showed to be due to very large numbers of unagglutinated cells.

Some of the results of testing the red cells of II-2, untreated and after separation of the A and O components, are shown in the Table. The groups of the two fractions are given in the pedigree.

Reactions of Certain Critical Antisera with the Red Cells of II-2 Before and After Separation of the Two Components

Red Cells of II-2	Anti						
	-A	-A ₁	-B	-s	-C	-E	-Fy ^a
Untreated	+++*	+++*	-	w	+++*	+	w*
A separated	+++	+++	-	+	+++	+++	-
O	-	-	-	-	-	-	++

The asterisk means that unagglutinated cells were very obvious.

Theoretically the separation could have been made with anti-C, with anti-E, with anti-s, with anti-Fy^a, or with anti-Jk^b, but the relative weakness of these agglutinations and the scarcity of the antisera made the separation with anti-A the obvious choice.

We did, however, make one cross-check. The red cells of II-2 were separated with anti-E (lacking incomplete anti-D) made very avid by the addition of Löw's (1955) papain solution. The separation was successful, for the supernatant unagglutinated cells were CDe/cde, and, as anticipated, they were group A. (They were strongly agglutinated by anti-A and practically no unagglutinated cells were to be seen—in marked contrast to the effect of anti-A on the untreated sample.) The E cells were separated by mixing the blood of II-2 with the same anti-E but without the papain solution. The collected agglutinates could be freed from antibody by simply shaking hard with cold saline. Tests showed these cells to be cDE/cde, and, as expected, group O. (The cells could not be freed from anti-E when papain had been used.)

Groups of the Twin Sister, II-3

The addition of anti-A caused very small agglutinates to appear, but the vast majority of the red cells were group O. The A cells were evidently too few in number to cause any difficulty in grouping by the other antisera, all of which are less sensitive than anti-A. The testing of the O cells was therefore straightforward, and, as expected, the groups were those of the O component in the blood of the twin brother. The separation of the A cells was rather laborious, but it was done by the method described above. The groups of both fractions are shown in the pedigree.

Proportions in the Mixtures

Counts of the proportion of the two kinds of red cells possessed by each twin were kindly made by Dr. P. L. Mollison and Miss Marie Cutbush, of the Medical Research Council Blood Transfusion Research Unit. Several ingenious methods were used and the results were:

Twin brother, II-2	..	A 86%	..	O 14%
Twin sister, II-3	..	A 1%	..	O 99%

Genotypes of the Twins

Both twins are secretors: the brother secretes in his saliva A and H (and Le^a), the sister secretes H (and Le^a). This would seem to establish beyond doubt that the genetic groups of the boy twin are those of the A series and of the girl twin those of the O series. The saliva of the boy twin did not differ detectably from that of his father in the amount of A and H substance it contained.

White Cells of the Twins

Dr. W. M. Davidson has kindly examined films of the blood of the twins and of their parents. In the films of the male twin polymorphs were found with the "drumstick" nuclear knobs present normally only in females (Davidson and Smith, 1954). The proportion of cells with "drumsticks" was compatible with a mixture of male and female blood in the proportion shown by the blood groups.

Discussion

Ninety per cent. of dizygotic bovine twins are said to have mixed blood, but in man it must be a great rarity. Were it not so the Transfusion Services would have detected more ABO mixtures, for, in England, about 34% of dizygotic twin pairs differ in their reactions with anti-A or with anti-B. (This figure is extracted from Smith and Penrose, 1955, Appendix Table 2, which gives phenotypic sib-sib frequencies for the ABO system in England.) The Blood Group Research Unit has tested, without finding a mixture, samples of blood from 77 pairs of twins thought by skilled observers to be dizygotic: 68 of them differed in their ABO, MNS, or Rh groups, and the antisera of these three systems should have been able to detect mixtures, had they occurred, in one or the other twin. (Of the remaining nine pairs, seven differed on other systems.)

It follows that anastomoses between dizygotic human twins either must be very rare or must develop at a time when the ancestral blood cells are losing their faculty to take root in a foreign bed, or when the host tissue is becoming less tolerant of immigrant cells. Professor J. D. Boyd thinks that anastomoses are rare but probably not as rare as the very infrequent recognition of chimeras would suggest. In monozygotic twins, on the other hand, mixed blood must be very common—though undemonstrable.

Judging by the W. twins it seems that, in man, the proportion of the two kinds of blood in one twin is independent of the proportion in the other twin. This is not what happens in cattle, for according to Irwin (1955) each of a pair usually has the same mixture; that is to say, if twin A has 60% A blood and 40% B blood then his fellow twin B will also have 60% A blood and 40% B blood.

Dr. Davidson's finding of female "drumsticks" in the nuclei of some of the polymorphs of the male twin shows that the ancestors of these cells too can be successfully grafted. The proportion of polymorphs with "drumsticks" was compatible with a graft of the extent shown by the red cells; if this proves a general rule it may have useful implications in the study of the lineage of these cells.

The female twin is of the genotype OO, and 99% of her red cells are group O. Her serum contains anti-B but no anti-A. The absence of anti-A is presumably a manifestation of the phenomenon of acquired tolerance, studied particularly by Billingham, Brent, and Medawar (1953, 1956); the presence of A cells early in uterine life has presumably inhibited the production of anti-A.

In cattle and in fowls the tolerance to foreign blood cells acquired in foetal life can later be shown not to be limited to blood cells: the majority of dizygotic twin cattle are fully tolerant to grafts of each other's skin (Anderson, Billingham, Lampkin, and Medawar, 1951), and the same is true of chickens (Billingham *et al.*, 1956). Professor Medawar and his colleagues think it probable that skin could be successfully grafted between Miss W. and her twin brother.

Both twins are secretors. They secrete the ABH antigens for which they have inherited genes: they do not secrete the antigens of their grafted red cells. From this we may assume that the ABO genes do their parallel work of manufacturing water-soluble A, B, and H substance in cells other than those in which they are busy providing alcohol-soluble A, B, and H substance for the red cells.

The first human chimera to be recognized, Mrs. McK., has demonstrated conclusively, by having three children, that the hormones of a human male foetus had no power to upset the normal sexual development of his female twin. In the parallel situation a cow is sterile. Evidently the human male is backward, compared with the bull, in developing his endocrines—which is perhaps not surprising considering the relative tempo of their two lives. In man we suppose that the embryonic female hormones have no effect on the development of the male twin—but on this point there is so far no evidence.

Summary

Two human blood chimeras are described—twins of different sex. The male twin has 86% A₁ and 14% O red cells; he also has female "drumsticks" in some of his polymorphonuclear white cells. The female twin has 99% O cells and 1% A cells.

The A₁ cells are MSMS, CDe/cde, Fy^bFy^b, Jk^aJk^b; the O cells are MSMS, cDe/cde, Fy^aFy^b, Jk^aJk^a; in their other groups they do not differ. Secretion tests on saliva show that the A₁ series belongs genetically to the male twin and the O series to the female.

We are grateful to the blood donor, Miss W., and to her family, who have been most generous in their help. We are indebted to Dr. Amos Cahan, of the Knickerbocker Foundation, New York, for a large supply of A substance.

HUMAN BLOOD CHIMERAS A STUDY OF SURVIVING TWINS

BY

J. W. NICHOLAS, M.R.C.S., L.R.C.P., D.C.P.
Pathology Laboratory, Essex County Hospital, Colchester

W. J. JENKINS, M.D.

AND

W. L. MARSH, F.I.M.L.T.
North-East Metropolitan Regional Blood Transfusion
Centre, Brentwood, Essex

The term "chimera" (originally a fabulous fire-spouting monster, part lion, part goat, and part serpent) has been used in botany for many years to denote an individual plant in which there are two or more tissues differing in their genetic constitution, such as a graft hybrid. Its first application in mammalian physiology appears to be that of Anderson, Billingham, Lampkin, and Medawar (1951), who applied it to the condition in cattle mentioned below.

It has long been known (Owen, 1945) that communication between the circulations of binovular bovine twins can occur *in utero*, resulting in an interchange of erythroblasts with persistence throughout life of mixed blood groups. The only such human chimera hitherto reported has been that of Dunsford, Bowley, Hutchison, Thompson, Sanger, and Race (1953), in which, unfortunately, one twin died in infancy. We now present a study of twins both of whom are chimeras and whose relatives were available. Simultaneously with this, another pair of chimeras is being reported by Booth, Plaut, James, Ikin, Moores, Sanger, and Race (1957).

The propositus, Mrs. W., is a healthy married woman aged 29 who attended for antenatal blood grouping in July, 1956. She has now had three pregnancies resulting in healthy children. When her blood was tested with anti-A serum moderate-sized agglutinates were seen in a sea of free cells. Further investigation showed her blood cells to be of two distinct groups. Her twin brother, both parents, husband, and all her three children were studied. The brother, as was first shown by Dr. Dorothy Parkin, is also a chimera. Neither of the twins has ever had a blood transfusion.

Methods

The mixture of cells in each chimera was separated by differential agglutination, using anti-A and group O sera in parallel, and the proportion of free group O cells determined by triplicate counts in a haemocytometer. Deposited group A cells were freed of the α -agglutinin by elution at 56° C., but then gave equivocal results with most antisera.

The A cells were also separated by differential agglutination with a potent anti-M serum, but became panagglutinable in human serum, having presumably been coated with incomplete anti-human species agglutinins. The genotype of the A cells was therefore largely deduced by comparison of the results of mixed-field agglutination with those obtained on the separated O cells. Dr. Race, Dr. Sanger, and Miss Moores also separated the A cells, using the method described by them (Booth *et al.*, 1957), and confirmed our deductions. We have since been able to elute the human anti-A used for our separation by a technique similar to theirs but using A-secretor saliva. We have checked the results on Mrs. W. on the A cells thus separated.

The antibodies used for grouping were: anti-A, A₁, B, A+B, H; anti-M, N; anti-P; anti-C, D, E, c, e; anti-Lu^a; anti-K; anti-Le^a, Le^b; anti-Fy^a. *Ulex europaeus* anti-H and rabbit anti-M and N sera were used, other sera being of human origin. Appropriate controls were employed throughout. Kidd and S grouping was done by the M.R.C. Blood Group Research Unit, who also checked the Lewis groups, using two anti-Le^a and two anti-Le^b sera.

In testing for Le^a substance serial doubling dilutions of saliva were mixed with one volume of diluted anti-Le^a serum and left at room temperature for 30 minutes. One volume of Le(a+) cells in albumin was then added and the mixture examined microscopically after two hours' incubation. The results are shown in the Table. Standard

Saliva	Anti-Le ^a	Anti-H	Anti-A
Control group O Le(a+) ..	1 in 64	No inhibition	No inhibition
" O Le(a-) ..	1 " 2	1 in 32	" "
Mr. G. " " " " " "	1 " 128	No inhibition	" "
Mrs. W. " " " " " "	1 " 2	1 in 32	" "

quantitative techniques were used for estimation of A and H substances in saliva. The sera of the family were tested against a panel of fully grouped cells covering the ABO, MNS, P, Rhesus, Lutheran, Kell, Lewis, Duffy, and Kidd groups in saline, serum/albumin (1:1), and by the indirect Coombs technique.

Coverslip films of capillary blood were made and examined for nuclear sex of the neutrophils by Dr. W. M. Davidson (see Davidson and Smith, 1954).

Results

The results of investigating the eight members of the family are shown in the pedigree (see Fig.). Each of the twins has blood of two distinct types, differing in ABO, MN, and Rhesus groups. All Mrs. W.'s cells are, however, Le(a-b+) and all Mr. G.'s Le(a+b-). The twins are of different secretor status; the Table shows their saliva reactions. The sera of both twins contain anti-B agglutinin to a titre of 1 in 64. Tests at various temperatures in saline, serum/albumin, and using anti-human globulin serum failed to demonstrate anti-A either free in the serum or blocking or coating the cells. No irregular antibodies were detected. The cells and sera of the remaining six members of the family showed no abnormality.

Nuclear sexing of the neutrophils revealed six "drumsticks" in 318 cells in Mrs. W.'s blood, and six in 338 in Mr. G.'s. Mrs. W.'s Arneht count was 3.27 and Mr. G.'s 3.30.

Discussion

There can be no doubt that the mixed blood groups arise from the interchange of erythroblasts *in utero*. The only alternative theory, that of somatic mutation, is excluded by the occurrence of a similar condition in both twins and the involvement of more than one blood group system and of the leucocytes.

Mrs. W.'s husband is of group MM and two of her children are of this group. It therefore follows that her genetic group must contain an M gene, and is therefore the O series given directly under her name in the Fig. This is confirmed by the fact that she is a secretor of H but not of A. Mr. G.'s genetic group cannot be determined with certainty as he is a non-secretor of ABH substance, and is unmarried. It seems reasonable, however, to presume that it is A₁, thus accounting for the A₁ cells in Mrs. W.'s blood.

It is now well established (see Race and Sanger, 1954) that Le(a+) individuals are all non-secretors of water-soluble ABH substance and secretors of Le^a, and that Le(a-) individuals are nearly all ABH secretors with only a trace of Le^a in the saliva. The secretor status of the twins corresponds to the Lewis groups found. Sneath and Sneath (1955) have shown that red cells take the Lewis group of the plasma in which they are suspended. This was demonstrated by transfusion experiments and also *in vitro*, and they suggest that the Lewis antigens are adsorbed to the cells from the plasma. Stormont (1949) has shown that the antigens of the J group of cattle behave similarly, and also that interchange of blood groups in bovine chimeras does not include the J group. The foreign cells in the circulation of each of the twins we have described have adopted the Lewis group of the host. Our results therefore bear out Sneath and Sneath's conclusions that the Lewis antigen belongs to the tissues and is only secondarily attached to the red cells; they also closely parallel Stormont's findings.

Our findings on Mrs. W. support the view that the early existence of group A cells has suppressed the formation of anti-A. It is of interest that Mr. G. has not produced anti-M or anti-e in response to the foreign MNEe cells. Although Mrs. W. is a secretor and although her blood contains 51% of borrowed group A cells she is not able to secrete A substance in her saliva.

We have so far shown the presence of foreign red cells in each twin. Foreign white cells of the "chromatin-positive" type normally found only in the female are also present in Mr. G.'s blood. It is probable that foreign leucocytes are present in Mrs. W., though it is more difficult to be certain in her case. On the basis of her Arneht count the number of chromatin-positive cells is rather low. The fact that the number of chromatin-positive leucocytes is similar in both twins is in keeping with our finding of roughly equal proportions of red cells of the two types in

each twin. Because of the presence of foreign leucocytes it seems more appropriate to call these people blood chimeras than blood-group chimeras. We have found no evidence of hormonal effects; Mrs. W. is a normal healthy woman with three healthy children and therefore not a freemartin.

There are two pairs of twins among first cousins, but one of each pair died in infancy. Attempts have been made to investigate the survivors, but so far without success.

Summary

A pair of binocular twins is described, each of whom has blood which is a mixture of the same two distinct types differing in ABO, MN, and Rhesus groups. Each twin has, however, only a single Lewis group, and the Lewis groups of the twins are different, each corresponding to that expected from the secretor status. A family study of the blood groups has been made. Nuclear sexing of neutrophils shows that foreign leucocytes are present in the blood of the male twin and probably present in the female twin.

It is considered that these are chimeras similar to that reported by Dunsford *et al.* The Lewis group findings confirm the demonstration by Sneath and Sneath that the Lewis antigen belongs to the tissues and is only secondarily attached to the red cells. Results in the Lewis group are comparable with those in the J group of bovine chimeras.

We are indebted to Mrs. W. and all her family for their co-operation in this investigation; to Dr. Dorothy Parkin, of the Medical Research Council Blood Group Reference Laboratory, for some of the preliminary investigations of the twins, and also for first demonstrating that Mr. G. is also a chimera; to Dr. R. R. Race, Dr. Ruth Sanger, and Miss Phyllis Moores, of the Medical Research Council Blood Group Research Unit, for checking our results, determining the Kidd and S groups, and examining A cells separated by their technique. We are also grateful to Dr. Race for much valuable advice and to Dr. W. M. Davidson, of King's College Hospital Medical School, for undertaking the nuclear sexing.

Medical Memorandum

Leukaemia and Oestrogen Therapy

Oestrogens have been shown by many workers to produce neoplasms in experimental animals. The risk of producing or accelerating neoplastic growth in human therapy is usually thought to be entirely hypothetical, provided that the dosage is within the usual therapeutic limits, which is much less than that used in experimental work.

Kirschbaum (1951), Burrows and Horning (1952), and Gardner (1953) have reviewed the literature on the effects of oestrogens on the incidence of leukaemia in mice. It is clear that, experimentally, oestrogens do increase the incidence of leukaemia in animals and that this is of the lymphatic type.

No record has been found of human lymphatic leukaemia associated with oestrogen therapy. A case is recorded in which lymphatic leukaemia occurred during stilboestrol therapy for carcinoma of the prostate.

CASE REPORT

A man aged 70 was seen as an out-patient in March, 1953, with symptoms of frequency and dysuria, said to be of six weeks' duration. The prostate was not enlarged, but was hard and nodular. The other findings relative to our story were that the liver was not palpable and that no abdominal mass was felt, indicating that the spleen was not palpable. Some posterior cervical glands were noted. Radiological examination revealed no metastases in spine, pelvis, and skull. The blood count on April 1 showed: haemoglobin, 86% (12.6 g./100 ml.); R.B.C., 4,410,000 per c.mm. A leucocyte count was not made. The formaldehyde stable acid phosphatase was 35 units per 100 ml. A diagnosis of prostatic carcinoma was made, and stilboestrol therapy was begun. He was treated as an out-patient. About the middle of April 10 mg. thrice daily was prescribed, and during the next few months he had 4,000 mg.

On September 19 his general practitioner observed marked oedema of the legs and an enlarged spleen. He was referred to the out-patient department, and the blood count on September 29 was: haemoglobin, 55% (8.1 g./100 ml.); R.B.C., 2,800,000 per c.mm.; formaldehyde stable acid phosphatase, 0.8 unit per 100 ml. A leucocyte count was not done.

On October 31 he was admitted to hospital with severe symptoms of anaemia. Blood count on November 1 showed haemoglobin, 28% (4 g./100 ml.); R.B.C., 1,620,000 per c.mm. Leucocytes 44,000 per c.mm. (lymphocytes and smear cells 95%, polymorphs 5%). Spleen was enlarged to the level of the umbilicus. Blood transfusions were given, and the degree of anaemia fluctuated accordingly. The total leucocyte count increased to 70,000 on November 12 and fell to 38,200 on the 16th, with no change in the type of cell present. Marrow aspirated from the ilium on November 10 showed the appearances typical of lymphocytic leukaemia. Death occurred on November 21.

At post-mortem examination enlarged glands were found in the neck, mediastinum, mesentery, and around the aorta and common iliac arteries. The spleen was grossly enlarged (1,400 g.), and had some infarcts. The prostate was enlarged, but not hard; it contained a few small firm masses. The marrow of the lower lumbar vertebrae was leukaemic. In the prostate was a moderately well differentiated carcinoma. The spleen and glands showed typical lymphatic leukaemia.

COMMENT

There is no proof that this patient did not have leukaemia before receiving stilboestrol therapy. The leucocyte count was not performed, but, if normal, lymphatic leukaemia would not have been excluded, as experience shows that when all cases of anaemia are exhaustively investigated the aleukaemic variety is relatively common. The haemoglobin and red-cell count were almost normal at the beginning of therapy; no splenic enlargement was noted, but posterior cervical glands were present. If leukaemia were already present before stilboestrol therapy, progress would at this age be slow, and the cell type was well differentiated.

Thus there are three alternatives: the stilboestrol induced the leukaemia; the stilboestrol accelerated the leukaemia; the lymphocytic leukaemia of well-differentiated cell type in an elderly person presented as a rapidly progressive and fatal anaemia. Therefore I regard this last alternative as improbable.

Co-operation from Mr. F. I. Evans, Dr. Blair Macaulay, and Dr. N. C. W. Owen is gratefully acknowledged.

Reviews

PAEDIATRICS FOR THE G.P.

Pediatrics. Edited by Donald Paterson, M.D., and John Ferguson McCreary, M.D. (Pp. 654+xvi; illustrated. £5 10s.) Philadelphia and Montreal: J. B. Lippincott Company. London: Pitman Medical Publishing Co. Ltd. 1956.

This Canadian textbook, to which 37 authors have contributed, has been "designed primarily for the physician in the general practice of medicine"; it is planned to be less comprehensive than the large textbooks for consultant paediatricians, but fuller than a synopsis. It should serve its purpose well, for it contains a great deal of information set out to emphasize diagnosis and treatment; and it may be accepted as authoritative. The editors are to be congratulated on their success in maintaining balance between the various sections, and they have added materially to the usefulness of the book by their careful attention to cross-references. The details of treatment are clear, and a praiseworthy attempt has been made to underline the importance of giving necessary explanations and guidance to parents. Many readers will find the chapters on paediatric gynaecology, adolescence, and therapy and procedures especially welcome.

There are surprisingly few spelling mistakes for a volume of this size, but please may we have Kinnier Wilson's name spelt correctly in the index? And the index as a whole might be made more helpful by some rearrangement—for example, by placing "mental retardation" and "cerebral palsy" under the main headings of "mental" and "cerebral" respectively. The book is well produced, with a paper of good quality, and there are nearly 200 illustrations, including radiographs and a few coloured plates.

N. B. CAPON.

CERVICAL DISK LESIONS

Lesions of the Cervical Intervertebral Disc. By R. Glen Spurling, M.D. (Pp. 134+xi; illustrated. 36s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1956.

This book is a companion to an earlier volume on lesions of the lumbar intervertebral disk by the same author. Unlike the lumbar lesions, however, cervical disk disease has not yet a well-established pathology and symptomatology, and it is therefore a more controversial subject. After a description of the anatomy of the cervical spine, Dr. Spurling gives his views on the clinical and pathological aspects. These, rather than a critical assessment and evaluation of current opinion, form the substance of the work. It is therefore not surprising that few readers will be in entire agreement with what he has written; but what is said is clearly said, and this makes the book most acceptable. The extent of difference of opinion is illustrated by the range in the reported incidence of soft cervical disk protrusions at operation. This varies from 17% to 85%, and is 64% in the present work. Opinion in Britain is more in accord with the lower figure (from Sweden). This may be because the disease behaves differently here, or because greater distinction is drawn between acute traumatic disk herniation and the sequelae of chronic degenerative disease—usually referred to here as cervical spondylosis (a term which is given a more restricted meaning in this book). Such differences naturally affect the emphasis laid on various methods of treatment and the indications for their use. Some of the recommendations are open to criticism, regardless of opinion about the cause of various symptoms. For example, many consider that myelography may aggravate demyelinating disease and would therefore not agree with the advice that this investigation should be done in most cases when this condition is suspected and cranial structures are not affected. Among technical points, the recommended use of hemilaminectomy has the disadvantage that exposure is limited and the dentate ligaments cannot be divided on both sides; post-operative

exercises are not mentioned; and the fluoroscopic technique described exposes the surgeon to considerable irradiation. In the management of the case conservative treatment is recommended initially, but the use of a collar is dismissed and intermittent halter traction is alone advised, regardless of the age of the patient or the condition of his vertebrae.

There is still an inadequate amount of information about the correlation of radiological abnormalities and clinical symptoms and signs of cervical intervertebral disk disease, and this book does not remedy the deficiency. Every aspect of the subject is under review, and this work is a useful record of current thought in an important neurosurgical centre by a surgeon of great experience.

P. H. SCHURR.

RHEUMATOLOGY

Contemporary Rheumatology. Proceedings of the Third European Rheumatology Congress, The Hague, 1955. Edited by J. Goslings and H. Van Swaay. (Pp. 683+xix; illustrated. 95s.) London: Cleaver-Hume Press Ltd. 1956.

This is a very handsome and well-edited volume. It contains a record of the proceedings of the Third European Rheumatology Congress, which was held in Holland in 1955. A full summary is given of all the papers presented, which seems a pity, as some of these are worthless. Luckily, however, many of the papers printed in this volume are of importance, and these justify the rather high price asked for it. The contents are arranged under five headings: (1) rheumatic fever, with eighteen papers; (2) connective tissue, with 22 papers; (3) spinal arthritis, with 33 papers; (4) rheumatism in its relationship to social medicine, 18 papers; (5) 33 papers on miscellaneous aspects of the rheumatic diseases. Nearly half of the papers are in English, but those which are not are followed by a brief summary in English, and many have a useful bibliography. There are also a full index and a number of illustrations.

W. S. C. COPEMAN.

CLINICAL PHYSIOLOGY AND PATHOLOGY

Klinische Physiologie und Pathologie. By Ferdinand Hoff. (Pp. 1,120+xii; illustrated. D.M. 79.50.) Fifth edition. Stuttgart: Georg Thieme. 1956.

The first edition of this work on clinical physiology and pathology by Professor Ferdinand Hoff was published in 1950, and it speaks well for the success it has achieved that the present volume should constitute the fifth edition in the short space of seven years. This latest edition has undergone complete revision and considerable enlargement in the light of modern research in the whole field of general medicine. The success of the book has also been recognized in several countries outside Germany. The author holds an almost religious belief in the dependence of clinical medicine on the application of anatomy, physiology, pathology, and psychosomatic and social medicine. He relates this interdependence in every system under discussion and shows the repercussions of these factors on the patient as a whole. So fervent is Professor Hoff's belief in the essential integration of medicine that he repeats himself somewhat too often. One is glad to see physiology and pathology brought, as it were, to the bedside—an attitude that is all too infrequent at the present time; but the thoroughness, not to mention discursiveness, with which this is done tends to detract from its real value.

The causes, symptoms, and manifestations of the diseases discussed—and they involve the whole of general medicine—are set forth clearly, but treatment does not come within the purview of the work, and to this extent, in my opinion, diminishes its usefulness. After reading the book, however, no student or postgraduate, in whatever sphere, should be guilty of divorcing illness at the bedside from the basic principles of applied physiology and pathology—the foundations of medicine—and the specialized worker should not fail to guard against the risks of a too narrow specialization. Turning from the general to a particular example; in the section on diseases of the lungs there is a singularly wide

breadth of approach to, among other things, the problems of the pulmonary circulation and respiratory function, embodying the researches of physiologists, pathologists, and clinical workers. Again, the anatomical and functional relationship of the heart and lungs, which work as a single oxygenating unit, is fully appreciated, and it is recognized that disorders of deranged function in the one may easily lead to secondary changes in the other. Professor Hoff emphasizes that damage to any part of the circuit will affect the efficiency of the whole.

The production of the book reaches the usual high standard of the Georg Thieme publishing house. The profuse illustrations comprise, in the main, good-quality clinical and x-ray photographs. One would have preferred to see the relevant bibliography at the end of each chapter rather than, as at present, at the end of the whole book. Criticisms notwithstanding, the author's broad and philosophic conception of medicine should appeal to British clinicians.

PHILIP ELLMAN.

HEARING DEFECTS IN CHILDREN

Hearing Defects of School Children. By the Committee on Defective Hearing of the Scottish Council for Research in Education. (Pp. 114+x. 10s. 6d.) London: University of London Press Ltd. 1956.

This report is by a committee of Scottish teachers and one medical officer of health, and is based on hearing tests by pure-tone audiometry of 4,170 12-year-old primary-school children in the County of Fife carried out by four second-year students from a teachers' training college after four weeks' training in such tests by a headmaster of a school for severely deafened children. The committee had originally envisaged a much larger survey, and regards this as a pilot scheme.

The early chapters on technical considerations of audiometry and on previous investigations are informative and interesting, but the rest of the report reveals little that is not already well known. No old stone has been left unturned, and perhaps the most useful feature is the committee's suggestions for further research. It feels that more research is needed on the relationship between the ability to hear speech and testing for pure tones; on improved tests of ability for deaf children; on the standard technique to be adopted in audiometric testing; on a more precise classification of children with defective hearing for educational purposes; and on the variability of defects of hearing. If the committee had widened the field from which its members were drawn and included at any rate a brace of otologists it is possible that some of what is suggested as further research might have formed part of the present investigation.

TERENCE CAWTHORNE.

STROKES

Management of Strokes. By Keith W. Sheldon, M.D. (Pp. 134+x; illustrated. 24s.) Philadelphia and Montreal: J. B. Lippincott Company. London: Pitman Medical Publishing Co. Ltd. 1956.

This short book is one of the "Practitioners' Pocket Book" series. Its basic purpose is excellent: to stress the fact that there are many possible causes for sudden cerebral catastrophes and that in a number of these cases active investigation and treatment are necessary. The author underlines the importance of adequate history-taking and examination, and apparently this truism needs restating if the comment that "spinal puncture is used as an excuse not to do a neurologic examination" is valid. The author's intention is not completely fulfilled by his book. There are short accounts of many conditions which may cause coma or sudden hemiplegia, and much useful information on their management, but the presentation is somewhat confusing and no clear indication is given of when special investigations such as angiography or air encephalography should be undertaken. The illustrations are copious and vary from reproductions of angiograms to line drawings

more reminiscent of a strip cartoon than of a medical book. This type of cartoon may perhaps be useful in stressing detail, but it should be accurate; the picture of a foot resting on an object labelled "foot on hot plate—no reaction" with the caption "Dejerine-Roussy syndrome" seems somewhat misleading when a prominent feature of the thalamic syndrome described by these authors is usually over-reaction to diffuse stimuli. It is unusual also to spell berry aneurysm with a capital B, which would seem to suggest that this is an eponym rather than a description of the lesion. In spite of these criticisms the book will be of real value if it interests doctors generally in the problem of acute cerebral episodes and their adequate treatment.

J. W. ALDREN TURNER.

ACUTE COR PULMONALE

Le Cœur Pulmonaire Aigu dans l'Embolie Pulmonaire. By A. Tourniaire, M. Tartulier, F. Deyrieux, and J. Blum, with the collaboration of Pierre Marion. Preface by R. Leriche. (Pp. 190; illustrated. 3,700 frs.) Paris: Expansion Scientifique Française. 1956.

This is a good monograph, the title of which may be translated as "The Acute Pulmonary Heart in Pulmonary Embolism," unless, as Gibbon once said, one veils the name in the obscurity of a learned language and calls it acute "cor pulmonale." There does not seem to be any satisfactory name for intense or chronic embarrassment of the right ventricle. As the authors point out, the term is not synonymous with pulmonary embolism, but denotes a more or less sudden failure of the right side of the heart from acute rise of pressure in the pulmonary arteries due to various causes. Stressing the importance of medical cases, the authors give a clear picture of the clinical findings, noting the importance of jugular engorgement and right ventricular *bruit de galop*. There is a long chapter on the important cardiographic aspects. The limb leads receive rather more notice than the precordial. The great difficulty in appreciating the very wide range of abnormalities is made clear, particularly in those cases where the heart is already abnormal, which is likely to be the case in patients with "medical" disease. The cardiograms are excellent. The chapter on physiopathology is particularly interesting, and surveys very well the effects of reflex pulmonary vasoconstriction and of the rise in pressure in the coronary sinus causing stagnation in the cardiac circulation. Finally the surgical treatment is discussed and the chances and risks weighed: whether to wait too long and kill a moribund patient, or embark on a dangerous and perhaps fatal operation and prevent possible recovery. All this is sanely dealt with. This monograph is an excellent piece of work. It lacks an index and table of contents, but there are 28 pages of references.

TERENCE EAST.

OBSTETRICS SIMPLIFIED

The Gist of Obstetrics. By H. B. Atlee, M.D., F.R.C.S., F.I.C.S. (Pp. 327+ix; illustrated. 45s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1957.

Dr. H. B. Atlee is Head of the Department of Obstetrics and Gynecology in Dalhousie University, Halifax, Canada. This small book, with large type and clear line-drawings, with a racy style and a touch of humour here and there, is based on lecture notes prepared for his students. It reduces obstetrics to very simple proportions by avoiding nearly all theory (even in the case of the "disease of theories"—toxaemia of pregnancy) and by dogmatically laying down only a few lines of treatment. The methods of management advised are not always in accord with general opinion or modern knowledge, but they are not supposed to be—the book purports to describe only those methods which have been found to work best in Dr. Atlee's clinic. Which only goes to show that obstetric practice is, and should be, largely determined by its environment.

EVIDENCE OF A DIVIDED PROFESSION

The Representative Body at its special meeting last week decided to give evidence to the Royal Commission. The meeting did not appear to reach this decision with any great pleasure. It was, it seemed, influenced to do this by the fact that the Royal College of Physicians had somewhat eagerly made the same decision some few weeks earlier—an action which made it all the more difficult for the meeting to vote in favour of the resolutions that made the giving of evidence conditional on the inclusion of public health doctors in the terms of reference of the Commission; or, alternatively, on the immediate setting up of an independent inquiry into their remuneration and status. Dr. S. Wand, the Chairman of Council, and had, with the Chairman of the Public Health Committee, strongly urged the Minister of Health in a personal interview to include the public health doctors in the Commission's review if the profession decided to give evidence. But Mr. Vosper's hands appear to have been tied by the local authorities. If the consultants had been content to hold their hand and had then joined with the other two branches of the profession in deciding finally on what terms the profession as a whole might have been prepared to co-operate with the Royal Commission the outcome might well have been different. If, in spite of difference of opinion on tactics and timing, the profession had remained united in achieving a common aim—because there were no differing views on this—then they could have advanced from a position of strength. But the lamentable fact is that unity was lacking, and many consultants as well as general practitioners have voiced their strong and justifiable dissatisfaction with the immediate causes of this.

The principal comfort offered to the medical officers in the public health service was expressed in the following resolution passed by the Representative Body last week.

"That in the opinion of this meeting, the Association should submit evidence to the Royal Commission but reiterate its strong disapproval of the

exclusion of doctors employed by local authorities from the terms of reference of the Commission, and should undertake, in any discussions connected with the findings of the Royal Commission and by all available means, to press for the safeguarding of the position of these doctors relative to that of other members of the profession."

If those speaking on behalf of medical officers of health last week were critical of their general practitioner and consultant colleagues in the Representative Body for not passing the resolution they pressed for, they were equally critical of the position they find themselves in as employees of local authorities—of the local governments of this country. Never before, we believe, has there been such outspoken demand for separation from local government, for, in fact, incorporation in the body of medicine. Never before, certainly, has there been such general discontent with the position all medical men find themselves in to-day. Indeed one venerable voice was heard to declare that doctors in the N.H.S. were in fact the employees of Parliament. Even though this may not be strictly the legal fact of the case of medicine in Britain to-day, support for this view may well be found in the fact that within recent months the Prime Minister has announced in Parliament what immediate increases in pay doctors are to receive. Many still do not seem to appreciate the implications of this. But a long debate on motions urging that Council should give evidence only if the validity of the Spens Reports were first tested in the Courts showed that the Representative Body realized what was at stake. These motions were not carried when the Representative Body learned from the Chairman of Council that Counsel's opinion was against such a course. Other motions, however, showed that the Representative Body is determined to be vigilant. For example, a motion by Torquay, agreeing that evidence should be given, at the same time stressed "the need for (1) negotiation in all disputes, and (2) arbitration in all cases where negotiation fails." Other motions were passed urging that the machinery and method of withdrawal from the N.H.S. be kept under constant review, that plans be formed for mass resignation if a satisfactory settlement is not reached, and that the Council should "proceed urgently with preparations for an alternative 'Health Scheme.'" Whatever the Government may think it has achieved, it cannot congratulate itself on the grave and widespread dissatisfaction it has provoked among doctors working in Britain's much-vaunted National Health Service.

It would be wrong to disguise the fact that the present controversy has revealed a profession divided in itself as it has never been before. We fear that the

fact that several different professional bodies are to give their separate pieces of evidence to the Royal Commission may increase this division. The profession has failed to present evidence as one body—evidence in which the views and claims of different sections of doctors could have been co-ordinated, and which, so presented, would have had the overwhelming force that united action alone can provide. Harsh things were said about this at the Representative Meeting last week, as the report in this week's *Supplement* shows. While it is salutary for these discontents to be brought to the surface and not allowed to smoulder, it is profitless to perpetuate them. A real and sincere effort must be made in the coming months to heal the differences that exist among members of the same profession—a profession that is at the cross-roads in its relationship with the State. General practitioners see themselves as having to bear the brunt of the battle if an open conflict breaks out. They see themselves, too, in an especially difficult position as their livelihood depends to-day almost entirely on their employment in the N.H.S. through their contracts with local executive councils. Consultants and specialists see that it is the hospitals owned by the State that for the most part provide the tools of their craft and accommodation for their patients. They can withdraw only to a very limited extent into other premises, and in this respect feel themselves at a disadvantage as compared with the general practitioners, who in their turn see the consultants enjoying still a large measure of private practice. Both regard the N.H.S. as having disrupted the mutual relationship and dependence that used to exist before, and that certainly made them conscious of their belonging together to the same profession. The public health doctors have seen their previous contacts with clinical medicine broken, their association with the hospital life of the country interrupted, and their status gravely impaired. And they give bitter expression to their feeling of being isolated in the profession to which they belong.

There is no quick and easy answer to these many urgent problems facing the medical profession to-day. Whatever mistakes may have been made from time to time by this or that section of our membership, what does stand out is that the N.H.S. is so constructed as to facilitate and indeed encourage them. If the N.H.S., as so many believe, awaits a much-needed reform, it will be re-shaped to the benefit of the public, and of the profession, only if we can compose our differences, close our ranks, and preserve that variety in unity which makes for a satisfactory relationship. To achieve this, magnanimity and tolerance will have to be joined to intelligence and energy.

SIR RONALD ROSS, 1857 TO 1932

Throughout history malaria has been one of the most persistent and most widespread of diseases. Once endemic in vast areas of the world and afflicting millions of people every year, its hold is now gradually being broken and an active campaign for its complete eradication is being pursued vigorously by the World Health Organization. That such an ambitious project could be conceived and planned is, as its Director, Dr. M. G. Candau, emphasized in his speech at the Ross Centenary luncheon on June 3, the result of the work of Sir Ronald Ross, who established the basic principles guiding this campaign 45 years before the introduction of D.D.T. and similar insecticides. Had Ross lived to hear these words the disappointment and frustration which filled his later years would all have been swept away. Awarded the highest scientific and public honours he was yet denied the greatest satisfaction which can be given to any discoverer—that of seeing his discovery bring immediate and universal benefit to his fellows. An uncompromising and outspoken individualist, he often showed impatience with what seemed to him the laggard and unimaginative methods of governments and civil servants. A phrase ever on his lips was one used by Edward VII, "If preventible, why not prevented?" By such phrases sovereigns can sometimes stir their governments into activity. To Ross it was a battle-cry backed by every argument of logic, economics, and duty. He was an idealist leading a crusade and those who were not obviously active in his cause were against him. It is of such stuff that all the great reformers are made but which is found more rarely in the laboratory. The eradication of malaria, once successful, will count as one of the greatest medical triumphs of all time, and it has taken a world organization to attempt it. That Ross could even foresee its possibility is characteristic of his imaginative and creative mind. To his work in the laboratory he brought the attributes of the poet and novelist in whose work such diverse critics as John Galsworthy and Sir Osbert Sitwell have seen the light of literary genius. Concentration to the point of obsession, combined with unswerving devotion to his aim, is one of the marks of the poet. That these same qualities served to reveal the truth about the transmission of malaria was no accident. By all the standards of academic research to-day, when individualism is at a discount, Ross would seem the most unlikely of candidates for such an important role. He once remarked that "as a matter of fact, nearly all the ideas in science are provided by amateurs, such as my uncle Ross; the other gentlemen write the textbooks and obtain the professorships." This shaft was a charac-

teristic one, and the attitude which inspired it may explain why his formal medical training, while satisfying the requirements, elicited little of the determination and ardour which he was to show in India when confronted with the tragic human problem of malaria.

Ronald Ross, the eldest of the ten children of General Sir Campbell Ross, was born on May 13, 1857, at Almora in India, where his family, of Scots descent, had long been established. It was at his father's wish that he enrolled at Bart's in 1874 in order to train for the Indian Medical Service, and after seven years of somewhat perfunctory studies his modest aim was achieved. For several years, in the leisure afforded by routine duties, he cultivated his undoubted literary talents and published two verse dramas and a novel. His work in India had interested him in sanitary matters, and during a year's leave in 1888-9 he obtained the then newly established diploma in public health and took a course in bacteriology with Professor Klein. In spite of this evidence of a more serious interest in medical problems he was, five years later, almost determined to give up medicine and devote himself entirely to literature, but another leave in London, in 1894-5, was to prove a turning point in his career. Already acquainted with the pioneer work of Laveran, who had first identified the malaria parasite in 1880, as well as with the theory that the mosquito was the carrier of the disease, he submitted a successful Parkes prize essay which convincingly refuted the older miasmatic theories, still widely held. Nobody in India had succeeded in demonstrating the malarial parasite, and Ross's first view of it was given him by Patrick Manson, who showed him specimens found in the blood of a patient in Charing Cross Hospital. Manson had discovered that the filariae of sufferers from elephantiasis were ingested by mosquitoes, and he had already formed a hypothesis which incriminated the mosquito as the insect vector of malaria. He thought, however, that the disease reached man in drinking water contaminated by parasites from the mosquitoes which rested on it. Nor did he know which of the many varieties of mosquitoes was the carrier. He urged Ross to find out.

Filled with determination to succeed in this task Ross returned to India. After two years of work which called for the utmost patience and courage a short and modest communication was sent to this *Journal* and published on December 18, 1897. It announced the discovery of *Plasmodium falciparum* in two *Anopheles* mosquitoes. Manson's theory of the vector had been proved correct and the species had been named. The date of this discovery, August 20, 1897, Ross himself named as "Mosquito day." Ross then went on to demonstrate scientifically the

route by which the parasite was transmitted and so to disprove the second part of Manson's hypothesis. At Manson's suggestion he studied the organism responsible for avian malaria and traced its passage from the stomach to the salivary gland of the mosquito whence it passes into the skin and blood stream of a healthy bird. The lesson for human malaria was obvious and was proved beyond doubt when put to the test. The news of this great step forward was given by Manson to the annual meeting of the British Medical Association at Edinburgh in July, 1898. Ross's own report was published in this *Journal* in the following February (p. 432).

With his scientific work on the aetiology of malaria completed Ross resigned from the I.M.S. in 1899 and took the chair of tropical medicine at Liverpool. There he began his long campaign for the application of the new knowledge which he had done so much to establish. The first handbook of the Liverpool school, published in 1900 (and in many later editions) was "Instructions for the prevention of malarial fever, for the use of residents in malarious places." A year later he visited the United States and examined and advised on malarial control in Panama. Surgeon-General Gorgas said many times that the building of the canal would have been impossible without the work of Ross. Others were not slow to appreciate the significance of his achievement. A fellowship of the Royal Society in 1901 was followed by the Nobel Prize for medicine in 1902 and many other distinctions from universities and learned societies all over the world. Official appointments and a knighthood (in 1911) failed to make him an orthodox committeeman. Literature was still a powerful attraction; he composed music and formulated ingenious and unorthodox mathematical theories and systems; for many years his editorship of *Science Progress* made that journal one of the most original and vigorous of scientific periodicals. But all these were diversions. His main energies were still given to the passionate advocacy of his great cause—prevention of malaria by mosquito control—and in this cause he attacked "obstructionists" wherever he found them with such pugnacity and candour that he antagonized many who might have welcomed a different approach. The general public responded readily to his fervour and indignation, and in 1926 he saw a tangible memorial of his endeavours when the Prince of Wales opened the Ross Institute and Hospital for Tropical Diseases at Putney (now in the London School of Hygiene and Tropical Medicine). It was, however, a heavy commitment for an ailing man of 70, and financial worries embittered his few remaining years. His death, in his own institute on September 16, 1932, was noted in newspapers throughout the world.

Now, twenty-five years later, when new technical aids and new materials, new national and international organizations have brought his great project within the bounds of possibility, it has not been necessary to argue the merits of the scheme. Although he did not realize it, Ross had won his case.

TOXICITY OF STREPTOMYCIN

It has been recognized since soon after its introduction to therapeutic use that streptomycin may damage the eighth nerve, more commonly the vestibular branch. Dihydrostreptomycin, at first thought to be free from this disadvantage, soon proved to be equally dangerous, and more often to the auditory branch. The results of such damage may be a fair price to pay for life-saving treatment, such as that for miliary tuberculosis or tuberculous meningitis, but the penalty is excessive when the indication for the treatment was some lesser condition and particularly when some innocuous form of chemotherapy might have served equally well. That even moderate doses may be dangerous to patients with impaired renal function was pointed out eight years ago by K. Graf,¹ who defined the maximum permissible dose for prolonged treatment if permanent vestibular damage is to be avoided as 24 mg. per kg. of body weight; lesser doses than this down to 16 mg. per kg. were said also to cause vestibular disturbance, but usually of a temporary nature. This author also observed that children tolerate the antibiotic better than adults. D. T. Carr and his co-workers² reviewed the records of 10 patients at the Mayo Clinic in whom vestibular disturbance or deafness was produced by dihydrostreptomycin, and found reasons for this effect in all but one of them. These authors believed that such damage is apt to result if the blood concentration exceeds 60 µg./ml.: this level was either shown or suspected to have been exceeded in four patients because of impaired renal function, and in five because of excessive doses, either individual or total (2 g. daily in one dose or 1 g. three times a day).

Most clinicians have probably heard of occasional patients who have suffered eighth-nerve damage from only a short course of streptomycin, the dose not being excessive, and have been content to assume either an idiosyncrasy or perhaps unrecognized impairment of renal function. That this is not a very rare occurrence and indeed apparently becoming more common is evident from the findings (see p. 1444) of Mr. T. Cawthorne and Mr. D. Ranger at the National Hospital for Nervous Diseases, Queen Square. In the past six successive years they have seen 2, 3, 2, 2, 4, and 9 patients (total 22) who have suffered eighth-nerve damage, affecting vestibular function in 21 and hearing in 3, from total doses of streptomycin not

exceeding 20 g. The total dose was 10 g. or less in 12 patients, and in only 7 was a daily dose of 1 g. exceeded. With one exception, a man of 25 with gross renal damage, they were middle-aged or elderly patients. This confirms the greater susceptibility of older people, but the paper also makes it very clear that re-education to compensate for loss of vestibular function becomes increasingly difficult with age, a point being reached at which the permanent disability is very great. Two of these patients are recorded as having demonstrable impairment of renal function, and in these it was evidently of a severe degree, the disorder treated being pyelitis in a solitary kidney. But it is noteworthy that in several others the indication for giving streptomycin suggests a possibility or likelihood of renal insufficiency: in two this was nephrectomy, in one tuberculosis in a solitary kidney, and in two nephrolithiasis. It would be interesting to know whether the remaining patients, in whom the diagnosis suggests no renal abnormality, had in fact normal renal function, at least for their age and so far as existing tests will reveal. It may well be that capacity to excrete streptomycin furnishes a more delicate test of renal function than those in routine use. If, on the other hand, these toxic effects can occur in patients who excrete streptomycin normally, another mechanism must be invoked to explain them. To know this is particularly important, because on it depends whether the risks of the treatment can be determined beforehand or not.

It is abundantly clear that streptomycin should be given with great caution, if at all, to patients with damaged kidneys, unless the indication for it is tuberculosis in a potentially fatal form. Only four of these 22 patients were treated for this infection: the diagnosis in the remainder either implies that the drug was given prophylactically as cover for surgery, or suggests an infection for which an alternative form of chemotherapy might well have served. It is to be hoped that few surgeons now feel it necessary to administer streptomycin or indeed any antibiotic as cover for "laparotomy," "arthrodesis of toe," or "hernia." In resection of the colon, oral neomycin is preferable to streptomycin by either route, and in various urinary and other infections sulphonamides, the older and newer urinary antiseptics, and a variety of other antibiotics are possible alternatives. Several years ago high medical authorities in the United States reached the conclusion that streptomycin should be reserved, with few exceptions, for the treatment of tuberculosis, and the findings reported here lend further support to such an attitude. This antibiotic should certainly never be administered without good and clear reasons. Perhaps the principal temptation to its unnecessary use is the existence of several proprietary mixtures of penicillin and streptomycin, the forerunners of other mixtures claimed to possess

virtues exceeding those of any single antibiotic. The indications for this combination with few very uncommon exceptions are doubtful, and those for which it is chiefly given are better served by penicillin alone.

BLOOD GROUP CHIMERAS

The chimera was a fabulous animal of classical mythology, made up of parts of three other known "ordinary" animals. The term was first applied scientifically to plants made up of tissues from more than one genetically separate individual. In the animal kingdom chimeras are much rarer than among plants and are almost entirely confined to the lower phyla. They are perhaps best known among insects, in which, since the secondary sexual characters are determined by the genotype of each separate tissue and not by hormones, sex chimeras are not uncommon and each component shows normal characters. It is not difficult to create chimeras in the lower vertebrates, but, as one ascends the scale, immune reactions make this progressively harder.

Among the mammals probably the first examples were found by F. R. Lillie,¹ who showed that in non-identical bovine twins the blood vascular systems frequently fused at the 10–20 mm. stage, thus making cross-transfusion possible: he also showed that the hormones of one twin may affect the other and that this effect is permanent, the adult female twin being sterile, owing presumably to the effects of her male twin's hormones *in utero*. This work was considerably extended in 1945 by R. D. Owen,² who showed conclusively that in cattle the red blood cells of each twin could survive in the body of the other in adult life—that is, that the cells were not merely crossing from one twin into the other but were tissue homografts surviving and regenerating themselves in the host and that the host was tolerant to them. He cites a case of superfecundation where each calf had, in addition to its "own" cells, cells of a group that it could have inherited only from the sire of the other calf, and it proved possible to separate the two types of blood cell *in vitro*. In 1953 the phenomenon was described in man.³ In this case a group O individual who lacked α agglutinin in her serum not only had A cells in her circulation, but was regenerating these A cells and tolerant of them, and was not sterile. This observation is of fundamental immunological importance.

In 1949 L. D. Felton⁴ defined the phenomenon of "immunological paralysis": he used it to describe the impairment of immunity caused by injecting adult mice with very large doses of type-specific pneumococcal polysaccharide. The non-appearance of antibody is

almost certainly due to the long persistence of the antigen in the tissues, but the effect, though long-lasting, is not necessarily permanent. The term "immunological tolerance" is used to describe the acceptance of homografts by animals which have been injected with living homologous cells before, or very shortly after, birth.⁵ It has further been shown that this state of tolerance can be induced by injecting foetal or newborn animals with foreign proteins, and that this state appears to be permanent. B. Cinader and J. M. Dubert⁶ demonstrated that this tolerance was specific, rabbits rendered tolerant to human albumin at birth being still capable of making antibodies to other proteins (for example, tobacco mosaic virus). This presumably explains why all the five reported chimeras—the original case of I. Dunsford and his co-workers³ and the two pairs reported in this issue by P. B. Booth *et al.* (p. 1456) and by J. W. Nicholas *et al.* (p. 1458)—contain β agglutinins in their sera and are normal and healthy. They do not appear, for example, to have a lowered resistance to infection owing to a general inability to make antibodies. One might venture to suppose from this that chimeras, truly group O but with A cells in their circulations, could in certain circumstances make some form of anti-A, and this has in fact been shown to happen. The original case, Mrs. McK., made anti-A during pregnancy and this subsequently disappeared.⁷

The implantation of primitive blood cells in the host may take place at an early stage by placental fusing—haemocytoblasts are found in placental tissue up to two months' gestation, and this agrees with Lillie's finding in cattle. However, in order to effect immunological tolerance the transplant need not necessarily take place as early as the 10-mm. stage. M. Simonsen⁸ showed in chickens that with non-persistent antigens the time of injection is critical, too early injection giving no response. This does not apply directly to homografts, when the antigen persists, but a later fusing of circulations (if, indeed, mixing of placental circulations is essential to explain this phenomenon) may explain why the human chimeras are not freemartins—the mixing taking place after each sex is firmly established. The presence of the opposite twin's white cells, as well as red cells, in the circulation of the chimera is strongly suggestive evidence of the transplantation of primitive haemocytoblasts before differentiation. In general the immunological characters of red cells are determined by the genotype of the primitive blood cell. That other characters (the presence or absence of Le^a and Le^b) could be acquired chameleon-like from the surrounding tissues was shown by J. S. Sneath and P. H. A. Sneath,⁹ who demonstrated this *in vitro* and also found it *in vivo* in recently transfused patients. The case reported by J. W. Nicholas *et al.* (p. 1458) is of particular interest in that this state of affairs has been found "occurring naturally." This may be taken, perhaps, as further evidence of R. Grubb's¹⁰ hypothesis (subsequently confirmed by R. Ceppellini¹¹) that the Lewis^a genotypes are expressed fundamentally in the body fluids and only incidentally in the red-cell agglutinogens.

Acquisition of tolerance to red blood cells may lead some to suggest that haemolytic disease of the new-

born due to anti-D could be prevented by the induction of immune tolerance, by injecting rh-negative girls with Rh-positive blood at birth. R. E. Billingham and L. Brent¹² have pointed out that this might be dangerous, for they demonstrated that mice injected at birth with spleen showed in development a deficiency of lymphoid tissue inversely proportional to the degree of tolerance, leading in extreme cases to non-development and early death.

A diagnosis of "chimera" must never be made on the blood-group picture alone; the microscopic appearance of group A₃ cells in the presence of α or $\alpha\beta$ grouping serum is characterized by the presence of small agglutinates in a field of unagglutinated cells. This appearance may be similar to that of chimera blood, and the resemblance may be enhanced by the absence of α from the serum of the A₃ blood. In the blood of all cases examined, both of Owen's cattle and of the human chimeras, there was evidence of mixed cell population on more than one blood-group system, though one cannot assume that in all cases twins will differ on more than one system or even on one. In suspected cases a history of a twin should be sought, and to confirm the diagnosis the bloods should be separated, with the recovery of at least one sample in pure form (in A₃ blood the sample cannot be separated into two lots of cells with different agglutination properties). When the diagnosis has been confirmed, further investigations on the case, and hence in this field generally, would be most desirable. It would be of great interest to interchange skin grafts between the twins to confirm or refute P. B. Medawar's belief (referred to in the paper by Booth and his colleagues) that such grafts would be permanently tolerated. In particular, it would be profitable to study the survival time of the homograft cells in the chimera, since this might show whether the organism is immunologically paralysed or, as one would expect, immunologically tolerant.

BIRTHDAY HONOURS

The elevation to the peerage of Sir Horace Evans will give great pleasure to his many friends and colleagues in the medical profession. The citation after his name in the official list reads simply, "Physician," and all will warmly welcome the recognition thus accorded to a most distinguished doctor and, through him, to clinical medicine. Sir Horace succeeded Lord Dawson of Penn as physician to Queen Mary in 1946 and was appointed physician to King George VI in 1949 and to Queen Elizabeth II in 1952. Few members of our profession can have had to bear, with such skill and devotion, such a grave responsibility as fell on Sir Horace during his care of King George VI in the serious illnesses which preceded his death in 1952.

Among those who receive a knighthood is Professor G. R. Cameron, F.R.S., who occupies the chair of morbid anatomy at University College Hospital Medical School. An Australian, he graduated at Melbourne University in 1922, and was appointed to a readership at U.C.H. in 1934. His name is associated particularly with profound studies of the structure and function of
