The circumstances under which loss of foetal blood might occur in a vaginal delivery or following a surgical induction of labour are such that only a small admixture by adult blood is likely. In this connexion it will be remembered that foetal blood itself is a mixture of adult (20%) and foetal (80%) haemoglobin at term, and before term the percentage of foetal haemoglobin is higher. Also the level of haemoglobin in the foetus is higher than the level in adults by 3 to 4 g. per 100 ml. It has been found by experiment that, provided the haemoglobin of the mixture of adult and foetal bloods is above 50%, as little as 1 part of foetal blood in 20 of adult can be detected. When the haemoglobin of the mixture is below 50%, this ratio becomes 1 in 10.

Foetal Haemoglobin in Adult Blood

Foetal haemoglobin in amounts that would be detected by the test described are not produced by normal adults. In sickle-cell anaemia and in thalassaemia (Cooley's anaemia; Mediterranean anaemia), however, appreciable amounts do occur. For all practical purposes these disorders are limited to the Negro and Mediterranean races, but an Italian woman with thalassaemia was recently seen in this hospital; foetal haemoglobin was present in the circulating blood and was detected by this test. The transplacental transfer of foetal red blood cells, first suggested by Wiener (1948), has been shown by Rucknagel and Chernoff (1955) to be an

uncommon occurrence. Using a more sensitive technique than alkali denaturation, they detected foetal haemoglobin in significant amounts in 10 out of 91 pregnant women, although the highest amount detected was only 1.37%. The original alkali-denaturation test of Singer *et al.* is insensitive to amounts of foetal haemoglobin of approximately 2% or less. The modified test, as we describe, is even less sensitive, detecting 5 to 10% of foetal haemoglobin, depending on the haemoglobin level of the sample.

To obtain a 5% mixture in a normal adult, assuming the total blood volume in the adult to be six litres, would require 300 ml. of foetal blood, and this seems to us to be more than could be lost from a viable infant. Bleeding by the foetus into the maternal circulation would not therefore invalidate the test.

Application and Interpretation of the Rapid Alkali-Denaturation Test

The following procedure is carried out in this hospital. In cases of ante- and intra-partum haemorrhage, and when a blood-stained tap has been obtained at surgical induction of labour, the sample of blood is collected and the haemoglobin is estimated. Blood is obtained by venepuncture from the mother and the haemoglobin estimated. The test, as outlined above, is carried out on both samples of blood and the interpretation made against the reading obtained on the venepuncture specimen and against the general background of colorimeter readings (Table II).*

If the colorimeter reading of the vaginal specimen of blood is 11 or above, then foetal blood is clearly present, although the mother's venous-blood reading must always be obtained to check the technique and to avoid the possibility that she is the source of the foetal haemoglobin. Where the vaginal specimen of blood gives a reading of from 7 to 11, then the various colorimeter results given in Table II cease to be of value, and one must then critically compare the colorimeter reading obtained on a venepuncture specimen of blood in which the haemoglobin level has been equated to that of the vaginal specimen. Since the experimental error in performing the test is not greater than one unit, it is considered safe to allow that, if the vaginal specimen of blood gives a reading of 2 or more units higher than the venepuncture specimen at an identical haemoglobin level, foetal blood is present.

Discussion

It has long been known that foetal vessels in the placenta may be damaged during a caesarean section. Leopold (1888) and Kelly (1891) both warned against the practice of boring through an anterior placenta; they pointed out that if this were done the foetus might bleed to death. Siddall and West (1952) and Wickster (1952) have drawn attention again to this accident. Neligan and Russell (1954, 1955) reported upon the circumstances of the accident, and upon its frequency and management. An operative technique was described in which they stressed the importance of circumventing the placenta and clamping the umbilical cord as soon as the baby's face had been delivered. Russell and Warwick (1955) have shown how radiology can help in the management of these cases by warning the obstetrician of the presence of an anterior placenta praevia. The operator may even receive guidance on how best to circumvent the placenta without injuring it. Since 1952 the obstetric and paediatric staffs in our hospital have followed the routine described by Neligan and Russell, and no baby born by caesarean section has lost its life from foetal exsanguination.

Whereas we feel confident that the risk to the baby's life incurred by damage to foetal vessels at caesarean section has been overcome, the danger of foetal exsanguination from other causes still remains. We have given details of nine known cases in the last five years, but there may have been others of lesser degree. Reliance on clinical features

*These results apply only to the E.E.L. colorimeter in this hospital.

alone will result in a high foetal mortality. In six of the nine cases foetal distress was either not noted or did not precede the vaginal bleeding by a sufficient length of time to be of practical value. This observation fits in well with the findings of Neligan and Russell (1954), who noted that the exsanguinated baby may appear deceptively well until shortly before death. In one case, however, foetal distress was present for almost one hour before delivery was effected by forceps. This baby received a blood transfusion and survived (Case 7). In Case 9, foetal distress was noted for half an hour before delivery by caesarean section. The warning, however, was too late, for the baby died in spite of blood transfusion. The other case (No. 1), an emergency admission, resulted in the death of the foetus before arrival in hospital, and no records are available about the duration of foetal distress.

A characteristic feature of the bleeding in eight of the nine cases has been its small amount—enough, however, in each case to warrant a diagnosis of ante-partum haemorrhage. Cases 7 and 8 are of some interest in that we could demonstrate no damaged foetal vessel, yet there was clear evidence of foetal exsanguination. These two cases may be examples of the foetus bleeding into the maternal circulation as has been reported by Wiener (1948), Wickster (1952), and Chown (1954). In both cases, however, there was some vaginal bleeding, and this may have been foetal blood from an undiscovered source. The exact pathological mechanism of blood loss in these cases still remains uncertain, but we record them because they draw attention to the possibility of haemorrhagic shock in babies noticed to be pallid at birth, despite the failure to detect damage to foetal vessels.

In the series of nine cases that we report here, only two babies survived. We hope that routine use of the test described above in cases of ante-partum haemorrhage will enable us to diagnose foetal blood loss earlier and lead to a higher foetal survival.

Summary

Foetal exsanguination, although an infrequent cause of perinatal death, is on occasion preventable.

By careful attention to obstetric and paediatric techniques it has been found possible to overcome the risk to the baby's life incurred by damage to foetal vessels at caesarean section.

The risk of foetal exsanguination from other causes remains, and nine cases are described. In these cases reliance on clinical features did not give sufficient warning for prompt treatment to be undertaken.

Attention is drawn to the need for a rapid, reliable test to show when foetal blood is present in the vaginal loss in cases of ante-partum haemorrhage. A rapid alkali denaturation test for the detection of foetal blood is described.

We are indebted to Professor Harvey Evers and Professor Donald Court for their advice and encouragement and for permission to publish details of cases admitted to the Princess Mary Maternity Hospital. We also thank Dr. R. B. Thompson for his interest and help in the development of the test to differentiate foetal from maternal blood.

INFLUENCE OF SELECTIVE INDUCTION OF LABOUR ON MORTALITY IN HAEMOLYTIC DISEASE OF THE NEWBORN

BY

O. D. FISHER, M.D., M.R.C.P., D.C.H.

Consultant Paediatrician, Medway and Gravesend Hospital Group; formerly Lecturer, Department of Child Health, Queen's University, Belfast

In the past few years the mortality in haemolytic disease of the newborn has fallen considerably, but obstetricians and paediatricians still differ in the management of the expectant mother with rhesus antibodies.

The Medical Research Council in 1949 initiated controlled trials of treatment: firstly, between exchange and simple transfusions; and, secondly, between routine induction of labour and spontaneous delivery. The preliminary results of the trials were published in 1952 by Mollison and Walker and showed that exchange transfusion resulted in a lower mortality (13%) than simple transfusion (37%), while the incidence of kernicterus was also lower after exchange transfusion than after simple transfusion. They concluded that routine premature induction of labour three to five weeks before the estimated date of delivery resulted in a higher mortality (36.4%) than when labour ended spontaneously (24.1%). A later review by Armitage and Mollison (1953) of the children born during these Medical Research Council trials showed that infants born prematurely were more liable to kernicterus and to mental and motor defects than those born spontaneously.

Since the official recommendations by the Medical Research Council in 1952 regarding exchange transfusion and premature induction of labour, other workers have also emphasized that premature induction of labour has no place in the routine treatment of haemolytic disease of the newborn—for example, Walker and Murray (1954). These expressed views have probably resulted in the virtual cessation of premature induction of labour for this disease in most obstetrical hospitals and units in the United Kingdom.

However, at the Royal Maternity Hospital, Belfast, these views have never been fully accepted in Professor Macafee's department, where induction of labour has been carried out when indicated. This approach has received support from Watson, Crosse, and Hatchuel (1954), who showed the strikingly beneficial results obtained by premature induction of labour on two occasions in one particular patient. Kelsall and Vos (1955) also reported a series of 246 consecutive cases of haemolytic disease of the newborn and suggested that the overall mortality could be lowered by the premature induction of labour at the optimal time after 35 weeks of gestation followed, where necessary, by exchange transfusion. The mortality rate of infants spontaneously delivered was 23.4%, compared with 10.7% in infants born after premature induction of labour. These figures show a statistically significant preference for controlled induction. Kelsall and Vos claimed to show that controlled induction of labour and subsequent exchange transfusion had virtually eliminated stillbirths after 35 weeks' gestation and had not been associated with an un-

due increase in neonatal deaths. They also stated that kernicterus had become so rare in their induced cases as to be practically never seen.

Present Investigation

Following these reports the results of 143 pregnancies complicated by rhesus incompatibility have been reviewed from January, 1951, to December 31, 1955, at the Royal Maternity Hospital, Belfast. Since the patients were admitted either to one unit in which, as a general rule, selective induction of labour was undertaken or to another unit in which spontaneous delivery was preferred, two roughly comparable series are available.

All the mothers were rhesus-negative and had rhesus antibodies in their serum. Each live-born infant had a positive Coombs test except in two cases. One was born with a cord haemoglobin level of 12.3 g. per 100 ml. (90%) and a negative Coombs test, but exchange transfusion was undertaken. The other infant was born with a cord haemoglobin level of 16 g. per 100 ml. (108%) and a serum bilirubin level of 3 mg. per 100 ml.; the Coombs test was not recorded but exchange transfusion was done, the mother having rhesus antibodies and a history of previous infants affected by haemolytic disease of the newborn. All stillbirths and neonatal deaths were assumed to be the result of haemolytic disease of the newborn. Only those patients delivered at or after the 36th week are considered, the period of gestation being calculated by Naegele's method from the date of the first day of the last menstrual period.

As a general rule, exchange transfusion was undertaken if the haemoglobin of the cord blood, estimated by the Medical Research Council photometer, was below 14.8 g. (100%) but not if it was above 17.7 g. (120%). When the haemoglobin was between 17.7 g. and 14.8 g. exchange transfusion was usually done if the serum bilirubin was greater than 2.7 mg. per 100 ml. (normal range, 1.5–2.5 mg. per 100 ml.; King, 1951), especially when associated with enlargement of the spleen, a previous family history of severe haemolytic disease of the newborn, prematurity, or if the umbilical cord was jaundiced. Warm rhesus-negative group O citrated blood was used, giving at least 50 ml. of packed cells per lb. (110 mg. per kg.) of body weight of the infant.

The obstetrician was responsible for the selection of patients for premature induction of labour, which was based on a clinical assessment of each case. The indications have been, to a certain extent, arbitrary, but a previous seriously affected or stillborn child with haemolytic disease, a rising rhesus antibody titre, and a homozygous rhesus-positive husband have had an important influence on the selection of cases for induction. During the last few weeks of a rhesus-incompatible pregnancy, alteration in the foetal heart or diminution of foetal movements may also indicate urgent delivery by caesarean section, and in some of the infants so born the cord haemoglobin has been found to be as low as 7.4 g. per 100 ml. (50%). In this series labour was usually induced in the 37th or 38th week, but the need for a more accurate method of determining when termination of pregnancy is indicated is discussed below.

Findings

If death *in utero* occurred before 36 weeks of gestation the possibility of induction of labour would have been excluded, and this might weight the total mortality unfavourably against the spontaneously delivered group. For this reason the mortality rate in the spontaneous group is shown in Table I, corrected by excluding any known deaths *in utero* before the 36th week of gestation (four in number). In the remainder, the foetal heart was heard after the 35th week; or the infant, if stillborn, was fresh and unmacerated. Table I also shows that the total mortality rate in the spontaneous group is notably higher (29%), than in the induced group (16%). Nevertheless, the severity of the haemolytic disease was probably greater in the induced cases, as the incidence of

exchange transfusion was higher (68 transfusions in 76 cases) in the induced group than in the spontaneous group (29 transfusions in 63 cases). The average haemoglobin level in the cord blood was slightly lower (87%) in the induced group than in the spontaneous group (93%). By conventional standards, however, the statistical analysis is not significant in such a small series.

Table II shows the duration of pregnancy at which delivery occurred after induction was carried out, compared with that at which spontaneous delivery occurred.

TABLE I.—Mortality At or After 36 Weeks in 139 Cases of Rhesus Incompatibility Known to be Viable After 35 Weeks (Royal Maternity Hospital, Belfast)

Labour	No. of Cases	Survival	Neo-natal Deaths	Still-births	Total Mortality	% Mortality

Average Hb level (%) ..	61	101	91	82	94	99	93

The beneficial effect of selective premature induction of labour in haemolytic disease of the newborn can also be illustrated by individual case records.

Case 1.—A patient aged 29 had the following history. Her first infant was born at term weighing 9 lb. (4 kg.) and is alive and well; her second was also born at term weighing 9 lb. (4 kg.) but died at 3 days of age with jaundice; her third and fourth infants were stillborn at 38 weeks. In her fifth pregnancy she was found to be rhesus-negative and to have a rhesus antibody titre of 1/16. An elective caesarean section was undertaken at 37 weeks; the infant was born suffering from haemolytic disease of the newborn with a haemoglobin level of 12 g. per 100 ml. (82%). Exchange transfusion was performed, and the infant's subsequent progress has been excellent.

Case 2.—A patient, aged 35 and rhesus-negative, had the following history. Her first two infants, born at term, are alive and well; her third infant was stillborn at 39 weeks; her fourth infant, born at term, died on the fifth day with jaundice; her fifth infant was stillborn at term; her sixth infant, born at term, died 12 hours later with jaundice; her seventh infant was born at term, became slightly jaundiced later, did not require a transfusion, and is alive and well; her eighth and ninth infants were each born at term; both had exchange transfusions, but died 12 hours later with severe jaundice. In her tenth pregnancy rhesus antibodies were present. She was induced and delivered at the 38th week; the infant was born suffering from haemolytic disease, with haemoglobin of 9.6 g. per 100 ml. (65%). Exchange transfusion was performed and the child is alive and well.

Discussion

These individual family histories and the comparison of results in 139 infants with haemolytic disease of the newborn

TABLE III.—Comparison of Mollison and Walker (1952), Kelsall and Vos (1955), and Royal Maternity Hospital, Belfast. Mortality Rates in Haemolytic Disease of Newborn

Deaths % ..	36.4	24.1	10.7	23.4	16.0	29.0

suggest that the mortality from this disease can be lowered by selective premature induction of labour rather than by awaiting spontaneous delivery. The reduction of the total mortality from 29% in the spontaneously delivered group to 16% in the induced group in this series is similar to that from 23.4% to 10.7% in Kelsall and Vos's series (Table III), but the reverse of the findings of the Medical Research Council trials.

Such results, however, cannot be compared with the findings in the Medical Research Council trials, where routine induction of labour was undertaken three to five weeks before term and the form of treatment was dictated by selection of random numbers. The difference in the mortality rates in the induced cases in the present series and in the Medical Research Council trials may have resulted partly because the random selection of patients for routine induction fails to distinguish between mildly and severely affected cases and therefore needlessly exposes to the hazards of prematurity a number of infants unaffected or only mildly affected. Likewise, the selected period for induction, about the 36th week, in the Medical Research Council trial, may not have been the optimal time to terminate a particular pregnancy.

It cannot be too strongly emphasized that each rhesus-incompatible pregnancy should be treated on its merits.

The mortality rates reported by Kelsall and Vos (1955) for the induced group and the group delivered spontaneously are much lower than those in the present series and may be due to several factors. An important difference in their technique of exchange transfusion is in the use of freshly collected heparinized blood in place of stored citrated blood. Campbell (1955) has drawn attention to the high plasma potassium content of stored blood and noted that toxic levels of potassium occur in infants undergoing exchange transfusion, which might be a factor in causing death during transfusion. Possibly of equal importance is an alteration of the ratio of diffusible to non-diffusible calcium in stored citrated blood, and work is proceeding on this problem.

Kelsall and Vos also exchanged larger quantities of blood, 150–250 ml. per lb. (330–550 ml. per kg.) body weight of the infant during transfusion, but this is not necessarily an advantage, as in the present series exchange transfusion has been repeated on a second or even a third occasion if indicated subsequently by a high serum bilirubin level.

It is obviously necessary to have a method of determining the severity of haemolytic disease of the newborn during the course of pregnancy so that the optimal time for induction of labour can be more accurately selected. In 1952 Kelsall and Vos published a method of carefully standardized and repeated antenatal titrations of maternal serum by the anti-globulin method of Coombs and found it to be an accurate guide to treatment. They tested the serum of pregnant rhesus-negative women at monthly intervals and, if antibodies were detected, at weekly intervals after the 32nd week. They claimed that a titre of 1/64 or higher was an indication for induction at 36 weeks or onwards. If the father was homozygous and the maternal antibodies were high but stationary, induction was carried out at 38 weeks. If the titre was lower and stationary, the pregnancy was allowed to continue, the antibody level being checked at weekly intervals.

On clinical grounds some guidance can be gained from the previous family history. Walker and Murray (1956) have shown that in their series of infants with haemolytic disease of the newborn there was a general trend to more severe disease in succeeding pregnancies. They also showed that the stillbirth rate was about 10% when there had been no previously affected baby but that it was nearly 30% in subsequently affected babies. Moreover, in families where a previous infant was stillborn as a result of haemolytic disease there was an 80% chance that the next baby, if allowed to go on to spontaneous delivery, would also be stillborn. This in itself justifies the need for premature induction of labour in these patients, for this procedure will increase the likelihood of the infant being born alive and give it a chance of survival with treatment in spite of the hazards of prematurity. It is, however, essential to know in such a rhesus-incompatible pregnancy that the husband is homozygous rhesus-positive, as this will influence the choice of treatment.

The rhesus antibody titres in saline and albumin media of the maternal blood in this series have not necessarily corresponded with the severity of the disease in the infant. The need for a reliable method of assessment such as the antibody titration method described by Kelsall and Vos (1952) and the importance of weekly estimations of antibody levels are well illustrated by the following case record.

A patient aged 30 had the following history. Her first infant, born weighing 4 lb. (1.8 kg.), suffers from cerebral palsy; her second infant is alive and well; her third child died at 9 days of age with jaundice; her fourth pregnancy terminated at 36 weeks and the infant was stillborn. In her fifth pregnancy she was found at 10 weeks to be rhesus-negative with an antibody titre of 1/2. At 34 weeks the foetal heart was heard. Arrangements were made for her to be admitted at 38 weeks for possible induction of labour. Spontaneous onset of labour at 37 weeks resulted in delivery of a macerated stillborn foetus which showed at post-mortem examination all the features of haemolytic disease of the newborn.

Allowing for the clinical difficulties and possible statistical variables inherent in comparing different series of such cases, selective induction of labour based on the family history and clinical assessment of each rhesus-incompatible pregnancy would seem to have reduced the total mortality in haemolytic disease of the newborn.

Summary and Conclusions

The results of 143 pregnancies of rhesus incompatibility delivered spontaneously or by selective premature induction of labour are reviewed.

There is a notable lowering in the total mortality in haemolytic disease of the newborn in the induced group (16%) compared with that of the group delivered spontaneously (29%).

The severity of the disease was probably greater in the induced group, as twice as many exchange transfusions were performed and the average haemoglobin level was lower than in the group spontaneously delivered.

The beneficial results of selective premature induction of labour are also illustrated by the individual case histories.

The time of induction was based on the previous maternal history and by clinical assessment of the individual patient.

Selective premature induction of labour is thought to reduce the total mortality from haemolytic disease of the newborn.

I thank my colleagues at the Royal Maternity Hospital, Belfast, and in particular Professor C. H. G. Macafee, Professor F. M. B. Allen, and Dr. Maurice Russell, for their assistance in preparing this report.

ADDENDUM.—Since this article was accepted for publication a further paper on the subject has been published by W. Walker, S. Murray, and G. K. Russell in the *Lancet* on February 16, 1957.

BRUCELLOSIS IN CHILDREN

BY

HUGH R. E. WALLIS, M.D., M.R.C.P., D.C.H.

Consultant Paediatrician, Bath Clinical Area;
Medical Officer, Kingswood School, Bath

Brucellosis is a disease of mistakes. If we do not think of it we miss it; or we may think of it and test for it, yet find nothing. It eludes us. Nevertheless, as a cause of pyrexia of undetermined origin it is important; and obscure headaches, lassitude, abdominal pain, or arthritis may be due to its smouldering activity.

Case 1.—A girl of 6 was referred to me because of abdominal pain, lassitude, and irritability. I could find no abnormality, and investigations proved negative. Her family had moved house a few months earlier and she had been sent to a new school. I assumed that her symptoms were due to psychological upset and hoped that they would settle down in the course of time. Three months later I was asked to see her again because she was no better. She then had some enlarged glands in the neck, axillae, and groins, and her liver was palpable. A white cell count showed a leucopenia, with a diminished number of neutrophil polymorphs. Serum agglutinations against *Brucella abortus* were positive at 1 in 320 dilution. Chlortetracycline and streptomycin were given for seven days. Her temperature fell rapidly and she felt better within a week. Her recovery was complete and permanent.

I was able to learn by my mistake in this case. From that time I was more keenly aware of the possibility that brucellosis might be the cause of vague or unexplained symptoms. In the course of time I met with a number of children who were undoubtedly suffering from brucella infection. I scrutinized the notes of 2,000 children I had seen in hospital during the previous four years and made a retrospective diagnosis in several others. It is important to record my findings in order that others may learn from my mistakes as I have done. I hope thereby to reduce the number of cases in which pain, fever, and arthritis remain unexplained, and also to shield children from unjustified accusations of neurosis and malingering.

Dalrymple-Champneys (1950) has given an excellent review of the history, ecology, and symptomatology of this disease, which he calls "a neglected problem." Full reference to the previous work has been made by Huddleson (1939) and Harris (1941, 1950) in their exhaustive monographs, and it is evident that any system of the body may be affected.

Sander (1933) said that the disease in children did not differ at all from that in adults; but Huddleson wrote that in Malta, where it is commonest in children, it is relatively mild and often passes unnoticed. Williamson

and Gibson (1931) reported the first case in this country, that of a boy of 20 months. Paterson and Hardwick (1938) also reported cases, and gave their opinion that many such cases are never recognized. In infancy the symptoms are more obscure. Repeated gastro-intestinal upsets, failure to gain weight, and pyelitis may be noted. Hagebusch and Frei (1941) believe that the infection may be acquired *in utero*. Epidemics have been reported in this country by Elkington *et al.* (1940) and Cruickshank and Stevenson (1942).

Case Reports

General.—For greater brevity all negative or normal investigations have been omitted. It may be assumed that the tuberculin and Widal reactions were negative, and that urine examinations and x-ray examinations of the chest, abdomen, and sinuses gave normal results unless otherwise stated. All the children lived in the country except one, who had recently moved into the city. All of them had drunk milk which had not been pasteurized, though in some cases it was from tuberculin-tested herds.

Case 2.—Acute Attack and Relapse

A boy of 8 lived in a village where there was an epidemic of brucellosis. He had drunk milk from a herd which was later proved to be infected with *Br. abortus*. In December, 1954, he had an acute attack of diarrhoea and abdominal pain. His temperature rose to 101° F. (38.3° C.), and he had a cough. The family doctor made a diagnosis of brucellosis, and the patient was admitted to hospital after a week. He was found to have glands in the neck, axillae, and groins, and a systolic murmur in the heart.

Investigations.—Haemoglobin, 98%; E.S.R., 22 mm.; total white count, 3,400 (polymorphs 1,750). Agglutinations against *Br. abortus*, negative. Brucellin skin test, strongly positive.

He was treated with chlortetracycline and streptomycin for one week. His temperature settled rapidly, and he was discharged home. A month later he had gained 4 lb. (1.8 kg.) weight, but was rather tired and irritable. His total white count was 7,200, with 3,000 polymorphs. Agglutinations were positive at 1 in 640 dilution.

He continued to make a good recovery, and at follow-up a year later he was very well. Soon after this he was kicked on the head while playing football. A week after the injury he had an attack of lethargy, anorexia, and malaise. On examination there were some small glands in the neck and axillae. The systolic murmur remained. At the site of the skin test there was still an area of induration and scaling of 5 by 5 mm. His mother said that the place broke down and wept after he left hospital, and that it had never healed since. During the next month he had headaches, irritability, and fever up to 102° F. (38.9° C.). He was admitted to hospital for further treatment. His liver was then palpable, and the agglutinations were positive at 1 in 160. After a second course of treatment he has again progressed well, and the systolic murmur is no longer audible.

Comment.—This may have been a reinfection; but in view of the behaviour of the skin test it is more likely to have been a relapse. Barrett and Rickards (1953) refer to the flaring-up of malaria after surgical operations and other insults, and suggest that the same may happen in brucellosis. Dalrymple-Champneys records a case where a fracture of the femur precipitated a relapse 35 years after the original attack.

Case 3.—“Influenza”

At a school in the country several boys had what was thought to be influenza. Most of them recovered rapidly, but one aged 8 had a persistent fever of 99 to 100° F. (37.2 to 37.8° C.) in the evenings for three weeks. Sulphonamides and penicillin had no effect. Examination then showed a fit pale boy with one gland in the left axilla.

Investigations.—Haemoglobin, 95%; E.S.R., 4 mm.; total white count, 7,000 (polymorphs, 3,500). Agglutinations against *Br. abortus*, positive 1 in 80. X-ray examination of the chest showed mottled shadows in the right and left lower zones and hilar enlargement on the left.

The temperature continued to be high in the evenings for another 14 days and he was seen again. His blood picture was unchanged except for a rise in titre of agglutinations to 1 in 160. The x-ray picture was clearer. A diagnosis of brucellosis was made at this time, and it was decided to wait before treating him. Fourteen days later he seemed to be worse. His appetite was poor and he had become short-tempered and apt to burst into tears without reason. He had had pain in one knee, and evening pyrexia. He was treated with chlortetracycline and streptomycin for 10 days, and made a good recovery.

Milk Supply.—The dairyman who supplied milk to the school obtained it from three farms. These were inspected, and positive evidence of infection of the herds with *Br. abortus* was found in two of them.

Case 4.—E.N.T. Problem

The patient was a boy of 10. His father worked on a farm and brought home raw milk in a can. In December, 1955, he had an acute pain in the neck. Next day his right knee and ankle were painful. The family doctor found that he had tenderness over one mastoid process and some meningism. He was admitted to an E.N.T. ward. On admission he had deep cervical adenitis, without definite ear disease. Haemoglobin, 87%; E.S.R., 42 mm.; total white count, 3,100 (polymorphs, 1,550).

Three days later his liver was found to be enlarged and tender and he was transferred to the paediatric department. He had a systolic murmur; but further investigations were negative. Agglutinations for *Br. abortus*, positive at 1 in 20 only. Fever up to 99° F. (37.2° C.) persisted, and he had some diarrhoea. A week later he complained of headaches and pain in the chest and abdomen. His spleen became palpable and there were glands in both axillae and posterior triangles. By this time the total white-cell count was 2,000, with only 1,020 polymorphs. The house-physician (who had trained in London and could not believe the diagnosis of brucellosis) became worried, and prepared to take a specimen of sternal marrow. However, a repeated test of the agglutinations showed a rise to 1 in 160. About this time there were some dry scaling patches on both cheeks, and the boy became constipated. A skin test was negative. His temperature settled, the liver and spleen receded, and he felt better. A month later there was a relapse, with abdominal pain and fever. He was treated for 14 days with chlortetracycline and streptomycin. Three months later he was well and considered to be cured. The systolic murmur was no longer heard.

Case 5.—Psychological Disturbance

A girl of 5 was referred by her family doctor with this note: “She is listless and pale, and has become rather a frightened child. Mamma has to work to keep herself and the child. A neighbour looks after the girl during the day, when she is not at school. I feel that the problem is really a social one, but would be glad of your reassurance that it is not physical.”

Examination revealed some glands in the neck, axillae, and groins, and a basal systolic murmur. There was also a golden-brown pigmentation on the forehead and temples.

Investigations.—Haemoglobin, 81%; E.S.R., 8 mm.; total white count, 4,500 (polymorphs, 3,150). Agglutinations against *Br. abortus*, positive 1 in 320. Brucellin skin test, positive. The urine contained 100 mg. of protein per litre and many pus cells, but it was sterile on culture.

She was treated with chlortetracycline and streptomycin for 10 days and made a rapid and complete recovery. A month after the end of treatment her mother said: “I

think you must have been feeding her with energy pills.” Three months later she was very well, the murmur had gone, and no glands were palpable in the neck or axillae.

Case 6.—Spontaneous Cure

A boy of 12 had had a dry cough, abdominal pain, and constipation for two months. On examination there were no abnormal physical signs.

Investigations.—Haemoglobin, 76%; E.S.R., 20 mm.; total white count, 3,200 (polymorphs 544). Agglutinations, negative. Brucellin skin test, negative. A month later the total white count was 7,000, with 4,760 polymorphs. The agglutinations were positive at 1 in 160. By then he had improved, and it was not thought justified to treat him. A year afterwards he was very well.

Comment.—A spontaneous cure. The very low polymorph count might have caused alarm if this disease had not been recognized.

Case 7.—Migraine

A boy of 9 had attacks of paroxysmal abdominal pain and headache associated with nausea and blurred vision. On admission to hospital no abnormalities were found except a few glands in the neck and groins and a systolic murmur. Haemoglobin, 90%; E.S.R., 2 mm.; total white count, 7,000 (polymorphs 2,590). Cerebral tumour and subdural haematoma were ruled out, and a diagnosis of migraine with a psychological background was made. A month later he was easily tired and could not concentrate at school. Brucellosis was considered, and he was admitted to hospital. Agglutination was positive at 1 in 40 only. A skin test was negative, and a week later the agglutination titre was unchanged. He was discharged with no firm diagnosis.

After another month he was still lacking in concentration, and had pains in the shoulders and knees. The headaches continued, and his evening temperature was raised to 99–100° F. (37.2–37.8° C.). A diagnosis of brucellosis was made on clinical grounds despite the absence of confirmatory pathological findings, and it was decided to treat him. He was given chlortetracycline and streptomycin for 10 days. After three days his temperature fell below 98° F. (36.7° C.) and remained low. He felt better and his cheeks became pink. Meanwhile the agglutinations had been repeated, and were reported as positive at 1 in 160. Since the end of treatment he has had no headaches or other symptoms. His mother states, “He is a different child.”

Milk Supply.—The medical officer of health was informed, and as a result herds at two farms were found to be affected.

Comment.—Note the delayed response to the skin test. The final specimen of serum which returned a titre of 1 in 160 was taken 40 days after the skin test, and after a diagnosis had been made without positive pathological evidence. Dixon and Roaf (1946) and Nichols (1951) have reported cases with transient migraine.

Cases Diagnosed in Retrospect

Case 8.—X-ray Picture Mimicking Miliary Tuberculosis

This boy of 11 lived on a farm. In November, 1953, he had an attack of vomiting and abdominal pain. A week later he had frontal headaches, dyspnoea, and a dry cough. On examination his temperature was 99° F. (37.2° C.), pulse rate 100, and respiratory rate 40. His breathing was shallow, and there were fine crepitations in all parts of the lungs. An x-ray film showed that both lung roots were rather prominent and there was a fine mottling throughout both lungs resembling miliary tuberculosis. Haemoglobin, 97%; E.S.R., 6 mm.; total white count, 6,000 (polymorphs 2,100). Mantoux test, negative to 100 T.U. His temperature settled quickly, and after 14 days he was discharged with a provisional diagnosis of bronchopneumonia. Six weeks later he was irritable and had no appetite. Small

glands were found in his axillae and neck. Crepitations were still heard in his lungs, and the x-ray picture was unchanged. He was admitted again. The tuberculin tests were still negative. A diagnosis of sarcoidosis was considered, but the plasma proteins and the albumin/globulin ratio were found to be normal. No abnormality was found in the x-ray films of his bones. He improved once more and was discharged again with a diagnosis of possible sarcoidosis.

He went downhill and was admitted for the third time six months after the onset of the disease. His spleen was then palpable, and extrasystoles were noted. Kahn and Wassermann reactions were negative. Brucellosis was considered and discarded as the agglutinations were negative. A lymph node removed from the axilla showed no histological evidence of lymphadenoma or sarcoidosis. An electrocardiogram was normal.

He again improved and was discharged with no final diagnosis. He was seen from time to time in the outpatient department. The x-ray picture cleared, and he was finally discharged from attendance over a year after the onset, still undiagnosed. A year after that he was sent for again. He was a fine fit boy, and had gained 19 lb. (8.6 kg.) weight. He had no symptoms. There were no abnormal physical signs, and x-ray films of the chest were normal. Haemoglobin, 89%; total white count, 5,000 (polymorphs 2,200). Agglutinations against *Br. abortus*, 1 in 160. Brucellin skin test, negative.

Comment.—If this boy had by chance been tuberculin-positive a diagnosis of miliary tuberculosis would have been almost irresistible. In the days before antibiotics were available there were a few legendary patients who recovered from miliary tuberculosis. Probably some of them were in fact suffering from brucellosis. It seems possible also that some obscure cases of “sarcoidosis” may really be victims of brucella infection. The only other child seen in this area with an index diagnosis of “query sarcoidosis” also had a leucopenia and a high titre of agglutinins. Note also that the leucopenia remains despite apparent clinical cure.

Case 9.—Spinal Radiculitis

A boy of 15 had an acute febrile illness with cough, lassitude, and anorexia. He was found to be tuberculin-positive and to have healed calcified glands in the abdomen. A month later he had pain in the chest, constipation, and fever. At this time the white count was 4,400, with 1,980 polymorphs. Six months later he had pain in the back which was unexplained. A year later there was an obscure disease of the right elbow which was variously diagnosed as early osteoarthritis and a cervical disk lesion. After another six months he complained of a stiff ankle with limited movement. A prolapsed intervertebral disk was suspected, and he was admitted to an orthopaedic hospital. Here the total white count was 2,800, with 1,512 polymorphs. The sedimentation rate was 2 mm. Some sensory loss appeared in the legs, and a diagnosis of cauda equina tumour was made. In a neurosurgical unit lumbar puncture was performed. The C.S.F. was faintly yellow. Protein, 208 mg. per 100 ml.; W.B.C., 87 per c.mm. (75% lymphocytes); Lange, 0001110000.

An operation was performed, and on opening the dura all of the roots of the cauda equina were seen to be injected and swollen to two or three times the normal diameter. This unexpected finding was noted as “a rare condition, not fully understood.” His progress after the operation was poor. He lost weight and became very depressed. The possibility of carcinomatous neuropathy was considered but not proved.

When the question of brucellosis was raised three years after the onset tests showed that agglutinations were negative and the skin test was strongly positive. Treatment with chlortetracycline brought much improvement.

Comment.—The leucopenia should have led to an earlier diagnosis, which would have saved this boy much suffering.

Huddleson (1939) and Nelson-Jones (1951) report cases of spinal radiculitis, and I have since seen one other. Neurologists should be on the alert for this disease.

Case 10.—"Tuberculous Rheumatism"

A girl of 12 had an acute attack of abdominal pain and constipation. In hospital her temperature and pulse rate were normal. Her appendix was removed and found to be normal also. Two months later she still had pain and some dysuria. A blood count showed: haemoglobin, 78%; E.S.R., 13 mm.; total white count, 4,200 (polymorphs 1,722). This was ignored.

Six months later she had a painful swollen knee. A systolic murmur was noted, and she was said to be nervous. A diagnosis of chondro-osteomalacia was made by an orthopaedic surgeon.

During the next six months she had low back pain and became easily tired. She was admitted to an orthopaedic hospital with the diagnosis of lumbo-sacral disk lesion. She was treated with a corset and some physiotherapy. Her response was not good. A tuberculin test was positive. Her urine contained a few pus cells on several occasions, but no tubercle bacilli could be found. An intravenous pyelogram was normal. Because of the constipation sigmoidoscopy was performed. Nothing abnormal was found. The house-surgeon wrote: "This child has probably been talked into her condition by over-solicitous parents. Away from them she seems to have improved a good deal. She should get up and persuade herself that she is not an ailing person."

About this time I saw her and made another mistake. Because an x-ray film of the abdomen revealed that there were calcified mesenteric glands, I made a diagnosis of tuberculous rheumatism. I advised treatment with calceferol, but there was no improvement. Later, as a result of this survey, she was sent for again. It was found that she had been sweating at night, her liver was palpable, and the systolic murmur remained. Her blood picture was normal and agglutinations against *Br. abortus* were less than 1 in 20. A brucellin skin test was negative; but a week later the agglutination titre was 1 in 80.

Comment.—The fourfold rise in titre after the skin test proves the diagnosis. This poor girl has been subjected to appendicectomy, intravenous pyelography, sigmoidoscopy, suspicion of psychoneurosis, and long months in hospital, all unnecessarily. If such cases of brucellosis could be recognized earlier not only would pain and suffering be relieved but the nation would be spared considerable expense.

Tuberculous rheumatism has been reported as an entity by Poncet and Leriche (1909) and Sheldon (1946). It consists of a short-lived and atypical arthritis occurring in the course of tuberculous disease. It seems possible that some of the cases so labelled are in fact suffering from two diseases, tuberculosis and brucellosis, both contracted from the same source—namely, infected milk. In Poncet and Leriche's book it is stated that one of their patients was "un vétérinaire de 50 ans." We now know that brucellosis is an occupational disease of veterinary surgeons, and perhaps that gentleman could be included among those diagnosed in retrospect.

Diagnosis

The proof of infection with brucella may be extremely difficult. The following steps should be taken.

1. Consideration of the history and clinical findings.
2. Studies of the blood. Usually the haemoglobin level is slightly but not severely lowered. The sedimentation rate of the red cells is often very low. The number of white cells is decreased, and there is a marked diminution in the number of neutrophil polymorphs. The total count is usually below 5,000, with fewer than 2,500 polymorphs. But a normal count does not rule out the disease.

3. Serum agglutination tests against a suspension of killed brucella organisms. According to Wilson and Miles

(1955) a positive reaction in a titre of 1/80 or over in a febrile patient can be regarded as indicative of active infection. But a negative reaction by no means excludes active infection, and a rising titre is usually indicative of activity. The history of Case 7 suggests that a titre of 1 in 40 can sometimes be accepted as evidence of activity.

4. An intradermal sensitivity test with brucellin. This is similar to the Mantoux test for tuberculosis. If it is positive it shows that the patient has at some time met with brucella infection, though it does not prove that his illness is due to such infection. On the other hand, unlike the Mantoux test, a negative result cannot be taken to preclude the diagnosis. Evans *et al.* (1938) found that the skin test was negative in 39% of affected patients. Harris (1941, 1950) has described delayed reactions, and it would seem wise to read the test at 48 hours and thereafter daily for a week or more.

5. A second estimate of the agglutinins. Sometimes the skin test provokes a rise in titre, but not always. A four-fold rise is usually taken as significant. It has been customary to take the second specimen for testing at six to eight days. Criscuolo (quoted by Harris) found in some cases that the rise was delayed till the 30th day (see also Case 7). The rise in titre may occur even though the skin test is negative (Cases 6, 7, and 10).

6. Blood culture. The results of this procedure seem to be variable, and are unsatisfactory in the obscure chronic cases where they would be of most help.

All of the five last-named investigations may give normal or negative results even though the patient is suffering from active infection. Failure to realize this fact has often led physicians into error in the past. It must be emphasized that laboratory aids are sometimes misleading, and that in obscure cases the diagnosis may have to be made on clinical grounds alone (see Case 7).

Various Factors

Time of Onset.—An analysis of the months of onset of these cases showed that the disease starts most often in the autumn and winter months. Organisms are excreted in the milk in greater numbers during the early months of lactation. In Malta the kidding season occurs in March and April, and there is a seasonal increase in brucellosis in the summer (Eyre, 1907). In this country calving takes place more commonly in the late summer and autumn. The increased autumnal incidence may also be due to the fact that many children nowadays go to the country or seaside for their summer holidays and to the modern practice of spending holidays in caravans. Even city children who have safe milk at home may be caught in this way, and practitioners in large cities should remember this. One drink may be enough. One boy of 8 had always had pasteurized milk. He went for a picnic but left the milk at home. He begged a drink from a farm and was given milk fresh from the cow. Three weeks later he had an acute attack of brucellosis.

Heart Murmurs.—Systolic murmurs were heard in half of the cases. This is a higher proportion than is generally found in healthy children. They were not due to dilution of the blood, as in no case was there any severe anaemia. In three cases they disappeared after treatment. Such murmurs may come to be regarded as useful pointers in the diagnosis. Care should be taken to rule out bacterial endocarditis and acute rheumatism. Hart, Morgan, and Lacey (1951) record cases of brucella endocarditis.

Pigmentation.—The type of pigmentation on the forehead and temples noted in Case 5 was seen in another case not included here. It has not previously been reported so far as I can determine, though Hughes (1897) describes "a certain amount of bronzing."

Urine.—In several cases protein or pus has been found in the urine. It seems likely that some chronic cases of low-grade pyelonephritis or abacterial pyuria may be due to brucellosis. Transient glycosuria was seen in one case.

Psychological Disturbances.—Several children were suspected by parents, family doctors, house staff, or consultants of being psychoneurotic. This is the fate at some time of most sufferers from chronic brucellosis, and we should guard against it.

Treatment, Prognosis, and Mortality

Good results have been reported from the use of various antibiotics, especially streptomycin and the tetracyclines. In America brucellin has been used alone. Léon *et al.* (1952) reported good results from a combination of these agents. Carpenter *et al.* (1955) found that in guinea-pigs the combination was more effective than either brucellin or oxytetracycline alone. This may be the method of choice in the future.

Most of the victims of brucellosis recover rapidly; but a few have a prolonged illness which entails investigations, repeated admissions to hospital, and even unnecessary operations, all of which have been noted in this small series. The number of deaths registered in England and Wales in 1953 as due to brucellosis was four (Registrar-General, 1954). It seems likely that death from this disease might easily be missed and classified as due to acute haemorrhagic pneumonia, nephritis, or possibly encephalitis.

Prophylaxis

The best method is to eradicate the disease from cattle. This can be done by inoculation of calves with a vaccine of attenuated *Brucella* known as strain 19. It is already in common use in this country, but it will be many years before all cows have been protected. In the meantime the only satisfactory way is to ensure that all milk is pasteurized. Tuberculin-tested milk is not safe. Unfortunately it has acquired amongst the general public a reputation for safety which is not justified.

It would be helpful if the disease were to be made compulsorily notifiable so that medical officers of health could apply their powers to stop the sale of infected milk.

In the modern world threat of legal process speaks louder than reasoned argument. Publicity might therefore be given to the following decisions. At Seattle, Washington, in 1937, a man who had contracted brucellosis from infected milk was awarded 1,946 dollars in a suit against the company which distributed the milk and the farmer who produced it (Harris, 1941, 1950). In London in 1939 a man was awarded £195 damages against a dairyman in a similar suit (*The Times*, 1939).

Conclusion

There is a tendency in the human race to look with suspicion on that which is new to it. The reaction of most doctors to the information that they have unwittingly been dealing with brucellosis is like that of M. Jourdain (*Le Bourgeois Gentilhomme*) when he found that he had been speaking prose for more than forty years: they can scarcely believe it.

Simpson (1941), introducing Harris's monograph in America, said that he hoped it would "help the great mass of people suffering from brucellosis by making their physicians brucellosis-minded." I trust that this paper may do the same in this country.

Summary

Ten cases of brucellosis in children are described. It is shown that the disease is common in country districts but is often missed. It may also be seen in cities, especially in the autumn after children have returned from holiday in the country, where they may have drunk raw milk. Of clinical importance are: fever; enlargement of the liver, lymph nodes, or spleen; arthritis; epistaxis; and chronic abdominal pain or headache. Constipation is common; and protein or pus cells may be found in the urine. A fallacious diagnosis of psychoneurosis

is often made. Systolic murmurs and skin pigmentation are two features of the disease described here for the first time.

Assistance in diagnosis may be had from pathological findings such as leucopenia with a low polymorph count, agglutinations of suspensions of *Brucella abortus* by the patient's serum, and by the reaction to the intradermal injection of brucellin. In some cases these tests may all be negative while the disease is still active, and the diagnosis must be made on clinical grounds alone.

Treatment with chlortetracycline and streptomycin appears to be successful, but relapses may occur. Prophylaxis is discussed, and universal pasteurization of milk is recommended.

I thank Dr. Paul Mann for his help and advice, and many general practitioners for their continued co-operation.

[ADDENDUM.—Extended experience shows that extra-systoles are fairly common in this disease, and that the abnormal bleeding tendency which causes epistaxis may also produce melaena, haematuria, and spontaneous bruising. Preliminary experiments with a multiple-puncture (Heaf) gun for the intradermal test have given good results. If a 1,000-fold concentrated solution of brucellin is used with it the results appear to be more reliable than those of the routine intradermal test. I am indebted to Messrs. Allen and Hanburys Ltd., who provided a Heaf gun for use in these experiments.]

A reminder of the importance of providing fixtures to hold fireguards in position has been sent to local authorities by the Minister of Housing and Local Government. There are indications that so far few local authorities have installed the fixtures in their council houses, yet surveys have shown that at least 50% of burning accidents in the home are caused by unprotected fires. Many local authorities appear to have taken the view that the wide variety of fireguards makes it impracticable to provide fixtures. However, the British Standards Institution has recently produced a specification for fireguards, incorporating fixing hooks, for open fires, so that the difficulty can now be overcome. The cost of providing a suitable fixture in the wall or fire surround is small, and the Ministry understands that various models and sizes of fireguards which comply with the new specification are becoming available.—Statement from the Ministry of Housing and Local Government, dated February 26.

CELL EXCRETION IN NORMAL URINE

BY

B. J. HOUGHTON, M.B., B.S.

Lately Resident Clinical Pathologist, St. Mary's Hospital,
London

AND

M. A. PEARS, M.D., M.R.C.P.

Lately Assistant to the Medical Unit, St. Mary's Hospital,
London

The examination of the urinary deposit has long been accepted as a useful procedure in the diagnosis of renal disease. As usually performed, however, the value of the information that it affords is limited by the inaccuracy of the method employed, since the deposit derived from the untimed random sample of urine is not susceptible of quantitative study. This latter is essential, for example, in the diagnosis of chronic pyelonephritis, in which it is well known that, at least until renal destruction has become gross and renal failure is at hand, the urinary deposit is commonly small and inconstant. Repeated cultures may be necessary before a growth is obtained.

In the course of an investigation of pyelonephritis we employed a method more sensitive than usual for the culture of urinary deposits, and, since this inevitably might have increased the frequency with which contaminant or saprophytic organisms appeared, we felt it necessary to check the significance of our cultural methods by attempting to correlate them with an accurate count of the cells excreted in the urine.

The best-known method of quantitative estimation of the constituents of the urinary deposit is that of Addis (1925). This, however, seemed to us to suffer from various disadvantages. The method makes it necessary for female subjects, who have to be catheterized, to hold their urine for 12 hours. Moreover, the time over which the urine is collected allows a proportion of the cells in the urine to break up: this point is discussed below. Finally, the number of elements actually counted by the Addis technique is so small that it is multiplied by a factor of one million in order to arrive at the presumed excretion rate; errors of sampling and of counting thus figure largely in the final result.

More recently, Rofe (1955) has described a method in which the leucocytes and epithelial cells excreted in the urine are counted after staining. We considered this method to be rather too elaborate to be suitable for routine use.

It is the purpose of this paper to present a reliable, simple, and rapid method of counting the leucocytes and non-squamous epithelial cells in the urine. The range of normal values in thousands per hour is established, and a comparison made between this and the numbers passed in a few abnormal urines that on examination of the usual type would almost certainly have been reported as normal. No attempt has been made to enumerate casts or red blood cells, since the method was primarily evolved as an ancillary investigation in the diagnosis of chronic pyelonephritis; but their excretion rates could be measured in the same way.

Subjects and Methods

All the subjects were afebrile and had no evidence of active infection in any system of the body. Their ages varied from 20 to 64 years. In none was there any evidence

of present or past illness referable to the urinary tract. None had hypertension or other cardiovascular disease.

Of the male subjects, 22 were medical students or members of the staff of this hospital, ambulant, and carrying out their normal duties, while 19 were patients who fulfilled the criteria set out above. None of these latter had recently had any operation, or any investigation involving interference with the urinary tract.

To obtain normal female subjects was more difficult, as we were reluctant to expose them to the risk of urethral catheterization. The 28 female subjects were all ward patients fulfilling the criteria above and free from evidence of pelvic disease; they had to be catheterized either pre-operatively or in the course of some routine investigation unrelated to their urinary tract.

All the samples of urine used for the 127 counts were sterile on culture and free from protein by the salicyl-sulphonic acid test.

Although the primary purpose of this paper is to report the cell excretion in normal subjects, a few counts obtained from patients with renal infection are included. Of these patients those with the lower cell counts had deposits which by the usual method of examination showed little or no deviation from normal.

The cellular excretion rates were determined as follows. The subject emptied the bladder as completely as possible and the time was carefully noted. Three to four hours later, the time again being noted, the bladder was emptied by catheter in the female, and naturally in the male, avoiding preputial contamination. No restrictions were placed on fluid intake, but diuretics were not given. The specimen obtained was measured, and within two hours of collection it was thoroughly shaken. Precipitated phosphates were dissolved by adding a few drops of glacial acetic acid, and 10 ml. was measured into a graduated centrifuge tube. After spinning at 2,000 r.p.m. for five minutes, 9 ml. of the supernatant was discarded and the remaining 1 ml. thoroughly mixed by a clean Pasteur pipette. The leucocytes and non-squamous epithelial cells were then counted in 2 c.mm. of the ruled area of a Fuchs-Rosenthal counting chamber under a $\frac{1}{4}$ -in. (4.3-mm.) objective. No attempt was made to include disrupted or degenerated cells.

The result was calculated as follows, and expressed as the number of leucocytes and non-squamous epithelial cells excreted per hour:

$$N = \frac{500 \times C \times V}{10 \times T} = \frac{50 C V}{T}$$

where C=actual number of cells counted, V=volume of specimen in millilitres, T=time in hours over which the specimen was formed, and 500=factor to convert 2 c.mm. to 1 millilitre.

In the normal subjects studied the volume of the specimens excreted in three to four hours varied between 100 and 400 ml. Between 5 and 30 cells were actually counted. Deposits from small volumes of highly concentrated urine were more difficult to count, since more cells were present, and these had to be distinguished from the inevitably greater amount of detritus, crystals, and squames.

Errors of the Method

Nearly all the counts reported were carried out in duplicate. In most cases the difference did not exceed 10%, and

TABLE I.—Proportion of Leucocytes "Recovered" in a Series of Counts Performed on Four Different Suspensions Obtained by Diluting Blood Samples in Saline

Blood Sample	Expected Number of Cells in Suspension as Calculated from W.B.C. Count	Observed Count Expressed as Total Cells Present	% Recovery

B	5,950,000	6,240,000	105
C	3,875,000	3,160,000	81
D	3,050,000	2,775,000	91

MARCH 16, 1957

in none did it exceed 30%. Independent duplicate counts made by each of us in six specimens did not differ by more than 10%.

To test the accuracy of the method, 0.5 ml. of fresh blood was diluted in 400 ml. of 0.9% saline which had been adjusted to pH 5 by the addition of a few drops of glacial acetic acid. Then 10 ml. of the suspension was taken and treated in the same way as the urine, and while one of us performed the count the other did a leucocyte count on the blood. Table I shows the results obtained in four separate experiments.

Results

In all, 127 counts were performed, 99 being on 41 male subjects and 28 on 28 females, and the results are shown in Fig. 1. The limits lie between 18,000 and 196,000 leucocytes and non-squamous epithelial cells an hour, irrespective of the time of day during which the specimen was collected and the sex and age of the subjects and their activity before and during the period of collection. Within these limits, however, the posture of the subject and the time of day have some slight influence on the rate of cell excretion, and for this reason Fig. 1 does not represent the results from a strictly homogeneous population. We have therefore not attempted to subject

Fig. 1.—Block diagram for 127 normal urines, to show the rate of excretion of leucocytes and non-squamous epithelial cells.

it to a detailed statistical analysis.

Diurnal Variation in Ambulant Males.—To compare the values obtained in morning and afternoon periods, 12 ambulant male subjects were taken at random and counts were done for each period of the same day (Fig. 2). For the morning counts the mean was 87,700 an hour, while for the afternoon counts the corresponding values were 54,300 an

Fig. 2.—Morning and afternoon periods on 12 ambulant male subjects.

Fig. 3.—Cell excretion rates in resting male subjects during the morning and afternoon.

Fig. 4.—Cell excretion rates in resting female subjects during the morning and afternoon.

hour. The differences between the morning and the afternoon counts for each individual were calculated and the mean of these (34,700 an hour) differed significantly from zero ($t=3.18$; $0.001 < P < 0.01$).

Diurnal Variation in Resting Males.—Twelve counts were carried out in the morning on 12 resting male subjects, and 14 in the afternoon (Fig. 3). The means were 47,500 an hour (standard error 7,400) in the former, and 68,000 an hour in the latter (S.E. 11,600). The difference of the means was thus 20,500, which was of no significance ($t=1.43$; $0.1 < P < 0.2$).

Diurnal Variation in Females.—All females studied were supine and only one count was carried out on each. Of a total of 28 counts, 16 were performed in the morning, with a mean value of 66,100 per hour, S.E. 9,800, and 12 in the afternoon, with a mean of 56,400 an hour, S.E. 7,900 (Fig. 4). The difference of means, 9,700, is not significant ($t=0.79$; $0.4 < P < 0.5$).

Sex Difference.—In order to establish whether or not there was any difference between the rates of cell excretion in the sexes a comparison was made between the results obtained in resting males and females at each period of the day (Figs. 3 and 4). In the morning the counts from females, with a mean of 66,100, exceeded those from the males, whose mean was 47,500; but the difference of 18,600 was of no significance ($t=1.41$; $0.1 < P < 0.2$). In the afternoon the position was reversed, but the difference of the mean values (11,600) was not significant ($t=0.79$; $0.4 < P < 0.5$).

Influence of Posture.—A comparison was next made between excretion rates of ambulant and supine males during each period of the day (Fig. 5). The mean value obtained from counts of 14 ambulant subjects in the morning was 87,500 an hour, S.E. 8,715, while for 12 resting subjects the corresponding values were 47,500 an hour, S.E. 7,400. The difference of the means, 40,000, is statistically significant ($t=3.42$; $0.001 < P < 0.01$). The afternoon counts were performed on 24 ambulant subjects and 14 supine subjects, the mean for the former being 71,200 an hour, S.E. 7,700, while for the latter it was 68,000 an hour, S.E. 11,600. There is no significant difference between these groups ($t=0.24$; $0.8 < P < 0.9$).

Influence of Age.—In Fig. 6 the results of counts made on 24 resting female subjects are plotted against age. No correlation between age and cell excretion rate is apparent.

Individual Variance.—In three ambulant males repeated counts were made to see whether the range of cell excretion rate in each individual differed significantly from that of the group as a whole. Ten counts were made on each of two

individuals and eight on a third, covering both the morning and the afternoon. No characteristic pattern of excretion was shown for an individual. For the morning the variance ratio was 3.09 with 13 degrees of freedom (total), $0.2 < P < 0.5$; the afternoon variance ratio was 0.36 ($0.2 < P$).

Pathological Urines.—A small number of known cases of renal infection were next selected, since it seemed of interest to see how far counts from these departed from the normal range. It should be emphasized that these subjects were chosen for comparison because on routine examination their urinary deposits did not appear abnormal. The results are shown in Fig. 7 and demonstrate how limited is the information given by accepted methods of examination of the urinary deposit.

Cellular Lysis in Urine.—It seemed possible that cells kept in the bladder for long periods of time, as in the Addis technique, might undergo lysis. To investigate this possibility, five specimens of urine, secreted over a period of four hours, were counted immediately they were pro-

duced, placed in sterile containers in an incubator at 37° C., and counted at two-hourly intervals thereafter. Table II shows the results obtained.

The progress of cell lysis was also investigated in urines stored at room temperature, since this obviously might influence the results of counts, especially if the rate varied according to the time of storage. The results of counts carried out at intervals on five specimens of urine stored at room temperature are included in Table II.

Discussion

The method presented is simple and quick and requires no elaborate equipment. It does not take more than 30 minutes to perform a duplicate count on a urinary specimen. There is no need for fluid restrictions, nor for a long period of urinary retention with the inaccuracies that it may produce. Table II shows what happened to the cell count of urinary specimens maintained at body temperature. Addis (1948) gives the average excretion of white and non-squamous epithelial cells as 650,000 for 24 hours. This gives a figure of 27,000 an hour, which is substantially lower

FIG. 5.—Cell excretion rates in tens of thousands an hour for ambulant and resting male subjects during the morning and afternoon.

FIG. 6.—Cell excretion rates in thousands an hour plotted against age.

than 66,000, the mean value for all the counts presented here. It is possible that this discrepancy is to some extent due to the factor of cellular lysis in urine. This method is accurate to about 10%, and the limits of the normal range coincide very closely with those found by Rofe (1955), who investigated the urinary cellular excretion of 12 normal male subjects by a method rather more elaborate than that described here.

Since the completion of the work presented above, it came to our notice that Hamburger *et al.* (1950) had already described a similar method of estimating the urinary cell excretion rate. No details are given in their paper of the number of subjects used or the number of counts performed. They gave 30,000 white and epithelial cells an hour as the maximum normal excretion rate. This method was subsequently employed by Richet (1953) for the estimation of red-cell excretion rates in the urines of cases of nephritis.

Faced as he often is with a report of positive culture from a urinary specimen and a report on the deposit which, owing to the method by which it is obtained, is often meaningless, the clinician may well be at a loss to decide whether or not his patient has an infected urinary tract or whether the organisms grown represent no more than contaminants. It is felt that this method, by providing a reasonably accurate quantitative evaluation of the urinary deposit, may resolve this all too common difficulty.

Although the primary purpose of this paper is the presentation of a method, some of the results we have obtained are of sufficient interest to merit brief discussion.

The highest counts were obtained from ambulant males in the morning, all of whom had voided their night urine prior to the period of collection of the specimen. The difference between these counts and those from ambulant males in the afternoon and from resting males in the morning was significant. On the other hand, no such differences existed between the counts for ambulant and resting males in the afternoon, while the differences between resting males in the two periods in the day were not significant.

It appears that the resumption of activity at the beginning of the day may be responsible for a rise in the rate of cellular excretion and that this rate then falls later in the day irrespective of the posture of the subject at that time. This conclusion is supported by the results obtained from the resting male subjects in the afternoon and the female subjects at each period of the day. The males who were resting in the afternoon had been ambulant in the morning, and the mean of their cell excretion rates was higher than that of the males resting in the morning, who had been in bed all night, and had not been allowed up before the period of the count. The resting female patients, however, who were used for morning counts had been up for an hour or two before the period of urine collection began, and the counts obtained on them are slightly higher than the corresponding ones for the males. Similarly, those female subjects used for the afternoon counts were allowed up in the morning and their cell excretion rates did not differ from those of the resting males counted during the same period. Most of these differences do not attain a level of statistical significance, perhaps because the groups studied were not large enough, but they all show a consistent trend.

It should be emphasized that, as the results of the assessment of variance show, there is no characteristic pattern of cell excretion in any one subject, and therefore that the limits of the normal as defined for the groups apply equally to the individual.

All female subjects were catheterized, thereby eliminating the urethra as the source of the cells observed, and no difference between the rates of cell excretion in sexes was found. This would suggest that the cells counted originated above the urethra.

Summary

The rate of excretion of leucocytes and non-squamous epithelial cells has been estimated in normal subjects by

a simple and reliable method. The normal rate varied between 18,000 and 196,000 an hour.

The results are analysed according to the time of day at which the urine was collected and the posture, sex, and age of the subjects. In three normal males no characteristic rate of excretion over a period of several days was observed.

The rates of excretion in normal urines and in a few pathological urines are compared.

Our thanks are due to Professor G. W. Pickering and Professor R. Cruickshank for their invaluable criticism, encouragement, and advice; to Dr. W. I. Cranston and Mr. J. K. Fawcett for their help and advice on the statistical analyses; and to members of the staff, medical students, and ward sisters for their co-operation and help.

MULTIPLE STOKES-ADAMS EPISODES DURING ANAESTHESIA

BY

R. J. HAMER HODGES,* F.F.A.R.C.S.

ROBERT A. WITZEMAN, M.D.

Department of Anaesthesia

AND

A. MACON LEIGH, M.D.

Department of Surgery

Western Reserve University School of Medicine,
Cleveland, Ohio

Many cases of cardiac arrest have been documented in the medical literature, and the treatment of such cases is becoming well established. An immediate diagnostic thoracotomy, should the peripheral pulses become impalpable, has been advocated by some authors (Rao *et al.*, 1954; Milstein and Brock, 1954; Mullens, 1955), but others have taken a more conservative attitude (Johnstone, 1955a). As thoracotomy may be definitely contraindicated in "arrest" associated with Stokes-Adams attacks, and because such episodes during anaesthesia have only rarely been reported, the recording of such a case appears justified. McLemore and Levine (1955) presented a series of cases in which, incidentally, Stokes-Adams episodes were associated with anaesthesia, but the details of the drugs administered and the techniques followed were not given.

Case Report

An 80-year-old white man (80 kg.) was admitted to hospital with acute intestinal obstruction. For 15 years he had had orthopnoea with arteriosclerotic heart disease, and for six years hypertension (170/100) with complete heart-block. Electrocardiograms had previously revealed myocardial infarction. He suffered from chronic pulmonary emphysema, and intermittent episodes of congestive heart failure had occurred until the time of admission, when he showed minimal oedema and crepitant rales at the lung bases. He had been fully digitalized. Abdominal distension and vomiting were present.

*At present consulting anaesthetist to the Portsmouth Group Hospitals and the Thoracic Surgical Unit, Southampton.

Laparotomy was planned for undiagnosed intestinal obstruction. Following premedication (pethidine hydrochloride 50 mg.) the abdomen was opened under an "arrow-head" block (Evans, 1949) (lignocaine, 700 mg., and adrenaline, 0.3 mg.). A further 40 mg. of pethidine hydrochloride was given in intermittent doses through the intravenous drip during this period. On exploration of the peritoneal cavity it became apparent that the surgical manipulations would require supplementary anaesthesia. Thiopentone sodium (80 mg., followed by 160 mg.) was given intravenously to produce light anaesthesia. Oxygen (100%) was administered by mask and later by manual ventilation following suxamethonium (25 mg.) intravenously. "Cyclaine" (5%) was used to anaesthetize the larynx, the patient was again ventilated with oxygen, and a cuffed endotracheal tube was passed. Ventilation was continued with nitrous oxide (60%) and oxygen (40%) until spontaneous respirations returned.

During this time the patient developed transient but recurrent episodes in which he appeared pallid and pulseless. The electrocardiogram showed intermittent asystole, ventricular tachycardia, or ventricular fibrillation. A diagnosis of Stokes-Adams episodes was made. During the episodes, which lasted up to three or more minutes, and which followed each other at one- to three-minute intervals, the respirations remained of good volume, but they underwent transient depression, and a few seconds of apnoea occurred, following the return of the peripheral pulse on each occasion. During the latter part of each attack the patient's pupils became transiently dilated.

A large internal hernia was reduced and the surgery rapidly completed (40 minutes), during which time 100% oxygen was continually administered, and suxamethonium (105 mg.) injected intravenously as required for surgical relaxation. The patient was then extubated and oxygen continued by mask. The episodes persisted almost continually during surgery and post-operatively, and disappeared quite suddenly two hours and forty minutes after the onset. At the start of these incidents procaine amide (100 mg.) had been twice administered, as it was felt that the ventricular fibrillation justified this medication, but no other specific treatment was given. Later nikethamide (5 ml.) was administered and repeated, to lighten the thiopentone hypnosis, and thereafter the patient was conscious and rational between attacks. As the respiratory pattern suggested that a "chemoreceptor" drive was controlling his respirations, the oxygen which had been administered during all the attacks was withheld on two occasions. Only one further attack occurred.

The patient showed no signs of cerebral damage following these long periods of "arrest" and made an uninterrupted recovery, being discharged home on the 17th post-operative day.

Discussion

The mechanisms which may have contributed to the sudden occurrence of Stokes-Adams attacks in this patient include vagal or sympathetic overactivity, or factors concerning ventilation management.

Vagal Stimuli.—Even in the presence of complete heart-block, visceral, laryngeal, or pulmonary reflexes may have contributed to these episodes. In this respect, however, Johnstone (1955b) concludes (as a result of observations of laryngeal movements and electrocardiographic changes) that suxamethonium provides better and safer conditions for endotracheal intubation than other relaxants. In this patient, also, topical anaesthesia of the larynx was performed, and no irritant vapours were used. In spite of his conclusion, however, Johnstone has shown that a definite slowing of pulse occurs in some patients (a muscarinic acetylcholine-like effect) following the administration of suxamethonium, and in retrospect there seems very little doubt that atropine should have been included in the premedication of this patient. In one of the more severe cases reported by McLemore and Levine (1955) atropine had also been omitted from the premedication.

Sympathetic Overactivity.—The effect of excessive adrenaline on the intact Purkinje cells may give rise to ventricular arrhythmias which may be depressed by procaine, but in this patient it seems unlikely that the adrenaline in the infiltration and block could have caused any deleterious effect, and the administration of procaine amide can be shown to be definitely contraindicated in Stokes-Adams syndrome.

Ventilatory Management.—Anoxia, which may always be a factor in the administration of an anaesthetic, and which could contribute to cardiovascular collapse, had been avoided in this instance. Conversely, it is difficult to dissociate the onset of the attacks from the administration of 100% oxygen by manual inflation. It is known that the administration of high oxygen concentrations may have a deleterious effect on the respiratory mechanism in chronic pulmonary disease associated with hypercarbia, and Stead *et al.* (1954) have shown, in animals, that sudden lowering of the alveolar carbon dioxide levels, after prolonged hypercarbia, may raise the plasma potassium to cardiotoxic levels, precipitating ventricular fibrillation. It is an interesting conjecture whether efficient ventilation with a high percentage of oxygen, to which he was unaccustomed, might not have been a factor on the onset of these attacks in this patient. There is little doubt that the episodes disappeared when manual oxygenation was withheld.

This experience brings to the fore several points of interest, particularly the differentiation between these attacks and "true" cardiac arrest. It is doubtful whether this man would have survived a thoracotomy, and it is worth noting that these patients seem to recover with little specific treatment.

HEPARIN AND SYMPATHETIC BLOCK IN TREATMENT OF VENOUS THROMBOSIS

EXPERIMENTAL INVESTIGATIONS

BY

WITOLD RUDOWSKI, M.D.

From the First Surgical Clinic, Warsaw Academy of Medicine

At present there are two main methods of treatment of venous thrombosis: (1) by anticoagulant agents, and especially by two main compounds of this group—heparin and dicoumarol; and (2) by paravertebral procaine block of the sympathetic system. Both methods are supported by evaluation of clinical results, but it is difficult to compare them with precision. Encouraged by Professor T. Butkiewicz, I decided to investigate this problem experimentally.

Experiments were designed to produce thrombosis and then to apply treatment either by heparin or by procaine block of the sympathetic system. The importance of experiments such as we carried out on 50 dogs may be gathered when it is realized that in the accessible medical world literature we could find no experimental work evaluating comparatively these methods of treatment.

The results of treatment of phlebothromboses were analysed with the aid of microscopical examination of excised specimens of veins affected by the thrombotic process and by phlebographic examination (the latter being the subject of a separate paper). In the Polish literature of the last 60 years I found many papers concerned with the production and treatment of thrombosis.

I. Experimental Production of Venous Thrombosis (8 Dogs)

I had first to get acquainted with the microscopical structure of the veins of normal dogs and with technical problems of the experimental production of thrombosis. On the basis of experiments described by Gruca (1928) and Ochsner and de Bakey (1941) thrombosis was produced by intravenous injections of 2.5 ml. of 50% solution of sodium salicylate. The injections were made into the saphenous vein.

Segments of veins, including the site of injection, were excised at 6, 12, 24, and 72 hours, and at 7 and 10 days after the production of thrombosis. The specimens were fixed in formol solution and sections were prepared for microscopy. Examination proved that intravenous injection of 2.5 ml. of 50% solution of sodium salicylate initiates the thrombotic process in dogs. The beginning of thrombosis was distinctly seen 12 hours after the injection, and the first symptoms of thrombosis were apparent in seven days. At later stages (7 to 10 days) the changes characteristic of hyaline degeneration of the intima were noticeable in the walls of the vessels.

II. Experimental Evaluation of Action of Heparin on Course of Thrombosis (19 Dogs)

These experiments were carried out in two groups. In the first group (10 dogs) the therapeutic action of heparin on the early stage of the thrombotic process was investigated. Heparin treatment was started six hours from the time of the intravenous injection of 50% solution of sodium salicylate and lasted 1 to 10 days. The heparin used contained 5,000 units (50 mg.) per ml. Every six hours 50 mg. was injected into the cephalic vein, 100 mg. being injected for the night. Veins were excised at intervals of 1 to 10 days from the beginning of treatment and sections were prepared.

In the second group (9 dogs) the action of heparin on more advanced stages of the thrombotic process was investigated. The treatment was begun in three dogs after 24 hours, in three after 72 hours, and in three after five days from the production of thrombosis. Heparin was given in the same amounts as in the first group of experiments over a period of 10 days regardless of the time the treatment started. Each dog in the second group received 40 ml. (2,000 mg.) of heparin during the 10-day period.

At the end of treatment the prothrombin time was measured (in the dog in normal conditions it is 10–11 seconds).

The second group of experiments proved that heparin administered 6 to 24 hours after the injection of concentrated solutions of sodium salicylate does not prevent the production of thrombosis, which after 10 days is well organized and enters the stage of vascularization. In my experiments I could not assess the fibrinolytic action of heparin in cases in which the drug was given three days after production of thrombosis.

The following changes were noticed in microscopical pictures: (1) The contraction of vessels even when the thrombosis was absent. This sign is clearly seen in the vein of a dog owing to the strong development of smooth muscle in the venous wall. As a result of chronic contractures, extension and rupture of elastic fibres was seen. (2) The stimulation and proliferation of the intima of vessels characterized by production of endothelial finger-like papillomatous growths. (3) The presence of fragmented erythrocytes and haemosiderin granules located near the internal surface of

the veins in those dogs in which the treatment began less than six hours after the intravenous injection of sodium salicylate solution. This finding can be regarded as the beginning of the thrombotic process, not fully developed because of the therapeutic action of heparin.

III. Experimental Evaluation of Action of Paravertebral Procaine Block on Course of Thrombosis (23 Dogs)

It was necessary to study the technique of lumbar procaine block in dogs before the experimental work began. The experiments were carried out in two groups. The first comprised 14 dogs, the second 9 dogs. In the first group treatment started soon after the production of thrombosis, and procaine block was made not later than six hours from the time of injection of a 50% solution of sodium salicylate (eight experiments). In two cases treatment began 24 hours after the production of thrombosis. In four dogs procaine block started 11 days after—that is, in the late stage of the development of the thrombosis. The treatment by procaine paravertebral block was done bilaterally (with 50 ml. of 0.25% procaine each) and lasted in the early stages of thrombosis for 1 to 10 days. It was shown that procaine block starting not later than six hours from the production of thrombosis was without result when one, three, or five blocks were done. In such cases the thrombosis was fully developed. In contrast, the therapeutic effect of procaine was evident in animals receiving four, six, seven, and eight procaine injections. Treatment by blocks beginning 24 hours after the production of thrombosis did not prevent its development and did not influence the microscopical appearances.

The treatment of venous thrombosis by procaine block beginning after 11 days—that is, in the late stage of its development—influenced neither the microscopical picture nor the progress of organization of the thrombosis.

In the second group (9 dogs) treatment by procaine sympathetic block started 24 and 72 hours from the production of thrombosis and in five days from the intravenous injection of the solution of sodium salicylate. Treatment lasted 10 days with bilateral lumbar procaine block done once daily.

This systematically conducted treatment, starting 24 hours, 72 hours, and 5 days after the production of thrombosis, did not result in its dispersal. Histological examination of specimens of veins in animals treated by paravertebral procaine block gave the following results: (1) the hyaline changes in the intima of vessels were seen more often than in the series of examinations on the therapeutic action of heparin; (2) absence of distinct signs of chronic contracture and the decrease in diameter of veins: such changes are, however, quite difficult to appraise by histological methods owing to the differences in size and weights of the dogs used for experiments; (3) absence of distinct proliferative changes in the intima of veins as seen in the series of dogs treated with heparin; and (4) in cases treated by paravertebral procaine block, in which the thrombosis did occur, the organization and vascularization were evident. Such changes appeared earlier and were more obvious in animals treated by procaine block than in control animals. On the other hand, the proliferation of endothelial cells was much more evident in dogs treated with heparin.

Discussion

Analysing the microscopical findings, it should be emphasized that the histological criterion can be applied to the evaluation of morphological and statistical aspects of the problem, but is inadequate for appraisal of dynamic changes in the blood supply of the extremities. Therefore the evaluation of the results of treatment of venous thrombosis by heparin and procaine block should also include the phlebographic examinations.

In six experiments carried out on dogs treated with heparin or with procaine block the prothrombin time was measured 10 days after the administration of heparin and after 10 lumbar blocks carried out over 10 days. In all these experiments the prothrombin time was not prolonged.

Conclusions

Many questions connected with the problems tackled remain unsolved; nevertheless, while further investigations are necessary it seems that the following conclusions are justified:

1. The intravenous injection of a 50% solution of sodium salicylate results in thrombosis appearing 6-12 hours later. The first evidence of organization is seen after seven days.

2. The administration of heparin, in amounts of 200 mg. daily, 6-24 hours after the production of thrombosis prevents the development of the thrombotic process.

3. Heparin treatment given three or more days after the production of thrombosis does not prevent its development. Microscopically, symptoms of the fibrinolytic action of heparin are absent.

4. Veins of dogs treated with heparin present in most cases papillomatous proliferations of the endothelium, whereas in dogs treated with procaine block the picture of hyaline degeneration of the intima is prevalent.

5. The application of procaine block less than six hours from the production of the thrombosis prevents the full development of the thrombus, provided the treatment lasts for at least four days.

6. Procaine block applied 24 or more hours after the time of the injection of sodium salicylate solution does not disperse the existing thrombus; nevertheless it accelerates organization of the thrombosis as compared with non-treated animals.

7. The degree of organization of the thrombosis in dogs treated with heparin or with procaine block is approximately the same. The proliferation of endothelial cells is more marked in thrombosis after heparin treatment.

8. The prothrombin time after 10 days of heparin or procaine block shows no significant changes from the normal.

9. The histopathological examinations are not sufficient for the evaluation of dynamic changes of blood supply of the extremity and should be supplemented by the analysis of the phlebographic appearances.

A SALICYLSULPHONIC ACID TABLET TEST FOR PROTEIN IN URINE

BY

D. N. BARON, M.D.

Reader in Chemical Pathology, Royal Free Hospital, London

AND

CELIA OAKLEY, M.B., M.R.C.P.

Formerly Resident Pathologist, Royal Free Hospital, London

This communication describes the trial of a commercially available tablet test for protein in urine (albuminuria), which has been designed to take the place of the standard salicylsulphonic acid test. It must be emphasized, because of the common use of the term "albuminuria," that in all circumstances protein present in urine is a mixture of albumin and globulins, with albumin predominating; and this tablet test, the standard salicylsulphonic acid test, and the boiling test all detect every type of protein in urine, not albumin alone. We shall therefore only employ the term "proteinuria." Each tablet ("altest") contains about 25 mg. of salicylsulphonic acid, effervescing agents, and a trace of bromocresol green. A similar tablet called "bumintest" is marketed in the U.S.A. The latter test cannot be recommended for convenience because it entails dissolving the bumintest salicylsulphonic acid tablet in water to make a solution with which to test the urine, and we understand that bumintest is not being introduced into this country.

Method

A series of solutions of protein in urine were prepared using (1) normal human serum, (2) standard albumin solution, (3) urine from a nephrotic patient, at total protein concentrations of approximately 0.01, 0.005, 0.0025, and 0.001 g. per 100 ml. of urine. Each protein concentration was prepared in urines of approximately specific gravities 1002, 1010, and 1020, and separate samples of each were adjusted to approximate pH 5, 6, 7, and 8.

Urine containing Bence Jones protein, a high concentration of urates, and the radio-opaque substances iopanoic acid, diodone, sodium acetoazotate, and "biligratin" and "urogratin" were also examined.

Each urine was tested by three methods: (1) standard "boiling test" (Harrison, 1947). (2) Standard salicylsulphonic acid solution test (about 5 ml. of urine plus about 0.5 ml. of salicylsulphonic acid (=125 mg.) (Harrison, 1947)—called "solution test" below. (3) altest; the method recommended by the manufacturers was found generally satisfactory—called "tablet test" below.

Urine which is cloudy should be filtered before carrying out the tablet test, as with other tests for proteinuria. An "inch" (about 4 ml.) of urine is placed in a test-tube, and one tablet added. When the tablet has dissolved completely (which takes about one minute) the tube is gently shaken, the froth is allowed to clear, and the mixture is examined. (We find, however, that the tablet dissolves more easily if the tube is continuously shaken.) The fluid should be yellow; if it is blue or green this indicates that the mixture is still alkaline, and one or more tablets are added until the final solution is acid and the fluid becomes yellow. The result is read in the same way as other tests for proteinuria: no protein—clear (yellow) solution; protein present—cloudy mixture or white precipitate, depending on the concentration of protein.

Results

The tablet test could regularly detect a protein concentration of 0.005 g. per 100 ml. of urine: at 0.0025 g. per 100 ml. detection of proteinuria was inconstant. It was equally sensitive to the different proteins tested, and throughout the pH and specific gravity ranges which were examined. The tablets appeared to be stable, and tablets which had been stored at room temperature for three months were as effective as at the time the bottle of tablets was first opened. The solution test was also sensitive to 0.005 g. per 100 ml. and usually to 0.0025 g. per 100 ml., and the boiling test was regularly sensitive to 0.0025 g. per 100 ml. while inconstant results were obtained at 0.001 g. per 100 ml.; both these tests were also unaffected by the nature of the protein and the pH or specific gravity of the urine.

The ingenious internal indicator of the tablet test enables successful correction of the pH of alkaline urines. The urines of pH 7 sometimes needed two tablets, and the urines of pH 8 needed two or three tablets. (The solution test adds the equivalent of four tablets when properly performed, and the problem of excessive alkalinity of the urine therefore very rarely arises.) However, minimal turbidity was more difficult to detect in the resulting deeply coloured yellow solution.

Both the tablet test and the solution test gave a positive reaction with Bence Jones protein and a negative reaction with urates in solution.

The radio-opaque substances do not precipitate on boiling. They give a pseudo-positive reaction (deposit of crystals) with the solution test, and a negative reaction with the tablet test (one or two tablets). This is a quantitative and not a qualitative difference, because when four tablets were added to 4 ml. of urine containing these substances precipitation immediately developed.

Fifty consecutive urines, received in the department for routine examination, were tested for protein in parallel by the solution test and tablet test. (Fifteen urines required two tablets, and two urines required three tablets.) Twelve of these contained protein in varying concentration, and identical positive results were given by the solution test and the tablet test.

Discussion

Two previous reports (Bryan, 1956; Whittet, 1956) have briefly described the altest without critically examining its properties.

Possible users of the tablet test are general practitioners who have to test occasional specimens of urine in their patient's home or in their consulting-room, or nurses, students, or laboratory technicians who have to test larger numbers of urine specimens on frequent occasions.

The tablet test can be recommended for general practitioners. It is sufficiently sensitive for all clinical purposes. It is simpler and much more convenient than the boiling test, though it is less sensitive than this test. The great convenience to the practitioner of having to carry a bottle of small tablets rather than a bottle of acid liquid reagent outweighs, in our view, the slight disadvantages of the tablet test when compared with the solution test.

However, for frequent use in a laboratory or side room we consider that the tablet test does not replace the salicylsulphonic acid solution test. Although the tablets are inexpensive, the salicylsulphonic acid solution (which is also stable) can be prepared in bulk by a hospital at less than half the price of the tablets. The tablet test is slightly slower, because of the time necessary to dissolve the tablets and disperse the froth which otherwise interferes with the reading. The tablet test does not seem to be quite as sensitive, probably because the colour of the indicator makes it less easy to read; this could probably largely be remedied by reducing the quantity of bromocresol green. When the solution test is done, using the proper technique, enough salicylsulphonic acid is added to counteract all but the grossest alkalinity.

We must deplore the manufacturer's name for the tablet, altest, because it perpetuates the "albuminuria" fallacy.

Summary

A new manufactured tablet (altest) has been compared with the boiling test and the salicylsulphonic acid solution test. It can detect a concentration of 0.005 g. of protein per 100 ml. of urine throughout the physiological range of urine pH and specific gravity, and the results of the tablet test are generally comparable to those of the salicylsulphonic acid solution test, but are slightly less sensitive than the results of the boiling test.

The tablets contain an indicator which shows when additional tablets need be added to ensure acidity of the solution. The advantages and disadvantages of the new test are discussed.

We thank the Ames Company (London) Limited for supplies of altest, and the department of radiology, Royal Free Hospital, for the urine specimens containing the contrast media.

Medical Memorandum

Marfan's Syndrome

A small number of patients with Marfan's syndrome (Marfan, 1896) have come to necropsy (Reynolds, 1950; Moses, 1951; Marvel and Genovese, 1951; Whittaker and Sheehan, 1954; McKusick, 1955). A further case, in which Marfan's syndrome was associated with a patent ductus arteriosus and aortic aneurysm from cystic medionecrosis of the aortic wall, is here reported.

CASE REPORT

A married woman aged 32 was admitted to hospital on December 22, 1954. At 18 months of age she had nephritis and an enlarged heart. When 5 years old she was said to have valvular heart disease. She was dyspnoeic as a child, and later had winter bronchitis. From the age of 18 she had oedema of the ankles. Since 1950 she had had attacks of gripping pain in the left chest which radiated into the left arm and occurred both at rest and on exercise. In 1952 she collapsed with a sudden attack of pain in the back and fullness in the chest. After recovery she was breathless on slight exertion and had persistent ankle oedema and attacks of palpitation. For the last six months she had nocturnal dyspnoea accompanied by sweating and palpitations and a gripping retrosternal pain radiating into the left arm. Two weeks before admission a pleuritic pain developed in the middle and lower thoracic regions of the back with dyspnoea, cough, and increased ankle swelling. These improved slightly with digitalis and rest, but her condition again deteriorated.

Examination showed her to be thin, orthopnoeic, and cyanosed. She had arachnodactyly; height 68½ in. (1.74 m.); palate highly arched. No changes in eyes, and no other skeletal deformities. She was in congestive heart failure; pulse regular, rapid, and collapsing; blood pressure 140/40 mm. Hg; femoral pulses palpable. Bed shook with each heart-beat; visible arterial pulsation in neck. Cardiac impulse moved anterior chest wall. Apex beat in 9th left intercostal space in posterior axillary line. Systolic pulsation felt over most of praecordium. In left axilla between 5th and 9th intercostal spaces a loud rumbling diastolic murmur and a blowing pansystolic murmur heard. Below left clavicle, in pulmonary area, and down left sternal

edge, soft diastolic and blowing systolic murmurs heard. Pulmonary second sound accentuated. Spleen not felt; no ascites.

Radiography showed a huge heart with a dilated ascending aorta; lung fields were mottled, suggesting left-sided failure. Electrocardiography showed right and left ventricular enlargement. There was moderate anaemia (Hb 67%). Wassermann reaction negative.

This patient was thought to have Marfan's syndrome with a heart lesion. Aortic regurgitation and patent ductus arteriosus were considered. A diastolic and systolic murmur heard below the left clavicle favoured the latter diagnosis. Marfan's syndrome is, however, more commonly associated with aortic regurgitation and dilatation of the ascending aorta (Reynolds, 1950).

For the first two days her condition improved. She was digitalized and given a course of soluble penicillin. Two days later there was a sudden onset of dyspnoea, cyanosis, and coma; the pulse was rapid and feeble until she died a few minutes later.

POST-MORTEM FINDINGS

Anatomical Diagnosis: Massive haemopericardium. Patent ductus arteriosus with aneurysm of the aorta associated with cystic medionecrosis. The aneurysm had ruptured. Marfan's syndrome. **Internal Examination:** There was brown induration of both lungs, and mucopus was present throughout the bronchial tree. The oesophageal and gastric mucosae, spleen, and pancreas were congested. There was early cardiac cirrhosis in an enlarged liver.

Cardiovascular System.—The heart was greatly enlarged. The pericardial sac was distended by about 850 ml. of blood. Both ventricles were hypertrophied and dilated. The left auricle was normal in size and thickness, but running on its anterior surface, in a linear fashion, was an irregular area of calcified scarring, partly raised above the surface. The mitral valve showed slight nodularity along the free margins, which were fibrotic and not calcified. There was dilatation of the aortic ring and regurgitation, but the aortic cusps were normal. The pulmonary artery was greatly dilated, its greatest circumference 10.5 cm. The ductus arteriosus was widely patent and had a diameter of 0.8 cm.; it opened into the aorta at the usual site just distal to the origin of the left subclavian artery. The ascending aorta and arch were grossly dilated and thinned as far as the ductus arteriosus, mainly involving the right lateral wall. The external site of rupture of the aorta was posterior, at the uppermost part of the pericardial sac, and at this point communicated with the lumen at the top end of a long vertical split of the media which extended down the left posterior part of the aortic wall as far as the left anterior sinus of Valsalva, just missing the left coronary orifice. There was a separate transverse crack involving the intima on the posterior wall of the aorta and measuring 4 cm. The whole internal surface of the dilated part of the aorta was roughened, resembling tissue-paper scarring from previous intimal ruptures which had become covered by fresh endothelium. The aorta below the ductus appeared normal in calibre and showed atheroma. The other parts of the heart were normal.

HISTOLOGY

The thickened intima of the aorta showed fibrosis and hyaline change with some fragmentation and loss of elastic tissue. In the media there was marked fragmentation of elastic tissue. Between the elastic fibres were spaces, some empty, but others containing material which stained positively with mucicarmine. There was patchy atrophy of medial smooth muscle with partial replacement by fibrous tissue, and very marked hyaline thickening of the adventitia, which contained numerous dilated vessels.

These changes resemble those described by Erdheim (1929) as idiopathic cystic medionecrosis. The area of calcification and scarring in the left auricle showed a rather acellular hyaline thickening of the endocardium. There was much less elastic tissue than normal, and this change was asso-

ciated with marked fragmentation. Deposits of calcium salts were present in the hyaline area. This appearance has previously been described in the left auricle in cases of Marfan's syndrome (Baer *et al.*, 1943).

COMMENT

The dilatation of the ascending aorta with cystic medionecrosis of the aortic wall is considered to be characteristic of Marfan's syndrome. Erdheim (1929) described the following histological changes in the ascending aorta: (1) rarefaction of the media with disarrangement of the elastic tissue; (2) absence of a definite internal and external elastic lamina; (3) atrophy of the muscle with irregular branching of the fibres, separated by cystic spaces; (4) small blood vessels starting in the adventitia and penetrating into the media; and (5) slight thickening of the intima.

As in this case, death from rupture of the weakened and dilated ascending aorta is common in Marfan's syndrome. The history and necropsy findings suggest that there had been a previous small rupture of the aortic wall.

Patent ductus arteriosus associated with arachnodactyly is sometimes said to have been described by Apert (1938). He describes the heart lesion as "une béance du trou de Botall," which has been wrongly translated as "a patent ductus arteriosus." He was, however, referring to a patent foramen Botalli or patent foramen ovale. Later in his paper Apert mentions a similar patient (Parkes-Weber, 1933) who had a patent foramen ovale.

More recently (McKusick, 1955) reference has been made to the association of patent ductus arteriosus and Marfan's syndrome. The present case demonstrates the skeletal changes of Marfan's syndrome and the characteristic aortic lesions accompanying a patent ductus arteriosus. Records of three other aneurysms of the ascending aorta with patent ductus arteriosus that have come to necropsy have been found (Caylor, 1918; Hubeny, 1920; Hall, 1926). In the patients of Caylor and of Hall the histology of the ascending aorta resembles that described by Erdheim as cystic medionecrosis, which is closely associated with Marfan's syndrome. In Hubeny's patient the aneurysm of the ascending aorta was considered to have had a syphilitic origin. In these cases there is no mention of the other changes in Marfan's syndrome, but they may represent *formes frustes*.

I would like to thank Dr. Maxwell Telling for permission to publish this case, and Dr. I. M. P. Dawson for the post-mortem report.

JOHN BINGLE, M.A., B.M., B.Ch., M.R.C.P.,
Late Assistant Resident Medical Officer, Leeds General Infirmary.

The third All-India Conference on Family Planning was held in Calcutta from January 5 to 10. The urgency of India's population problem was summed up by the Governor of West Bengal, SRIMATI PADMAJA NAIDU, when he opened a family planning exhibition, as follows: "If this mistake of increasing our population is not effectively checked, all our schemes of the second Five-year Plan for national development will prove to be pitifully inadequate." Among the subjects discussed at the conference were the shortage of family planning clinics and suitably trained staff for them; the use of group discussion to familiarize husbands and wives with the work of the clinics; marriage guidance; the use of metaxylhydroquinone as an oral contraceptive; and the Government's contraceptive-testing centre in Bombay.

Reviews

MINIMAL TUBERCULOUS LESIONS

Minimal Pulmonary Tuberculosis Found by Mass Radiography (Fluorography). A report to the Prophit Committee of the Royal College of Physicians by V. H. Springett, M.D., M.R.C.P., including results of work done by A. J. Eley, M.A., M.B., B.S., D.M.R.(D). (Pp. 233+xiv; illustrated. 42s.) London: H. K. Lewis and Co. Ltd. 1956.

There are few more debatable problems in tuberculosis than the minimal lesion; doubts and arguments arise with every aspect of the subject. Publication of the report by Dr. V. H. Springett to the Prophit Committee is an event of great importance and will be welcomed by all concerned.

The report covers diagnosis, treatment, and prognosis, and gives valuable information on the efficiency of static miniature radiographic units as compared with mobile ones. In the appendices are technical details of the methods and materials used, followed by the tables and references related to the text. The survey began in January, 1946, and was completed towards the end of 1953, during which period 1,213 patients with minimal tuberculous lesions were accepted into the survey from a total of 181,391 persons from London, aged 15-44 years, who were examined by two 35-mm. mass radiographic units, one static and one mobile. The patients were observed for a period of five years, at the end of which time 767 (63.2%) showed no change, 358 (29.5%) were worse, and in 88 (7.3%) the records were incomplete. Among those who deteriorated nine died, three from progressive tuberculosis, one from air embolism during an A.P. refill, and five from non-tuberculous causes. These are the results of the survey in the broadest outline.

The report gives much detail, particularly on the background of the patients examined, the relationship between clinical, radiological, and bacteriological findings, and the results of treatment. There is also a concise and informative chapter on the general management of the minimal lesion which should be of practical value to all who have to deal with these cases.

There are many points that arouse interest and suggest further lines of research. For instance, no association was found between the level of tuberculin sensitivity, either at first examination or subsequently, and the detection of activity. It is recommended that all homogeneous round foci more than 2 cm. in diameter should be treated by resection. On the other hand, it is concluded that one positive finding in a lesion of more than a few square centimetres should be taken as evidence that further spread is likely in the absence of treatment, but that in a few selected cases with very small lesions it is possible that the culture of tubercle bacilli on one occasion should not be regarded as of overriding importance but as an indication for close observation. It is, however, agreed that no lesion of determined recency should be considered safe and stable. These observations show how difficult it is to decide how to treat a minimal tuberculous lesion, and the need for careful observation and judgment in every case. An interesting feature was the rise in tuberculin sensitivity that occurred during the first six months of observation, followed in most cases by a decline. The reasons for this are discussed, but the conclusion that the rise is due to a process of supersensitization is not very satisfactory and does not solve the problem.

The committee is well aware of the incompleteness and shortcomings of the report, and points out that there were very few male patients in the two lowest social groups and in the 15-24 age group. Much of the treatment was carried out in the pre-antibiotic days and is therefore out of date. It will be noted that 121 patients were treated by artificial pneumothorax. Tubercle bacilli were isolated at some time within the five years from 369 patients (30.4%), so that the diagnosis was radiological in 59.6%. A great deal of work has been done on detailed analysis of the statistics in order to determine the relationship between the many factors influencing the prognosis of each case. This has tended to throw emphasis on the relative values of static and mobile miniature radiographic units, which is a side-issue that will

be of value in the immediate future. The report will stand as a milestone in our knowledge of minimal tuberculosis and will be a standard book of reference for many years to come.

FREDERICK HEAF.

PULMONARY TUBERCULOSIS

Die Lungentuberkulose: Diagnose und Therapie. By P. G. Schmidt. Third edition. (Pp. 384+xii; illustrated. D.M.58.) Stuttgart: Georg Thieme Verlag. 1956.

The third edition of Professor Schmidt's work on the diagnosis and treatment of pulmonary tuberculosis has necessarily been completely revised and brought up to date, for there is no doubt that the last decade has witnessed revolutionary changes in the treatment of this disease. It is a comprehensive work, and includes historical, bacteriological, immunological, pathological, clinical, radiological, and therapeutic aspects of pulmonary tuberculosis. The book lays great stress on history-taking and full clinical examination. The interpretation of physical signs in the light of modern advances is commendable, although in this connexion there is perhaps a tendency to foster certain traditions which have little factual basis. It is, however, noteworthy that chest radioscopy and radiography are regarded as part of the clinical examination. The anatomy of the bronchial tree and the modern international classification of the broncho-pulmonary segments are outlined. Ancillary aids such as tomography, bronchography, and bronchoscopy receive their due recognition, while a proper balance is maintained between bedside medicine and modern technical developments. The remarkable decline in tuberculosis mortality in striking contrast to the incidence of cases is apparently common to all Western civilizations and gives no cause for complacency.

Professor Schmidt devotes adequate space to chemotherapy (although prolonged chemotherapy receives little attention) and resectional surgery, while the somewhat disproportionate amount he allocates to collapse therapy does not suggest that this procedure has suffered even a partial eclipse, such as it unquestionably has in this country. It is disappointing to find so little on the preventive aspects, for surely in the management of this disease prevention, diagnosis, treatment, and aftercare should be co-ordinated as one continuous process. It is particularly disappointing that pressure on space should have been responsible for exclusion from this edition of a chapter on differential diagnosis, since many non-tuberculous diseases of the chest can closely simulate pulmonary tuberculosis and this disease itself can simulate many diseases in thoracic and, indeed, in general medicine as well. The book contains a good bibliography, but there are comparatively few references to the British literature. The views expressed are in the main acceptable to British workers and the volume is admirably produced, with x-ray illustrations of high quality—positive prints throughout—suitably interspersed through the text, so that, some criticisms apart, it is one that can be recommended.

PHILIP ELLMAN.

CARCINOMA OF THE BRONCHUS

Pulmonary Carcinoma: Pathogenesis, Diagnosis, and Treatment. Edited by Edgar Mayer, M.D., and Herbert C. Maier, M.D. (Pp. 540+xvi; illustrated. £6.) New York: University Press. London: Pitman Medical Publishing Co. Ltd. 1956.

Cancer of the Lung: Pathology, Diagnosis, and Treatment. By Milton B. Rosenblatt, M.D., and James R. Lisa, M.D. (Pp. 330+xiii; illustrated. £6.) New York: Oxford University Press. London: Oxford University Press. 1956.

These books concern carcinoma of the bronchus, and they are topical because the disease is increasing in frequency; it has become an important cause of death in men. Each contains a description of all aspects of the subject and both stress the following points. The only treatment which offers the patient any hope of cure is surgical excision, and this depends for its success upon early diagnosis. But the figures analysing the results of surgical treatment are still disappointing and suggest that early diagnosis is not being

made by general practitioners. It is hoped that, having read these books, the practitioners will be "alerted" to their responsibility. It is also agreed that early diagnosis is not the only factor upon which success depends; surgeons are well aware that the nature of the tumour itself is just as important in prognosis. Both books are well produced, fully illustrated, and each contains an index and long lists of references at the end of the chapters. They have been written by a variety of different authorities, and neither is uniformly excellent. Each costs £6, and this high price is bound to limit the circulations in the United Kingdom. The monograph edited by Rosenblatt and Lisa is the simpler of the two, and should be valuable to general practitioners in that it contains the facts which are accepted to-day; it is not a stimulating book. That edited by Mayer and Maier is more interesting and thoughtful; it will commend itself to those who have a special interest in this topic; and, being somewhat longer than the other book, it contains more information, some of which is speculative. There are sections devoted to experimental work, the biology of cancer, the functional and social aspects, psychology, and medical treatments. The chapter on the surgical treatment is by Dr. H. C. Maier, and the problems are clearly stated. Reading this book one gets the impression that none of the contributors are at all satisfied with the present methods of diagnosis or treatment of carcinoma of the bronchus.

DIRTY AIR

Atmospheric Pollution: Its Origins and Prevention. By A. R. Meetham, D.Sc. Second edition. (Pp. 302+viii; illustrated. 63s.) London and New York: Pergamon Press. 1956.

It is four years since the first edition of this book appeared. Since then we have had the London "smog" of December, 1952, which killed 4,000 people, the appointment and report of the Beaver Committee, the enactment of the Clean Air Act, and developments in the peaceful uses of atomic energy with the consequent risk of a new form of danger from the air. All these are dealt with in the course of a comprehensive account of fuels of all types, where and how they are used, and the measurement, distribution, and effects of atmospheric pollution. There is a chapter on prevention, and another on the law and its administration. The large contribution to air pollution by coal burnt in open grates is well brought out. The origin of, and damage done by, sulphur dioxide in the air are described adequately. The harmful effects of the Los Angeles smog are attributed to ozone produced by the hot Californian sun acting on the products of combustion of petrol and oil. It is not generally realized that ozone is a toxic gas. A further interesting point is that the prize cattle killed by the London smog of 1952 might have survived if they had not been kept so clean. The near-by sheep and pigs did not have their straw changed so often; they lived. It may be that the ammonia produced by bacterial action on their urine and faeces neutralized the sulphur acids in the air they breathed.

For those interested, professionally or otherwise, in problems of air pollution the book will be a useful work of reference. Defects are that the figures showing the amounts of coal and coke used in industry and for domestic purposes are those for 1949, and therefore not up to date; the estimates of the cost of damage done by air pollution do not include those of the Beaver report; and pages 87-91 are missing from the review copy. Apart from these few criticisms the book can be recommended.

ALLEN DALEY.

A HISTORY OF PUBLIC HEALTH

A Short History of Public Health. By C. Fraser Brockington, M.A., M.D., D.P.H., B.Chir., M.Sc. (Pp. 235+vii. 15s.) London: J. and A. Churchill Ltd. 1956.

This book is divided into two parts. The first traces the development and growth of the public health movement in a general way from the early years of the eighteenth century to the present time, while the second deals in greater detail

with the growth of certain special aspects of public health. The story of the many vicissitudes which beset the development of present-day public health practice is well written, concise, and on the whole lucid, while the style is easy, though it is apt to be a little racy in places. The first part, however, tends to be rather sketchy—especially in the early chapters—while in a number of places in the second part of the book there is repetition of what has been said earlier. A number of omissions are noticeable. For instance, there is no reference to Ramazzini, and in the chapters on the growth of care for neglected children there is no reference to the pioneer work of George Armstrong or the observations of George Buchan, or to the establishment of the London Foundling Hospital by Thomas Coram. Elsewhere there are further omissions of less importance. A certain looseness of expression is noticeable when the author refers to a few of the great people of the past who played such valuable parts in the development of public health practice. The first time Sir Edwin Chadwick is mentioned, for example, he is simply referred to as "Chadwick," while elsewhere the majority of these personalities have been given their full and correct titles. Of the many footnotes throughout the book, most could with advantage have been incorporated in the text, while the occasional foot reference would have been better placed in the good bibliographical section at the end of the book.

These are but minor criticisms of an enjoyable book packed with detail, dates, and facts, a book which should prove to be of interest not only to that section of the profession associated with the several branches of public health practice, but to others, including the large numbers of laymen who to-day have a close and personal interest in the medical services of this country.

HOSPITAL ADMINISTRATION

Administering the Hospital Group: The Work of the Management Committee Member. By A. C. Stuart-Clark, M.A. (Pp. 66. 3s. 6d.) London: Institute of Hospital Administrators. 1956.

This valuable handbook was compiled in order to describe the essential background of the hospital service to hospital management committee members in general and to new members in particular, but also contains well-informed, albeit guarded, comments on some of the existing contentious problems in the hospital service.

The hospital management committee's place in the health service and the committee structure are outlined clearly, and there are chapters dealing with the more specific responsibilities of the management committee in group administration, finance, staffing, and the handling of complaints. There are some very enlightened observations concerning the relationship and respective responsibilities of management committees and regional hospital boards.

The methods of selection and training of the various grades of hospital staff—professional, technical, and administrative—are fully dealt with, and emphasis is thus placed upon a very important problem confronting hospital management committees to-day. The prominent role of group medical advisory committees is rightly stressed—in fact, the matter warrants a little more attention than is actually given in this handbook, so that lay members of management committees can fully appreciate the essential part which such committees can play in helping and guiding management committees in their local responsibilities.

The tripartite concept of hospital administration is described objectively and due acknowledgment given to the need for medical administration where professional medical knowledge is essential, but more details as to the content of medical administration would have been helpful.

This intelligent appraisal of the essentials of hospital administration will be of value not only to committee members but also to all who are interested in the efficient running of our hospitals.

TUBERCULOSIS AND ENVIRONMENT

It might well be supposed that bad housing would increase the risk of general respiratory disease and at the same time lower resistance through poor nutrition, mental depression, and the like. Yet it is by no means easy to find unequivocal evidence that such conditions make for increased incidence of tuberculosis. One method of study is to correlate a series of towns or counties according to their tuberculosis death rate and their overcrowding index. Investigations of this kind have often failed to show any significant relationship between overcrowding in the home and the death rate from phthisis. Familial contact rather than numerical crowding is the factor of importance. Even in studies of the actual housing conditions found among persons diagnosed as tuberculous, there is apt to be a conflict of evidence. In Edinburgh (1950) and in Glasgow (1952) Lili Stein¹ made a careful analysis of well-defined localities, each of which was comparable in such respects as overcrowding, type of tenant, and economic situation. Her results showed a close association between overcrowding and respiratory tuberculosis.

There have been many inquiries of a similar kind in the United States, also with a conflict of evidence, except in the foremost place given to familial infection. One of the most recent of these investigations was conducted by A. M. Lowell² in New York City, covering the years 1949 to 1951. During the 1880s J. S. Billings³ made a detailed study of the population, general living conditions, and vital statistics of the different parts of New York. In commenting on the physical environment he noted the high mortality rates in the crowded areas of the city. In downtown Manhattan, above Maiden Lane, for example, the death rate from phthisis was 776 per 100,000 population. By contrast, the residential area on the West Side, between 68th and 77th Streets, had a death rate of only 49 per 100,000. In the first half of the present century similar findings have been consistently

reported. The city of New York to-day has just over 8 million residents, many of them concentrated in a small area in Manhattan. The whole area within the city boundaries now covers 315 square miles, and it is divided into five boroughs. For the purpose of health administration each borough, except Richmond, is further divided into health-centre districts, with a further break-up for statistical purposes into health areas. At the 1950 census there were just under 8 million residents (6,900,000 white, 730,000 negro, and nearly 250,000 Puerto Rican), but since then the population has increased by several hundred thousands. The non-white population and the Puerto Ricans tend at first to concentrate in certain neighbourhoods, but they are steadily becoming widely distributed. The following data for the three-year period 1949 to 1951 are useful as a guide:

Rate	White	Non-white	Total
Deaths per 1,000	9.5	9.1	9.5
Births	17.9	28.9	18.9
Infant deaths per 1,000 live births	22.0	38.1	24.4
Maternal deaths	0.58	1.77	0.76
Deaths from tuberculosis per 100,000 population	20	91	27

One of the most interesting features of this study is that the index used is the total annual tuberculosis prevalence rate, in this case for the three years 1949 to 1951. This is the yearly average of the known tuberculosis cases—namely, the active cases already known on the first day of the year, the new cases reported during the year, and the small number of former cases resumed (thus excluding the arrested or inactive cases). The rate is expressed as the number of active cases known during the year per 100,000 population. As to housing, "poor" conditions meant either dilapidation or inadequate plumbing, the latter covering lack of private toilet or bathing facilities or indoor water supply. The "cold-water" houses provided with toilet and bath were not included in the term "inadequate." It should also be noted, by way of contrast with the British figures, that overcrowding is expressed as the percentage of dwelling units with 1.51 or more persons per room, with the usual exclusions of bathrooms, pantries, halls, porches, and unfinished attics or basements.

In New York City tuberculosis rates in ten health areas with highest prevalence rates, located in the Borough of Manhattan, ranged from 1,087 to 2,392 and the family income from \$1,778 to \$2,637. Dwelling units reported as dilapidated or with inadequate plumbing rose from 19.1% in one health area to 57.5% in another. Overcrowding was present in from 5.8% to 17.5% of the dwellings, and the proportion of white population rose from 0.3% to 92.1%. At the other end of the scale, in ten health areas with

⁴ Topley, W. W. C., and Wilson, G. S., *The Principles of Bacteriology and Immunity*, 1946, London, vol. 2, p. 1291.

⁵ Frost, W. H., *Papers of Wade H. Frost*, edited by K. F. Maxcy, 1941, London, p. 612.

the lowest tuberculosis prevalence rates, located in the Borough of Brooklyn, the rates ranged from 59 to 113. The family income was substantially higher (\$3,701 to \$4,798). For "poor" housing the percentages (0.8% to 2.4%) were much lower than the city average. The percentage of overcrowded dwellings in nine areas ranged from 2.4 to 4.2, but in the tenth area (Sheepshead Bay) the percentage was 15.7. The white residents made up 99% of the population. The age differences between the two groups was small, but the distribution of occupations was as follows:

Percentage of Population by Occupation

Occupation Group	High Tuberculosis Areas	Low Tuberculosis Areas
Professional, etc. . .	7.6	32.1
Clerical . . .	11.9	32.0
Skilled workers . . .	37.9	28.6
Unskilled . . .	42.6	7.3

There are, as might be expected, anomalies which require special investigation. In lower east Manhattan, for example, there are two areas of modern housing development, Stuyvesant Town and Cooper Village. Here only 0.2% of the dwelling units were listed as unfit, and the high tuberculosis rate of 790 seemed to contradict the general experience. Further study showed that the upper part of the area contained a large number of "homeless persons" who had been examined radiologically for pulmonary disease. Of the 216 new cases reported in this health area only 18 were in the part occupied by the new estates. Fifty new cases were found in 1954, and of these Stuyvesant Town contributed 5 and Cooper Village 1. It became obvious during the investigation that some adjustment would have to be made for an area of this kind in the neighbourhood of the Bellevue Hospital, where many persons with no permanent home address were assigned.

The report, which includes references to a long series of previous studies, examines the problem of housing and tuberculosis in great detail, both historically and as it is seen to-day. The comparison of American and English figures is instructive, the conflict of evidence being apparent in both countries. Probably New York is a more suitable socio-economic laboratory than any other city because areas of good housing are so often adjacent to, yet sharply differentiated from, the slums. The "old law" tenements were multiple dwellings built before 1901 to let at low rents under pressure of the rapid growth of population at the end of the nineteenth century. Mr. Lowell quotes Mr. J. P. McMurray, commissioner of housing in the State of New York, as saying that these tenements "were designed to permit the most concentrated use of land with a minimum regard for tenant convenience and sanitation. Interior bedrooms and

shared hall toilets were standard features, and the existence of running cold water or the availability of any sort of interior sanitary facilities were luxuries to many of the tenants." This account might well have been written of the English towns of half a century before, and indeed our records abound with similar descriptions. Mr. McMurray continued: "At the turn of the century new standards were prescribed by the Tenement House Law, and the construction of these 'ready-made slums' ended. But there were between 85,000 and 100,000 such dwellings in existence. To-day, more than fifty years later, over 50,000 of these remain, containing in the neighbourhood of 415,000 dwelling units and housing between 1,250,000 and 1,500,000 persons. While many of these have been reconditioned in accordance with newer laws, their continued prevalence is an indication of housing conditions generally. . . . It is probable that the total number of units that would need to be built would approach half a million."

There is a notable uniformity in the studies of the inverse correlation of economic status with tuberculosis mortality on both sides of the Atlantic, in Canada as well as the United States. The New York report adds its strong confirmation, in both white and non-white populations, of the association of tuberculosis with poor housing and inadequate income, and concludes that, "if optimum benefits are to be realized in mastering tuberculosis, progress in medicine and public health must be accompanied by comparable and parallel socio-economic improvements in living conditions." Nevertheless, without setting one approach against another, where both are essential, most epidemiologists would stress the importance of Topley and Wilson's comment⁴: "The spread of tuberculosis in the community is in great part the result of slowly progressive household epidemics which often lead to the transmission of the disease by contagion from one generation to another." As to the prevention of tuberculosis in the future, experience gathered during the last twenty years lends force to the advice given by Wade Frost⁵ in 1937:

"The soundest principle to follow seems to me that, as the cases become fewer and fewer, preventive measures should be centred more and more upon the open cases; that the protection thrown around these infective cases and their immediate contacts be not relaxed, but steadily and progressively increased. This is a sound principle of epidemiology, for it is to be expected that, as the prevalence of the tubercle bacillus in the general environment is diminished, infection and disease will become more distinctly focalized. In fact, there is already evidence of increasingly wide differentiation between the most sheltered and the most exposed groups of our population; and even now we should take more cognizance of this in directing our efforts."

PROGNOSIS OF NEPHRITIS IN CHILDHOOD

Reports on the prognosis of nephritis in childhood are widely conflicting, and recovery rates have ranged from 37%¹ to almost 100%.² The reasons for this are several. Various workers have used different classifications. Those who have regarded the nephrotic syndrome (subacute oedematous nephritis, Type 2) as a stage in the natural course of acute haemorrhagic nephritis (acute glomerulonephritis, Type 1) report a poorer prognosis than those who regard them as separate pathological processes.³ Writers who have reported the prognosis of only those patients who have been observed from the initial attack of acute haemorrhagic nephritis have recorded a higher recovery rate than those who have included patients referred to them at different stages of renal disease. The criteria of cure have also varied. Any discussion on the prognosis of nephritis must therefore begin by defining the diagnostic terms used and the criteria of cure.

Acute haemorrhagic nephritis, which usually follows a streptococcal infection, is a clearly defined disease. It may end in recovery, cause death in the initial stage, progress rapidly with persisting hypertension, haematuria, and oedema to death in uraemia some months later, or pass into a latent stage, with persistent albuminuria and raised Addis count of cells in the urinary sediment, which ends in death from hypertension or uraemia some years later.⁴ The nephrotic syndrome has an insidious onset with gross oedema, heavy albuminuria, low serum albumin, and high serum cholesterol. A history of a previous attack of acute haemorrhagic nephritis is rarely obtainable, and the textbook description of oedematous nephritis as a usual intermediate stage between acute and chronic nephritis is not in accord with clinical experience.⁴ N. S. Clark⁵ has recently analysed 265 cases of nephritis in children. While he agrees that a history of acute haemorrhagic nephritis is the exception in cases of subacute oedematous nephritis, he prefers to regard these two conditions as different expressions of the same disease. Although it would be wise at present to reserve judgment on this question, it is certainly true that they have a distinctly different

prognosis as well as a different mode of onset and clinical course. In the important matter of hazarding a prognosis, therefore, the physician will wish to know the probable course of acute haemorrhagic nephritis observed from the onset, and also what happens to cases of the nephrotic syndrome (or subacute oedematous nephritis) with its onset of oedema and massive albuminuria. It is generally accepted that the most sensitive index of recovery in acute haemorrhagic nephritis is the Addis count, and that cure is possible up to but not after two years from the onset. In the nephrotic syndrome it is safer to think in terms of remission than cure.

In 1939 A. W. Snoke,⁶ from Rochester, N.Y., described the outcome of 141 cases of glomerulonephritis with a definite initial stage one to nine years earlier. His findings were very different from those previously reported by him in 1937 from San Francisco.¹ In the Rochester series 74.5% had recovered; 13.7% were still active; 11.8% had died. J. H. Davis and H. K. Faber⁷ in 1945 published their findings in 102 cases from the same centre as Snoke's 1937 series,¹ and in fact 82 were of the original series. The second series,⁷ however, included only those patients seen in the initial stage of the disease and excluded those who had been transferred to the centre already in an advanced stage of nephritis. Of the 102 patients so selected, 81.3% recovered, 7.8% had active disease after two years, and 10.8% died. F. S. Gachet⁸ reported on 166 patients admitted to hospital early in the disease; twelve (7.2%) died, and forty were not adequately studied; of the other 114, complete recovery ensued in 90.5%, in 6.1% the disease became chronic, and 3.4% had residual albuminuria but normal Addis counts. The results reported by M. D. Giles⁹ from Glasgow show the same high recovery rate as in the American series. She followed up 218 cases of acute haemorrhagic nephritis for one to seven years, of which 72.9% ended in recovery, 18.8% remained in the latent stage, 1.4% were in the terminal stage, and 6.9% had ended fatally. None had passed into the subacute or oedematous stage.

A large and recent series in the British literature has been reported by N. S. Clark¹⁰ from Aberdeen. He studied the outcome in 265 cases of nephritis of all types. Within one year of onset 7.5% had died. Of the 245 survivors, 67 were followed up for less than a year. The remaining 178 included some with subacute oedematous nephritis, which would influence the prognosis adversely. None the less, 75% recovered, 8% were in the latent stage, 4% had active disease, 3% were dead, and 11% showed only slight albuminuria. The Addis count

¹⁴ Squire, J. R., *British Medical Journal*, 1953, 2, 1389.

was recorded in only 34 cases. Analysis of the fatal cases in these series shows that death in many of the patients was due to intercurrent infections which would nowadays respond to the antibiotics. It is possible, therefore, to reach a fairly satisfactory assessment of the prognosis of acute haemorrhagic nephritis in modern practice. At least 80% will recover; less than 15% will pass into the latent stage on the way to terminal renal failure; the immediate mortality should not exceed 5%.

Much less information is available about the prognosis of the nephrotic syndrome, but the outlook is much better in children than in adults. This is related to the fact that in children "pure lipoid nephrosis" is not uncommon, but is rare in adults. M. H. Roscoe¹¹ has recently reviewed a series of 40 patients with the nephrotic syndrome only two of whom were young children. Even though she excluded cases due to amyloid disease, thrombosis of renal vein, diabetic glomerulosclerosis, and generalized lupus erythematosus, the rate of complete remission was only 12.5%; 50% had ended fatally, while in 37.5% the disease was still active after 2½ to 29 years. On the other hand, L. A. Barness, G. H. Moll, and C. A. Janeway¹² have reported complete remission in 41% of 107 children with lipoid nephrosis. G. C. Arneil¹³ has stressed that nephrosis is a disease largely confined to childhood. The average age at onset of 120 cases was 3.7 years. He notes "a recovery rate of at least 40%." Deaths from intercurrent infection such as pneumococcal peritonitis have been greatly reduced by the use of antibiotics, while new drugs such as corticotrophin, cortisone, and prednisolone can initiate remissions in many patients. J. R. Squire has emphasized the need for a diet high in protein.¹⁴ It is clear, therefore, that patients with acute haemorrhagic nephritis are likely to recover, and that the nephrotic syndrome in childhood, though still a serious and indeed depressing disease, no longer justifies a deeply pessimistic prognosis.

SERUM HEPATITIS AND DENTAL INJECTIONS

It is generally assumed that infectious hepatitis and serum hepatitis (or homologous serum jaundice) are different conditions caused by different viruses. Despite these differences there are also many points of resemblance, and there is little doubt that many cases labelled "infectious hepatitis" would be called "serum hepatitis" if a clear history were obtained of injections of serum or other material which might be contaminated with virus. Recently F. F. Foley and R. N. Gutheim¹ reported fifteen cases of hepatitis which followed dental

procedures, and they suggest that these were in fact cases of serum hepatitis transmitted by contaminated syringes or needles.

During a two-year period from June, 1953, to May 1955, fifty-seven patients were discharged from the General Hospital in Rochester, New York, with the diagnosis of viral hepatitis. Seven of these were known to have received blood or plasma transfusions. The remaining fifty patients would normally have been diagnosed as having suffered from infectious hepatitis, but fifteen of them gave a history of a dental injection within the preceding six months. In these fifteen patients there was no history of contact with a known case of infectious hepatitis, whereas there was such a history in six of the thirty-five patients who had no dental history. The incubation period in the fifteen cases varied from 47 to 142 days, with a mean of 96 days. The onset of illness was fairly gradual in most patients. The first symptoms were usually malaise, fatigue, and loss of appetite, with nausea and abdominal ache. The interval from the first symptom to the onset of jaundice was usually one to two weeks. Three patients died with diffuse or focal necrosis of the liver cells. Foley and Gutheim suggest that the association of these patients with a history of past dental treatment was not just due to chance. Whereas in the whole group of fifty patients with hepatitis included in this investigation fifteen (or 30%) had a history of dental injections, in two other control groups of patients the frequency of dental injections was five to seven times less—4.4% in one group of sixty-eight patients and 6% in another group of fifty patients.

These and other data which the authors give strongly suggest that dental injections must now be added to the list of injections which can be responsible for the transmission of virus hepatitis. Certainly the authors have established a case for careful investigation of this potential hazard. The risks of introducing infections by means of contaminated syringes or needles are not as widely appreciated as they should be. This is partly because many doctors and dentists are not aware of having had any trouble of this kind in their own practices, and if challenged on their technique for sterilizing syringes would point to the large numbers of injections they have given without any ill effects. But there is to-day an increased awareness that methods of sterilization both of syringes and of solutions frequently used in hospital and in general practice are far from safe. Foley and Gutheim recommend that chemical sterilization should be abandoned, and advise careful cleaning of syringes and needles and heat sterilization both of these and of procaine solutions. The days when every dentist will have his own small autoclave in his surgery may be some way off, but, if the risk of serum hepatitis suggested by Foley and Gutheim is confirmed by further investigation, then there will certainly be a case for overhauling the methods at present in use. The high mortality of serum hepatitis makes it a disease with which no chances must be taken.

¹ Foley, F. F., and Gutheim, R. N., *Ann. intern. Med.*, 1956, 45, 369.

DEFORMITIES OF THE CHEST

What Shakespeare said of greatness might be applied, in different words, to deformities of the chest, for they can be classified as congenital, acquired, or traumatic. The traumatic varieties, such as the cobbler's funnel chest, are becoming rare. Argument continues about the aetiology of the other types, congenital or acquired. J. M. Naish and H. R. E. Wallis¹ investigated the causes of Harrison's grooves and concluded that the insertion of the diaphragm had nothing to do with the production of these deformities, but that they occur at the site of a muscular gap or neutral zone between two parts of the thorax which normally move in different directions. In their opinion the important factors in the causation of the grooves were severe rickets, congenital heart disease, asthma, and deficient expansion of the lungs due to respiratory infections. Little work has been done in Britain on this subject since the appearance of Naish and Wallis's paper nearly ten years ago—though Wallis² has described several methods of recording the shape of the chest—and it has been left to American workers to explore the field further.

H. A. Brodtkin,^{3,4} of Newark, New Jersey, having previously ascribed funnel chest and pigeon breast to congenital weakness of the anterior segment of the diaphragm, now comes forward with a similar explanation for the appearance of Harrison's grooves.⁵ He points out that the diaphragm does not move up and down like a piston, but is more like a pair of balloons deflating. If there is a weak anterior segment, and "if greater and greater demands are made on the diaphragm for stronger and stronger contractions, the weak anterior segment will reach the limits of its power first. Beyond this point it will be overpowered by the stronger lateral and posterior segments, as in a tug of war, and will be pulled back." This causes an inspiratory retraction of the sixth costal cartilages, and so leads to the formation of grooves. The reasons for the strong contractions of the diaphragm may be dyspnoea or respiratory obstruction. Brodtkin stresses the importance of determining the age at which the deformities first occurred. His main argument for their congenital nature is that they are seen in newborn children and in those who have never suffered from respiratory infections. It seems that he is in agreement with Naish and Wallis on the factors which cause the grooves, but differs in his interpretation of the mechanism. His arguments, though interesting, are mainly theoretical, and proof should be forthcoming before they are accepted. It should be possible to learn something from post-mortem studies of patients with deformities of the chest, and from watching or filming the contractions of the diaphragm under fluoroscopy. Children with bronchial asthma might prove rewarding subjects, for here the obstruction is to expiratory effort rather than inspiration and yet grooves often occur.

¹ Naish, J. M., and Wallis, H. R. E., *British Medical Journal*, 1948, 1, 541.

² Wallis, H. R. E., *Brit. J. Tuberc.*, 1952, 46, 136.

³ Brodtkin, H. A., *Pediatrics*, 1949, 3, 286.

⁴ *Dis. Chest*, 1951, 19, 288.

⁵ *J. Amer. med. Ass.*, 1956, 161, 1555.

As to treatment, there is again division of opinion. Operations for purely cosmetic reasons are undertaken more commonly in the United States than in Britain. Symptoms which have been attributed to funnel chest, such as palpitations, retrosternal pain, and dyspnoea, could just as well be due to anxiety. Severe deformities no doubt require surgical correction, but the minor manifestations are probably best left alone.

THE PRIME MINISTER'S TERMS

Mr. Macmillan met Sir Russell Brain and Dr. A. Talbot Rogers, joint chairmen of the Negotiating Committee, on Tuesday this week. In the House of Commons, on the same day, Mr. Macmillan said that as from April 1 junior hospital staff up to and including senior registrars would receive a 10% increase in pay. They were considering what should be done by way of an interim adjustment for the other doctors and dentists covered by the Royal Commission's terms of reference, and he would make a further statement on this "in due course." It may be assumed that this will be after the Budget. Mr. Macmillan also gave the composition of the Royal Commission, whose terms of reference were published in last week's *Journal*. Sir Harry Pilkington, aged 51, chairman of Pilkington Brothers Ltd. and a director of the Bank of England, is to be chairman. The other members are as follows: Mrs. Baxter, secretary of Cambridge University Women's Appointments Board; Mr. J. H. Gunlake, vice-chairman of the Institute of Actuaries; Professor John Jewkes, Professor of Economic Organization, Oxford; Mr. A. D. Bonham-Carter, a director of Unilevers; Mr. I. D. McIntosh, headmaster of George Watson's College, Edinburgh; Sir David Hughes Parry, Q.C., Professor of English Law, University of London; Sir Hugh Watson, Edinburgh, Deputy Keeper of Her Majesty's Signet; Mr. Samuel Watson, secretary of the Durham Miners' Association.

Mr. Macmillan, in his letter of February 25 to the chairmen of the Negotiating Committee, said that "the work of the Royal Commission would not preclude some interim adjustment of doctors' remuneration." When explaining this in the Commons about a fortnight ago he said that a statement would be made at the appropriate moment. The Council of the B.M.A. considered the appropriate moment was now, and that was why the Negotiating Committee chairmen met Mr. Macmillan this week. All he has added now is that he would make a further statement "in due course." It is astonishing that the 10% increase for junior hospital staff was announced by the Prime Minister in the House of Commons when barely a fortnight ago the Government announced that the Management Side of Whitley Committee B would be instructed to negotiate an increase. Mr. Macmillan seems temporarily to have assumed the office of Minister of Health. So once again the Government has shifted its position. What is the profession to make of all this? What a confusion of tongues! In the meanwhile the Government refuses

to negotiate with the profession on its claim for a 24% increase or to agree to arbitration: its silence on this must be read as a refusal. Mr. Macmillan's replies to questions in the Commons on Tuesday were not designed to clear up the muddle, and the profession will find the present position more unsatisfactory and confusing than before.

DEODORANTS AND DEPILATORIES

From the time of ancient Egypt and perhaps earlier the axillae, especially in women, have received much attention for cosmetic reasons. The secretions of the apocrine glands, which abound in that situation and are a secondary sexual characteristic, have a peculiar odour which may become offensive, since fermentation readily occurs.¹ The search for deodorants is therefore an age-old problem. Moreover, in some periods of history fashion has demanded exposure of the axillae and required removal of hair from that site.

Deodorants must not only lessen or abolish odour but also reduce perspiration locally. They are usually astringent and may be applied as liquids, powders, creams, pastes, or as a stick made of a fat-wax mixture. Aluminium chloride or some other salt of aluminium is commonly used, and so are formaldehyde, boric acid, oxyquinoline sulphate, and zinc salts. The sticks, powders, and pastes usually contain some talc and occasionally kaolin. The removal of hair has probably been achieved more commonly by shaving than by other means such as the application of depilatory preparations. These often contain barium, calcium, strontium, or sodium sulphide, and in many powders and pastes there is talc or kaolin. Because it is dangerous, thallium acetate is no longer used. Cosmetic preparations designed to remove hair are, as a group, potentially more toxic than any other class of compounds applied for non-medical purposes to the skin and require discrimination in their use. Nevertheless, complications resulting from established brands of deodorant and depilatory agents must be extremely rare. Occasionally eczematous dermatitis is provoked in a person whose skin is liable to this affection, either by the development of sensitization to some constituent of the application or as the result of a primary irritant effect. Hidradenitis suppurativa, an acute inflammatory reaction of the apocrine glands, has been said to be caused by damage to the duct openings by deodorant applications or depilatories, though maceration of the skin by sweat, especially when rubber dress-protectors are worn, and endocrine factors are probably more important.

Recently L. Rubin and colleagues² have described an apparently new eruption of the axillae resulting from deodorants. Reddish-brown papules 1-4 mm. in diameter appeared in profusion after applying a deodorant stick (in three patients) or lotion (in one) for a few days or weeks. Histologically the papules were found to be granulomata with a tuberculoid re-

action. Talc and kaolin are not mentioned as constituents of the deodorants used, and polaroscopic examination of the sections showed no foreign bodies. Zirconium was present in the three sticks used but not in the lotion, which contained chlorhydroxy-aluminium sulphate. The cause of this unusual condition is still unknown, but the role of abrasion is being investigated, since the makers of these deodorants suggest in their advertisements that they may be used immediately after shaving.

NEW WAYS OF DRILLING TEETH

In recent years there have been a number of improvements in the conventional methods of preparing teeth for fillings and other restorations. These improvements aim at faster and more accurate cutting of the tooth and at reducing the risk of temporary discomfort or permanent damage to the sensitive dental pulp. Very much higher speeds are now attainable with the dental electric engine, and commercial models are available with hand-piece speeds of up to 25,000 revolutions per minute. This speed enables cutting instruments made with tungsten carbide or diamonds to be used with much greater efficiency than was possible with the old 3,000 to 3,500 r.p.m. normally achieved. As the cutting efficiency is increased so the working pressure on the tooth can be reduced, giving less discomfort to the patient and far more accurate control to the operator. The problem of the heat developed with this fast cutting is overcome by the use of a continuous spray of water on to the cutting instrument; this in itself reduces discomfort by "cushioning" the vibration inevitably produced when toothed burrs or diamond abrasives are used, besides maintaining a normal, or even slightly reduced, temperature of the tooth. Much higher speeds are attained by the use of newly developed motors of turbine type driven by compressed air, and speeds of 60,000 to 80,000 r.p.m. are reported. With these instruments the stream of used air is generally directed on to the tooth to disperse debris and effect cooling. Even higher speeds are being experimented with, but the maintenance of such high-speed equipment becomes a major difficulty.

An entirely different method of preparing teeth for fillings has been developed in the U.S.A.: a stream of compressed gas carrying particles of abrasive is directed on to the tooth through a small nozzle. The advantages claimed are that vibration, conducted noise, pressure, and heat can be entirely eliminated. But in using this method the operator lacks the guidance of his sense of touch and accurate shaping of cavities is difficult. It is not a complete replacement for the dental engine. Experimental work is being carried out with high-frequency vibrating instruments in conjunction with abrasives. These instruments are made to vibrate at frequencies of 25,000 cycles per second, which are beyond the range of human hearing and so are referred to as ultrasonic. Such instruments are widely used industrially and their possibilities in dentistry are promising, but work with them so far has not gone beyond the experimental stage.

NOTES ON PREVENTION OF TETANUS IN INJURED PERSONS

BY

H. J. PARISH, M.D., F.R.C.P.Ed.

Wellcome Research Laboratories, Beckenham

L. J. M. LAURENT, M.D., M.R.C.P.

Hither Green Hospital

AND

N. H. MOYNIHAN, M.B., B.Chir.

Chelsea

The need for these notes was brought home to us by several requests for guidance from surgeons, casualty officers, and others. We do not consider the decision concerning which injuries require tetanus prevention falls within the scope of this paper,* but when, after clinical assessment of the injury, it has been decided that there is a risk of tetanus infection and that suitable preventive measures should therefore be taken, it is suggested that the following procedures should be adopted.

Suggested Procedures

Determination of Immunity Status.—Inquiry should be made into the possibility of previous tetanus toxoid administration, in order to determine whether the patient is non-immune or actively immune. (A difficulty may arise in taking the patient's history, as he may confuse previous injections of serum or various prophylactics with injections of tetanus toxoid.)

Definitions.—The following definitions are derived from those used in British Army practice. A person is considered to be:

Non-immune (this category includes those who may be incompletely immunized) (a) when he/she has never received any injection of tetanus toxoid; (b) when he/she has received only one injection of tetanus toxoid; (c) when more than six months have elapsed after two injections of tetanus toxoid, or when more than five years have elapsed after the initial course of three injections of tetanus toxoid or a subsequent boosting (reinforcing) dose; (d) where there is any doubt about previous tetanus toxoid administration.

Actively immune (a) for a period up to six months when he/she has received two injections of tetanus toxoid, the second injection being given not less than six weeks and not more than twelve weeks after the first injection; (b) for a period up to five years when he/she has received three injections of tetanus toxoid, the third injection being

*The following summary of the types of injuries which require specific preventive measures against tetanus is quoted by kind permission of Mr. W. Gissane, F.R.C.S., and Dr. E. J. L. Lowbury, of the Birmingham Accident Hospital: Tetanus antitoxin should not be given as a blind routine for all open wounds. Reactions are not uncommon, and may, though rarely, be fatal. Prophylactic injections against tetanus need not be given in the case of clean superficial wounds or abrasions not more than three to four hours old. Physical removal of any organisms by gentle or thorough washing for three to four minutes may be relied upon. Subsequent contamination must be prevented by a good cover dressing with or without closure by suture or grafting.

Prophylactic injection of either tetanus antitoxin or tetanus toxoid, according to the patient's state of immunity, is indicated in the following cases: (1) wounds more than three to four hours old; (2) wounds already infected by pyogenic organisms; (3) wounds through skin that may have been contaminated by soil or manure—for example, wounds in farmers, stablemen, agricultural labourers, sewage workers, gardeners, garage mechanics, football players, etc., and most children; (4) deep and punctured wounds, however small; (5) wounds in which the tissues have been devitalized by the force of the injury—for example, hand-press injuries; and (6) wounds that cannot be closed properly and may therefore be infected later.

given not less than six months and not more than twelve months after the second injection mentioned above; (c) for a period up to five years after he/she has received a boosting dose following a full primary course of immunization.

Preventive Measures Recommended

Non-immune (as defined above).—Passive immunization with tetanus antitoxin will be required. Keep a small sterile syringe and needle and a 1:1,000 solution of adrenaline ready for emergency use whenever antitoxin is injected. Keep the patient warm and under observation for at least 30 minutes after receiving antitoxin by any route.

Give tetanus antitoxin in accordance with the following procedure:

(1) Try to obtain the patient's previous history of: (a) injections of horse serum of any kind, and (b) allergic conditions, especially asthma and infantile eczema.

(2) If no previous serum and no history of allergy, give full dose of tetanus antitoxin, 1,500 international units subcutaneously or intramuscularly. If there are any doubts about previous injections of serum or allergic diathesis, proceed as in (3).

(3) If the patient has had serum before, but has no history of allergy, give a "trial dose" of 0.2 ml. of undiluted antitoxin subcutaneously. If no general symptoms develop within 30 minutes, give a full dose of tetanus antitoxin, 1,500 international units, subcutaneously or intramuscularly.

(4) If history of allergy, give a trial dose of 0.2 ml. of 1:10 dilution of antitoxin subcutaneously. If no general reaction within 30 minutes, give 0.2 ml. of undiluted antitoxin subcutaneously. If no general reaction within a further 30 minutes, give full dose of tetanus antitoxin, 1,500 international units subcutaneously or intramuscularly. The object of the trial dose is to determine any predisposition to general reaction and not to detect any local reaction, the latter having no practical significance. If symptoms develop, see "Types of Reactions which may follow Administration of Antitoxin, and their Treatment" and "Antitoxin after Anaphylaxis," below.

(5) Additional prophylactic doses (usually 1,500 international units), subcutaneously or intramuscularly, may be given at weekly intervals if the surgeon in charge of the case considers this necessary.

(6) Whenever antitoxin has been given, recommend toxoid later—see "Active Immunization," below.

Actively Immune.—Tetanus antitoxin will not be required. Give a boosting dose of 1 ml. of tetanus toxoid (unless the third dose of the primary course or a boosting dose has been given less than 18 months previously, when even a boosting dose is unnecessary).

Children in both non-immune and actively immune groups should be given the same dosage of antitoxin or toxoid as adults.

Records

Keep careful records of all injections (antitoxin, toxoid, etc.) noting: the dates of inoculation; the correct name of the preparations; the batch numbers; the dosage administered; and reactions, if any (local, general, etc.).

Give a record card to the patient or parent, and ask him/her to keep it in a safe place, as in the event of injury it will be required as soon as possible by either the hospital or the private doctor.

Types of Reaction which may follow Administration of Antitoxin, and their Treatment

Anaphylactic Shock.—Onset within few minutes, or, with less intensity, up to two hours. Dyspnoea, pallor, collapse; sometimes oedema or rash. **Treatment.**—Give 0.5 to 1 ml. of 1:1,000 solution of adrenaline intramuscularly. If recovery is not rapid, repeat the injection in 15 to 20 minutes. Give an antihistamine drug in full doses intramuscularly: specially useful if urticaria or oedema develops. Keep the patient recumbent with the head low, and warmed with blankets and hot-water bottles. Recovery from anaphylactic shock is usually rapid after adrenaline. Very rarely, the return of the blood pressure to normal is delayed for some hours; in these cases give a slow intravenous

¹ *British Medical Journal*, 1954, 1, 1198.

² Rubin, L., Slepian, A. H., Weber, L. F., and Neuhauser, I. J. *Amer. med. Ass.*, 1956, 162, 953.

drip of diluted noradrenaline, blood-pressure readings being taken frequently in order to avoid an unduly elevated pressure.

Serum Sickness.—Common ("delayed") type after 7 to 12 days; "accelerated" type after three to four days (typically seen in persons who have had a previous serum injection). Urticaria and other rashes, oedema of the tissues, joint pains, and pyrexia. **Treatment.**—Give an antihistamine drug by mouth for one to three days. In more serious cases, antihistamine drug, by injection; soothing lotions such as calamine to the skin. In rare cases of severe serum sickness, when symptoms reappear in spite of antihistamine drugs, give prednisolone, orally in doses of 5 mg. six-hourly or eight-hourly for one or two days; discontinue the drug gradually over the next two days. While this treatment will be found successful, bear in mind the dangers of prednisolone in the presence of peptic ulcer, diabetes, tuberculosis, and any uncontrolled infection.

Local Reaction without Constitutional Disturbance.—Often after 7 to 10 days, lasting two days. Localized erythema and urticaria: may be very irritating but never dangerous. **Treatment.**—Give an antihistamine drug orally; soothing lotions to the skin.

Local Hypersensitivity Analogous to the Arthus Phenomenon.—Swelling and induration, leading to sloughing of skin, subcutaneous tissues, and even muscle. Very rare. May appear after repeated injections of serum. The administration of serum should be avoided so far as possible while the patient is already suffering from serum sickness due to a previous injection.

Thermal Reaction.—Sudden pyrexia and severe chill, mostly after intravenous injections. Rare. **Treatment.**—Give adrenaline as above. Keep the patient warm.

Antitoxin after Anaphylaxis

Wait till blood pressure is normal and rashes (if any) have subsided. (This takes between 6 and 12 hours.)

Repeat the "trial dose" of 0.2 ml. of undiluted tetanus antitoxin subcutaneously. If no general reaction occurs after 30 minutes, give a full dose subcutaneously or intramuscularly.

The recurrence of anaphylactic shock is extremely rare, but the patient may develop so-called accelerated serum sickness.

Supplementary Notes

Active Immunization.—There is now general agreement that the ideal method for the prevention of tetanus is by active immunization. Patients who have been given tetanus antitoxin as a matter of urgency should be actively immunized afterwards. Some of them may have become sensitized to serum, with the result that if they are given antitoxin again at some future date they may eliminate it too rapidly for protection to be adequate. Active immunization may be achieved by either (a) inviting the patient to return to the hospital in six or eight weeks for active immunization with tetanus toxoid; or (b), when making a report on the case to the usual medical attendant, recommending that a full course of active immunization should be commenced six to eight weeks later. For primary immunization three 1-ml. doses of tetanus toxoid are injected subcutaneously or intramuscularly at intervals of 6 to 12 weeks between the first and second injections and 6 to 12 months between the second and third injections. A boosting dose of 1 ml. of toxoid needs to be given every five years to maintain immunity. As active immunization against tetanus is not yet undertaken routinely by either the general practitioner or the local public health authority, those hospitals which receive a large number of casualties with injuries of a type likely to develop tetanus may find it convenient to set up a monthly immunization clinic for implementing the above recommendations.

Routine Immunization of Allergic Subjects.—In our opinion known asthmatic and other allergic subjects should

always be actively immunized as a routine against both tetanus and diphtheria in order that injections of antitoxin for prophylaxis or treatment at a later date may be avoided.

Intravenous Injections of Antitoxin.—Intravenous injections of tetanus antitoxin are not necessary for prophylaxis: they are required only for the treatment of tetanus. The intravenous route should never be used unless an intramuscular injection (if necessary preceded by a trial dose), given at least half an hour before, has been tolerated. The antitoxin should be at room temperature, and the patient recumbent and kept warm. Everything should be in readiness for the treatment of anaphylactic shock. Intravenous injection should be given very slowly. The patient should be kept under observation for at least one hour afterwards.

Conclusion

The above notes and recommendations have been drafted in an attempt to assist all who are called upon to treat wounds which may be infected with *Clostridium tetani*. It is hoped that the recommendations made would facilitate the drawing up of a concise guide to procedure, as, for example, the preparation of a wall chart.

We would welcome criticism of our suggestions and an expression of the views of the many different categories of the doctors concerned.

We are grateful to a number of friends and colleagues, especially Dr. E. T. Conybeare, Ministry of Health, and Mr. A. T. Glenny, F.R.S., for helpful comments.

COLLECTIVE NEUROSES OF OUR DAY

A distinguished Viennese psychiatrist, Professor V. FRANKL, addressed the Austrian Institute in London on February 21 on "Collective Neuroses of the Present Day." Professor Frankl is head of the Neurological Polyclinic at Vienna. Professor E. STENGEL, of Sheffield University, presided, and he introduced Professor Frankl as one of the most productive of living psychiatrists. He had developed his theories, said Professor Stengel, not just from his armchair, but in the hard school of life. During the years Professor Frankl had spent in concentration camps he had had ample opportunity to observe both himself and others under conditions of extreme stress.

Contemporary Man and His Sickness

"Am I expected to give the opinion of psychiatrists on contemporary man?" asked Professor Frankl of his audience. They might well be tempted to think so, he said, if they had come across a book entitled *The Nervous Condition and Diseases of our Time*, particularly as the date was '53; but the full date was 1853, not 1953, and the nervous condition was not exactly a contemporary disease.

Neurosis had by no means increased in frequency during the last decade. All that had changed were the symptoms. But it was surprising to find that anxiety had decreased in prominence, although it could be said, not altogether untruthfully, that anxiety was at the root of the diseases of our time. What gave rise to the impression that neurosis had increased was that, thanks to the growth of psychotherapy, some of those who would do far better to see a priest—as in former days they would have done—now went to the psychiatrists. To-day they refused to go to the priest and the doctor was forced to become a medical minister.

There had been only a change of aspect—different symptoms. One was left with the impression that the content of patients' delusions was shaped by the spirit of the age and changed with it. The spirit of the age also made itself felt in the depth of spiritual life. But clinical neurosis had by no means become collective. Nor did it threaten to engulf mankind as a whole. What it was justifiable to call "collective neurosis" was not even necessarily a neurotic condition.

Ephemerism, Fatalism, and Collective Thinking

In contemporary man four categories of symptoms akin to collective neurosis could be discerned. There was first an *ephemeral attitude* towards life. In the last world war man learned of necessity to live from one day to the next. He never knew if he would see the next one dawn. Since the war that ephemeral attitude had remained and was to some extent justified by the fear of the atomic bomb. Such people gave up planning for the future or organizing their lives.

The second was the *fatalistic attitude*. This supposed it was not possible for man to plan his life. Man, it was thought, was the plaything of external circumstances—or conditions—and therefore had to submit to being pushed around; he felt himself the product of his physical make-up—just a reflex automaton. The popular misinterpretation of psycho-analysis provided plenty of arguments to support such fatalism.

Then there was *collective thinking*, which showed itself when the average man in ordinary life desired to be as little conspicuous as possible, preferring to be submerged in the mass. It was important in this context to distinguish between mass and community. The community needed personality to be a real community, just as personality was needed in the sphere of real activity. The mass was different; it was disturbed by personality and therefore it suppressed freedom of the individual and levelled personality down. Finally there was *fanaticism*. The fanatic denied the personality of others while in actual fact he had no personality of his own.

The Machine Age

They should not conceal from themselves, Professor Frankl continued, that the first two symptoms, ephemerism and fatalism, were widespread in the Western world. But to-day there was a further factor—a sense of meaninglessness in life: not a sense of being of less value than others, but a feeling that life itself no longer had meaning. This showed itself as a feeling of boredom, and boredom brought yet further problems for the psychologist. Boredom was a symptom which would become increasingly more typical. The second industrial revolution would probably give the average worker an enormous increase in his leisure, and he

would not know what to do with it. There were other dangers too. Man might begin to misinterpret himself by false analogy with the machine age in which he lived. Man first understood himself as a creature in the image of his creator, God; then came the machine age and he began to see himself as a creator; now he might see himself in the image of his creation, the machine. Already some serious psychiatrists believed that the electrical computer differed from the human mind only in that it worked almost faultlessly—something which could not be claimed for man.

But man was not driven, he was free, he was able to take decisions. We spoke with pride of our responsibilities and accepted liability for them. This was the stepping-stone to full personal freedom, said Professor Frankl; it was the realization of that unique and individual meaning which every one of us had to fulfil. It was dangerous and misleading to speak of self-fulfilment as the final goal of self-realization.

"This is all very fine, Hippocrates, but there's nothing here about pay."

APPROVED NAMES

On September 8, 1956 (p. 602), we printed the last supplement (dated August, 1956) to the consolidated list of "approved names" selected by the British Pharmacopoeia Commission. Below is the latest list, dated February, 1957. We have added a brief note on the main use of each drug. Communications relating to "approved names" should be addressed to the secretary, British Pharmacopoeia Commission, General Medical Council Office, 44, Hallam Street, London, W.1.

Approved Name	Chemical and Other Names	Notes
Anileridine	Ethyl 1-(2- <i>p</i> -aminophenyl-ethyl)-4-phenylpiperidine-4-carboxylate	Morphine-like analgesic
Chlorisondamine chloride	4 : 5 : 6 : 7 : -Tetrachloro-2-(2-dimethylaminoethyl) iso-indoline dimethochloride "Ecolid"	Ganglionic blocking agent
Crotamiton	Croton- <i>N</i> -ethyl- <i>o</i> -toluidide "Eurax"	Acaricide
Dichlorophen	Di-(5-chloro-2-hydroxy-phenyl)methane "Anthiphen"	Anthelmintic
Dioxaphetyl butyrate	Ethyl 4-morpholino-2 : 2-diphenylbutyrate	Morphine-like analgesic
Diphenamyl methylsulphate	4-Diphenylmethylene-1 : 1-dimethylpiperidinium methylsulphate "Diphenamyl"	Anticholinergic
Ethinamate	1-Ethynylcyclohexyl carbamate "Valmid"; "Valmidate"	Hypnotic
Fludrocortisone	9 α -Fluorohydrocortisone "Alflorone"; "Florinef"	Modification of hydrocortisone for topical use
Hexetidine	5-Amino-1 : 3-di-(2-ethyl-hexyl)hexahydro-5-methylpyrimidine "Sterisil"	For use against <i>Trichomonas vaginalis</i>
Hydroxyzine	1- <i>p</i> -Chlorobenzhydryl-4-(2-(2-hydroxyethoxy)-ethyl)piperazine "Atarax"; is the hydrochloride	Tranquillizer
Morpheridine	Morpholinoethylmorphine	Analgesic
Novobiocin	An antibiotic produced by <i>Streptomyces niveus</i> and <i>Streptomyces spheroides</i> "Streptonivacin" "Albamycin" is the calcium salt; "Biotoxin" is the sodium salt; "Cathomycin" is the sodium salt	Antibiotic
Oleandomycin	An antibiotic produced by certain strains of <i>Streptomyces antibioticus</i> "Matromycin"; "Romicil"	Antibiotic
Ostreogrycin	An antibiotic produced by <i>Streptomyces ostreogriseus</i> "Ostreocin"	Antibiotic
Oxeladin	Diethylaminoethoxyethyl α : α -diethylphenylacetate "Pectamol" is the citrate	Cough sedative
Paracetamol	<i>p</i> -Acetamidophenol "Panadol"	Mild analgesic
Phenobutiodil	α -(2 : 4 : 6-Tri-iodophenoxy)-butyric acid "Biliodyl"	Oral cholecystographic agent
Phenomorphin	3-Hydroxy- <i>N</i> -(2-phenylethyl)morphinan	Morphine-like analgesic
Propoxyphene	4-Dimethylamino-1 : 2-diphenyl-3-methyl-2-propionyl oxybutane	Morphine-like analgesic
Thenalidine	1-Methyl-4- <i>N</i> -(2-thenyl)-anilino-piperidine "Sandosten" is the tartrate	Antihistaminic
Thyrotrophin	Thyrotrophic hormone "Thyrophin"	Thyrotrophic hormone
Vancomycin	An antibiotic produced by <i>Streptomyces orientalis</i> "Vancocin"	Antibiotic
Warfarin	3-(2-Acetyl-1-phenylethyl)-4-hydroxycoumarin "Coumadin"	Anticoagulant

Correspondence

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

Polyradiculitis

SIR,—Since cortisone has become freely available several articles reporting its use in the Guillain-Barré syndrome have been published. The most recent of these, by Drs. R. Hugh Jackson, Henry Miller, and Kurt Schapira, appeared in your issue of March 2 (p. 480).

In order to justify the institution of a new treatment for a disease known to have a remarkable tendency towards spontaneous recovery it is clearly most desirable to have a rational concept of the mode of action of the treatment in question. The case for the administration of cortisone rests upon the supposition that the disease has an allergic basis. Recent advocates of its use (Graveson¹ and Dr. Jackson *et al.*) are at pains to bring to the reader's notice evidence which they consider suggestive of such a basis. They make, however, scant reference to other possible aetiologies, and, in particular, ignore Guillain's² recent statement of his belief in a viral origin, the evidence he puts forward in support of this, and his rejection of the allergic hypothesis. Guillain's article is of considerable interest. In it he puts forward certain criteria for the diagnosis of the Guillain-Barré syndrome which are an amplification of his earlier criteria, in the light of collective experience. By the application of these criteria it should be possible to prevent what may still be a disease entity, with a single cause, from being expanded into a group of miscellaneous conditions, united only by their involvement of the lower motor neurone and the acellular hyperalbuminosis of the cerebrospinal fluid. The cases collected by Landry over a hundred years ago are certainly a heterogeneous group. To add them to the Guillain-Barré syndrome will undoubtedly hamper our efforts to discover the aetiology of this syndrome, as originally described. We shall be forced to admit, as Dr. Jackson *et al.* have already done, that the aetiologies are multiple, and in this way we shall lose sight of our disease entity with the possible single cause. Oppenheim was less protective of his syndrome (amyotonia congenita) than Guillain, and in fifty years it was buried beneath a welter of infantile hypotonic states, of widely differing aetiology, dignified by the term "amyotonia congenita" syndrome. Only recently has it been possible for Walton³ to rediscover the original condition of amyotonia congenita—still without a known cause, but with a new name. We should be warned against repeating history by turning the rigidly defined Guillain-Barré syndrome into a nebulous "Landry-Guillain-Barré" syndrome.

The authors, favouring an allergic origin for the disease, base their theory, in part, upon the pathological changes. I do not wish to discuss these in detail, but would only say that, owing to the benign nature of the illness (as defined by Guillain), necropsy material is extremely scanty, and that the changes so far described are as compatible with a viral origin as they are with an allergic origin. It would seem that if we are to obtain more information as to the pathology of this disease we must rely largely upon biopsy study of the intramuscular nerve fibres and their endings. It is true that such changes as are observed in the endings may be secondary to involvement of more proximal portions of the neurone, but this is not certain. Nor is it certain that the changes in the spinal roots—which have attracted more than their share of attention—are not themselves secondary to disease of the anterior horn cells, which is unrecognizable or inconspicuous with available histological techniques.

Biopsy study of the intramuscular nerve endings has already proved of great value, in other forms of peripheral neuritis, in revealing a mechanism of reinnervation at the intramuscular level.⁴ This mechanism depends upon axona-

sprouts, which arise from surviving subterminal nerve fibres and eventually make contact with the denervated muscle fibres, upon which they form new end-plates. This mechanism is far easier to envisage as an explanation of gradual recovery of some months' duration than that postulated by Dr. Jackson *et al.*, who would suggest that, if oedema of the roots is unduly severe, recovery can only take place by growth of sprouts (presumably from the intrathecal part of the anterior roots), past the scarred area where the roots have been compressed at the intervertebral foramina, and on for 2-3 ft. (60-90 cm.) down the nerves to the muscles. Accepting the figure given by Seddon *et al.*⁵ for the rate of advance of the regenerating tip of a peripheral nerve after suture (1.5 mm. per day), it will be seen that even under the best conditions, which will certainly not obtain, it would take well over a year for regenerating sprouts to travel down the nerves from the lumbar roots to the distal muscles of the leg. Add to this time the period which elapses between onset of paralysis and the subsiding of oedema in the spinal roots and it will be obvious that the sprouts, should they ever reach the muscle, would find the latter almost completely atrophied and fibrosed. The formation of an end-plate on any surviving muscle fibre would be impossible. Of course, the clinical history of these cases would be quite incompatible with such a method of reinnervation. Recovery is gradual and continuous from within a few weeks of the paralysis reaching its maximum. If the explanation just rejected were correct, recovery would suddenly set in after many months. This mechanism of axonal growth down peripheral nerves, while so acceptable in the case of complete nerve section a short distance proximal to a muscle,⁶ must therefore be considered as improbable in the extreme as an explanation of the usually complete functional recovery which characterizes the Guillain-Barré syndrome. These observations do not in any way lessen the danger of severe damage to the nerve fibres in the spinal roots as emphasized by Graveson and Dr. Jackson and his collaborators. On the contrary, the significance of the damage is increased, since once the nerve fibres are totally destroyed at this level their regeneration is impossible, and if all are destroyed reinnervation even at the intramuscular level will also be impossible, and not, as Dr. Jackson *et al.* suggest, merely delayed. However, the good functional results usually obtained, even in untreated cases, suggest that total destruction of nerve fibres is rare, and it is usually well within the capacity of the surviving neurones to reinnervate such muscle fibres as have been denervated.

May I suggest, in conclusion, that before cortisone can be accepted as having a rational basis in the therapy of the Guillain-Barré syndrome much more information is required concerning the pathological changes, and that, in the absence of necropsy material, muscle biopsy using Coers's techniques may not be entirely without value.—I am, etc.,

A. L. WOOLF.

Smerthwick.

Police Evidence Preferred

SIR,—May I comment on the report (*Journal*, February 23, p. 468) under the title "Police Evidence Preferred"? An experienced police officer who sees a motorist at the time he is driving, or attempting to drive, is in a far better position to assess his ability to drive than a doctor remotely, by tests, in a police station.

I quote another case to illustrate this. One evening a motorist, whose speech was slurred and who was excited, brought to my house a cyclist he had knocked over. I told him he had had too much to drink and advised him to leave his car and walk home. He was very incensed at this and

demanded that I should call a policeman, as I had insulted him. I rang up the police station, and asked the constable who arrived to persuade him to go home quietly without his car. The constable got him outside on the pavement, and, after testing his walking, told him that he would be wise to follow my advice but that he was at liberty to make his own choice.

The driver thereupon got into his car, started off at a fast speed down a hill, mounted the pavement on the opposite side of the road, returned to his own side, crossed the pavement there, and collided with the wall bordering the churchyard. He had no explanation to offer for this driving. He was arrested, brought back to my house, and I was asked to certify him. I refused to do this, and he was examined later at the station by a colleague who told me the rest of the story. After submitting the defendant to various inconclusive tests and fortified by the history, he told him he was drunk. He was then asked by the motorist: "Doctor, could a drunk man stand up in the middle of this room, jump into the air, turn a complete somersault, and land down on his feet?" My colleague was injudicious enough to say, "Certainly not"—and was then and there proved wrong.

Your correspondent's report induces further thoughts. The borderline case is mentioned. It can be proved that a single drink will invariably lengthen the reaction time, and must therefore impair the control of a vehicle. With further alcohol other impairments follow—lack of concentration, faulty visual accommodation, muscular incoordination, and so on—until the patient ultimately becomes paralytic. At this stage he is quite safe to be "in charge" of his car, as he can no longer start it. Where is the borderline? There is a perfectly good measure of alcoholism if it is really wanted, and that is the urine alcohol concentration. A figure can be fixed and it can be proved which side of the borderline any motorist may be. It has been argued that this is unfair to the man who can carry his drink, but it is no more unreasonable than the 30 m.p.h. limit is to the first-class driver. The limit is set for the average man and all must conform.

Finally, your correspondent asks why accused persons should be asked to submit to examination by a doctor. The purpose of the medical examination should be to exclude illness, accident, or infirmity which might be mistaken for alcoholism or contribute to its effects. The medical profession should be allowed to confine its evidence to such matters; for on these it is qualified to speak. On other matters, police evidence is to be preferred.—I am, etc.,

Warwick.

CHARLES L. WORTHINGTON.

Fatal Reactions to Local Anaesthetics

SIR,—Your annotation on fatal reactions to local anaesthetics (*Journal*, February 2, p. 276) is most timely, particularly in view of the tendency to look upon very ill cases as those best suited to surgical interference under this form of anaesthesia. Unfortunately, it is this particular type of case in whom untoward reactions are most likely to occur. It should be stressed that in such cases, as indeed in all cases, the least amount and the lowest concentration of the least toxic agent should be the rule in the application of local anaesthetic agents. Your annotation notes that adrenaline is often included in local anaesthetics in order to retard absorption and prolong effect. While this is true, and indeed desirable, I would underline the danger of too high concentrations of adrenaline being employed. A concentration of 1 in 300,000 is quite sufficient for all practical purposes.

Adequate sedative premedication with either a barbiturate or an opiate is not only humane but undoubtedly does raise the individual's threshold to the toxic effect of local anaesthetic agents. It should rarely, therefore, be omitted. 30 ml. of 2% lignocaine is mentioned in your annotation as constituting an overdose, and with this few would argue, although it was not sufficiently stressed that such an amount should be combined with adrenaline. But why use 2% lignocaine in such quantities? Lower concentrations provide adequate sensory loss. Indeed, the only justification

for using 2% lignocaine is where motor loss is required as well. When used in low concentrations with appropriate amounts of adrenaline in patients suitably premedicated, relatively large amounts of lignocaine can be used with safety. Scurr¹ and Wilson and Gordon² reported the routine use of as much as 1,000–1,200 mg. of lignocaine in cases of thoracoplasty, and they emphasize that the safety factors lie in premedication, low concentration of lignocaine, and low concentration of adrenaline. Perhaps as important as all these precautions is a more than passing knowledge of the techniques of performing local anaesthesia.—I am, etc.,

Aberdeen.

HOWARD BRUCE WILSON.

SIR,—May I congratulate you on your excellent and timely annotation on fatal reactions to local anaesthetics (*Journal*, February 2, p. 276)? There is, however, one small point in it which may confuse the inexperienced. It is stated that "more than 30 ml. of this strength [2%] would constitute an overdose in most patients." I would suggest that more than 25 ml. of 2% lignocaine should be considered an overdose, whereas the maximum dose of procaine is definitely higher than this, and is usually considered to be 1 g. Goldberg¹⁻³ and Hunter,⁴ after careful experiments with lignocaine, recommend that the safe maximum dose should not exceed 500 mg. (25 ml. of 2% solution). Since Goldberg considered lignocaine 2% to be twice as toxic as 2% procaine, it behoves the anaesthetist to be particularly careful when injecting the former into a particularly vascular area.

At St. Mark's Hospital, Mr. W. B. Gabriel has been using 2% procaine with 1 in 80,000 adrenaline into the perianal space and ischiorectal space, 20 ml. on each side, without any untoward result for many years. This amount of adrenaline is necessary to overcome the strong vasodilator action of procaine, and certainly delays absorption, the analgesia sometimes lasting for as much as five hours. I have never seen any reaction to this concentration of adrenaline other than a transient rise of pulse rate in some patients. Lignocaine 2% with 1 in 80,000 adrenaline is also used in the same manner at St. Mark's, but the dose injected is 10 ml. each side with equally good results. It has been my practice lately to give thiopentone 300 mg., followed by chlorpromazine 12 mg., promethazine 25 mg., and pethidine 25 mg. prior to the local injection in nervous patients, with excellent results. The patient does not rouse when the lignocaine is injected and sleeps for about two hours post-operatively. "Omnopon" $\frac{1}{2}$ gr. (22 mg.) and scopolamine $\frac{1}{150}$ gr. (0.43 mg.) are given as premedication one hour before operation.—I am, etc.,

London, W.1.

Paediatric Anaesthesia

SIR,—I read with interest Dr. W. N. Rollason's reply (*Journal*, September 29, 1956, p. 769) to Dr. John Bullough's letter (*Journal*, August 11, 1956, p. 360), in reference to premedication and anaesthesia for guillotine tonsillectomy in children. I agree with Dr. Rollason's criticism, and add with sincerity of purpose that in this era of prolific manufacture of drugs some of the older innocuous tranquillizers, in particular chloral hydrate, are not given the publicity they deserve. The crux of the matter is to achieve the tranquillity of the patient with safety before, during, and after the operation. I have used syrup of chloral in 4 gr. per stone (0.3 g. per 6.4 kg.) body weight, with excellent results, and would suggest that its overall safety should certainly justify its continued use as a sedative pre-operatively and post-operatively if necessary.—I am, etc.,

Gisborne, N. Zealand.

R. M. B. PENHEAROW.

Tonsils and Adenoids

SIR,—I have just read the article by Dr. J. Fry (*Journal*, January 19, p. 124). My comment is, I could not agree more. Tonsillectomy is recommended too often by some practitioners.

As far as my work as a school medical officer is concerned, practically speaking I never recommend tonsil or adenoid removal in school entrants (5- or 6-year-olds). I think a child has some tonsillar infection I arrange to see him again the following year, and often a third time another year or more later, before I refer him to an otolaryngologist. All indications mentioned by Dr. Fry are taken into account including the history as given by the parents. One thing is certain: we do see patients at school inspections who never attend their general practitioners and who eventually do require tonsillectomy. Even in these days of an apparent free Health Service some parents do not take their children to the doctor or call him when they ought to do so. These children have a history of frequent colds (the catarrhal child which I am convinced are undiagnosed (because not seen by a doctor) tonsillitis).

Dr. Fry says quite truthfully that children grow out of their tonsillitis tendency. In one's "critical assessment" one must take into account the amount of continuous or repeated discomfort and misery that the child may have to go through before growing out of it. I can remember vividly one poor boy whose parents would not give consent that he should see an otolaryngologist with a view to tonsillectomy. He was persistently deaf from his hypertrophic adenoids. Eventually at about the age of 10 years (not 6 as this passed off and the tonsils shrank. He was well behind the other children in his education, as, even when present at school, he could not hear properly. I could say more about this case and why tonsillectomy was not done, but I will not as I should probably get a come-back.—I am, etc.,

Kettering.

MURIEL C. GOODCHILD.

Antiseptics in Midwifery

SIR,—We have read with interest the paper "Antiseptic in Midwifery," by Dr. R. M. Calman and Dr. J. Murra (*Journal*, July 28, 1956, p. 200), and we note particularly the comparison of the quaternary ammonium (Q.A.) compounds, such as cetrimide and benzalkonium chloride, with chlorhexidine. These results are of particular interest in the light of similar investigations now being carried out in our laboratories with benzalkonium chloride and chlorhexidine.

The general intention of the authors is that the field of investigation should cover the value of the compounds not only *in vitro* but also in the field of the sterilization of the skin in midwifery practice and in the treatment of wounds. While we would agree that the *in vitro* tests show chlorhexidine to possess an advantage in activity over benzalkonium chloride against *Ps. pyocyanea*, we would submit that *in vitro* conditions are not those appertaining when attempting to measure sterilization of the skin. The authors have not attempted to measure the activity of chlorhexidine on the skin in the same manner as Colebrook¹ did in his investigations on chloroxylonol. It is now well known that the Q.A. compounds are highly adsorbed on certain surfaces and when so adsorbed retain their bactericidal action over a long period. Thus Steingold *et al.*² showed that benzalkonium chloride is adsorbed on to wool, such as blankets and that the adsorption is so pronounced and so firm that the blanket yielded three successive water extractions, all of which inhibited the growth of *Staphylococcus aureus* and streptococci in nutrient broth.

Blankets on which Q.A. compounds are adsorbed, even after rinsing with water and drying, have a surface which is highly bactericidal to droplet-infection of these organisms. We have now evidence that Q.A. compounds are similarly adsorbed on to the skin, and it would be interesting to know if chlorhexidine is adsorbed in the same manner. It

is therefore of importance to take this factor into account when assessing the value of a skin-sterilizing agent. We would suggest, therefore, that the authors should extend their work on chlorhexidine and the Q.A. compounds to include actual experiments on skin, as in Colebrook's experiments, and that the test organisms be the natural skin flora and a haemolytic streptococcus in blood. Our preliminary experiments in this field have shown that there is little difference between chlorhexidine and benzalkonium chloride against the natural skin flora, but a difference does occur in favour of the latter against a haemolytic streptococcus, which, after all, is of major importance in gynaecology.—I am, etc.,

Hospital Confinement

SIR,—In many areas, our own included, there is still a shortage of beds for hospital confinement. The emphasis has therefore been on persuading patients to stay at home.

A recent tragedy, and several near tragedies, have made us think it necessary to stress once more those patients who should not be accepted for home confinement. They include: (1) patients having their fifth (or later) child; (2) patients with medical or surgical complications; (3) patients with past obstetric complications; (4) cases of pre-eclamptic toxæmia, essential hypertension, or kidney disease; (5) multiple pregnancies; (6) persistent breech presentation; (7) premature labours. This is a minimal list. Of course, some of these conditions may only become apparent late in pregnancy in a patient already booked for domiciliary delivery, but most hospitals reserve some beds for such late bookings, and all should do so.

We feel that all general practitioners and midwives should realize that a domiciliary booking is not irrevocable, and a direct simple reference to a hospital antenatal clinic, or a direct contact with the hospital, should enable them to shift the responsibility for such worrying cases. We would appreciate the views of general practitioners, midwives, and other obstetricians.—We are, etc.,

Windsor.

C. T. F. EALAND. D. MAXWELL.

Gestation and Sex

SIR,—The suggestion made by McKeown,¹ as quoted in your leading article (*Journal*, February 23, p. 451), that the sex of a child might be related to the time in the menstrual cycle when intercourse occurs, has already been investigated many years ago.

W. M. Feldman² relates an investigation carried out on 57 Jewish families where the ritual laws of "nidah" relating to intercourse had been strictly observed. These ritual laws prevent intercourse taking place at least 12 days from the beginning or seven days from the end of the menstrual flow. The figures show that, out of a total of 402 children, 205 were males and 197 were females, giving a sex ratio of 1,040:1,000, which is practically identical to the sex ratio given in the Registrar-General's return for 1911.³

On the strength of these statistics it was concluded at that time that "there is no evidence that in the human race the time of fertilization of the egg relative to the catamenial period has any influence on the sex ratio exhibited by the offspring." These same observations would also tend to discredit the suggestion of a relationship between the sex ratio of the offspring as related to the time of mating (pre- or post-ovulatory).—I am, etc.,

Stafford.

The Pill-box Mystery

SIR,—I appeal to the medical profession for support to my protest against the modern practice of dispensing chemists in Britain of removing proprietary drugs from their original containers into their own labelled bottles or cartons. This practice may occasion only temporary difficulty for people in Britain, but for people travelling abroad the consequences can be serious or even disastrous.

Nowadays, for the most part medicinal treatment is by proprietary drugs and to a minor degree by dispensed medicine. In France only drugs actually manufactured in France are on sale, and drugs issued in France the same as those made in other countries are generally given a different name. Constantly a doctor in France is faced by the problem of a travelling patient with one or several containers of tablets or capsules which bear only the dispensing chemist's name and address and a caption such as "One thrice daily."

This complaint is precipitated because of a very seriously ill patient who arrived with six containers each having drugs which it was impossible to identify. In the same week I was asked by a London consultant to administer an English drug which I do not know and is not sold in France under the same name, so I cabled to London for it to be sent out. Still I know nothing about it, nor how to administer it, because on arrival it had been removed from its original packing and put in the dispensing chemist's labelled box. I feel sure that it must be only in exceptional cases that doctors wish to disguise from patients the drugs they are being given.—I am, etc.,

Monte Carlo.

H. R. B. GIBSON.

The Hurt Brain

SIR,—Dr. E. E. Prebble's remarks (*Journal*, February 16, p. 399) on the validity of penicillin treatment of neurosyphilis is at variance with that of most authorities. J. Purdon Martin¹ says that penicillin is the standard and only remedy. If that fails nothing else will work. He says malaria is not justified and that arsenicals and bismuth are of no value. W. D. Nicol² recommends penicillin as the treatment of choice, but does occasionally favour malaria. C. S. Nicol³ concludes that penicillin alone is as good as penicillin plus malaria except in optic atrophy. He also warns that malarial therapy, except in expert hands, is dangerous.

Certainly the small number of cases I have treated during the last three years tends to support the view of these authorities. Out of six cases, four young acute cases with C.S.F. cell counts of over 100 showed complete or almost complete clinical recovery, and the cell counts returned to normal after not more than 10 injections of penicillin, each of one million units. One middle-aged case did not respond and died one month after malarial therapy. The other received malaria and arsenicals and bismuth and progressed to complete dementia. I should be interested to know the views of others, as, although as far as I can ascertain the authorities I have quoted and all the American authorities are agreed that penicillin is the only treatment, one does from time to time meet those who hold Dr. Prebble's opinion.—I am, etc.,

Wakefield, Yorks.

The Black Sheep

SIR,—Most members of the public health service would endorse what Dr. Allen Glenn says in his letter (*Journal*, March 2, p. 523), though with something of a rueful smile at his reference to "more stringent supervision by the sanitary authorities." In the first place, not even the new clean food legislation of the last year has given the health

department adequate powers. Broadly speaking, the law now requires that the food-handler and the food-seller shall be provided with the basic equipment in the way of premises and sanitary appliances and that persons who have good reason to believe that they may be sources of infection shall confess the fact and be excluded from food-handling. It does not demand that the premises and appliances shall be assiduously and intelligently used. One may lead the shop assistant to the wash-basin, but one cannot compel him to wash.

We might or might not get universal cleanliness in food-handling if public health inspectors were able to pay unheralded calls at every food-shop several times a day, but not even a quadrupling of the present strength of our staffs would provide for this. Even then there would be risks in momentary forgetfulness or deliberate time-saving dirtiness as soon as the inspector's back was turned. The long-term answer will have to be a multiple approach on some such lines as these:

(1) The individual food-handler will have to be educated in the importance of food hygiene and trained in its practice until scrupulous personal cleanliness and the use of "no-touch" techniques become virtually second nature. Most health departments are trying to do something on these lines, but the task is a big one and not all food-handlers are interested and intelligent enough to profit by such education.

(2) The public must be taught to understand at least the basic facts about food hygiene and to demand it of the shops from which they buy food (in the U.S.A. a good many food-handling establishments have realized that hygiene is a "selling-point," and have themselves helped to teach the public that it pays to buy hygienically processed, packed, and handled food).

(3) The law must no longer fight shy of the question of the protection of food in the shops, in handling, and in transit. There is no practical reason why all bread should not be wrapped, all meat covered while being carried across the street, all contaminable foods protected from contamination while on display, and all cooked meats ready weighed and wrapped before they are taken into the shop. Some of these might involve slight increases in cost (or decreases in profits), but others would not; some shops have found that the pre-packing of cooked meat actually saves cost and labour in the shop.

(4) The issue of compulsory registration of all food-handling and catering establishments must be squarely faced. The human element will always be present, and in the last resort what matters is the way in which a particular food or catering business is conducted. The carelessly conducted business is a public menace and ought not to be allowed to continue to operate. Again, some cities in the U.S.A. are a long way ahead of us. To quote from the report of one city's commissioner, "if the health inspector notifies a violation of the health code and the proprietor has not corrected it by the date of the inspector's next visit, the shop is closed down." It is a typical human paradox that if we had these powers the threat of their use would be enough and we should probably never need to use them.

The community, in short, has never taken its clean-food problems seriously, and every attempt to bring in progressive legislation has been impeded, delayed, and, in the event, partly frustrated by the vested interests. Perhaps if doctors as a whole woke up to the position their combined influence might possibly achieve something.—I am, etc.,

Colchester.

JOHN D. KERSHAW.

SIR,—I work in a mainly industrial practice, and cannot agree that 95% of bacillary dysentery is due to *Sonne bacillus* (*Journal*, January 26, p. 217). My figures are: 60% salmonella group (mainly *typhi-murium*); 35% *Sonne bacillus*; 5% miscellaneous. Both *Sonne* and salmonella are very difficult to control and treat because of the following: (1) the low standard of true hygiene in all walks of life—e.g., white coats often mean apparent rather than true cleanliness; (2) cloth towelling in toilets of schools, etc., used by numerous people before being washed—paper towelling is the ideal form; (3) working mothers are often prepared to send ill children to nursery or primary school because of loss of income if they stay at home; quite often the nursery staff are not informed of diarrhoea; (4) some women earn their living by caring for the children of several

working mothers, and are prepared to take children with diarrhoea, etc. When I tell mothers to keep cases of diarrhoea away from others the usual answer is, "I have to work, and it is only diarrhoea." To the average person "diarrhoea" means very little, but when labelled dysentery or gastro-enteritis everyone goes into a panic.

Clinically, bacillary dysentery varies from the apparently normal case (found by mass swabbing), or those with one small loose motion a day, to those with diarrhoea, vomiting, meningismus, and high pyrexia. The diarrhoea may not occur for up to three days after the onset of illness. I swab all cases of diarrhoea as a routine. My belief is that some of the increase in incidence of bacillary dysentery is real, but most is apparent. Mist. kaolin, and tab. vitamin B co., fluids (small and often), and grated raw apple relieve the diarrhoea and pain in 80% of cases, irrespective of the cause. *Sonne* dysentery responds well to sulphonamides, neomycin, or both, giving negative swabs in about 10 days. *Salmonella* responds to the above treatments clinically but not bacteriologically, and negative swabs are not obtained before four to six weeks. I tend to believe that sulphonamides and neomycin have a very small, if any, place in the treatment of salmonella. At least two negative swabs at weekly intervals are necessary to confirm successful treatment.

Recurrences in the same patient tend to suggest the possibility that the organisms, especially salmonella, are capable of existence in dust, clothing, or furniture.

With the increase in hospital confinements the possibility of introducing infection into maternity wards is great, if not real. The same applies to children.—I am, etc.,

Bradford, 1.

E. BREEN.

Hospital Falls

SIR,—A survivor can only welcome Dr. Gavin Thurston's article on this unpleasant subject (*Journal*, February 16, p. 396). There are, of course, certain objections to the placing of bars at windows, but at least let staff be discouraged from actually facilitating matters when there is already evidence of, for example, a toxic psychosis. One does not seek to make excuses for one's conduct, but the fact remains that the arrangement beside an open window of a table and chair with the chair pointing outwards may ultimately be the deciding factor for a mind that is confused, desperate, but still wavering.—I am, etc.,

Cambridge.

J. C. HALL.

Operation for Midline Epigastric Hernia

SIR,—Mr. H. A. McDonald has described (*Journal*, February 23, p. 446) an interesting repair of an epigastric incisional hernia, but admits to a fair amount of troublesome bleeding during the procedure. For some years I have followed the method first described by Cattell in 1942¹ and again in 1949,² and doubt if it can be bettered. It may be used for a ventral hernia above or below the umbilicus. As it does not seem to be widely known, a brief description may be helpful.

An oval of excess skin with the scar is first excised, the lateral flaps being dissected back to expose the fascia. The sac is opened, and then follows the principal point of his technique, which is very ingenious. He does not attempt to dissect out the various layers of the abdominal wall, but forthwith uses a continuous suture, passing it from within the sac through the full thickness of the hernial "ring," which consists of all the layers of the abdominal wall except skin and fat. When the "ring" is thus obliterated the recti are found to be drawn together. Then follows the suturing of the edges of the neck of the sac after its redundant portion has been excised. Next the rectus sheath on each side, close to the midline, is incised longitudinally and the medial flaps of fascia so formed are sutured. Thereafter by interrupted sutures, in separate layers, the rectus muscle of each side, the lateral cut edges of the rectus sheath of both sides (though it may not be possible to approximate these without relieving incisions still further out), and finally skin are brought together. Thus there are six rows of

suture overlying one another. The material used is optional. The technique is not difficult and relatively bloodless, and I have used it in a number of cases with satisfactory results. In some cases all the above layers may not require suturing. It does of course mean opening into the peritoneal cavity, but this allows of a quick exploration and freeing of near-by adhesions. On the other hand, Maingot³ advocates a "keel" repair and stresses the advantages of not opening the peritoneum. However, any surgeon interested in trying out this operation should read, if possible, Cattell's articles, or at least his later one.—I am, etc.,

Hitchin, Herts.

Treatment of Hypopituitarism

SIR,—The interesting article by Drs. R. N. Beck and D. A. D. Montgomery (*Journal*, February 23, p. 441) contains the statement: "From a study of the patients and their response to treatment it seems clear that the only drugs which played a significant part in their recovery were thyroid and cortisone."

It is well known that the symptoms of hypopituitarism usually evolve slowly, often over a period of many years; the cases they cite had had post-partum haemorrhage 3, 15, and 17 years previously. Following diagnosis these were given what the authors call "combined therapy" for 10, 9, 9, and 20 months respectively. Subsequently they were given cortisone alone; one of the four required the addition of thyroid. Similar experience was mentioned in three other patients, one of whom needed thyroid also. The maximum specified time on this treatment was 11 months. Surely this period is inadequate to justify the statement they make.—I am, etc.,

Glasgow.

T. B. STRETTON.

Glycyrrhetic Acid

SIR,—Recently numbers of clinical trials have been carried out comparing the actions of glycyrrhetic acid and hydrocortisone as local applications in cases of eczema and other skin conditions. These have been based on a theory that glycyrrhetic acid has cortisone-like properties, and thus may be a substitute for the more expensive cortisone. The short review of the subject which follows shows that, far from having any cortisone-like anti-inflammatory effects, glycyrrhetic acid may actually increase the inflammatory response of the tissues to injury.

Card *et al.*¹ found that crude liquorice extract caused salt and water retention and potassium loss in normal persons, and that glycyrrhetic acid had the same effect. Although they were able to reverse the abnormal electrolyte pattern in a case of Addison's disease, yet they found the glycyrrhetic acid did not prolong the lives of adrenalectomized rats. Pelsner *et al.*² treated several cases of Addison's disease, and were able to correct the salt and water balance, but they found that there was no cortisone-like effect on the circulating eosinophils or the blood-sugar levels. Borst *et al.*³ found that glycyrrhetic acid did not correct the electrolyte balance in certain cases of Addison's disease until small amounts of cortisone were added, and therefore concluded that some functional adrenocortical tissue must be present before glycyrrhetic acid became effective. Rowland J. Calvert⁴ found that there was no significant change in the Kepler test, or in the blood-sugar levels, in a case of Addison's disease during treatment with glycyrrhetic acid. Louis and Conn⁵ found that glycyrrhetic acid caused great retention of sodium, chloride, and water, and had a mild effect in increasing urinary potassium, and that it had no demonstrable effect in the metabolism of protein, carbohydrate, uric acid, creatinine, or on the level of the circulating eosinophils, and they found a persistent diminution of the excretion of 17-ketosteroids and some inhibition of the production of corticotrophin. This evidence shows that

glycyrrhetic acid does resemble to some extent the desoxycorticoids, but, as it does not affect the metabolism of carbohydrate, protein, and uric acid, and has no effect on the circulating eosinophils, it cannot be said to have a cortisone-like action. Ingle and Baker⁶ state that the desoxycorticoids may increase the inflammatory response to tissue injury.

The position therefore seems to be that glycyrrhetic acid has no anti-inflammatory effects of a cortisone-like nature, and there would seem to be little or no justification for its use in the acute inflammatory dermatoses, either locally or systemically, especially in view of the observation of Louis and Conn that it inhibits the production of corticotrophin and therefore actually reduces the amount of cortisone available.—I am, etc.,

Glasgow.

SIR,—In a recent letter (*Journal*, February 23, p. 463) our colleague, Dr. G. F. Somers, reported that in his experiments some fractions of glycyrrhetic acid were active against certain types of induced inflammation. We have also carried out animal experiments independently of Dr. Somers and have tested a sample of glycyrrhetic acid, obtained from a different source (melting point: 291–3°C.; specific rotation +156 in absolute alcohol at 19°C.). The sample was tested for anti-inflammatory activity by our modification of the cotton-pellet granulation tissue method of Meier, Schuler, and Desaulles.¹ Our results show that the sample has anti-inflammatory activity in this test, in which cortisone acetate and hydrocortisone acetate are active when tested under the same experimental conditions.

Dr. B. F. Russell, writing on this topic (*Journal*, December 22, 1956, p. 1483), mentioned that, although the first use of glycyrrhetic acid as a topical anti-inflammatory agent was based on the assumption that liquorice had a deoxycortone-like action, he was unaware of any report suggesting that deoxycortone had an anti-inflammatory action when applied to the skin. In our experiments we have also been able to show that deoxycortone has anti-inflammatory activity in the cotton-pellet test. We are carrying out further experiments to investigate the mode of action of glycyrrhetic acid in induced inflammatory conditions.—We are, etc.,

Medical Advice in the Lay Press

SIR,—In a recent number of a national newspaper the newspaper's doctor published the following question and answer.

Question.—"I am troubled with shortness of breath and a fullness in the stomach. I can hardly eat anything, especially sweet food. My age is 60 and I am getting depressed."

Answer.—"Flatulence responds to half a teaspoonful of olive oil half an hour before each meal. If you are overweight, as I suspect, you should also diet. Cut down on everything made with flour, take no fat or greasy food, don't add salt to your food and reduce your fluid intake to a minimum."

The symptoms of the questioner, as published, could be due to heart failure or a carcinoma of the stomach, for example. This seems to raise the question of the desirability of such a postal service for making a diagnosis and prescribing treatment. In reply to my protest I was told that the question was abbreviated from a longer letter which seemed

to permit the answer given. If the service is for the individual questioner, then there is no need to publish question or answer. If both are intended for a wider public, then surely the answer published must apply to the question as published, for others beside the questioner may act on the advice given.

I draw attention to this in the probably vain hope that wider publicity may discourage such potentially dangerous practices in the lay press.—I am, etc.,

Edinburgh, 9.

M. B. MATTHEWS.

Relaxant Technique

SIR,—Drs. D. D. B. Morris and C. H. Dunn (*Journal*, February 16, p. 383) conclude that suxamethonium is not the relaxant of choice for anaesthesia in patients discharged from hospital within 48 hours. With this I would not disagree. I must strongly reject, however, their alternative recommendation that, to avoid post-operative muscle pains in these patients, D-tubocurarine should be administered before the suxamethonium. Their advice may lead anaesthetists to suppose that this technique is without danger of complications. Merely to observe the effects of a "test-dose" of D-tubocurarine is no guard against some of the possible mechanisms which may be initiated subsequently by such relaxant sequences.

It has recently been stressed that mixed relaxant techniques should be discouraged,^{1,2} a conclusion based on evidence that prolonged administration of a depolarizing drug makes the end-plate resistant to depolarizing influences—and consequently more susceptible to non-depolarizing relaxants. In the D-tubocurarine-suxamethonium technique recommended, should the surgical requirements necessitate an extended period of relaxation the resistance of the end-plate to depolarization may reach such a degree that the previously ineffective (but possibly still circulating) non-depolarizing drug might now lead to recurarization. Cases of prolonged apnoea have been reported after similar circumstances, and maybe it is not always justified to presume that the paralysis "could be definitely attributed to the suxamethonium."³

Other possible mechanisms by which this sequence of relaxants may not infrequently produce unexpected results can easily be demonstrated and have been experienced by anaesthetists who make a practice of using suxamethonium for closure of the surgical wound following D-tubocurarine maintenance. The administration of suxamethonium to a patient who has a minimal dose of a competitive blocking agent circulating is an encouragement to the former to act as a non-depolarizing drug. The non-depolarizing action of suxamethonium is still relatively "short-acting," but it is of a lesser intensity and of longer duration than its comparable depolarizing effect.⁴ Therefore, if attempts are made to maintain the level of paralysis usually associated with the normal action of suxamethonium, rapid accumulation may occur.

Some would have us believe that the relaxant agents are wayward drugs, continually running off the rails deliberately to betray the innocent administrator. Atypical, unexpected, and unpredictable are some of the adjectives used to describe their effects when the administrator finds himself in difficulties. In the light of the new facts now being established, these effects are to be expected; they are quite typical; they can be predicted with a great degree of certainty. Let the relaxants be your friend, and do not abuse them. The indiscriminate use of these agents in mixed sequences when the possible mechanisms and dangers involved are not fully understood can only aggravate much of the unpleasant and undeserved notoriety which neuromuscular blocking agents have received of late.—I am, etc.,

Portsmouth.

Obituary

EVARTS A. GRAHAM, M.D., LL.D., F.A.C.S.

Hon. F.R.C.S., Hon. F.R.C.S.Ed.

Dr. Evarts A. Graham, emeritus professor of surgery at the Washington University School of Medicine, St. Louis, and formerly surgeon-in-chief at the Barnes Hospital and St. Louis Children's Hospital, died in hospital at St. Louis on March 4 at the age of 73. Because of his technical brilliance and personal qualities as a teacher and leader he was one of the most distinguished surgeons in the world and will be remembered both for his research work and for his contributions to clinical surgery, which included the first successful removal of a lung for carcinoma of the bronchus.

Evarts Ambrose Graham was born in Chicago on March 19, 1883, and educated at Princeton University.

He studied medicine at Rush Medical College, Chicago, graduating M.D. in 1907 and shortly afterwards being appointed assistant surgeon there. In 1919 he became professor of surgery at Washington University School of Medicine, St. Louis, where for the next thirty years he worked as surgeon-in-chief at the Barnes Hospital and at the Children's Hospital. One of the advances with which his name will always be associated was

the introduction of cholecystography, his paper on the roentgenological examination of the gall-bladder being published in the *Journal of the American Medical Association* in 1924. One of the first to specialize in thoracic surgery, Dr. Graham in 1933 operated on a medical man with cancer of the lung. This was the first successful removal of an entire lung for this condition: the patient is still alive and for many years after the operation carried on a large obstetric practice.

Dr. Graham retired in 1951 from the active staff of the hospitals and university with which he had been so long associated, but he continued to undertake important research. During the second world war he served on many Government committees, holding among other important posts the chairmanship of the Committee in Surgery of the National Research Council in Washington, and did much to raise the standards of surgery throughout the United States, especially as one of the founders of the American Board of Surgery. In recent years he had assisted in the statistical investigation into the connexion between lung cancer and cigarette smoking, and in 1950, with Professor Wynder, he published one of the earliest reports on the subject.

Dr. Graham paid many visits to Britain, and in 1939 he worked for a time at St. Bartholomew's Hospital, London, as temporary professor; the medical college there awarded him the title of Honorary Perpetual Student, the highest honour in its power to confer on strangers. In his own country Dr. Graham was honoured by the presidency of the American College of Surgeons, of the American Surgical Association, and of

MARCH 16, 1957

OBITUARY

the Association for Thoracic Surgery. He received numerous prizes, medals, and honorary degrees, including the honorary LL.D. of the Universities of Glasgow and Leeds. He was admitted to the honorary Fellowship of the Royal College of Surgeons of England in 1943, when Major-General W. H. (now Sir Heneage) Ogilvie visited Washington, and at the same time he was awarded the Lister Medal. He was also an honorary Fellow of the Royal Society of Medicine and an honorary member of the British Thoracic Society, and of many similar societies in other countries. It was not until 1947 that he was able to come to Britain to deliver the Lister Oration, the subject of which was "Some Aspects of Bronchogenic Carcinoma."

In addition to his other work Dr. Graham was a notable medical editor. For many years he was one of the co-editors of the *Archives of Surgery*, and he also edited the *Journal of Thoracic Surgery* and the *Year Book of Surgery*. In 1950 he was awarded the Distinguished Service Medal of the American Medical Association. Three years ago Dr. Graham came with other Fellows of the American College of Surgeons on a visit to Great Britain, and he was admitted to the honorary Fellowship of the Royal College of Surgeons of Edinburgh a few days after giving the second Sir John Fraser Memorial Lecture in the University of Edinburgh on the subject of cancer of the lung. In recent years he was chairman of the Board of Regents of the American College of Surgeons, and in 1953 he was President of the International Congress of Surgeons. A distinction he particularly valued was the Charles A. Mickle Fellowship, awarded to him in 1943 by the Council of the Faculty of Medicine of the University of Toronto. This honour is given "to that member of the medical profession who is considered by the council to have done the most during the preceding ten years to advance sound knowledge of a practical kind in medical art or science."

We are indebted to Sir RUSSELL BROCK for the following appreciation:

Evarts Graham was probably the greatest surgeon produced anywhere in the world in the first fifty years of this century. He went to St. Louis as professor of surgery after the first world war with already a considerable reputation as a surgical investigator as a result of his work on empyema. He found Barnes Hospital a rather small and unimportant place. When he retired two or three years ago it was transformed in many ways, all due to his genius. It had become a large collection of well-organized and well-equipped buildings comprising over 1,000 hospital beds. He had an unusual and apparently a very simple efficiency in persuading wealthy donors to provide what he wanted for expansion.

The hospital had become a world-renowned centre for much that was new and progressive in surgery. In the 1920's cholecystography was born and has continued a healthy existence. In the 1930's came his pioneer work on thoracic surgery, culminating in the first successful pneumonectomy for bronchial carcinoma. That first patient, still alive 24 years after, became an inspiration and stimulus to all surgeons who followed Graham's footsteps in those early difficult days of the surgical treatment of lung cancer, in which despair could easily quench enthusiasm.

By the time of the second world war he had become an elder statesman of surgery and nearly exhausted himself in the many government duties which he added to his routine work. In the last years of his active work he led the statistical and experimental research which drew world-wide attention to the causal relationship between cigarette smoking and lung cancer.

His personal contributions to surgery make him a surgical immortal, but to those who had the privilege of working with him he had yet another greatness, the power of inspiring and guiding young surgeons. Graham's "boys" are to be found the world over, many of them holding top-rank surgical professorships. There are at least half a dozen surgeons in Great Britain who can attest to the great and lifelong influence that he had on them and their work.

Graham was on the whole a quietly diffident man with a pleasant and friendly smile. When necessary, however, he was capable of holding his own with anyone. He was a charming and accomplished lecturer who put over his strongly held views with sincerity and conviction.

An honorary fellow of the Royal College of Surgeons of England, he was looked upon as a real friend and, indeed, almost an elder statesman of English surgery. We look back with pleasure to the numerous visits he was able to pay to Europe and to London during the last few years. The irony of fate decreed that he should die from the very disease he had done so much to alleviate. Fate, however, was kind in that the course of his final illness was mercifully swift.

D. W. CARMALT JONES, D.M., F.R.C.P.
F.R.A.C.P.

Professor D. W. Carmalt Jones, emeritus professor of systematic medicine in the University of Otago, New Zealand, died peacefully at his home at Edgware, Middlesex, on March 5. He was 82 years of age.

Dudley William Carmalt Jones was born in London on August 30, 1874, the eldest son of Mr. T. W. Carmalt Jones, who was a laryngologist. From Uppingham School he went on to Corpus Christi College, Oxford, where, intending to enter the teaching profession, he at first took classics. However, a year or two later he decided to become a doctor and entered St. Mary's Hospital for his clinical training, graduating B.M., B.Ch. in 1903. After holding the appointments of house-surgeon and house-physician at St. Mary's, he became senior house-physician at the National Hospital for the Paralyzed, Maida Vale. Returning to St. Mary's,

he was appointed an assistant in the laboratory of Sir Almroth Wright, whom he revered, saying that for him the world consisted of two kinds of people—Sir Almroth Wright and all the others. Elected a Member of the Royal College of Physicians of London in 1907, he joined the staff of the Seamen's Hospital, Greenwich, as an assistant physician. In the following year he became assistant physician at the Westminster Hospital, and in 1910 was appointed honorary director of the department of bacterio-therapeutics, a post he held until the end of 1913. Earlier in that year he was elected full physician to the hospital, and for a time was dean of the medical school. He proceeded to the D.M. in 1911 and was elected F.R.C.P. in 1914. He served in the R.A.M.C. throughout the first world war, in France from 1915 to 1918 and as consulting physician to the Egyptian Expeditionary Force in 1918–19, attaining the rank of temporary colonel. As a result of his wartime experience he published papers in *Brain* and

in the *Quarterly Journal of Medicine* on "war-neurasthenia" and on segmental hyperalgesia in visceral lesions.

Carmalt Jones was appointed Mary Glendining professor of systematic medicine in the University of Otago in 1920. When he resigned from the staff of the Westminster in order to take up his new appointment he was made consulting physician to the hospital, retaining this honorary appointment until his death. His work in New Zealand hardly offered the opportunities for research he had in London, for his main duty—and one he gladly accepted—was to teach elementary medicine to undergraduates. His clinical teaching was given in the wards of Dunedin Hospital, to which he became physician and, later, consulting physician. For a good many years he had a private consulting practice, but his work at the university and hospital increased to such an extent that he decided to give his whole time to it. In the wards he taught by example, insisting on a thorough examination of the patient and on the keeping of full and accurate records of clinical findings. By nature he was gentle and kindly, and patients were human beings to be treated with courtesy, kindness, and patience. All this was readily gleaned by his students, and he did not falter in his determination to give them the soundest possible instruction in the basic principles of medicine. His efforts did much to enhance the reputation of the New Zealand school of medicine, and many of his students made their mark in later years in Britain and elsewhere. Carmalt Jones retired from the chair of systematic medicine in 1939 and in the following year was appointed professor emeritus. Later he returned to live in England.

The Dunedin representative on the editorial committee of the *New Zealand Medical Journal* for many years, Carmalt Jones was also responsible for the first publication of the *Proceedings of the University of Otago Medical School*, which reached its sixteenth number in 1939 under his sole editorship. He was the author of *An Introduction to Therapeutic Inoculation* (1911) and *Organic Substances, Sera and Vaccines in Physiological Therapeutics* (1924). He also wrote *Elementary Medicine in Terms of Physiology* in 1929—a book clearly from the pen of a first-class teacher—and the *Annals of the University of Otago Medical School, 1875-1939*, published in 1945, which is an interesting volume recording not only the history of medicine in New Zealand but also the general history of the Dominion, with a chapter on its fauna and flora.

A member of the British Medical Association for nearly fifty years, he was president of the New Zealand Branch in 1935-6. In 1938 he became a foundation Fellow and Vice-President and a member of the first council of the Royal Australasian College of Physicians.

Carmalt Jones was a cultured man, educated in the old classical tradition. He had many interests outside medicine, literature in particular. Some of the sonnets which he wrote were put to music. He had an enviable talent as a draughtsman and often illustrated his own Christmas cards. In New Zealand he developed a keen interest in ceramics, and helped to look after one of the national collections. A great walker, he also became a renowned trout fisherman. In recent years, after his return to England, his eyesight began to fail, and this prompted his interest in the Edgware and District Club for the Blind, of which he was honorary secretary for some time.

In 1907 he married Miss Mabel G. Tottenham and had one son and one daughter. Mrs. Carmalt Jones died in 1955.

H. C. ELDER, M.B., M.R.C.P.Ed., D.P.H.

Dr. H. C. Elder, formerly chief tuberculosis officer for the Corporation of Edinburgh, died at his home in that city on February 23 at the age of 68.

A native of Dundee, Herbert Calder Elder studied medicine at the University of St. Andrews, and later at Edinburgh, where he graduated M.B., Ch.B. in 1917. He was then appointed house-physician to Sir Robert Philip's wards in the Royal Infirmary. In 1920 he was elected a Member of the Royal College of Physicians of Edinburgh and he took the D.P.H. of the Scottish Royal Colleges in 1929. His association for the first two years of his medical career with the most eminent phthisiologist of the period provoked and maintained an enthusiastic interest in tuberculosis for the remainder of his lifetime. This subsequently led to his appointment as consultant tuberculosis officer to Edinburgh Corporation in 1921 and to his promotion nine years later as chief of the department, from which he retired in December, 1953, after 32 years of conscientious service.

The clarity of vision which Elder brought to the diagnostic study of diseases of the chest and his excellent command of the French language allowed him to appreciate the significance of Forrester's work on the investigation of the broncho-pulmonary system by means of "lipiodol" at an early stage, and he was one of the first clinicians to introduce the method into this country. Written in collaboration with Dr. John Guy and published in the *Edinburgh Medical Journal* of May, 1926, their article on the results of their research into the possibilities of bronchography was the first British contribution to the literature on this subject. With his great ability as a linguist Elder gained a profound knowledge of the Continental literature on his subject, and he did not hesitate to adopt from this source any further innovations which he considered to be of advantage in his practice as a chest physician. His attainments were eventually recognized by his appointment as lecturer in tuberculosis to the medical school of the Edinburgh Royal College of Physicians in 1930, from which post he resigned in 1939.

Elder had many and diverse interests to which he brought the same concentration and scrupulous care for detail which characterized his professional life. He was an accomplished pianist, and had an extensive knowledge of classical literature, from which he quickly produced many a pertinent quotation to suit the occasion, no matter how unexpected it might be. In the realm of sport he concentrated mainly on golf, a game at which he was a scratch player. Shy and retiring by nature, he was apt to hide his reserve with a brusqueness which gave a mistaken impression of his essential kindness and sympathy and made him a difficult man with whom to establish any degree of intimacy. As physician-superintendent of the Royal Victoria Hospital, and physician in charge of the tuberculosis wards in the City Hospital and of the out-patient clinic at the Royal Victoria Dispensary during his tenure as chief tuberculosis officer, he had the affection of his patients, who seldom failed to appreciate his warm devotion and interest in their welfare. He is survived by his wife, to whom our sympathy is extended.—J. McD. S.

H. S. STANNUS, C.B.E., M.D., Ph.D., F.R.C.P., D.T.M.&H.

Dr. J. MOORE writes:

It was with great sorrow, I am sure, that those who knew him heard of the death of Hugh Stannus Stannus, whose obituary was published in the *Journal* of March 9 (p. 589). Having known him more than twoscore years and having been a colleague of his at the French Hospital for more than 30 years, it is with much emotion that I write these too few lines concerning him; frequent exchange of views on the same professional occupation and especially in medicine fosters most friendly ties and esteem. Having accepted the compliment of being chosen to honour his memory, I began to wonder why it had fallen upon me. I came to realize that, though academically different, our careers had often coincided with each other. I became a postgraduate student at St. Thomas's Hospital, where he had been house-physician and senior ophthalmic house-surgeon. I was resident medical officer at the British Hospital in Paris a few years after he had held that post; he had followed a postgraduate course in a Paris hospital where I was house-physician; I was appointed physician to the French Hospital, and for a number of years we were both in charge of out-patients on alternate days. If I mention these coincidences it is because they gave me the opportunities to discover to what extent he had been appreciated by staff and patients in all those instances. I also remember deputizing for him during two periods of six weeks at the Board of Inland Revenue, where he was medical adviser, and again I heard his praise. He was an inborn common-sense psychologist. His special knowledge in tropical medicine was recognized when he became physician on the associate staff to the Hospital for Tropical Diseases in London and examiner in tropical medicine at the University of Liverpool. I cannot illustrate better how he linked his enthusiastic scientific interest with his human feelings than by putting on record his attitude when, fresh from Paris, I told him of the successes obtained there with Wagner von Jauregg's malaria therapy in G.P.I., and I asked him to help me to give such pyrexia-choc-therapy to a man patient suffering from this condition and who after the cure was able to resume his occupation as manager to a large hotel. I recall this case because I shall never forget the great scientific care he took over it, as well as his most human anxiety for the patient in the course of the therapeutic procedure. On his retirement as senior physician to the French Hospital in London he was made consultant physician, and since 1934 had been a member of the committee of management, which will I am sure miss his impartial opinion. I feel that all the Fellows of the Royal Society of Medicine who knew him will, like myself, miss his greeting smile in the library and talks with him in the lounge, as well as his amiable manner and that happy smile which so often developed into a discreet, almost bashful, laugh: and we shall all keep the pleasant memory of very interesting and most congenial moments spent with him.

Medical Notes in Parliament

PRIME MINISTER ON DOCTORS' PAY

The PRIME MINISTER announced on March 12 the names of the Royal Commission to consider the remuneration of doctors in the Health Service. The chairman is Sir Harry Pilkington, chairman of Pilkington Bros., company director, director of the Bank of England, president of the F.B.I., 1953-5. The other members are: Mrs. Baxter, secretary to the Cambridge University Women's Appointments Board; Mr. A. D. Bonham-Carter, a director of Unilevers; Mr. J. H. Gunlake, vice-chairman of the Institute of Actuaries; Professor J. Jewkes, Professor of Economic Organization, Oxford University; Mr. I. D. McIntosh, headmaster of George Watson's College, Edinburgh; Sir D. Hughes Parry,

Q.C., Professor of English Law, London University; Sir Hugh Watson, Edinburgh, Deputy Keeper of Her Majesty's Signet; and Mr. Samuel Watson, secretary to the Durham Miners' Association.

More for Junior Hospital Staff

The PRIME MINISTER said he had asked the chairman to treat the work of the Royal Commission as a matter of urgency. He also explained that the appointment of the commission did not preclude an interim adjustment in advance and without prejudice to the recommendations. The Government had already decided to make such an adjustment without delay in the remuneration of junior hospital staff, medical and dental, up to and including the grade of senior registrar, all of whose remuneration would be increased by 10% from April 1. They were also considering what should be done by way of an interim adjustment for the other doctors and dentists covered by the commission's terms of reference. He would make a further statement on this in due course. The Government were convinced that this procedure was a fair and proper one. They were also confident that with good will on all sides it would result in the position of the medical and dental professions in the Health Service being placed on a mutually satisfactory and lasting basis.

Spens Recommendations

Dr. EDITH SUMMERSKILL (Warrington, Lab.) opened the interrogation of the Prime Minister by asking if this meant that the Spens recommendations were entirely repudiated and whether there would be some kind of arbitration machinery pending final recommendations of the commission. Mr. MACMILLAN said the Spens recommendations would be within the terms of the Royal Commission to consider. With regard to any interim arrangement, they were considering what could be done for those other than junior hospital staff who were covered by the commission's terms of reference. He also stated in answer to other questions that he thought the terms of reference were wide enough to deal with all the relevant matters, including assistant doctors. That would be for the commission itself to decide. He was asked what he meant by the phrase "in due course" and said he used these words because other expressions appeared to be unduly optimistic or unduly pessimistic.

Mr. SOMERVILLE HASTINGS (Barking, Lab.) said there was a strong feeling in the profession which had not existed with the passing of the Health Service Act, and he asked if the Prime Minister would instruct the commission to issue an interim report within a given time—say three months. Mr. MACMILLAN said he had considered that, but thought it better to deal immediately with the case that everybody thought well made out—the junior hospital staff—to try to get an interim adjustment for the remainder, and to let the commission produce a proper report as soon as it could.

Mr. M. LIPTON (Brixton, Lab.) said there would be a strong case for back-dating any interim adjustment for general practitioners to April 1, as for hospital doctors. Mr. MACMILLAN replied, "You had better wait and see from what date it is to start."

Hydrogen Bomb Tests

The Prime Minister was urged again on March 5 to take the initiative in halting further hydrogen bomb tests. Mr. W. WARBEY (Ashfield, Lab.) suggested that this should be done because of newly published evidence that the amount of strontium-90 and other radioactive particles released by such explosions had already reached a potentially dangerous level. Mr. MACMILLAN said he understood that the Medical Research Council had no evidence that the amount of strontium-90 and other radioactive particles released by hydrogen bomb explosions which might become sources of internal radiation had reached a potentially dangerous level. The present and foreseeable hazards, including genetic effects from external radiation due to fall-out from the test

explosions of nuclear weapons, fired at the present rate and in the present proportion of the different kinds, were considered to be negligible. Accordingly he was not prepared to postpone the forthcoming test in the Pacific. So far, however, as long-term policy was concerned, the policy of the Government had been clearly defined. Various proposals on nuclear and conventional disarmament would be considered when the United Nations Disarmament Subcommittee met on March 18.

Mr. WARBEY asked when the M.R.C. gave the Prime Minister this information, and if they took into account the new evidence produced by Dr. Libby, the American atomic energy commissioner, who according to a report showed that the level of strontium-90 would by 1970 reach a level as dangerous as that laid down in the M.R.C. standards. Mr. MACMILLAN said the M.R.C. report was published last June. The Council was in continuous touch with the matter. He stated in subsequent replies that the Government would prefer a broad disarmament agreement, covering the conventional as well as the unconventional weapons. Failing that, they would like an agreement for the limitation of tests. But he was not prepared to postpone the impending tests. Dr. EDITH SUMMERSKILL (Warrington, Lab.) said the Prime Minister's statement was considered out of date by the authorities, and could not be reconciled with what had been said by Professor Haddow, who was regarded as the greatest authority in this country on this subject. Mr. MACMILLAN replied that Governments could only rely on the best authorities they could find. The Medical Research Council comprised the best-organized and most efficient research on this matter that could be found.

Five Seconds Too Soon

Mr. GEOFFREY DE FREITAS (Lincoln, Lab.) asked the Minister of Supply by what type of Royal Air Force aircraft the damage done during an operation to the glass roof of the operating theatre of the Southport Infirmary was caused; and whether he would see that, in future, flights of this kind took place over the sea.

Mr. WILLIAM J. TAYLOR, the Parliamentary Secretary, stated that the aircraft concerned was a P.1 fighter flown by a pilot of the English Electric Company under contract with the Department. The aircraft was headed out to sea where the test was to take place. The pilot was obliged to get his position by radio bearings because there was cloud below him, and he passed through the sound barrier five seconds too early and just before crossing the coast. It was much regretted that damage was caused. For reasons that had been previously explained, no undertaking could be given to confine supersonic flying wholly to sea areas, although the Ministry did their utmost to avoid causing damage and inconvenience.

Meeting with Prime Minister

Mr. M. LIPTON (Brixton, Lab.) asked the Prime Minister on March 11 why he was arranging to meet representatives of the B.M.A. for the second time. Mr. R. A. BUTLER, who replied in the absence of Mr. Macmillan, said the Prime Minister would meet representatives of the joint negotiating committee of the medical profession on March 12, at their request. This would be the first time they had met. Mr. LIPTON.—If the Prime Minister is at last going to agree that the general practitioners are entitled to an interim adjustment of pay, why did he not say so clearly at the start, thus avoiding a lot of unnecessary ill-feeling? Is he trying to tiptoe out of an impossible situation? Mr. BUTLER replied "No," and explained that there were a number of questions on this subject for the following day, and he could not anticipate them. With reference to the Prime Minister's gait, he was not nearly so flat-footed as Mr. Lipton.

Royal Commission and Merit Awards

Mrs. LENA JEGER (Holborn and St. Pancras, South, Lab.) asked the Minister of Health whether it would be within

the terms of reference of the Royal Commission on doctors' and dentists' remuneration to consider the abolition of merit awards. Mr. VOSPER.—The Royal Commission will normally be concerned with levels of remuneration, not with methods as such. Whether or not questions such as that referred to are within its terms of reference must rest with the Commission itself to decide.

Group Practices

Sir KEITH JOSEPH (Leeds, North-east, Con.) asked the Minister of Health what was the proportion of general practitioners who at the latest available date were working single-handed, as opposed to working in partnership or group practice; and whether this was higher or lower than a year previously, and by how much. Mr. VOSPER said that on July 1, 1956, 34.42% of the general practitioners providing unrestricted medical services in the Health Service were in single-handed practice. This figure was 1.33% lower than the corresponding figure for a year earlier.

Prison Examination

Dr. BARNET STROSS (Stoke-on-Trent, Central, Lab.) asked the Home Secretary on March 7 whether he would institute procedure whereby every prisoner on entering prison would be fully examined in order to ascertain his full case history, and to assess his personality, in order that planned treatment should be available.

Mr. J. E. S. SIMON, Under-Secretary, Home Office, stated that such procedure already existed, and for prisoners sentenced to corrective training or preventive detention was carried out at an allocation centre with a specialized staff. For those sentenced to imprisonment it was not possible, pending the establishment of remand and observation centres, to carry out personality assessment on an equally satisfactory basis. In reply to a further question he said that, where the nature of the offence or other considerations suggested the need for special mental examination, the medical officer would make such an examination, and where there was a psychologist in post he would also have a psychological report.

Mr. Simon also told Dr. Stross that there were 46 doctors employed full-time in prisons in England and Wales, and six of them held the diploma of psychological medicine. Dr. STROSS suggested that it would be reasonable to ensure that as many as possible should have the diploma. Mr. SIMON said that for applications to the prison service the diploma was regarded as an advantage but not a prerequisite, because the posts did not involve full-time psychiatric work. When an outside consultant was brought in he was always a specialist.

Dental Repairs.—The cost to the general dental service of repairs to dental appliances is about £1m. a year in England and Wales. The Ministry of Health has no evidence suggesting that undue expenditure on repairs is being caused by deficiencies in the technical processes or materials employed.

Medico-Legal

PNEUMOCONIOSIS CASE RE-TRIED

A man who contracted pneumoconiosis and was awarded £9,645 damages against his employers in 1955 had the decision reversed at a re-trial by Mr. Justice Pearson in the High Court on March 7. Entering judgment with costs for defendants, Highway Ironfounders (West Bromwich) Ltd., his lordship said the misfortune of the case fell on the plaintiff, Walter Richards, of West Bromwich, and he was not entitled to damages.

In 1929 or 1930 Richards became a moulder in the employment of this firm. His job entailed filling moulds with molten metal, and, when they had cooled, knocking out the forms. During the knocking-out process clouds of

dust and sand are emitted. By 1946 Richards was seriously affected with silicosis; by 1948 he was incurably ill. By 1954, when he was in his forties, he was largely incapacitated. He then brought an action against his employers, claiming that, under s. 47 of the Factories Act, 1937, they ought to have provided him with a mask or respirator. Evidence was given at the original hearing that the silicosis had taken 15 years to develop and that in 1950 there were twenty different types of respirator, of which only one, the Mark IV, was known, in the light of later knowledge, to be capable of providing protection.

Mr. Justice Devlin had then decided that the mask ought to have been provided, and awarded £9,645 damages. On appeal the Court of Appeal directed a new trial on the question whether failure to provide Mark IV masks was a breach of the employers' obligation under s. 47, and, if so, to what extent Richards's condition was caused by their absence, since he had been in his job for 10 years before the masks became available.

Mr. Justice Pearson, giving judgment, said it was not appreciated by any competent person until about 1950 that a man doing the ordinary work of a foundry moulder could get pneumoconiosis. It was not known at the time the plaintiff contracted the disease, and the Master of the Rolls, during the Court of Appeal hearing, had said that precautions taken had to be in the light of established knowledge. It was admitted that the plaintiff contracted the disease in the course of his employment at the defendants' ironworks foundry from fine dust inhaled while making moulds. The materials used included sand and coal-dust, and the room was comparatively low. The silica dust which did the damage was in such small particles that it was invisible, but there was other dust which could be seen. Richards contended that, while it was true that the danger from the invisible dust was not known at the material time, masks should have been provided as a protection against the visible dust, and this would have afforded protection against the unknown invisible particles. This, said the judge, was an artificial issue. The employers had pleaded that it would have been futile to supply the masks, because the men would not have worn them. His lordship said this was untenable in law and did not absolve the defendants from their statutory duty, but he held that the use of the particular type of mask necessary under the circumstances—the Mark IV—would not have been a practicable measure. There had been no negligence or breach of statutory duty.

Vital Statistics

Tetanus in Hospital

Five cases of tetanus, two of them fatal, were reported last week as having occurred after surgical operations at the North Staffordshire Royal Infirmary, Stoke-on-Trent. On March 11 the city coroner, Mr. G. W. Huntbach, opened (and adjourned) an inquest on the two patients who died—men aged 52 and 43 respectively. The source of the infection is being investigated. When the inquest is resumed it will be held before a jury.

Defective Poliomyelitis Vaccine

The defect in the 47 vials of poliomyelitis vaccine in the latest batch (*Journal*, March 9, p. 594) has been traced to contamination by a non-pathogenic organism, *Pseudomonas fluorescens*. The contamination is attributed to faulty containers. Repeated sterility tests on the remainder of the batch have been negative, and tests by incubation at various temperatures have caused no discoloration of normally coloured vaccine. It has consequently been decided in agreement with the Medical Research Council to issue the rest

¹ *British Medical Journal*, 1955, 2, 1035.

of the vaccine. This information was given by the Chief Medical Officer of the Ministry of Health in a letter sent on March 11 to all medical officers of health.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases (deaths for influenza) of certain diseases notified weekly in England and Wales (great towns for influenza). Highest and lowest figures reported in each week during the years 1948–56 (influenza 1952–6) are shown thus ———, the figures for 1957 thus ———. Except for the curves showing notifications in 1957, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

The largest rises in the notifications of infectious diseases in England and Wales during the week ending February 23 were 1,607 for measles, from 19,710 to 21,317, 60 for scarlet fever, from 830 to 890, 27 for whooping-cough, from 3,163 to 3,190, and 22 for dysentery, from 1,274 to 1,296; the only large falls were 51 for acute pneumonia, from 676 to 625, and 48 for food-poisoning, from 187 to 139.

The largest rises in the incidence of measles were 437 in London, from 1,508 to 1,945, 233 in Warwickshire, from 381 to 614, 233 in Yorkshire West Riding, from 1,196 to 1,429, 218 in Essex, from 1,545 to 1,763, 187 in Middlesex, from 929 to 1,116, and 159 in Durham, from 1,393 to 1,552; the largest falls were 99 in Yorkshire East Riding, from 578 to 479, 72 in Oxfordshire, from 346 to 274, and 61 in Cornwall, from 230 to 169. The largest fluctuations in the trends of whooping-cough were a rise of 51 in Durham, from 153 to 204, and a fall of 37 in Hertfordshire, from 101 to 64. Only small variations were recorded in the local returns of scarlet fever. 2 cases of diphtheria were notified, the same number as in the preceding week.

6 of the 8 cases of paratyphoid fever were notified in Yorkshire East Riding, Kingston-upon-Hull C.B.

39 cases of acute poliomyelitis were notified, and these were 1 fewer for paralytic and 3 more for non-paralytic cases than in the preceding week. The largest returns were Buckinghamshire 5 (Wing R.D. 3), Northamptonshire 4 (Brackley R.D. 3).

The chief centres of dysentery were Lancashire 272 (Accrington M.B. 47, Stretford M.B. 29, Tyldesley U.D. 26, Urmston U.D. 25, Ashton-under-Lyme M.B. 22, Blackburn C.B. 17, Salford C.B. 15, Liverpool C.B. 11); Yorkshire West Riding 267 (York C.B. 82, Rotherham C.B. 49, Leeds C.B. 41, Wetherby R.D. 19, Batley M.B. 17, Sheffield C.B. 11), London 93 (Wandsworth 28, Kensington 11, Fulham 10), Warwickshire 82 (Coventry C.B. 50, Birmingham C.B. 20), Carmarthenshire 76 (Kidwelly M.B. 59, Llanelly R.D. 10), Northumberland 60 (Blyth M.B. 32, Newcastle upon Tyne C.B. 13, Alnwick U.D. 11), Durham 58 (Sunderland C.B. 26, Gateshead C.B. 25), Middlesex 57 (Hayes and Harlington U.D. 32), Essex 57 (East Ham C.B. 24, Thurrock U.D. 16), Staffordshire 51 (West Bromwich C.B. 20, Kidsgrove U.D. 10), Nottinghamshire 42 (Arnold U.D. 13, Nottingham C.B. 10), Bedfordshire 40 (Luton M.B. 25, Bedford M.B. 13), Yorkshire East Riding 36 (Kingston-upon-Hull C.B. 27), Surrey 25 (Woking U.D. 14), Wiltshire 25 (Calne and Chippenham R.D. 23), and Yorkshire North Riding 21 (Middlesbrough C.B. 20).

414 cases of dysentery were notified in Scotland, 196 more than in the preceding week. The largest returns were Glasgow 209, Edinburgh 51, Lanark county 34, and Aberdeen 24.

Week Ending March 2

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 833, whooping-cough 3,000, diphtheria 7, measles 23,060, acute pneumonia 664, acute poliomyelitis 30, dysentery 1,291, paratyphoid fever 10.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending February 23 (No. 8) and corresponding week 1956.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available.

The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

† Includes primary and influenza pneumonia.
§ Includes puerperal pyrexia.

Medical News

Medical Society of London.—The Medical Society of London was founded in 1773 by John Coakley Lettson, and last week the Society held its 177th anniversary dinner in commemoration of this notable event. Lord EVERSHED proposed the health of the Society; in response, the President, Dr. T. C. HUNT, said that it was going from strength to strength, with a membership now of 700. He paid a special tribute to their newly elected honorary fellow, Sir Gordon Gordon-Taylor, and to the registrar and honorary secretaries. Dr. J. S. RICHARDSON proposed the health of the guests. In reply Dr. MACDONALD CRITCHLEY entertained the company by reading to it a note—apparently from the patient's doctor—which accompanied a very deaf old lady whom he had seen that morning as an out-patient. It read as follows: "Go to any hospital. Ask to see the psychiatrist. Tell him you are for ever moaning. I really can't stand it. I have my own troubles."

International Federation of Medical Student Associations.—Last week the federation's executive board met in London for the first time, the British Medical Students' Association acting as hosts. Sir CECIL WAKELEY performed the official welcoming ceremony. Receptions in honour of the federation were given by the B.M.A., London University, the *Practitioner*, and the Lord Mayor of London. The board's business included arrangements for student exchanges, summer schools, and European tours for medical students from Africa and Asia. The chairman of the board was Mr. ANDERS MOBERG, of Sweden, and other members came from Britain, Denmark, Germany, Holland, Italy, Norway, and Yugoslavia.

Nuclear Explosions.—On February 27 Professor A. HADDOW addressed the Parliamentary Association for World Government on the subject of nuclear test explosions. Professor Haddow is director of the Chester Beatty Research Institute at the Institute of Cancer Research, London. Even in the nine months since the publication of the reports by the Medical Research Council and the U.S. National Academy of Sciences on radiation hazards there had been certain significant shifts of emphasis, he said, which showed the need for continuous appraisal. Thus, newer ideas on selective or differential mutagenesis could, if substantiated, render obsolete even recent discussion of what were genetically significant doses. Second thoughts on permissible radiation levels were suggested by the proposal of the U.S. National Bureau of Standards for a threefold reduction in the maximum permissible exposure to high-energy radiation at present recommended by the International Commission on Radiological Protection. As to the risk of bone tumours from radiostrontium, this was not immediately alarming but could become so, and might prove a limiting factor to test explosions. It was estimated that if tests were to continue at their present rate the average world-wide concentration would in 1970 reach a figure corresponding at its upper limit to only 1/125 of the accepted maximum permissible concentration, but one which approached the level considered significant in the M.R.C. report, *The Hazards to Man of Nuclear and Allied Radiations*. Further, the probability of individual variation was of extreme importance. Professor Haddow made a plea that the hazards—both genetical and individual—should be neither over- nor under-estimated. Fuller and more frequent information should be provided, so that medical men, and the general public, could more easily judge the risks.

Doctor at Large.—This is the third of Richard Gordon's medical comedies to be filmed (Leicester Square Cinema), and it is just as entertaining as the others. The education offered by St. Swithin's Hospital in *Doctor in the House* was undoubtedly a broad one. It seems to have been just what was needed to equip Dr. Sparrow (Dirk Bogarde) for entry into

general practice. He soon discovers that an assistant can run into trouble with his principal if the principal's wife is young, pretty, ardent, and frustrated. Patients, too, are not what they were, or at least they have different ways of impressing that unpalatable truth on young doctors. Barrack-room lawyers who know their rights under the Health Service give Dr. Sparrow some trouble, and it is with relief that he finds himself in a locum job somewhere west of Harley Street. His first lesson here is that a good suit is worth more than a good stethoscope. His second is that patients, like principals' wives, can be troublesomely amorous. A pastoral interlude in the country follows, then a visit to the Riviera. But in the end he abandons the hazards of an on the whole enviable series of assistantships for the rigours of St. Swithin's again, this time as house-surgeon to the roaring Sir Lancelot Spratt (James Robertson Justice). And, as is customary in this genre, he puts a girl (Muriel Pavlow) out of her misery by intimating, albeit reluctantly, that he would like to marry her.

Universities in South Africa.—On March 11 the Government of South Africa introduced its university apartheid Bill in the House of Assembly. This Bill provides for compulsory apartheid in South Africa's universities, and for the transfer of control of the Durban Medical School and Fort Hare University College to the Government (see *British Medical Journal*, March 2, p. 532).

Awards for Bravery.—Flying Officer J. C. M. WILKINSON, medical officer to the R.A.F. station at Changi, Singapore, has been awarded the Air Force Cross. He executed a parachute landing on Christmas Island in very bad weather last December to render medical aid to a doctor's wife suffering from a severe post-partum haemorrhage. His "action, in parachuting over strange territory in adverse weather conditions, showed courage and determination of a very high order," states the citation. The drop was carried out when the wind over the island was blowing at about 18 knots. Dr. J. W. MORGAN, of Port Talbot, Glamorgan, has been awarded the Queen's Commendation for Brave Conduct for his services when two men were trapped in an iron-ore bunker.

Will Edmonds Clinical Research Fund.—Registered medical practitioners are invited to apply for a whole-time fellowship for clinical research in hospitals in the metropolitan area of London. The starting salary is at the rate of £1,250 a year, and the fellowship is renewable annually up to a total of three years. Further details may be obtained from the assistant secretary, Royal College of Physicians, Pall Mall East, London, S.W.1. The closing date for applications is May 31.

Glasgow Offers Prizes.—To stimulate attendance at the city's mass radiography campaign, the Corporation of Glasgow is offering substantial prizes, such as a motor-car, a bedroom suite, and a refrigerator. The prizes have been given by local firms. A scheme is also being worked out for smaller prizes. Another important incentive is an assurance from Dr. H. K. COWAN, chief medical officer of the Department of Health for Scotland, that anyone found to have tuberculosis will be admitted immediately to hospital should his condition require it.

Antihistamines for Motion Sickness.—Regulations are being drafted to exclude antihistamine preparations for motion sickness from the provisions of the Pharmacy and Poisons Act, 1933, and the Poisons Rules. This is stated in a notice from the Home Office.

Professor H. A. Krebs, F.R.S., Whitley professor of biochemistry at Oxford, has been elected to the University's hebdomadal council.

Dr. Frank Falkner, assistant professor of child health at Louisville University, Kentucky, has been appointed a Markle Foundation scholar in medicine. Dr. Falkner is co-ordinator of the International Children's Centre's growth studies of children.

COMING EVENTS

"Pleasure Painting."—Exhibition at the South London Art Gallery, Peckham Road, London, S.E.5. Included are works by members of the Medical Art Society. Open daily except Fridays, March 16 to April 11 (1-8 p.m.; Sundays, 3-7 p.m.).

C.M.F./M.E.F. Physicians' Dinner.—On March 30 at Simpson's-in-the-Strand, London. Details from Dr. A. Willcox, 59, Harley Street, London, W.1.

Boat Race.—Messrs. Vitamins Limited have available a number of tickets for doctors who may wish to view the Oxford and Cambridge Boat Race on March 30 from the Bemax premises. Early application should be made to Dept. B.R.1, Vitamins Limited, Upper Mall, London, W.6.

International Congress of Clinical Chemistry.—Stockholm, August 19-23, under the auspices of the Scandinavian Society for Clinical Chemistry and Clinical Physiology. Latest date for submission of papers, April 15; for registration, May 15. Details from Congress Secretariat, Box 12024, Stockholm, 12.

British Occupational Hygiene Society.—Conference on "Instruments used in Industrial Hygiene," April 16 and 17 in London. Fee for non-members one guinea (includes proceedings). Details from the hon. scientific secretary, M.R.C. Laboratories, Holly Hill, London, N.W.3.

Disorders of the Liver.—International conference at the Institute of Clinical Medicine, Perugia University, June 18-20. Liver biopsy and acute and subacute liver atrophy will be discussed. Last date for contributions, April 30. Further details from Dr. G. MENGHINI, Clinica Medica (Policlinico), Perugia, Italy.

Clinical Psychopharmacology.—International symposium at Milan, May 9-11. Details from the secretariat, 21, Via A. del Sarto, Milan, Italy.

NEW ISSUES

Ophthalmic Literature.—The new issue (Vol. 9, No. 6) is now available. It contains a comprehensive selection of abstracts of the literature on ophthalmology and related subjects. Six issues and a volume index each year; annual subscription £4 4s. (or in combination with *British Journal of Ophthalmology*, £7 7s.); single copy 25s.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

Abstracts of World Medicine.—Issued in the first week of each month, this journal contains abstracts of important papers selected from the current medical literature of the world. Annual subscription £4 4s., single copy 8s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, March 18

● **HUNTERIAN SOCIETY.**—At Talbot Restaurant, E.C., 7 for 7.30 p.m., dinner meeting. 8.30 p.m., discussion to be opened by Dr. Raymond Greene and Dr. E. F. Scowen: Hormonal Treatment of Disease.
● **INSTITUTE OF DERMATOLOGY.**—5.30 p.m., Dr. I. A. Magnus: Respiratory Activity of the Skin.
● **POSTGRADUATE MEDICAL SCHOOL OF LONDON.**—4 p.m., Professor G. M. Wilson: Thyrotoxicosis and Heart Disease.
● **UNITED HOSPITALS CATHOLIC SOCIETY.**—At 13, Devonshire Place, W., 6.15 p.m., Mr. J. V. O'Sullivan: Sterilization, Infertility, and Artificial Insemination.
● **UNIVERSITY COLLEGE LONDON: DEPARTMENT OF BIOCHEMISTRY.**—At Physiology Theatre, Gower Street, W.C., 5 p.m., public lecture by Dr. G. J. Popják: Biochemistry of Fatty Acids and Cholesterol—Biosynthesis of Cholesterol.

Tuesday, March 19

● **INSTITUTE OF DERMATOLOGY.**—5.30 p.m., Dr. F. R. Bettley: Industrial Dermatitis.
● **SOUTH-WEST LONDON MEDICAL SOCIETY.**—At Bolingbroke Hospital, Wandsworth Common, S.W., 8.30 p.m., Dr. R. T. Brain: Eczema and Dermatitis.
● **WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.**—5.30 p.m., Mr. K. I. Nissen: Orthopaedic Surgery for Neurological Conditions.

Wednesday, March 20

● **BRITISH ASSOCIATION OF SPORT AND MEDICINE.** At St. Mary's Hospital Medical School, 5.45 p.m., Dr. D. J. Cussey: Medical Aspect of the Olympic Games at Melbourne.
● **EUGENICS SOCIETY.**—At Royal Society, Burlington House, W., 5.30 p.m., Mr. G. Ainsworth Harrison, B.Sc.: Measurement and Inheritance of Skin Colour in Man.
● **INSTITUTE OF DERMATOLOGY.**—5.30 p.m., Dr. A. Tickner: Recent Experimental Work on Hormones.
● **INSTITUTE OF DISEASES OF THE CHEST.**—5 p.m., Dr. F. J. Prime: Physiological Mechanisms in Acute Asthma.
● **INSTITUTE OF UROLOGY.**—4.30 for 5 p.m., Mr. C. I. Murphy: Tuberculosis of the Urinary Tract.
● **MIDLAND MEDICAL SOCIETY.**—At Dudley Road Hospital, Birmingham, 8.15 p.m., clinical meeting.
● **POSTGRADUATE MEDICAL SCHOOL OF LONDON.**—2 p.m., Professor W. St. C. Symmers: Thrombotic Microangiopathy.
● **ROYAL COLLEGE OF SURGEONS OF ENGLAND.**—4 p.m., Joseph Clover Lecture by Sir James Learmonth: A Surgeon's Outlook.
● **ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.**—3.30 p.m., Dr. J. M. Alison: Lepidospiral Infection as an Occupational Risk to Health Throughout the World (illustrated).
● **ROYAL MICROSCOPICAL SOCIETY.**—5.30 p.m., Mr. E. H. Leach: Structural Changes in the Eye Caused by Various Diets.

● **Thomas.**—On February 22, 1957, at 46, The Croft, Barnet, Herts, John Llewellyn Thomas, F.R.C.S., aged 92.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Two Malformed Stillbirths in a Radiographer

Q.—A woman aged 24 has had two stillbirths with congenital malformations. They had different fathers. She has been employed as a radiographer since the age of 18. There is no family history of hereditary defect or disease during the pregnancies. Should she be advised to start another pregnancy?

A.—(a) No satisfactory empiric figure is available for the risk of further congenital malformations at each birth after two malformed children. A figure often quoted is the 1 in 9 risk after one malformed child given by Murphy.¹ This referred to malformations of any type, nearly all severe or moderately severe, although the majority of the second malformations were in fact similar to the index malformation. In addition Murphy's figure is almost certainly too high; it was computed from the proportion of children born malformed after the first malformed child in the family, which gives an incorrect estimation of the hazard; and also it is known that the risk after each of the commonly occurring individual malformations is less than 1 in 9. Empiric figures are available for the risks after many of the individual malformations, and advice on risks should always be based so far as possible on the nature of the malformation as well as the family history. The fact that there were two different fathers in this case does not necessarily suggest a particular maternal predisposition to have malformed children, though such a predisposition—for example, due to a sex-linked recessive gene—is possible. Unless, therefore, either of the malformations was one of the rare types known to carry a high risk of recurrence, there is no reason to advise this woman against further pregnancies.

(b) It is unlikely that this woman's employment as a radiographer was responsible for the malformations in her children even if proper precautions were not observed. The genetic risks to an individual woman are small, as has been shown for women exposed to but surviving the Hiroshima and Nagasaki atomic explosions.² Direct radiation of the developing foetus may produce malformation, but large doses are required to cause this damage, and the most common malformation produced is microcephaly. There are no figures for the reproductive efficiency of radiographers. A survey by questionnaire sent in America to radiologists and other physicians disclosed a small but significant increase in the number of malformed children born to the radiologists compared with the remainder.³ But the response to the survey was far from complete and the value of the findings is in doubt.

Gym Shoes in School

Q.—Is it harmful for schoolchildren to wear gym shoes throughout the day at school?

A.—Gym shoes cannot be regarded as satisfactory footwear—especially for the young child—to wear all day. When the foot is being actively used on natural surfaces such as grass, no footwear is necessary except to protect the sole of the foot from possible damage. When standing and walking on hard surfaces, however, some extra support is desir-

able for the young growing foot. Gym shoes do not provide this, and they have the added disadvantage that they rarely fit well and are likely to cramp the toes. On the other hand, as children often travel to school in Wellington boots, it is clearly desirable that they should change them on arrival, and it is economically unfair to expect parents to supply extra shoes to be worn only at school. Perhaps the best compromise is for the children to change into the instep-strap (not ankle-strap) type of sandals, of which there are several good makes on the market. These should, however, belong individually to the child and not just be picked out at random from a communal store. They should be checked at the beginning of each term for size and fit, and could be taken home at the end of term for use during holidays.

Excessive Wax in the Ears

Q.—Is there any effective way of preventing the accumulation of wax in the ears of those so predisposed—especially children?

A.—The normal secretion and elimination of aural cerumen is the means by which dust and other foreign material is removed from the external auditory meatus. Elimination takes place by virtue of a process of displacement from the tympanic membrane as far as the middle third of the meatus, where desquamation then occurs.¹ In congestive or inflammatory conditions of the external ear there is increased secretion of cerumen, and the normal displacement movement is replaced by desquamation in the depths of the meatus. This causes accumulation of ceruminous plugs.

The only effective way of preventing this condition is to avoid, so far as possible, the causes of excessive secretion and any interference with the normal elimination of cerumen—in particular, exposure of the ears to dirt and dust, the introduction of foreign bodies, and any misguided manoeuvres which push the wax deeper into the bony part of the canal.

Ulcer Diets and Coronary Disease

Q.—Do patients with peptic ulcer have an increased incidence of atherosclerosis? One would expect this because of their diet, which theoretically would increase the lipaemia. If this is not the case, then must one postulate a naturally occurring "protective factor"?—or perhaps the alkalis usually taken with the diet act in this way.

A.—On theoretical grounds it would appear likely that the classical dietary treatment of peptic ulcer, rich in cholesterol, might induce lipaemia and an increased risk of atherosclerosis. Similarly attractive theories exist for relating ulcer and coronary sclerosis; both have been termed "stress diseases," both have shown similar devastating increases in the male population in recent decades, while in the experimental animal prolonged vagal stimulation is said to induce a "viscerocardiac reflex" producing eventually both peptic ulcer and coronary thrombosis. Female sex-hormones are thought to exert a protective action against ulcer and atherosclerosis in the child-bearing years, the post-menopausal increase of clinical peptic ulcer and coronary disease in women further supporting this hypothesis.

Little controlled clinical information of any association exists and would indeed be difficult to collect. Necropsy surveys have yielded conflicting results and have the serious limitations that the standard of examination must vary from observer to observer, a varying proportion of the hospital population studied is submitted to necropsy, and at best the hospital population studied does not mirror the general population. Some surveys,^{1,2} open to some statistical criticism, have failed to show any relationship between coronary atheroma and ulcer, but in two recent studies^{3,4} some effort

was made to minimize the effects of population selection and of the variable observer error. The first of the latter two surveys, a retrospective study of some 13,000 necropsy records, showed that in male subjects in whom chronic ulcers had been found incidentally or had caused death the incidence and severity of coronary sclerosis were significantly greater than a control population of "non-ulcer deaths" suitably corrected for age distribution. No similar trend could be demonstrated in female subjects with ulcers. In the second forward planned study of the epidemiology of coronary artery disease, again an increased incidence of coronary sclerosis was demonstrated in male subjects dying from peptic ulcer. While these two surveys certainly suggest that there may be an association between ulcer and coronary disease, the fact that the populations studied were selected tends to reduce the value of the information obtained. Furthermore, the mechanism of any such association, whether dietary or neurogenically determined, and the presence of protective factors to explain sex differences are still open to conjecture.

Treatment of Alopecia Areata

Q.—What remedies are worth trying in alopecia areata? Have there been any useful recent advances, and what formerly commonly advocated remedies have now been shown to be ineffective? Is ultra-violet light therapy any use, and would it be safe to give a few weeks after treatment with thorium X?

A.—Only local remedies are worth trying in alopecia areata. Most dermatologists accept that in general rubefacients encourage the hair to grow rather sooner than it otherwise would, but it is not at all certain whether the outcome of the disorder is very much altered. However, treatments with applications such as cantharides lotion are still in favour. Thorium X and ultra-violet light are also still used.

Thorium X has the effect of inducing a temporary sensitivity to ultra-violet light, but provided two or three weeks have elapsed since the thorium-X therapy there is no objection to ultra-violet light being used. Some success has recently been recorded from the injection of hydrocortisone into the bald area, but the method is not of established practical value. It is generally agreed that hydrocortisone ointment is not effective.

Absorption Spectra and Therapeutic Activity

Q.—What part does spectroscopy play in selecting members of a series of related chemicals for trial of their therapeutic effect? Are there any established relationships between spectrographic appearances and therapeutic action?

A.—Absorption spectroscopy does not play any direct part in the selection of individual members of a series of related compounds for therapeutic trials. Furthermore, there are no established direct relationships between molecular absorption spectra and therapeutic properties.

The electronic (ultra-violet and visible) absorption spectrum of a compound is determined by the presence of one or more "chromophoric" structural elements with characteristic absorption properties. It follows that a group of therapeutically active compounds containing the same chromophoric structures will have similar electronic spectra (subject to certain reservations). Conversely other compounds with similar electronic spectra are likely to be structurally related and may also exhibit similar therapeutic activity, to the extent that this latter property is related to the presence of the chromophoric structural elements. The vibrational (infra-red) absorption spectrum of a compound is also deter-

mined by its molecular structure, but is much more sensitive than the electronic spectrum to small changes in molecular structure, symmetry, and polarity, and is in general more useful for distinguishing between closely related compounds.

Both electronic and vibrational absorption spectra are therefore techniques of great value in the elucidation of detailed molecular structure. The establishment of direct correlations between spectroscopic characteristics and therapeutic activity will have to be based, however, on fundamental correlations between molecular structure and therapeutic effect.

NOTES AND COMMENTS

Dental Caries During Pregnancy and Lactation.—Professor V. H. MOTTRAM (Donhead St. Mary, near Shaftesbury) writes: The work of the Toveruds¹ gives good evidence that a positive balance of calcium can be obtained in pregnant women by increasing their intake of calcium-containing foods ("Any Questions?" January 26, p. 239; "Notes and Comments," March 2, p. 536). The calcium intake had to be raised to 1.6 g. per day, and in the winter months cod-liver oil was added to the diet to obtain a positive balance. The use of cod-liver oil is perhaps significant. It is well known that vitamin D enables the gut to pick up calcium even from a diet deficient in that element. Consequently, when attempting to increase the uptake of calcium into the system it would be reasonable not only to increase the calcium-containing foods but also the vitamin D. Graham and Oakley² found that in cases of renal rickets 1 g. calcium per day needed 3,000–6,000 I.U. of vitamin D (as "calciferol") to obtain a positive balance. Someone ought to do some work on the calcium content of saliva as the result of a high-calcium, high-vitamin-D diet.

Granuloma Annulare.—Dr. ROBERT J. D. TEMPLE (Ormskirk, Lancs) writes: It appears that the aetiology of granuloma annulare remains obscure ("Any Questions?" February 2, p. 297). Recently a patient of mine aged 10 years had a successful valvotomy for congenital pulmonary stenosis. Prior to this operation she had suffered continually from granuloma annulare on the hands for over six years, and it is interesting that this condition has remained clear and apparently cured since her operation four months ago. I am not in a position to say whether this observation is of any significance, but I should be very interested to know if there is any known association between this condition and congenital heart disease.

OUR EXPERT replies: I have never heard of any association with heart disease, and, indeed, circulatory conditions in the limbs do not seem to influence the development of granuloma annulare on those sites. It is, of course, in the nature of the disorder to clear up suddenly, and one can only attribute the sequence of events in the case described to coincidence.

PENTOXYLON

COMPREHENSIVE THERAPY FOR ANGINA PECTORIS

- Prevents coronary spasm
- Averts attacks
- Dispels fear

PENTOXYLON

- * reduces nitro-glycerin requirements.
- * reduces severity of attacks.
- * reduces incidence of attacks.
- * reduces tachycardia.
- * reduces anxiety, allays apprehension.
- * reduces blood-pressure in hypertension.
- * increases exercise tolerance.
- * produces objective improvement demonstrable by electro-cardiograph.

It is recognised that complete angina therapy should not only relieve the coronary spasm, but should help to prevent attacks. This has been accomplished by 'Pentoxylon' to a considerable degree. 'Pentoxylon' combines the benefits of two powerful and reliable agents — 'Rauwiloid' and P.E.T.N. 'Rauwiloid', an alkaloidal extract of *Rauwolfia serpentina*, has bradycardic, tranquillising and stress-relieving properties, and stabilises the patient emotionally. P.E.T.N. produces a long-sustained dilatation of the coronary blood vessels, so improving the circulation to the myocardium, reducing the severity of attacks when they occur. The dual action of 'Pentoxylon' provides a more comprehensive... more effective... therapy than has hitherto been possible using a single medicament, and it infuses the anginal patient with a feeling of well-being and hope.

Each 'Pentoxylon' tablet contains 1mg. 'Rauwiloid' and 10mg. pentaerythrityl tetranitrate. The usual dosage is one tablet four times daily before meals. Occasionally it is desirable to increase the dosage — up to 8 tablets daily are well tolerated.

RIKER

'Pentoxylon'

THIRTY YEARS OF CARDIOLOGY*

BY

HAROLD COOKSON, M.D., B.Sc., F.R.C.P.

Physician, Poole General Hospital

I shall try to outline the growth of cardiology as I have seen it in the past 30 years. In the early 1920's cardiology was hardly admitted to be a specialty, whereas now it is said that there is a separate specialist for each heart valve. So far we have managed without one for each cusp. No science advances entirely on its own, of course, but mainly by using and adapting new techniques and ideas from other sciences. Among these the use of precision instruments takes a prominent place, so that we have electrocardiographs able to take four leads at once, and in the three dimensions of space, an instrument to record the complex movements of the body produced by each heart beat, one to record heart sounds, x-ray pictures to show the size and shape of the heart, and the kymograph to record its movements, and we can discover what the inside of the heart is like by x-ray examination after the intravenous injection of a radio-opaque substance; with a catheter pushed into the heart and vessels we can record the pressure in them and find out the state of oxygenation of the blood in each chamber.

Advances in pharmacology, bacteriology, and immunology have helped in the control of the infections of the heart, while improvements in anaesthesia and surgical technique, along with more exact diagnosis, opened up the field of heart and great vessel surgery to which there now seems no limit. A good knowledge of physics, algebra, and trigonometry is very useful in reading some of the papers in heart journals to-day.

Cardiology in 1923

Let me try to give some idea of the cardiology of 1923, when I was house-physician to the late Dr. W. H. Wynn and Dr. A. P. Thomson in the Birmingham General Hospital. We had not yet got an electrocardiograph, but used the polygraph to take simultaneous curves of the arterial and venous pulses. This allowed us to distinguish the various cardiac arrhythmias, but told us nothing about myocardial injury. We rarely had the heart x-rayed, but thought we could estimate its size by percussion, and this we recorded to as little as a quarter of an inch (6 mm.). Heart failure, if not due to valve disease, was caused by myocardial degeneration, either fibroid or fatty. Blood-pressure readings even then were taken as a routine, but the part played by hypertension in causing heart failure was not realized. Nor was the

right heart failure of chronic lung disease or other causes of pulmonary hypertension. Virus pericarditis, tuberculous constrictive pericarditis, familial cardiomegaly, and other rare but important kinds of heart disease were unknown. The terms "coronary thrombosis" and "cardiac infarction" had not arrived, and I remember only one case of prolonged angina in 18 months' hospital residence. This man was given incessant inhalations of amyl nitrite, but I do not think morphine was given or thought of. We called it status anginosus. At the necropsy, coronary disease was demonstrated, though I cannot remember that intra-arterial clot or infarction was mentioned.

The chest pains which must have been occurring at that time from coronary thrombosis were either overlooked or called indigestion, influenza, pleurisy, rheumatism, or fibrositis of the chest. Operations on the heart were undreamed of, but patients with toxic goitre were operated upon and there was a heavy mortality. The sight of the well-nourished body of a girl or young woman in the post-mortem room was familiar at that time after thyroidectomy. This was just before it was discovered that iodine was good for toxic goitre; there were medical measures such as removal to a cool bracing climate, or the use of milk or serum from goats and sheep which had had their thyroids removed, and x-radiation was just coming in.

For the treatment of congestive heart failure there was of course digitalis, and in doses little different from those used to-day, though its value in failure when the heart was regular was questioned. Mild salt restriction was considered useful and there was a feeble mercury diuretic in the form of Guy's pill. Other drugs were purges and iodides, and there was the usual recommendation regarding climate and geography: the patient would do best to be on a sandy or gravelly soil, where the rainfall was low but there was plenty of sunshine, a treatment to which the earlier practitioners of Bournemouth may have owed some of their prosperity.

In the 1920's the commonest infectious diseases which damaged the heart were rheumatic fever, syphilis, diphtheria, and bacterial endocarditis. Table I lists these and indicates how these have since been largely overcome.

TABLE I.—The Four Common Infections which Damage the Heart, and the Changes in Incidence in the Past 30 Years

Rheumatic fever	..	Lessening, but still a problem
Syphilis	..	Disappearing
Diphtheritic carditis	..	Almost wiped out
Bacterial endocarditis	..	Under control

*Presidential address delivered to the Bournemouth Medical Society on October 10, 1956.

counting the cost...of living

It is estimated that over 50 per cent of the average practitioner's patients show some degree of anxiety neurosis. Such is the price exacted by the tempo of today. In this type of case MILTOWN meprobamate has far-reaching applications. MILTOWN is superior to other conventional sedatives and is remarkably free from side reactions. It acts safely and selectively to ease emotional and muscular tension without autonomic effects. MILTOWN helps to 'unwind' the patient relieving his worry, agitation and anxiety. It induces true sedation by day and natural sleep without narcosis at night.

Tablets (400 mg.): bottles of 50 and 500

Rheumatic Fever

In my own experience rheumatic fever of the recognizable kind is becoming less common, while chorea in childhood has become rare. There is still the insidious rheumatic infection which damages the valves without obvious acute illness, and it may be that this form accounts for most cases of rheumatic heart disease now occurring. But it is difficult to get figures on the incidence of rheumatic fever. In 1945 there were 937 deaths certified as due to rheumatic fever in England and Wales, while in 1954 the total was only 299. The compulsory notification of rheumatic fever is confined to a few areas in the country, and even that is too recent for assessment of whatever change there may be in the incidence. On the other hand, notifications of scarlet fever, with which rheumatic fever is closely associated, have almost halved between 1948 and 1954.

Apart from this indirect evidence it would seem natural, with improved social conditions and new drugs to treat upper respiratory infections, that rheumatic fever should diminish. Perhaps its age incidence has also changed, with relatively more attacks in young adults and in the middle-aged. I have also seen, in young Service men, many cases of rheumatic fever typical in its joint symptoms and response to salicylates, but with no evidence of subsequent valve injury. As to treatment of the acute attacks, it is doubtful if there is much gain in the past few decades; the larger doses of salicylates given now may be more effective, but apart from that there is little to record. Cortisone has so far not been proved to have much to offer.

Syphilis

Thirty years ago syphilis accounted for about 10% of cases of heart disease, but the incidence has gradually diminished as a result of early treatment with arsenicals and later with penicillin. Effective treatment with arsenical preparations came in about 1910, and this accounts for the fact that cardiovascular syphilis is to-day generally seen in elderly people, usually over 65. The only case I have seen in recent years below this age was that of a man of 42 who, though he noticed the signs of his primary infection, was told by the friend responsible for it that it was due to sugar in the water and he did nothing about it. His specific lesions involved the ascending aorta, with aortic incompetence and obstruction of the coronary orifices and the right subclavian artery, which was almost obliterated. As students we were taught that aortic incompetence was most likely to be rheumatic in the young, luteic in the middle-aged, and atheromatous in the old. Nowadays it would be true to say that at all ages it is most likely to be rheumatic. In the 1920's lues was in mind whenever the murmur of aortic incompetence was heard and also whenever there was a suspicion of heart-block. But to-day the outlook is different, and it is not a case of

Ev'ry little breeze
Seems to whisper Louise.

Diphtheritic Carditis

Diphtheria causes the most intense form of infective or toxic myocardial damage known. In a large local outbreak of the disease in 1943 I was able to study 83 cases and see how the heart was affected. Several hundred electrocardiograms were taken, and 63 of the patients (76%) gave an abnormal picture. All kinds of rhythms and abnormal patterns were seen, including that characteristic of acute myocardial infarction. Six patients died of carditis, all of whom had been given antitoxin as early as the second day and not later than the fifth day of the disease. None had been immunized against diphtheria. Histology of the myocardium, which was undertaken by Dr. William McNaughton, showed the most widespread degeneration, necrosis, and areas of haemorrhage; little normal muscle might remain. The following details of one of the fatal cases shows the course taken by progressive cardiac damage.

A child aged 12 was admitted on the second day of the disease. Antitoxin was given 26 hours after the onset. Facial diphtheria,

bull-neck, and heavy albuminuria were present. An electrocardiogram on the third day showed normal rhythm with sinus arrhythmia, rate 120; depression of ST segments in leads II and III. Eighth day: neck swelling almost gone; palatal palsy; electrocardiogram showed regular rhythm with no visible P wave, rate 80; some widening of QRS and considerable depression of ST segments. Tenth day: vomiting; the duration of P-R and of QRS had increased; pattern of QRST as in posterior cardiac infarction; died suddenly on this day. Sections of the myocardium showed congestion, oedema, degeneration, necrosis, and cellular infiltration mainly with plasma cells in all chambers, particularly in the left ventricle; the pericardium also showed intense congestion and cellular infiltration.

As a result of prophylactic immunization the position to-day is that diphtheria is an almost extinct disease. In the county of Dorset only two cases have been notified in the past five years, and not one in 1955. This magnificent achievement in immunology is one for which Dr. G. Chesney, an early enthusiast for the method, deserves a share of credit.

Infective Endocarditis

Until the late 1930's both the acute and subacute forms of infective endocarditis were generally regarded as inevitably fatal. Then the introduction of chemotherapy and later the antibiotics changed the outlook from hopeless to hopeful. The infection can be eradicated in a high proportion, but certain complications and accidents mar the picture. Early recognition and treatment before the infection has bored holes in the valve cusps is essential, and to be able to kill the organism at this late stage is of little help. In fact, the healing process seems sometimes to aggravate the condition. I have also seen one or two fatalities, after the blood had been sterilized, from rupture of a mycotic cerebral aneurysm. Another cause of failure is the organism which is resistant to all antibiotics. I saw one such case, that of an elderly woman with recurrent pneumonitis, in which it seemed possible that a virus was the responsible organism. The necropsy showed that little was left of the aortic cusps.

Toxic Goitre

Hyperthyroidism is a common cause of auricular fibrillation in the middle-aged and elderly. If unrecognized this leads to congestive failure and death. Toxic goitre is now one of the most treatable diseases, but it was only in 1923 that treatment with iodine was introduced. This was found valuable for medical management alone, and it also reduced the mortality when used as a preparation for thyroidectomy. There was a further big step forward in 1943, when more powerful antithyroid drugs, thiouracil in particular, were discovered. Nearly always this drug can neutralize thyroid overactivity and make operation as safe as in non-toxic goitre. In some cases it may be used as the sole treatment. Particularly suitable subjects for this are the elderly, who may be averse from operation, who do not mind having a lump in the neck, and who often have other diseases which make them less safe for surgery.

A haggard emaciated woman of 77 was admitted to hospital although her doctor thought she was moribund and that the bed might be more profitably filled. A small nodular goitre just palpable in the suprasternal notch was the cause of her illness. After two weeks on thiouracil she had gained 19 lb. (8.6 kg.). After three months she had fully recovered.

Cardiac Surgery

The relief by surgery of defects within the heart and neighbouring great vessels is one of the great achievements in the history of cardiology.

The first attempt to relieve mitral stenosis by operation was made by Mr. Souttar (now Sir Henry) in 1925. He opened the left auricle in a young girl, and was able to stretch the mitral valve. I saw this patient a year or two later in the London Hospital, when she was in an advanced state of congestive failure, but in her opinion the operation had helped her considerably. Thirty to forty

years ago an operation on the outside of the heart, cardiomyolysis, was done to relieve external pericardial adhesions. This has been discarded, but a decade later came the valuable procedure of pericardectomy for chronic constrictive pericarditis. Also at about this time O'Shaughnessy, in this

FIG. 1.—Chest x-ray film of man aged 41 with mitral stenosis; showing cardiac enlargement and severe pulmonary congestion.

FIG. 2.—Same case as in Fig. 1 after mitral valvotomy; decrease in heart size and disappearance of pulmonary congestion.

country, and Beck, in America, devised another operation on the outside of the heart, which was designed to increase the blood supply of the ischaemic myocardium by stitching omentum or chest-wall tissue to its surface. This procedure has not stood the test of time. Not till 20 years after Souttar's attempt to relieve mitral stenosis was this operation successfully carried out, but in the past 10 years it has been done thousands of times. Given wise and perhaps lucky selection of cases, the results are good, sometimes dramatic and life-saving. The following is an example in this last category.

A man of 34 came under observation for haemoptysis due to mitral stenosis in 1943; over the next eight years there was increasing disability and recurrent haemoptysis; in 1950 aortic incompetence was discovered; attacks of acute pulmonary oedema and paroxysms of auricular fibrillation occurred and there was left recurrent laryngeal palsy. Fig. 1 shows the cardiac enlargement and pulmonary congestion. A successful valvotomy was done at Guy's Hospital, followed by decrease in heart size, disappearance of pulmonary congestion (Fig. 2), and return of good physical capacity.

Aortic stenosis, the other common acquired obstructive valve lesion, is now being treated by operation, but it presents a more difficult problem than the mitral valve. It is harder to get at, the subject is older, and the rigid ring of calcified cusps may be widened only at the cost of serious incompetence. A procedure for the relief of severe aortic incompetence has been practised in

America, and consists in placing a plastic valve in the upper part of the descending thoracic aorta. The operative mortality was heavy, but I was able to examine two patients at Georgetown Hospital. Washington, who had benefited. One said he played golf and was driving his car 500 miles (800 km.) that day to attend the meeting; while talking to him the triple click of his plastic valve was audible, and extreme pulsation of the neck arteries was visible. On the other hand, there was little pulsation in the abdominal aorta or popliteal arteries.

Congenital Lesions.—The operative cure of congenital lesions began when Gross, in 1939, reported successful closure of the persistent ductus arteriosus in four patients. To-day there is hardly one of the various abnormal orifices and obstructions in the heart and great vessels which constitute congenital heart disease which has not been operated upon. Operation on the ductus was followed by one for coarctation of the aorta, and these, lying beyond the heart itself, are relatively easy to deal with. Nowadays defects in the auricular and ventricular septa and stenosis of the pulmonary and aortic valves are being dealt with by operation. These are aided by developments such as hypothermia—that is, cooling of the body to 25–28° C. so that the circulation through the heart can be cut off for short periods; or, better and more logically, by carrying on the circulation artificially by a pump or by anastomosis with another subject.

Fig. 3 shows a congenital defect which is incompatible with long survival. There is transposition of the aorta and pulmonary artery, the aorta arising from the right ventricle and the pulmonary artery from the left. The patent ductus arteriosus is seen passing from the main pulmonary artery at its bifurcation to the aorta beyond the origin of the arteries from the aortic arch. The infant lived 12 hours. Such a defect is beyond surgery now, but it is no more unthinkable now than was any congenital heart operation 30 years ago.

FIG. 3.—Transposition of aorta and pulmonary artery in an infant who lived 12 hours.

Hypertension

Table II shows in the left-hand column the known causes of arterial hypertension as given in the first edition of Fishberg's book, *Hypertension and Nephritis*, published in 1931.

TABLE II.—Known Causes of High Blood Pressure; Adapted from "Hypertension and Nephritis," by A. M. Fishberg (Baillière, Tindall and Cox). Left-hand Column Shows Causes Listed in First Edition, 1931; Right-hand Column Shows Causes Listed in Fifth Edition, Published in 1954

1931	1954
Kidney disease—6 types	Diseases of kidney and renal blood vessels, 13 types
Toxaemia of pregnancy	Disseminated lupus

Coarctation of aorta	Section of moderator nerves
	Androgenic stimulation of rats

Twenty-three years later, in the fifth edition of this book, several new causes are added, as shown in the right-hand column. But now, as in 1931, the vast majority of cases of hypertension cannot be attributed to any of the causes shown. The work of Goldblatt in showing that hypertension could be produced in animals by clamping the renal artery was very important, but no one has yet provided enough evidence that hypertension without apparent cause is due to lesions of renal arteries without impairment of kidney function. There is therefore little more known about the aetiology of hypertension than there was 25 years ago, and we are thus handicapped in treatment. But symptomatic treatment has had some success in measures to reduce the tone of arterioles by depression of the sympathetic nervous system. This was first carried out by operation, now more often by drugs which depress the sympathetic ganglia, such as pentolinium and mecamylamine. These are certainly valuable in preventing hypertensive heart failure and may be life-saving in malignant hypertension, as exemplified by the following case.

A married woman aged 35 was seen in December, 1955, with all the cardinal symptoms of malignant hypertension: grade IV neuro-retinopathy, cardiac enlargement, triple heart sounds, tachycardia, albuminuria; blood urea, 26 mg. per 100 ml.; B.P. 285/170 mm. Hg; electrocardiogram showing the pattern of left ventricular predominance. Treatment with "rauwilloid" and "ansolysen" reversed these changes, retinal exudates and papilloedema cleared up, and the heart slowed and became normal in size. On October 1, 1956, the standing B.P. was 130/95; and the electrocardiogram showed return to normal. The patient is pursuing ordinary activities.

Coronary Heart Disease

In Sir James Mackenzie's book on angina pectoris published in 1923 he demonstrated the frequency of gross obstruction in the coronary arteries, and even mentions the presence in them of clots. However, the term "coronary thrombosis" is not to be found in the book, and the association of this condition with major attacks of cardiac pain was not then appreciated. The article by Parkinson and Bedford published in the *Lancet* in 1928 may be regarded as the source of a torrent of papers, and, although it was only accorded the secondary position in that journal, it became one of the most quoted papers in the medical literature. To-day patients, their relatives, and nurses diagnose what they call a "coronary," and may do so in any case of sudden collapse or for any pain between the neck and the abdomen. Perhaps the disease is on the increase, but it was undoubtedly occurring in large numbers 30 to 40 years ago, when some of the labels already mentioned were applied. Characteristic examples can be found in the careful case records in Mackenzie's book. Improved recognition is largely due to the electrocardiograph and the introduction of new leads. Whereas 20 years ago we were

content with three leads, we now rarely use fewer than 10 and sometimes twice that number.

In the treatment of acute coronary thrombosis the use of the anticlotting drugs may represent a slight advance, but their efficacy is still uncertain and the precise regulation of the coagulation and prothrombin times is difficult, not to say impossible. Obviously the prevention of coronary obstruction is the aim, and considerable work is now being done on these lines. This, however, is handicapped by doubt about the pathological nature of the obstruction. According to J. B. Duguid the main factor, apart from the occurrence of large clots, in obstructing the artery is a slow mural thrombosis which becomes organized, whereas the fatty changes and calcification of atherosclerosis tend to weaken the wall and thereby widen the lumen of the artery. So far as the prevention of atherosclerosis is concerned, diets low in fat content, oestrogenic sex hormones, and plant sterols are able to lower serum cholesterol and lipids, and are of potential though as yet unproved value. Heparin in doses insufficient to have a sustained anticoagulant effect is said to correct high serum lipoprotein levels, and may also prevent intimal deposits of platelets. Another possible line of attack on slow intravascular thrombosis is the use of enzymes such as trypsin and streptokinase, which are able to break up fibrin.

Conclusion

To summarize, the last 30 years or so have seen the conquest of three of the four common cardiac infections. Rheumatic fever alone remains a considerable source of disability; the position in thyrotoxic heart disease is very favourable; cardiac surgery has revolutionized the outlook in congenital heart disease and in some acquired valve lesions; and in hypertension, though the causes are still largely unknown, there is promising symptomatic treatment. Coronary disease has become the great problem of the day.

PERSISTENCE OF URINARY OESTROGEN EXCRETION AFTER OOPHORECTOMY AND ADRENALECTOMY

BY

R. D. BULBROOK, M.Sc., Ph.D.

AND

F. C. GREENWOOD, M.Sc., Ph.D.

From the Clinico-pathological Laboratories, Imperial
Cancer Research Fund, Royal College of
Surgeons of England

The development of a new and accurate method for the separate estimation of urinary oestrone, oestradiol-17 β , and oestriol (Brown, 1955a) made it possible for us to measure the amounts of these compounds in urine from a series of patients with cancer of the breast, to follow the effects of endocrine ablation on their urinary oestrogen levels, and to show that oophorectomy and adrenalectomy do not necessarily abolish oestrogen excretion. This study is based on the results of 500 oestrogen estimations from 40 patients.

Methods

Twenty-four-hour specimens of urine were collected, without preservative, and the amounts of oestrone, oestradiol-17 β , and oestriol were estimated in duplicate 200-ml. aliquots by Brown's method. We have obtained evidence (Brown *et al.*, 1957) that the method is considerably more sensitive than the author originally claimed.

About 1 μ g. of oestrone or oestradiol-17 β and 1.5 μ g. of oestriol a day have been taken as the lower limits; values below this are recorded as zero.

Phenolphthalein, which is used in a wide variety of aperients, interferes with the method (Brown, unpublished work). We have found that oestradiol-17 β cannot be measured in the urine of patients receiving stilb-oestrol. Oestrogen values in urine from patients treated with testosterone do not reflect endogenous secretion, since some conversion of testosterone to oestrogen has been demonstrated (see, for example, West *et al.*, 1956).

The two new oestrogens isolated by Marrian and Bauld (1955) and by Watson and Marrian (1955) cannot be estimated by Brown's method. The significance of these compounds as an additional measure of endogenous oestrogen production has not been evaluated.

The validity of any conclusions concerning the production of oestrogens in the body derived from the amount of oestrogen excreted in the urine may be questioned, for we have no definite knowledge of the nature and amount of circulating oestrogen; the nature, action, and metabolism of the primary hormone, or the differences in "target-organ" sensitivity. There is, however, indirect evidence that different levels of oestrogen excretion reflect differing levels of production, for there is close agreement between changes in the urinary oestrogen levels and the physiological sequence of the normal menstrual cycle and of pregnancy and lactation (Brown, 1955b, 1956). A significant correlation has been demonstrated between oestrogen excretion and the degree of oestrogenic stimulation of the vaginal mucosa as judged by the vaginal smear technique (Bulbrook *et al.*, 1955).

In this survey, with the exception of No. 2 (Fig. 2), all urine specimens examined were obtained from women with metastatic breast cancer.

Excretion Following Oophorectomy in Pre-menopausal Women

Women who were menstruating regularly are described as "pre-menopausal." The ovaries produce oestrogen during the menstrual cycle; their removal should therefore reduce urinary oestrogen levels. An example of this is shown (Fig. 1). This patient had previously menstruated regularly, and the first pre-operative specimen was obtained on the ninth day of the cycle, which proved to be abnormal, as menstruation started on the eighteenth day and continued until operation five days later. The amount of oestrogen excreted in the pre-operative period, however, was normal until bleeding started—according to the figures given by Brown (1955b) and our own controls. The pattern of ex-

FIG. 1.—Excretion of oestrogen before and after oophorectomy. Patient 1, aged 49; pre-menopausal. Bleeding shown by horizontal bar. In Figs. 1 and 3-7 the day of operation (day 0) is indicated by a vertical arrow. The individual components of oestrogen excreted making up the total are denoted thus: black shading = oestrone; dotted area = oestradiol; white = oestriol.

cretion—that is, the relative amounts of oestrone, oestradiol-17 β , and oestriol—was also normal. Oophorectomy reduced the oestrogen excretion of this patient to a third of the pre-operative level, mainly at the expense of the oestriol fraction. Similar results were obtained before and after operation in a second pre-menopausal woman, but in this case rather more oestrogen than usual was excreted at the beginning of the luteal phase of the cycle.

Excretion in Menopausal and Post-menopausal Women

We have defined the "menopause" as the three-year period after the cessation of menstruation; women who have not menstruated for at least three years are designated as "post-menopausal."

There are almost no published data on the excretion of oestrogen by normal post-menopausal women. In one volunteer from whom we have been able to obtain serial urine specimens there was evidence of a cycle of oestrogen excretion shortly after the cessation of menstruation (Fig. 2), although the amount excreted was sub-normal when compared with that in the menstrual cycle. Six months later excretion became irregular, with no evidence of a cyclic rise and fall. It is possible that this cyclic excretion is a general occurrence of the beginning of the menopause.

The effect of oophorectomy on the excretion of oestrogen by a woman who had ceased to menstruate (as a result of palliative x-ray treatment) shortly before operation is shown in Fig. 3. In the 16 days after operation this patient excreted a good deal more oestrogen than in the pre-operative period; three months later oestrogen excretion had ceased. Seven months later oestrogen was again present in the urine in quantities greater than those found before operation.

A second menopausal patient ceased to excrete oestrogen directly after oophorectomy. Only two estimations were carried out, and in the absence of further specimens it was not possible to ascertain whether there was a return of oestrogen excretion.

Three post-menopausal women subjected to oophorectomy were studied. In one there was no change in the pattern or the amount of oestrogen excreted; in the second there was a slightly increased amount of oestrogen excreted in the 13

days after operation. In the third there was a slight increase in the amount of oestrogen excreted in the 13 days after operation.

FIG. 3.—Excretion of oestrogen before and after oophorectomy. Patient 3, aged 45; menopausal.

post-operative days (Fig. 4). The third post-menopausal woman studied over a similar period showed an identical lack of response to oophorectomy.

Table I shows the amounts of oestrogen excreted by 14 patients at various times after removal of the ovaries. In

Excretion Following Oophorectomy-adrenalectomy

Oestrogen excretion was measured in two patients who had both ovaries and one adrenal gland removed at operation, and the second adrenal gland removed about 10 days later. In Case 5 the patient was menopausal. Excretion was erratic from day to day (Fig. 5), but the proportions of oestrone, oestradiol-17 β , and oestriol were normal compared with those found in the menstrual cycle. After removal of both ovaries and one adrenal gland oestrogen excretion had ceased by the sixth day, but by the twelfth day small amounts of oestrogen could be detected in the urine. After removal of the second adrenal there was a transient but marked increase in oestrogen excretion, followed by a fall to zero. However, nine weeks later oestrogen excretion was at about pre-operative level. A second patient was 20 years post-menopausal, and in more than one-third of the number of specimens obtained before operation no oestrogen could be detected. Bilateral oophorectomy and unilateral adrenalectomy were followed by a sharp increase in oestriol excretion to 10 µg. on the day

after operation, but, unlike the preceding case, the level of excretion did not fall to zero until after the removal of the second adrenal gland. Death followed four days after the second operation.

FIG. 5.—Excretion of oestrogen before and after oophorectomy-adrenalectomy. Patient 5, aged 48; menopausal.

Excretion Following Adrenalectomy

Three adrenalectomy cases are shown in Figs. 6, 7, and 8. In two it is difficult to assess the effects of the operation because an insufficient number of pre-operative specimens were examined. With this reservation in mind it should be noted that Case 6 excreted twice as much oestrogen after adrenalectomy as before (Fig. 6). Three months later oestrogen was still present in the urine. Almost a year after adrenalectomy the amount of oestrogen was practically double the pre-operative level. There was a change in the excretion pattern, previously characterized by the complete

FIG. 6.—Excretion of oestrogen before and after adrenalectomy. Patient 6, aged 37. Oophorectomized 13 months before adrenalectomy.

FIG. 7.—Excretion of oestrogen before and after adrenalectomy. Patient 7, aged 43. Oophorectomized 2½ years before adrenalectomy.

absence of oestriol, since after a year this compound was the main excretion product. In Case 17 there was a reduction in oestrogen excretion after adrenalectomy. Intermittent estimations showed an occasional zero titre (Fig. 7). Eight months after operation the amount of oestrogen found was higher than the pre-operative level, but three months later almost no oestrogen could be detected. The change in the oestrogen excretion pattern was similar to that in Case 6. Oestrone, oestradiol-17 β , and oestriol were found in the pre-operative specimens, but oestriol was completely absent immediately after adrenalectomy. Eight months later oestriol again predominated.

No specimens were obtained before operation from the third adrenalectomized patient (Fig. 8). On three occasions the amounts of oestrogen excreted were comparable with

adrenalectomy cannot be based on a single estimation. Serial estimations over long periods are essential; this is clearly demonstrated in Fig. 7.

A separate series of eight patients after oophorectomy and adrenalectomy is at present being investigated. In this group—referred to later as the “new series”—oestrogen excretion is determined each month on a 24-hour specimen of urine brought to an out-patient clinic. Two of these patients, from each of whom five specimens have been examined, were not excreting oestrogen. In 9 of 24 specimens obtained from the remaining six patients, amounts of oestrone varied from 1.1 to 3.7 µg. per 24 hours; trace amounts of oestradiol-17 β were found in three specimens and of oestriol in one specimen only.

Discussion

The main conclusion to be drawn from the results in this series of patients is that oestrogen excretion continues after oophorectomy and is not necessarily abolished by subsequent adrenalectomy. It is well established that endocrine ablation results in a temporary remission in some cases of mammary cancer. It remains to be determined whether the levels of oestrogen after oophorectomy and oophorectomy-adrenalectomy are correlated with the patient's clinical course.

Dao (1953) and Smith and Emerson (1954), using a biological assay, have detected oestrogen in the urine of oophorectomized women. Struthers (1956) has often found positive vaginal smears in such women. These findings agree with our results.

The extra-ovarian source of oestrogen is thought to be the adrenal glands. In addition to the evidence reviewed by Paschkis and Rakoff (1950) this concept is supported by reports that oestrogen excretion shows a transient rise after the injection of corticotrophin in oophorectomized women (Brown, unpublished results), after burns in men (Heller, 1944), and after oophorectomy in post-menopausal women (Smith and Smith, 1944). We have found that oestrogens, 17-ketosteroids, and ketogenic steroids rise together after prostatic biopsy. The reaction of the adrenal glands to stimulation by corticotrophin best explains the post-operative increases in oestrogen excretion shown in Figs. 3 and 4. The increase noted in Fig. 5 after the removal of the second adrenal gland supports the pathological evidence that in this patient the first adrenal was incompletely removed at operation.

If the adrenal glands are the main source of extra-ovarian oestrogen, the immediate effect of adrenalectomy should be the reduction or abolition of oestrogen excretion. We have only a few estimations in the period immediately after adrenalectomy, but in these cases (Figs. 5 to 7) oestrogen excretion fell to zero shortly after the operation. The fall to zero seems to be a temporary effect. Case 5, after an initial fall in oestrogen level, was excreting considerable quantities nine weeks after oophorectomy and adrenalectomy. In addition, with four exceptions (P and R in Table II and two patients in the “new series”) all patients studied excreted oestrogen in the urine at various times after adrenalectomy.

These results agree with the finding of positive vaginal smears in oophorectomized and adrenalectomized women, reported by Struthers (1956); but Dao (1953), using a bioassay method, was unable to detect oestrogen in the urine of such patients.

The oestrogen excreted may originate *inter alia* from diet or from cortisone metabolism. It seems most unlikely that these are important sources, since two of nine patients, all on fairly standard diet and on similar maintenance doses of cortisone, failed to excrete any oestrogen, and in two of the eight out-patients no oestrogen could be detected. Adrenal gland tissue not removed at operation and accessory adrenal tissue (Graham, 1953; Falls, 1955) are more likely sources of the oestrogen found in some patients after adrenalectomy.

One patient was treated with adrenocorticotrophin (100 units of corticotrophin gel, intramuscularly, daily for three days) in an attempt to test for the presence of adrenal tissue,

FIG. 8.—Excretion of oestrogen after adrenalectomy. Patient 8, aged 44. Oophorectomized 14 months before adrenalectomy.

those in the menstrual cycle (25, 52, and 36 µg. per 24 hours). This patient was not receiving testosterone. The extreme variation in the oestrogen excretion is shown by the fact that three days after an output of 36 µg. in 24 hours, no oestrogen was detected.

In one further case adrenalectomy reduced a mean pre-operative level of 12 µg. a day to zero in two specimens available before death.

Further studies limited to the post-adrenalectomy period are shown in Table II; this does not include post-operative figures of Cases 6, 7, and 8 already reported.

* On testosterone.

A consideration of the post-adrenalectomy levels of oestrogen excretion in Table II and in Figs. 6 to 8 shows that oestrogen excretion by patients in this survey was generally not abolished by the operation. In only one case (P in Table II) was a consistent absence of oestrogen established over the period studied. Conclusions regarding continuation or cessation of oestrogen production in a patient after

but no stimulation of oestrogen excretion was observed. This test may be of doubtful value as an index of the capacity of the remaining adrenal tissue to secrete oestrogens. After adrenalectomy, with relatively low doses of oral cortisone, it is possible that the secretion of endogenous corticotrophin is sufficient to cause maximal or near maximal secretion rate by any remaining adrenal tissue. Exogenous corticotrophin would thus be likely to have little or no effect.

Taylor *et al.* (1949) found elevated corticotrophin levels in the blood of untreated patients with Addison's disease, and the levels did not return to normal with maintenance doses of cortisone (Sydnor *et al.*, 1953). It is well known that the level of urinary 17-ketosteroids and ketogenic steroids found in patients with Addison's disease cannot be elevated by administration of corticotrophin. On the other hand, Sayers (1955) has reported that the high level of corticotrophin in adrenalectomized patients is reduced by treatment with cortisone.

Whatever the origin of the urinary oestrogen found in some of our patients after oophorectomy and adrenalectomy may be, its immediate source is the oestrogen of the circulating blood. The hypothesis of oestrogen independence is often invoked when a breast cancer recurs in the absence of those endocrine organs assumed to produce oestrogen. The observations recorded in this paper strongly suggest that oestrogen independence cannot be assumed until oestrogen excretion has been fully investigated.

Summary

A chemical method has been applied to a study of urinary oestrogen levels of patients undergoing bilateral oophorectomy or bilateral adrenalectomy for metastatic breast cancer. Oophorectomy reduced oestrogen excretion in premenopausal women but had no effect after the menopause. Adrenalectomy carried out after oophorectomy did not always abolish oestrogen excretion.

It is concluded that, since oestrogen excretion continues after oophorectomy and may continue after adrenalectomy, failure to respond clinically to these operations is not necessarily due to the oestrogen independence of the tumour.

We are indebted to Dr. E. F. Scowen and Dr. H. E. Archer for arranging the supply of urine specimens, and to Professor C. H. Gray for specimens from two patients. We thank Mr. D. H. Patey and Dr. J. D. N. Nabarro for permission to report on the preliminary results of joint work on the "new series" of patients.

EFFECT OF HYPOPHYSECTOMY ON URINARY OESTROGEN IN BREAST CANCER

BY

F. C. GREENWOOD, M.Sc., Ph.D.

AND

R. D. BULBROOK, M.Sc., Ph.D.

From the Clinico-pathological Laboratories,
Imperial Cancer Research Fund,
Lincoln's Inn Fields, London

It has been shown that patients with breast cancer may continue to excrete oestrogen in the urine after oophorectomy, adrenalectomy, or hypophysectomy (Greenwood and Bulbrook, 1956). The detailed results of the effects of the first two operations are published at page 662 in this issue (Bulbrook and Greenwood, 1957). The present paper, based on over 200 estimations on specimens from ten women and one man, describes the effect of hypophysectomy on urinary oestrogen excretion.

Method.—The method of Brown (1955a) was used to determine the amounts of oestrone, oestradiol-17 β , and oestriol in duplicate aliquots from 24-hour specimens of urine. Generally, 200-ml. aliquots were taken, but with very dilute post-hypophysectomy urine 400-ml. aliquots have occasionally been analysed. The accuracy, precision, sensitivity, and specificity of the method have been described by Brown, Bulbrook, and Greenwood (1957a). The specificity of the method has been checked in the urines obtained from one patient after hypophysectomy. There was a close agreement between chemical and biological assays of the urine in this patient (Bulbrook, Greenwood, and Williams, to be published). In some patients after hypophysectomy, maintained on cortisone, the levels of oestriol may be underestimated owing to interference in the final colour reaction. This interference is removed by an extra purification step involving saponification of the oestrogen fractions (Brown, Bulbrook, and Greenwood, 1957b).

Results

In all cases described in this paper the pituitary gland was removed surgically and the pituitary fossa was filled with Zenker's solution. The effect of hypophysectomy on the urinary oestrogen excretion of 10 patients is summarized in the Table.

Effect of Hypophysectomy on Urinary Oestrogens

* Estimations immediately after castration.

† On testosterone.

‡ Estimations immediately after hypophysectomy.

The figures in this table refer to the mean excretion of O=oestrone, D=oestradiol-17 β , T=oestriol, and their sum, the total amount of oestrogen excreted, expressed in μ g. per 24 hours.

The results fall roughly into three groups. The first consists of patients in whom hypophysectomy had virtually no effect on the total amount of oestrogen excreted. Patient 1, aged 41, ceased menstruating nine months before hypophysectomy. The amount of oestrogen excreted before operation (presumably of adrenal origin) fluctuated widely from day to day (Fig. 1), but the relative amounts of

Fig. 1.—Excretion of oestrogen before and after hypophysectomy. Patient 1, aged 41; menopausal. (In all four graphs the ordinate shows the number of days or weeks before and after operation, the day of the operation being taken as day 0 and indicated by the vertical arrow. Height of vertical columns shows total amount of oestrogen excreted in 24 hours. Individual components are: black shading=oestrone, dotted area=oestradiol, white area=oestriol.)

oestrone, oestradiol, and oestriol were normal compared with the proportions found during the normal menstrual cycle (Brown, 1955b). After operation there was no change either in the pattern or in the amount of oestrogen excreted.

Patient 2, aged 39, was oophorectomized nine months before hypophysectomy. While there was little change in the total amount of oestrogen excreted after operation, a change in pattern occurred in that oestrone and oestriol were excreted in smaller amounts while the excretion of oestradiol increased. Patient 3, aged 45, was oophorectomized two years before hypophysectomy. After removal of the pituitary gland there was no significant change in either the pattern of excretion or the amount of oestrogen excreted.

The second group (Nos. 4-7) consists of patients who excreted either no oestrogen or only trace amounts after hypophysectomy. Patients 4 (Fig. 2) had not been previously oophorectomized, and the pre-operative level of

Fig. 2.—Excretion of oestrogen before and after hypophysectomy. Patient 4, aged 60; post-menopausal.

excretion seemed high for a woman aged 60. Abnormal amounts of oestradiol-17 β (relative to the amounts of oestrone and oestriol) were found in these specimens. After hypophysectomy no oestrogen could be found in the four specimens of urine available for analysis.

Patient 5, aged 50, had been oophorectomized three years before hypophysectomy. Twenty-four specimens of urine obtained intermittently over a period of 16 months before operation contained little oestrogen (mean=3.2 μ g. total oestrogen per 24 hours), and in the single specimen of urine available after hypophysectomy no oestrogen could be detected. Since only one analysis was possible this patient has not been included in the Table.

Patient 6, a man aged 58, had been castrated six months before hypophysectomy. Immediately after castration an average amount of 11.3 μ g. total oestrogen per 24 hours was excreted over an eight-day period, but just before hypophysectomy only trace amounts of oestrogen—that is, amounts approaching the limit of sensitivity of the method—could be detected in the urine. One month after hypophysectomy trace amounts of oestrone and oestriol were found in two of four specimens of urine.

Patient 7, aged 48, was oophorectomized 11 months before hypophysectomy. After the latter operation 2 μ g. of oestrone was found in one of six specimens. Later, appreciable amounts of oestrogen were found in the urine, but this oestrogen was almost certainly derived from administered testosterone (see, for example, West *et al.*, 1956).

The third group is made up of patients who showed an increased excretion of oestrogen after hypophysectomy (Nos. 8, 9, and 10).

Patient 8, aged 49, was oophorectomized three months before hypophysectomy. Only three specimens of urine were obtained before operation, and it is possible that the amount of oestrogen in these specimens may not have given a true picture of the functional activity of the adrenal glands. After removal of the pituitary gland this patient's oestrone excretion dropped to half the pre-operative level, but oestradiol excretion increased four-fold, and oestriol, absent in the pre-operative specimens of urine, was found in appreciable amounts (Fig. 3).

Patient 9, aged 46, was oophorectomized six months before hypophysectomy. Post-operatively the oestrone and oestradiol levels fell but the amount of oestriol excreted was almost doubled.

In Patient 10, a post-menopausal woman aged 64, hypophysectomy caused a temporary increase in oestrogen excretion. In four of seven specimens obtained before operation 1.5 to 2 μ g.

Fig. 3.—Excretion of oestrogen before and after hypophysectomy. Patient 8, aged 49; previously oophorectomized.

of oestrone per 24 hours was found. Twelve days after hypophysectomy amounts of oestrogen ranging from 2.7 to 7.4 μg . (total oestrogen per 24 hours) were found in five of six specimens. In nine subsequent assays no oestrogen could be detected in the urine.

The last patient, (No. 11, Fig. 4) cannot be grouped with the preceding ten since no pre-operative assays were carried out. However, specimens of urine were obtained intermittently between 8 and 11 months after hypophysectomy. This patient,

FIG. 4.—Excretion of oestrogen after hypophysectomy. Patient 11, aged 48; menopausal. DXR=deep x-ray treatment.

aged 48, with intact ovaries and adrenal glands, excreted between 1 and 12 μg . of total oestrogen per 24 hours over most of this period. After x-ray treatment there appeared to be a steady decline in the amount of oestrogen excreted, and in the last three specimens of urine available before death no oestrogen could be detected.

Discussion

The results show that oestrogen excretion continued after hypophysectomy in 7 of 11 patients in this series. If the secretion of oestrogen is controlled solely by the pituitary gland the simplest explanation of these results is that in only four cases (Nos. 4, 5, 6, and 7) was hypophysectomy effective in lowering the amount of circulating trophic hormones below that required for the continued secretion of oestrogen by the target organs. In the remaining cases enough pituitary tissue may have been left at operation to enable the target organs to function at an unchanged rate (Patients 1, 2, and 3), or rapidly regenerating tissue may have been responsible for an excessive production of trophic hormones to account for the increased excretion of oestrogen seen in Patients 8 and 9, and occurring temporarily in Patient 10.

An additional factor which may account for some part of the continued secretion of oestrogen is the presence of accessory pituitary tissue, which is often found in man (see Melchionna and Moore, 1938; Boyd, 1956). From a comparison of the histological appearance of this tissue in the presence and absence of the pituitary, Müller (1956) concluded that pharyngeal pituitary tissue in man after hypophysectomy is capable of secretory activity.

It is unlikely that the continued secretion of oestrogen was due to incomplete atrophy of the adrenal glands at the time the oestrogen estimations were carried out. Judged by 17-oxy steroid production, adrenal atrophy is complete within nine days (Luft *et al.*, 1955), but it is possible that different mechanisms for the synthesis of the various adrenal hormones may be differentially affected by removal of the pituitary gland. Most of the estimations were carried out at least three weeks after the removal of the pituitary, and Patient 11 was excreting oestrogen almost a year after operation.

Whatever the source of the oestrogen found in the urine of these patients, and whatever the factors controlling oestrogen secretion, it is clear that some caution must be exercised before the failure of a patient to respond clinically to hypophysectomy is ascribed to hormone independence of the tumour. Hormone independence cannot be assumed without appropriate measurement of hormone secretion.

Summary

In 4 of 10 patients little or no oestrogen was found in the urine after hypophysectomy. Three patients showed unchanged levels of oestrogen excretion and three showed increased levels. Yet another patient studied almost a year after operation was excreting appreciable amounts of oestrogen.

Since 7 of the 11 patients continued to excrete oestrogen after hypophysectomy, it cannot be safely assumed that a breast cancer is hormone-independent if, following operation, there is no favourable clinical response.

We are indebted to Dr. H. E. Archer and Dr. E. F. Scowen, of St. Bartholomew's Hospital, for arranging the supply of specimens of urine from nine patients, and to Mr. A. Dickson Wright, of St. Mary's Hospital, for specimens from two patients.

ACUTE DISSEMINATED ENCEPHALOMYELITIS AND RELATED SYNDROMES

BY

H. G. MILLER, M.D., F.R.C.P.

Physician in Neurology, Royal Victoria Infirmary,
Newcastle upon Tyne

J. B. STANTON, M.B., M.R.C.P.

Physician, Neurological Unit, Northern General Hospital,
Edinburgh

AND

J. L. GIBBONS, M.B., M.R.C.P.

Senior Registrar, the Maudsley Hospital, London

In addition to their clinical interest the well-defined neurological syndromes which occur in the course of the acute specific fevers form a useful starting-point for a consideration of the aetiology and pathogenesis of similar syndromes encountered in other clinical contexts. There is, for example, a well-recognized resemblance between post-exanthematous encephalitis and the similar illnesses which sometimes complicate Jennerian vaccination (Miller, 1953a) and other prophylactic inoculations (Miller and Stanton, 1954a). It is tempting also to speculate on possible relationships between these syndromes and other acute demyelinating diseases in which no such clear-cut aetiological agent is evident, and to compare such naturally occurring forms with the examples of demyelinating encephalitis which have been produced in experimental animals. It is our purpose in the present paper to compare and contrast these various

syndromes to see if we may reach any valid conclusions regarding the underlying pathogenetic mechanisms involved.

Complications of the Acute Specific Fevers

At the outset of this study we became aware of the paucity of reliable information about the natural history of neurological complications of the acute specific fevers, which constitute the paradigm of this group of diseases, and our first step was to review the available world literature on this subject. The results of this study, comprehensive in the case of measles, chicken-pox, and rubella, and less exhaustive but fairly complete in mumps, scarlet fever, and pertussis, are now complete (Miller, Stanton, and Gibbons, 1956). From this work we have been able to obtain a fairly clear picture of the forms which these complications may take. We have few valid figures regarding their incidence, but a good deal of reasonably reliable comparative information about their clinical features, natural history, prognosis, and sequelae. From a consideration of the relatively few fatal cases which have been adequately studied and reported we have also gained useful information concerning the march of histopathological changes involved.

If for a moment we consider only the neurological complications of measles, varicella, and rubella, on which our information is more complete, we can say that in all three fevers about 90% of neurological complications take the form of encephalitis or encephalomyelitis, the small minority comprising examples of uncomplicated myelitis or polyradiculitis. The average latent period between the appearance of the rash and the onset of encephalitis is from four days (rubella) to six days (varicella). In each disease polyradiculitis has an average latent period twice as long as that of encephalitis, myelitis occupying an intermediate position. Occasionally, and especially in rubella, encephalitis precedes the rash, but this has not been recorded in the case of myelitis or polyradiculitis. There is no correlation, positive or negative, between the severity of the exanthem and the appearance of encephalitis. Both sexes may be affected, but the sex ratio varies somewhat between the three diseases, while all these neurological complications are much commoner in the older subjects of the exanthemata—for example, over 10 years of age. Only in the case of measles are the data adequate for a reliable assessment of incidence, and in this disease encephalitis probably complicates 1 in every 1,000 cases: the incidence in rubella is almost certainly less. The mortality in measles and rubella encephalitis is about 20%, that of varicella encephalitis 10%.

Most often these encephalitic illnesses begin abruptly with convulsions followed by coma. Rather less frequently there is a gradual lapse into stupor. A rise of temperature usually accompanies the onset, and the neurological picture is polymorphic, some of the signs being transient and others more persistent. Hemiplegia, tetraplegia, ataxia, involuntary movements, retention of urine, cranial nerve palsies, and meningism are all common findings, and it is not possible to distinguish on neurological grounds between the encephalitis of measles and that of rubella or varicella. However, in the latter form coma, convulsions, hemiplegia, and extensor plantar responses are all comparatively less common, while ataxia and nystagmus are seen more than twice as often as in measles or rubella. The spinal fluid may be normal throughout, but often shows a lymphocytic pleocytosis, occasionally with a slight rise of protein content. When death occurs in para-exanthematous encephalitis, it usually takes place within three days, and practically always within a week of the onset. In surviving cases, a remarkable degree of recovery is usual, and 80% of surviving patients show no disability by the end of six weeks. Sequelae are more common in younger patients, and except for residual hemiplegia or paraplegia are more often psychiatric than neurological. The lowest incidence of sequelae appears to be after rubella encephalitis, though this may be in part due to the fact that this form of encephalitis, like the initiating exanthem, has the highest age incidence of the three.

Myelitis, both transverse and ascending in type, has been reported in measles, varicella, and rubella, also polyradiculitis, clinically indistinguishable from "acute infective polyneuritis" and in many cases showing the cyto-albuminological dissociation in the spinal fluid characteristic of the Landry-Guillain-Barré syndrome. Good recovery is usual in both the polyradicular and the myelitic forms, though the latter may have a mortality of up to 20% and occasionally results in a severe residual paraplegia.

Pathological Findings in Fatal Cases

The reports of pathological findings in fatal cases of encephalitis complicating measles, varicella, and rubella describe acute lesions disseminated throughout the nervous system, beginning with congestion and oedema and ending, if the patient survives long enough, with the fully developed picture of perivenous infiltration and demyelination (perivenous encephalomyelitis). These changes cannot be rigidly correlated with the severity or duration of clinical symptoms, but they do reveal a fairly well defined progression, which can be reconstructed by a consideration of material drawn from patients dying at varying intervals after the onset of encephalitic symptoms. The initial change in the brain appears to be congestion, followed within a few hours by patchy swelling in the walls of the smaller venules and their mural infiltration with mononuclear cells. Patchy perivenous oedema, which may progress to haemorrhage, follows rapidly.

In fulminating illnesses these changes give rise to rapidly fatal cerebral purpura, but in progressive cases perivenous infiltration with lymphocytes and microglial elements is seen, followed by demyelination. Such changes may be encountered within 48 hours of the clinical onset, and a few days later fat phagocytosis ensues, leaving demyelinated areas which may appear confluent. These changes affect mainly the white matter of the nervous system (leuco-encephalitis), while nerve-cell changes are much less constant and may indeed be absent throughout. Valuable information is provided by the reports of Malamud (1939) and Van Bogaert (1949) on cerebral histopathology in three patients dying from unrelated causes some years after measles encephalitis. Van Bogaert interpreted the findings in his case as revealing no residual pathological evidence of the preceding encephalitis, which must have arisen on the basis of entirely reversible changes, while Malamud found only well-defined areas of demyelination, non-progressive and with no sign of the extending fibrous gliosis characteristic of disseminated sclerosis.

Pathological evidence is not available in polyradiculitis complicating these fevers, but in myelitic cases both diffuse perivascular demyelinating lesions and focal vascular occlusions have been described, the latter possibly based on the arteritic lesions which are so common a histopathological feature of this group of disorders.

We have also found some evidence (Miller *et al.*, 1956) that a clinically and pathologically identical triad of encephalitis, myelitis, and polyradiculitis is occasionally encountered as a complication both of mumps and of scarlet fever. In both these diseases, however, such syndromes are much less frequent than a benign lymphocytic meningitis. In the case of scarlet fever, the situation is further confused by a group of neurological complications arising on the basis of secondary factors such as venous thrombophlebitis and renal hypertension. There can be no doubt, on the other hand, that the neurological complications of pertussis fall into an entirely separate class, radically different both clinically and pathologically from the perivenous demyelinating encephalomyelitis characteristic of measles, varicella, and rubella.

Syndromes Following Non-specific Infections

In comparing these para-exanthematous syndromes with other forms of encephalitis, myelitis, and polyradiculitis, we will leave aside both the virus encephalitides, and also such entities as syphilitic myelitis, and will consider primarily

those forms which fall within the group of acute disseminated encephalomyelitis, the diagnostic criteria of which were formulated in a classical paper by McAlpine (1931). These include forms of encephalitis, encephalomyelitis, myelitis, and neuromyelitis optica (Devic's disease) arising after comparatively trivial non-specific infections, body-chilling, mild or surgical trauma, or on occasion without any apparent external provoking factor. Such diseases are not very uncommon, and manifest themselves by an acute onset with coma or stupor in encephalitic forms, and rapidly increasing signs of spinal-cord damage in the myelitic forms, which may be transverse or ascending in type. After progressing for a period which varies from a few days to a few weeks, the condition becomes stationary and subsequent recovery is often surprisingly complete, although sequelae such as hemiplegia, paraplegia, or symptomless extensor plantar responses may be demonstrable. The mortality in encephalomyelitic types is between 20 and 30%.

It is interesting that in these spontaneous forms recurrence has often been observed (Miller and Evans, 1953; Miller and Gibbons, 1954), whereas it has never been reported in those cases arising in relation to the specific fevers. It is possible, however, that relapse may occasionally occur in the latter, and Sir Russell Brain (1956, personal communication) has seen this in a case of mumps polyradiculitis. Neuromyelitis optica, as well as occurring spontaneously and after banal infections, has also been observed as a complication of measles (Brain, 1951; Janbon *et al.*, 1951).

Histopathologically these cases are characterized by areas of patchy demyelination, but inflammatory cells and neuronal degeneration are both inconspicuous. Some perivascular cuffs of lymphocytes are present, and occasional petechial haemorrhages are found. These changes are clearly very similar qualitatively to those of para-exanthematous encephalomyelitis; indeed, pathologically as well as clinically it is impossible to identify any single feature which permits of clear differentiation between the two groups. In the absence of adequate pathological evidence we can do no more than draw attention at this point to the parallel similarity in clinical features of the Landry-Guillain-Barré syndrome whether it occurs "spontaneously" or as a complication of the acute specific fevers.

Mention has already been made of post-vaccinal encephalitis, and a further group of neurological cases bearing a striking resemblance to those complicating the exanthemata is encountered following the administration of serum and other prophylactic inoculations. We have described these in detail elsewhere (Miller and Stanton, 1954a), and here would merely emphasize that such complications may involve the neuraxis at any or every level, giving rise to encephalitis, myelitis, or polyradiculitis, in pure or mixed forms, and in proportions which vary to some extent with the nature of the antigen employed. Such pathological reports as have been made in these cases reveal changes analogous to those seen in non-specific acute disseminated encephalomyelitis, post-vaccinal encephalitis, and the para-exanthematous syndromes already described.

A Common Pattern

In all the conditions discussed above it is possible to discern a broad common pattern. The pathogenetic mechanisms involved, whatever they are, can damage the neuraxis at any level, whether nerve root, cord, or brain. The resulting clinical picture may be discrete or mixed, but the histopathological basis in all cases is remarkably similar, and essentially based on a lesion the end-result of which is perivenous demyelination. The origin of such a non-specific syndrome in invasion of the nervous system by a neurotropic virus is unsupported by any positive evidence, lies in the face of the aetiological facts, and has been generally discarded. The dissimilarity between the histopathological changes of perivenous encephalomyelitis and those of any authenticated virus infection of the nervous system militates equally against acceptance of the alternative hypothesis,

which regarded these diseases as manifestations of the activity of an unidentified latent and ubiquitous virus already present in the patient's tissues, potentiated by the recently preceding infection or other insult to the nervous system.

In this connexion it seems likely that some importance may attach to the evidence now available of experimental demyelination produced in animals by repeated injections of heterologous or homologous brain emulsions, with or without adjuvants. This evidence has been reviewed by Wolf (1952). By these means a perivenous demyelinating lesion can be produced, disseminated throughout brain and cord, which is closely analogous histopathologically to the human diseases under consideration. More recently Waksman and Adams (1955) have produced in rabbits a comparable experimental allergic polyneuritis with cyto-albuminological dissociation in the spinal fluid and characteristic lesions in spinal nerve roots, ganglia, and nerves. The similarity of these experiments to the occasional disastrous "neuromyolytic accidents" occurring during human inoculation with extracts of animal nervous tissue in the course of antirabic treatment is striking.

The resemblance of the histopathological changes described in these experimental animals to those of acute disseminated and para-exanthematous encephalitis in man suggests the possibility that these latter conditions may also be allergic in origin. Russell (1955), in comparing the rare acute haemorrhagic leuco-encephalitis in man with acute disseminated encephalomyelitis, has suggested that these are variants of a single pathological process, differing mainly in the acuteness and intensity with which the nervous system is attacked by a common pathological process. In support of the view that this process is allergic, she has demonstrated the development of foci of plasma cells in the human spleen both in acute disseminated encephalomyelitis and in haemorrhagic leuco-encephalitis. Marshall and White (1950) had already shown that plasma blasts, and later mature plasma cells, appear in the spleen in a few days when antigens are administered to rabbits. In this connexion also the recent finding by Lander (1955) of typical acute haemorrhagic leuco-encephalitis in the brain of a man dying on the fifth day of haemorrhagic varicella, and the earlier report by Shallard and Latham (1945) of the same condition complicating measles, are of particular interest.

Appearances similar to those of acute haemorrhagic leuco-encephalitis are occasionally encountered in fatal cases of drug encephalopathy, and Russell (1937), dealing with "encephalitis" due to arsphenamine, and Cavanagh (1953), describing similar cases following the administration of streptomycin and P.A.S., raise the possibility of hypersensitivity as the probable underlying mechanism.

Conclusions

A whole range of apparently related and strikingly similar syndromes of damage to the neuraxis can arise in widely differing clinical circumstances in man. Such syndromes may appear after chilling or trivial injury, following non-specific infections or the specific exanthemata, and after Jennerian vaccination, serum administration, or prophylactic inoculation of many kinds. There is evidence also that they may follow the administration of such drugs as arsphenamine, streptomycin, and P.A.S., and it would seem unlikely that these particular drugs will prove to be unique in this connexion. The neurological disorders under discussion may also arise apparently spontaneously. In all these varying circumstances the histopathological findings are those of an acute disseminated perivenous demyelinating encephalomyelitis or of acute haemorrhagic leuco-encephalitis, a variant of the same condition in hyperacute form.

These diseases seem to be essentially mesodermal, based primarily on an inflammatory-exudative reaction arising in the vascular and supporting tissues of the neuraxis, secondarily involving neuronal elements (axons), and producing neurological symptoms, either by pressure (radiculitis) or by toxic effusion (perivenous reaction). It seems probable that

some common pathogenetic factor intervenes between the operation of the initial aetiological agent and this non-specific disseminated tissue-reaction in the nervous system which is responsible for the clinical end-result. That the common intervening factor is anaphylactic sensitization is suggested not only by the striking similarity of the syndromes to the allergic encephalomyelitis and polyradiculitis which have been experimentally produced in the laboratory animal, but also by the graphic illustration of the "neuromyolytic accidents" of rabies therapy.

The not very infrequent recurrence of acute disseminated encephalomyelitis when it follows non-specific infections—for example, of the upper respiratory tract—and its extreme rarity in post-exanthematous cases is in such circumstances to be interpreted as a reflection of the brief immunity bestowed by banal infections, with the opportunities afforded for repeated antigenic insults to the nervous system, in contrast with the lasting immunity usually conferred by a specific fever. Evidence of some clinical variation within the group—for example, the predilection of varicella encephalitis for the cerebellar system, or that of allergic reactions to horse serum for the spinal roots—can also on this hypothesis be attributed, in part at any rate, to qualitative differences in the antigen involved. There is convincing evidence of an analogous variation in the localization of somatic pathological changes in serum reactions when changes are made in the serum fractions injected (Hawn and Janeway, 1947), while more direct evidence has recently been furnished by the demonstration of Waksman and Adams (1955) that, while an allergic encephalomyelitis can be regularly provoked in the rabbit by single or repeated injection of an extract prepared from brain, spinal cord, or optic nerve, this syndrome is replaced by polyradiculitis if peripheral nerve is the source of the extract employed. It is probable that there are other factors, both endogenous and exogenous, which operate in the localization of these pathological changes.

That some individuals are especially prone to such reactions appears to be beyond doubt: there are a number of cases on record where a patient survived one post-exanthematous illness to fall victim to a further neurological disorder in relation either to another fever or to a non-specific infection. The occurrence of familial cases both after specific and after banal infections similarly argues a familial as well as personal predisposition, and in one family personally reported (Miller and Gibbons, 1954) recurrent episodes of encephalitic illness in three patients followed a very similar clinical pattern, though they varied in severity. Like other observers we have been impressed also by the frequently encephalitic incidence of such syndromes in dull and backward, socially inadequate, or frankly psychopathic subjects. It is our impression that this does not apply in myelitic illnesses, in which there is fairly often, however, an unequivocal history of recent exposure to cold or wet, or of violent exertion.

As we have shown elsewhere (Stanton *et al.*, 1953), the conception of a disseminated neuraxitis of varying aetiology which may involve the nervous system at any level also makes it easier to understand some well-recognized clinical phenomena which remain inexplicable if we continue to think of encephalitis, myelitis, and polyradiculoneuritis as separate disease-entities; we have in mind such events as a phase of meningism and mental disorientation in myelitis or the Landry-Guillain-Barré syndrome, the discovery of a localized flaccid palsy of root distribution after recovery from measles encephalitis, or the finding of a transient sensory level on the trunk in a patient with encephalitis following vaccination.

The hypothesis that acute disseminated encephalomyelitis is an allergic disorder has led to various attempts at treatment. In view of the natural history of the syndrome, and especially its frequent tendency to dramatic spontaneous improvement, the assessment of such trials is difficult and cannot at present be considered to have furnished any valid evidence on the question of aetiology. That the development of allergic encephalomyelitis in the experimental animal can

be prevented by the prior administration of corticotrophin has, however, been conclusively demonstrated by Moyer *et al.* (1950). The use of corticotrophin and cortisone in human acute disseminated encephalomyelitis has been described by Ligerink (1951), Garrison (1952), Miller (1953b), and Miller and Gibbons (1953, 1954). This experience has recently been summarized by Selling and Meilman (1955). We find ourselves in substantial agreement with their assessment that two-thirds of such cases treated may be regarded as benefited, in that early unequivocal improvement has been observed in patients previously deteriorating. Very severe cases and illnesses of some duration may show little or no response. Occasionally, however, rapid restoration of consciousness or unequivocal improvement in spinal-cord function may occur within a few hours of instituting treatment, relapsing as quickly when the hormone is withdrawn, and promptly responding to further therapy. This has been observed too often to be coincidental.

Opportunities for the treatment of neurological complications of serum sickness are rare, but response was observed in one case personally treated with cortisone (Miller and Stanton, 1954b), while in a subsequent instance of acute polyradiculitis complicating severe serum sickness dramatic relief of paresis with restoration of deep reflexes was obtained within a matter of hours. The results of treatment of polyradiculitis with cortisone have recently been reviewed (Jackson, Miller, and Schapira, 1957). About three-quarters of such cases seem to show a response. In about half of these it would appear that the natural course of the disease is appreciably shortened. Many such patients make a complete recovery within a month, which is certainly very uncommon in untreated cases. In a considerable number of instances, however, striking partial initial improvement during the first few days of treatment is rapidly arrested, and, despite the continued administration of the drug, recovery thereafter takes its accustomed slow course. Jackson *et al.* (1957) suggest that symptoms of neurological deficit directly resulting from oedema are dissipated under the influence of the drug, which does not, however, affect signs due to axonal damage, repairable only by the slower natural processes of regeneration.

In general it may be said that the results of corticotrophin and cortisone therapy in these acute neurological illnesses do nothing to discredit the allergic hypothesis of their origin and even yield some admittedly equivocal evidence in its favour. Recorded evidence is compatible with the hypothesis that the hormone may diminish the initial mesodermal inflammatory reaction, but is without influence on symptoms due to established axonal damage.

Summary

The natural history of the neurological complications of various specific fevers is briefly indicated. These syndromes are compared with other forms of acute demyelinating encephalomyelitis arising after non-specific infections, vaccination and prophylactic inoculation, the administration of drugs, trivial injury, or occurring spontaneously. The clinical and histopathological resemblance between these diseases and the experimental allergic encephalomyelitis and polyradiculitis produced in animals by the injection of brain emulsions suggests that all these syndromes in man may represent manifestations of an anaphylactic neuraxitis. The implications of this conclusion in the field of therapy are discussed.

LYMPHADENOID GOITRE (HASHIMOTO'S DISEASE)

DIAGNOSTIC AND BIOCHEMICAL ASPECTS

BY

DEBORAH DONIACH, M.D.

Thyroid Research Assistant, Institute of Clinical Research

AND

R. VAUGHAN HUDSON, F.R.C.S.

Middlesex Hospital, London, W.1

In most cases the diagnosis of lymphadenoid goitre is first made by the pathologist after thyroidectomy (Statland *et al.*, 1951; Lindsay *et al.*, 1952). Clinically, this type of goitre may be confused with "simple" non-toxic goitre; but thyroid carcinoma is often suspected because of the firm texture of the gland, leading the surgeon to undertake total thyroidectomy, with the attendant risk of post-operative tetany and vocal-cord paralysis. Since lymphadenoid goitres are non-malignant and many respond to thyroxine administration, it is important to establish the diagnosis pre-operatively.

The clinical picture has already been fully described (Joll, 1939; Schilling, 1945; Statland *et al.*, 1951; Lindsay *et al.*, 1952; Blake and Sturgeon, 1953). In diagnosis much help can be obtained with radioactive iodine (^{131}I) tracer tests combined with basal metabolic rate (B.M.R.) and serum cholesterol estimation; the changes in serum protein pattern which occur are also of diagnostic value.

We report here various tests with ^{131}I on 28 patients with Hashimoto's disease, and biochemical studies in which the serum protein abnormalities before and after treatment with thyroid hormones were observed and correlated with the state of thyroid activity in 11 of the patients (Table I). Serum protein studies were also made in 25 cases previously subjected to thyroidectomy for Hashimoto's struma, and in two control series consisting of 25 patients with other types of goitre and 8 myxoedematous patients without goitre.

Clinical Features

The group tested with ^{131}I consisted of 26 women and two men aged 28–68 (mean 52 years) who had noticed the goitre a few weeks to 15 years previously. There was a history of thyrotoxicosis in one case, but most patients presented with a feeling of pressure in the neck and symptoms suggesting hypothyroidism (17 of the 28). Thyroid pain was present in four cases. All the goitres were firm, of uniform consistency, and involved the entire gland, the enlargement

being mostly symmetrical and thyroid-shaped with well-delineated upper poles and pyramidal lobe; but in five cases the swelling was predominantly unilateral, and in three others the gland had a nodular surface. Histological proof of lymphadenoid goitre is available in 12 cases, the diagnosis in the remainder being based on clinical findings and investigations and the subsequent shrinkage of the goitre on administration of thyroid hormones.

Five cases are described, two to illustrate atypical clinical features suggestive of subacute thyroiditis, and the other three for the detailed investigations.

Illustrative Cases

Case 1

E. M., housewife aged 43. May, 1953, rapid swelling of thyroid, with increasing tenderness and throbbing, four weeks after onset of stomatitis and gingivitis associated with removal of septic teeth, symptoms reaching a maximum within next two months, with general lassitude and pain radiating to ears and back of head, accompanied by feeling of pressure in neck. September, 1953, thyroid estimated three to four times normal size, right lobe large, firm, and tender, left lobe softer and smaller. Gingivitis still present, with enlarged, tender lymph nodes in neck. Skin cool, no tremor. T. 98° F. (36.7° C.), P.R. 70, B.P. 140/65 mm. Hg. W.B.C. 5,300 per c.mm. E.S.R. 49 mm. (Wintrobe). ^{131}I uptake 72% in 24 hours, with thyroid-shaped distribution showing uptake over area of maximum swelling and pain. Swelling gradually subsided without thyroid medication, reaching almost normal size in December, 1953, though gland still firm and tender. Repeat ^{131}I uptake 69%; E.S.R. 48 mm.; B.M.R. –26%. Partial thyroidectomy performed in view of persistent pain and pressure symptoms; weight of gland 20 g. Histology, lymphadenoid goitre.

Case 2

Y. C., housewife aged 56. On admission: three weeks' painful, firm thyroid swelling, more marked on right, with feeling of pressure. B.M.R. –10%. Serum cholesterol 233 mg. per 100 ml. E.S.R. 77 mm. (Westergren). Plasma proteins: total 8.25 g. per 100 ml. (albumin 4.45 g., globulin 3.8 g., gamma globulin 2.3 g.). Thymol turbidity 15 units; alkaline phosphatase 4.2 units; bilirubin 0.12 mg. per 100 ml. ^{131}I uptake 65%, urine excretion 13%, in 24 hours. Topography showed bilateral uptake with maximum over tender right lobe. Within two weeks pain subsided and swelling diminished. ^{131}I uptake three months later, 52% in 24 hours. Owing to persistent discomfort and patient's fear of cancer, subtotal thyroidectomy performed five months after onset of goitre; weight of gland 42 g. Histology, lymphadenoid goitre.

Comment.—Clinically, Cases 1 and 2 suggested either haemorrhage into a thyroid cyst or subacute thyroiditis. The tender, firm goitre and the raised E.S.R. were thought to indicate thyroiditis (Blake and Sturgeon, 1953). Iodine uptake is usually completely suppressed in the acute stage of de Quervain's thyroiditis (McConahey and Keating, 1951; Crile, 1952; Fraser and Harrison, 1952), but a raised uptake has been reported in the recovery stage (Freedberg *et al.*, 1952; Trunnell, 1955) and is thought to be a rebound phenomenon. Our patients were tested some time after the onset of illness, and this delay was thought to explain their high iodine uptake. The distribution of ^{131}I was unlike that in thyroid cyst or carcinoma. The other atypical feature was the fairly rapid onset and the subsequent recession of the goitre without treatment.

Case 3

J. C., housewife aged 38. Goitre since 1947, with attacks of neck pain since 1948 and increasing lassitude since 1950. When seen in 1953 there was a large, firm, horseshoe-shaped goitre. B.M.R. –18%. ^{131}I uptake 66% in 24 hours, with symmetrical distribution. Treated with thyroid, 2–3 gr. (0.13–0.2 g.) daily, with return of normal energy and reduction in size of goitre to less than half. Twice stopped taking

thyroid for two to four months, with prompt return of symptoms and increase in goitre. Results of serum protein estimations are shown in Table I. In February, 1956, following exacerbation of neck pain with enlargement of goitre in spite of continuous thyroid medication, operation decided on to establish diagnosis with more certainty. Tracer tests repeated pre-operatively showed neck uptake of ^{131}I 20%

FIG. 1.—Case 3: Cut surface of thyroid gland.

FIG. 2.—Case 3: Contact autoradiograph from 10 μ section of gland.

FIG. 3.—Case 3: Histological autoradiograph (S. R. Pelc) showing uptake of ^{131}I in colloid of scattered thyroid follicles.

in 24 hours (thyroxine suppression), biological half-life (B.H.L.) 2.8 days; 48-hour plasma ^{131}I 0.41% of dose per litre; protein-bound fraction 72% of total. B.M.R. –26%. Weight of thyroid removed, 80 g. Histology, lymphadenoid goitre. (Figs 1–3.)

Comment.—Pain is uncommon in Hashimoto's disease, and all four cases in which it was present had a greater iodine uptake than is usual, yet were indistinguishable histologically from cases without this symptom. We have noticed that patients often complain of aching in the thyroid after T.S.H. injections, and that tenderness also occurs in thyrotoxic patients overtreated with antithyroid drugs and whose goitre has enlarged owing to endogenous T.S.H. overproduction; medicinal goitres in which the enlargement is equally due to T.S.H. overproduction have also been reported to be occasionally painful (Bredahl and Fraser, 1955). In view of the evidence of T.S.H. overstimulation in Hashimoto goitres, it is conceivable that pain may be connected with a rapid hypertrophy of glandular elements and lymphoid invasion with resulting intracapsular tension in these firm glands.

Case 4

G. L., housewife aged 59. Two years' painless goitre with 6–12 months' slowing down, hoarseness, paraesthesiae of hands, puffiness of face. Clinically hypothyroid with large, firm, symmetrical goitre showing prominent pyramidal lobe. B.M.R. –8%. Serum cholesterol 380 mg. per 100 ml. ^{131}I uptake 63%. Plasma clearance rate at one hour, 29 ml. per minute. 48-hour plasma ^{131}I , 0.32% of dose per litre; B.H.L. 8.5 days. Potassium perchlorate, given one hour

FIG. 4.—Case 4: Electrophoretic pattern of serum proteins, obtained by scanning of paper strip. A, Initial pattern before operation, showed raised gamma-globulin fraction. B, Four and a half months after operation, showing return of protein pattern to normal after removal of thyroid.

after a dose of ^{131}I to test protein-binding capacity of gland, produced a fall in neck uptake from 32% to 25%. Serum protein estimations are shown in Table I. Treated with thyroid, 2 gr. (0.13 g.) daily, but, as goitre was no smaller after two months, operation undertaken for pressure symptoms. Thyroid weight 165 g. Histology, lymphadenoid goitre with marked fibrosis. Four and a half months after operation serum protein pattern and flocculation tests returned to normal values.

Case 5

N. E., housekeeper aged 60. Eighteen months' increasing myxoedema; goitre noticed last three months. Firm, rubbery, diffuse enlargement of thyroid, estimated 2½ times normal size. B.M.R. –22%. Serum cholesterol 170 mg. per 100 ml. ^{131}I uptake 44%, excretion 32%, in 24 hours. Plasma clearance rate, 25 ml. per minute; 48-hour plasma activity, 0.4% per litre; protein-bound fraction, 65% of total. B.H.L. 12 days. No increase in iodine uptake after 5 units of T.S.H., suggesting impaired thyroid reserve. Goitre decreased on thyroid medication.

TABLE I—Differential Serum Protein Estimations and Liver Function Tests in Hashimoto's Disease

Patient	Sex and Age	Duration of Thyroid Treatment (2-3 gr. Daily) (Months)	Serum Cholesterol (mg. per 100 ml.)	E.S.R. (Wintrobe) P.C.V. of 45% (mm. in 1 Hour)	Serum Proteins*										Liver Function Tests					Clinical Details and Thyroid Function

* The serum proteins were fractionated by paper electrophoresis after the method of Flynn and de Mayo; the strips were stained with azocarmine B and graphs made with a recording reflectance scanner (Joyce and Loebel). The patterns obtained were cut into their five component peaks and the area of paper corresponding to each was weighed to 0.1 mg. and expressed as a percentage of the total area. The total serum proteins were estimated by the biuret method; from this and the percentages obtained by scanning, the protein fractions were calculated in g. per 100 ml. Electrophoretic strips and flocculation tests were carried out in the routine laboratory of the Courtauld Institute.

* Results in this group represent the average of 26 tests done on 11 patients.
† Results of flocculation tests are not usually expressed in fractions of units; these averages were calculated for comparison of the four groups.
‡ Zinc sulphate test carried out on only 14 patients and alkaline phosphatase on 16 patients in the control group.

Results of Radioactive Iodine Tests

Fig. 5 shows the thyroid ^{131}I uptake and B.M.R. in the 28 patients tested; 24-hour uptake varied between 19% and 73% and B.M.R. between -29% and $+3\%$, the mean being -16% as compared with -5% in normal subjects.

FIG. 5.—Twenty-four-hour neck uptake of ^{131}I and B.M.R. in 28 patients with untreated lymphadenoid goitre.

B.M.R. with the size of the goitre in our patients. Isotope distribution was invariably uniform and followed the outline of the goitre, the uptake being greater on the side of the larger lobe in asymmetric goitres.

In patients investigated more fully the results illustrate the functional behaviour of the thyroid in this condition. The biological half-life was short and varied between 2.8 and 12 days; 48-hour plasma activity was 0.39%, 0.41%, 0.32%, and 0.4% of the dose per litre in four patients tested, 65-75% of the total being protein-bound. These results are high, especially in view of the low B.M.R.s in these cases. Five units of T.S.H. had no effect on iodine uptake in a case of Hashimoto's disease, whereas the same dose in normal subjects increased the three- and six-hour readings two- to three-fold. Potassium perchlorate, 400 mg., caused the neck uptake to fall by 22% in 30 minutes, the drug having no effect in normal or thyrotoxic patients under the same conditions.

In Case 3, in which 800 microcuries of ^{131}I had been given 48 hours pre-operatively, direct analysis of the extirpated gland, using combined isotope and chromatography techniques (Mrs. R. Pitt-Rivers), showed only 12% of the total iodine stored as thyroxine, whereas a normal gland analysed by the same method contained 24.3% of thyroxine iodine. Figs. 2 and 3 show the macroscopic and histological autoradiographs of this gland; the isotope was taken up in fairly evenly scattered small foci, which explains why topographical surveys *in vivo* produce isocount pictures which follow the outline of the palpable goitre in Hashimoto's disease. The histological autoradiograph shows protein-bound iodine in the colloid of some follicles, none being present in the many clumps of epithelial cells devoid of colloid.

Biochemical Results

Serum protein studies were first undertaken to explain the consistently raised E.S.R. in Hashimoto's disease; a rise in gamma globulins was found, though total and differential serum proteins appeared normal in most cases when estimated by the conventional biuret method. Results of flocculation tests of liver function which depend on the relative concentrations of globulins and albumin were also abnormal, though none of the patients had a history or symptoms of liver disease. Since these studies were started, other reports of similar findings in lymphadenoid goitre have appeared. Table I shows the results in 11 cases of Hashimoto's disease; the rise in gamma globulins is still present after 2½ years of thyroid medication in some cases, but returned

to normal 4½ months after removal of the goitre in one case (Fig. 5) and after 8 months in another. The mean value for gamma globulins in these 11 cases was 2.13 g. per 100 ml. (29.3% of total protein). Table II shows the corresponding figures in the other three groups of patients tested.

The two control groups consisted of (1) 25 euthyroid and hyperthyroid patients, 21 with "simple" non-toxic goitre, and 4 with untreated Graves's disease; and (2) 8 cases of primary or secondary myxoedema, in view of the possible influence of thyroid deficiency on the gamma globulins. In the first group the average gamma globulin level was 1.22 g. per 100 ml. (19.1%). Results of flocculation tests were: colloidal gold "negative" in 19 patients, 1 unit in four, and 2 units in two patients. For thymol turbidity the highest value obtained was 4 units (5 cases); zinc sulphate turbidity ranged between 3 and 11 units. Group 2 had an average gamma globulin level of 1.4 g. per 100 ml. (21.1%) and normal flocculation values, except for one patient who had a thymol turbidity of 7 units with a colloidal gold of 2 units.

The post-operative group consisted of 25 proved cases of Hashimoto's disease thyroidectomized 6 months to 22 years previously, collected from the records of the Middlesex Hospital. The mean value for gamma globulins in this group was 1.5 g. per 100 ml. (21.8%). The colloidal gold test was "negative" in 15 cases, 1 unit in five, 2 units in one, 3 units in two, and 4 and 5 units in one case each. All the patients with negative colloidal gold results and five with colloidal gold of 1-3 units also had normal values for the other flocculation tests, except one with a thymol turbidity of 7 units, a zinc sulphate of 14 units, and gamma globulin 1.9 g. per 100 ml. This patient had had a hemithyroidectomy two years previously and still had an enlarged left thyroid lobe. Three other patients in this group had markedly raised gamma globulins and flocculation results, one of them (Case 2 described above) having gamma globulins 2.97 g. per 100 ml., colloidal gold 5 units, thymol turbidity 12 units, and zinc sulphate turbidity 29 units, three years after partial thyroidectomy.

Table II further shows that the other globulin fractions do not differ significantly in the four groups, and that the gamma globulins appear to be raised at the expense of the albumin fraction in cases of Hashimoto's disease.

Discussion

Radio-iodine Studies

The ^{131}I studies in patients with lymphadenoid goitre show a normal or high thyroid uptake, even in the presence of clinical myxoedema and a low B.M.R., and a uniform distribution of iodine which follows the outline of the palpable swelling. These characteristics help to distinguish lymphadenoid goitre from non-toxic nodular and from malignant goitres. In non-toxic nodular goitre the ^{131}I distribution is uneven and the isocount picture rarely portrays the shape and extent of the goitre. In malignant goitres and thyroid cysts the uptake is usually diminished or absent over the affected side, and the over-all uptake is never high unless the patient also shows signs of hyperthyroidism.

The more detailed studies carried out in four clinically subthyroid patients show a relatively high 48-hour plasma activity and a short B.H.L. compared with the normal, which was 55 to 106 days in four subjects studied by Hickey and Brownell (1954) and varied between 30 and 180 days in ten cases of non-toxic colloid goitre studied by us. These results suggest that in lymphadenoid goitre there is a small thyroidal iodine pool with a high specific activity. The same feature is often found in carcinoma of the thyroid, but here the isotope is localized to a small remnant of normal but overstimulated tissue (Rotblat and Owen, 1954). The lack of response to T.S.H. has also been reported by other workers (Levy *et al.*, 1955; Skillern *et al.*, 1956), and supports the histological evidence of T.S.H. overstimulation of the gland in Hashimoto's disease: the small number of intact follicles work at full capacity and cannot be further

MARCH 23, 1957

LYMPHADENOID GOITRE

stimulated. Protein-binding of iodine does not appear to proceed at a normal rate as shown by the perchlorate test. Dr. W. R. Trotter (personal communication), who suggested the test to us, has obtained similar results in other cases of lymphadenoid goitre. In health and in thyrotoxicosis protein-binding is so rapid and complete that no unbound iodide can be released, and neck readings continue to rise after giving perchlorate (Berson and Yalow, 1955). Direct analysis of the gland indicates that thyroxine storage is defective in Hashimoto's disease, since the percentage of thyroxine iodine was only half the normal in our patient.

Biochemical Studies

The first report of the occurrence of raised gamma globulins in Hashimoto's disease appeared in 1953, when Fromm *et al.* published differential protein estimations in four cases of this disease and one case each of de Quervain's and Riedel's thyroiditis. In three of their cases of Hashimoto's disease the gamma globulins were over 2 g. and in the other cases between 1.66 and 1.83 g. per 100 ml. Cooke and his colleagues (Cooke and Wilder, 1954; Cooke and Luxton, 1955; Luxton and Cooke, 1956) have reported abnormal colloidal gold curves in Hashimoto's disease. Observing patients on prolonged thyroid medication, they found that with adequate dosage the liver-function tests tended to return to normal, though the reversal was usually slow and took up to 29 months. At their suggestion an extensive study was made at the Cleveland Clinic, and the results (Skillern *et al.* 1956) confirm and extend previous observations.

Our findings similarly show the presence of raised gamma globulins and flocculation values in untreated lymphadenoid goitre, and it appears that the larger goitres were associated with the most striking changes in electrophoretic pattern, though the flocculation tests were also abnormal in patients with small lymphadenoid goitres whose gamma globulins were still within the normal range.

The thymol, colloidal gold, and zinc tests usually gave concordant results, though in a few instances the colloidal gold results disagreed with the other flocculation reactions and with the electrophoretic strip. The cephalin-cholesterol test proved least useful and gave the same results in simple goitre, thyrotoxicosis, myxoedema, and Hashimoto's disease, which was to be expected, since the test is more influenced by the beta-globulins than by those in the gamma fraction. The E.S.R. was always raised in Hashimoto's disease, but is so unspecific (Meyers *et al.*, 1953) that it was not infrequently raised in the control groups when all other tests were normal. In three cases of thyroid carcinoma so far tested we have found normal gamma globulins and flocculation tests. In one of the cases the goitre was uniform, the B.M.R. in the hypothyroid range, and the E.S.R. very high. Normal serum protein values and a unilateral iodine uptake decided in favour of thyroid carcinoma, and this was proved at operation.

Myxoedema is often associated with a raised E.S.R. (McAlpine, 1955) and sometimes with a rise in total serum proteins. The electrophoretic pattern did not show increased gamma globulins in our myxoedematous controls, though some had a raised beta fraction, as expected in the presence of high serum lipids.

Our post-operative survey shows that serum proteins are normal in most cases of Hashimoto's disease after removal of the goitre, and in two cases we have actual proof of this change from high pre-operative gamma globulins to normal values after operation. There was a lag of several months before this reversal took place, for three patients tested 10 days, 2½ months, and 3½ months post-operatively still had abnormal results.

It appears, therefore, that the abnormal gamma globulins are closely associated with the presence of the goitre, and we are unable to agree with Skillern *et al.* that they are entirely due to thyroid deficiency, since abnormal results were seen in patients who were euthyroid and had received more than physiological doses of thyroxine for over two years.

It is well known that gamma globulins are the serum protein fraction mainly associated with antibodies; moreover, the thyroid is grossly infiltrated with lymphoid tissue and plasma cells in Hashimoto's disease, and these cells have been shown to produce gamma-globulin antibodies elsewhere in the body (Harris and Harris, 1956). It is possible that a qualitative alteration of thyroid proteins or other special circumstances could provoke the formation of auto-antibodies. The presence of an antigen in the thyroid would explain the accumulation of antibody-producing cells in the gland and the enlargement of surrounding lymph nodes. If the antigenic protein escaped from the gland by breakdown of follicles, antibody production could also occur at other sites, which would account for the large quantity of gamma globulin produced and for the lag period in their disappearance after operation; since when the source of antigen is removed at thyroidectomy there might be some delay in the cessation of antibody production by the reticulo-endothelial system.

Summary

The pre-operative diagnosis of lymphadenoid goitre can now be made by a combination of ^{131}I tracer tests with the older tests of thyroid function and the addition of serum protein tests made available by the recent finding of increased gamma globulins in the serum in Hashimoto's disease, which, in the absence of liver disease, give rise to abnormal results of flocculation tests.

Five cases of lymphadenoid goitre are described, two of which were clinically atypical and suggested subacute thyroiditis, and three studied in some detail with ^{131}I and biochemically.

¹³¹I tests in 28 cases of Hashimoto's disease showed normal or high uptakes even in the presence of myxoedema, and a uniform distribution of isotope corresponding with the outline of the goitre. Short biological half-life and high plasma activity suggest a small thyroïdal iodine pool, other tests providing further evidence of deficient protein-binding and thyroxine storage in this type of goitre.

Liver function tests and differential serum protein estimations were carried out in 11 cases of Hashimoto's disease with 25 cases of other goitres and 8 of myxoedema as controls, and a post-operative group of 25 cases of Hashimoto's disease tested in order to study the effect of removal of the goitre on the serum proteins. The findings suggest that paper electrophoresis in combination with flocculation tests provide diagnostic help and distinguish lymphadenoid goitre from simple non-toxic goitre and from carcinoma of the thyroid. Results obtained in the post-operative survey suggest that removal of the goitre is associated with a return to normal of the gamma globulins.

It is put forward as a working hypothesis that the raised serum gamma globulins represent an immune response to an antigen released by the goitre.

This investigation was in part supported by a grant from the Clinical Research Fund of the Middlesex Hospital.

We are grateful to Professor Sir Charles Dodds and his staff at the Courtauld Institute of Biochemistry for their untiring co-operation in these investigations, and to Professor J. E. Roberts and his staff for the isotope tests. Fourteen of the isotope tests were carried out by one of us during tenure of a research scholarship at the Royal Free Hospital. Our thanks are due to Miss G. Barry, senior surgeon, and to Mr. H. S. Williams, hospital physicist; to the surgeons of the Middlesex Hospital who allowed us to test the post-operative patients; to Dr. R. P. K. Coe for permission to quote case C.F., and Dr. W. R. Trotter for case E. N.; to Mrs. R. Pitt-Rivers for her analyses; and to Dr. S. Pelc for the histological autoradiographs. We are particularly

grateful to Dr. E. T. Knudsen and Mr. C. F. M. Rose for their help and advice, and to Dr. K. M. Jones for his interest, co-operation, and assistance in the analysis of the radio-iodine tests.

ADDENDUM

Since this paper was submitted, immunological studies have shown that the serum of patients with Hashimoto's disease contains a precipitating auto-antibody which reacts specifically with human thyroglobulin. A preliminary communication of this work has appeared (Roitt *et al.*, 1956). The thyroglobulin precipitin test was positive in all the patients listed in Table I and in several from the post-operative group where only part of the thyroid had been removed; Case 3 and Case 4 still show the precipitin nine and twelve months after subtotal thyroidectomy, though results of serum protein tests are now normal. Case 5 has failed to show precipitins by the method used after 3 years of thyroid administration. Full results will be published elsewhere.

VISCERAL LESIONS IN HERPES ZOSTER

BY

R. WYBURN-MASON, M.A., M.D.

The peripheral nerves and posterior and trigeminal sensory nerve roots contain not only various sizes of myelinated, but also unmyelinated "afferent" fibres. Distally the afferent unmyelinated fibres originate (or end) as free nerve endings not only in the epidermis or dermis, but also between the deeper tissues, including muscles, periosteum, joints, and fascia (Ranson and Davenport, 1931; Feindel, Weddell, and Sinclair, 1948). They also arise (or end) on the blood-vessel walls. Some of them are visceral in origin (Kuntz and Hamilton, 1938). All the evidence suggests that in the somatic tissues these fibres conduct impulses which give rise to diffuse, radiating, compelling burning pain (see Fulton, 1949).

In the posterior nerve roots all the afferent unmyelinated fibres of the peripheral nerves, whether they originate in the skin, deep somatic tissues, blood vessels, or viscera, are grouped together laterally. Division of the lateral part of these roots cuts the unmyelinated fibres, and now on stimulation of the peripheral nerve

distal to the section no autonomic reflex changes occur as they do in intact animals (Ranson and Davenport, 1931; Clark, Hughes, and Gasser, 1935).

Mode of Production of Lesions of Herpes Zoster

The skin lesions of herpes zoster lie in the area of sensory supply of the posterior and trigeminal nerve roots. They manifest themselves firstly as a reddening of the skin followed by oedema and blister formation—that is, the appearance of fluid between the epidermal layers. Typical inflammatory changes are found in the skin papillae, in the deeper parts of the corium, and in the hair follicles. Subcutaneous fat may also contain knots of inflammatory cells. Lewis (1927), in his classical researches, showed that irritation of sensory nerves and the posterior nerve roots results in vasodilatation and the release of a vasodilator substance (H-substance), probably histamine, in the skin. He further demonstrated that in cases of herpes zoster the same substance was released in the affected tissues and that "herpetic and herpeticiform eruptions occur as sequels to lesions of the sensory nerve tracts; not only do they follow irritative lesions of the (root) ganglion, but they are produced also by lesions of those tracts distal to the ganglia themselves." It seems probable that the unmyelinated fibres of the posterior roots with free nerve endings in the skin and other tissues and on the blood vessels are those concerned.

Herpes Zoster and Lesions of Deep Somatic Tissues

When zoster is of gangrenous type the lesions extend deeply and lead to much scarring. Glandular swelling and inflammation in the region of the affected skin lesions is usual and may precede the latter (Bichelon, 1907; Lebel, 1920; Ramond, 1923), so that they cannot be due to secondary infection of the skin. The subcutaneous tissues, fat, and muscles may contain painful and swollen areas identical in character with "fibrositis" and "myositis" (see Brain, 1931; Wilson, 1940; Ford, 1946). Synovial effusions occur in the affected areas and the joints may become ankylosed with fibrous tissue. The pericapsular joint tissues are often swollen and painful, and, when the hand is affected, this gives appearances indistinguishable from those of rheumatoid arthritis, so-called "periartthritis chronica rheumatica" (Guillain and Pernet, 1910; Guillain and Rouvillier, 1913). The affected limb may exhibit oedema and cyanosis. When the lower limb is involved, permanent pitting oedema may remain (Wilson, 1940). The muscles sometimes waste either immediately or after a variable period. When a limb is affected, its bones may become osteoporotic (see Schönfeld, 1929), or show Sudeck's atrophy (Sudeck, 1910). Schleicher (1949) describes chronic inflammatory changes in the marrow of the affected bones. Pleural reactions and haemorrhagic pleural effusions may appear beneath zoster of the chest wall (Curtin, 1902; Mann, 1931) or there may be symptoms and signs of irritation of the parietal peritoneum (Ford, 1946).

In cases of ophthalmic herpes sterile inflammatory changes often occur in the eye, resulting in a panophthalmitis and not infrequently in the appearance of haemorrhages and thromboses in the retinal vessels. Afterwards the eyelids may remain permanently oedematous. It is reasonable to suppose that these manifestations in the deeper somatic tissues are produced in a manner analogous to those in the skin—namely, by disturbance in the unmyelinated fibres of the posterior spinal and trigeminal sensory nerve roots.

Herpes Zoster Accompanied by Visceral Lesions

Unmyelinated afferent fibres with their cell bodies in the posterior root ganglia run from the viscera uninterruptedly through the autonomic ganglia and white rami communicantes to enter the posterior nerve roots with those from somatic tissues. The posterior nerve roots through which

the afferent fibres from the various viscera enter the cord are as follows (Lewis, 1942; White and Smithwick, 1947; Kuntz, 1953):

Heart	C 8-D 4 (?)
Lungs	D 2-5
Oesophagus	D 4-5
Stomach and duodenum	D 6-8
Liver and gall-bladder	D 7-8 right
Pancreas	D 8 left
Small intestine	D 9-10
Appendix and ascending colon	D 10-L 1
Epididymis	D 10
Ovary, testis, and suprarenal	D 10-11
Bladder fundus	D 11-L 1
Kidney	
Uterine fundus	
Colonic flexure	L 2-3
Sigmoid and rectum	
Cervix	S 2-5
Neck of bladder, prostate, and urethra	

It might be expected that irritation of the unmyelinated afferent fibres in the posterior nerve roots or peripheral nerves, or their cell bodies in the posterior root ganglia, would produce changes not only in the skin and somatic tissues, but also in the viscera. In his classical paper on herpes zoster Head (1893) did not specifically mention visceral involvement. In the literature on herpes zoster, however, there are a number of descriptions of localized visceral disturbances accompanying the skin lesions. I have observed this association in numerous cases, of which Cases 1-8 cited below are typical examples. These cases and those taken from the literature are summarized in the Table.

Author	Site of Zoster	Visceral Disturbance
Case 1, present series	C 3-4	Redness, oedema, inflammatory changes, and bleeding on right side of larynx and trachea. Endocarditis and tachyarrhythmia.
Andréassian (1934)	L. cervico-scapulo-thoracic	Paroxysmal tachycardia during and following attack.
Turner (1909)	D 2	Marked bradycardia.
Mann (1931)	D 3-4	Followed 34 years later by progressively severe anginal pain at site of zoster, cardiac enlargement, and E.C.G. changes.
Case 2 of Spillane and White (1939)	C 8-D 2, and D 4-6	Pleuritic pain, friction rub or pleural effusion.
Curtin (1902)	D 7-8	" " "
Mann (1931)	D 7-8	" " "
Brain (1932)	D 7-8	" " "
Ryle (1932)	D 3-4	Gastro-intestinal disturbance.
Varior (1907)	Intercostal	Disturbance of passage of food down oesophagus.
Curtin (1902)	Upper abdominal	Anorexia and constipation.
" "	Lower thoracic	Bowel atony and abdominal distension.
Rayer (1935)	Abdominal	Gastro-intestinal disturbance preceding, during, and following rash.
Frisch (1908)	"	" " "
Bielschowsky (1914)	"	" " "
Fuchs (1840)	"	" " "
Case 2, present series	D 6-8	Abdominal colic. Severe spasm of pyloric region of stomach (Fig. 1) with reddening of gastric mucosa, symptoms being partly relieved by atropine.
Case 3, present series	D 7-8	Nausea, vomiting, and anorexia, followed by haematemesis and appearance of gastric ulcer on lesser curvature (Fig. 2).
Hess and Faltischek (1925)	D 6-10	Gastric hyperacidity cured by paravertebral sympathetic block.
Stone (1948)	D 9-10	Haematemesis.
Fitzpatrick (1948)	D 9-10	Nausea, anorexia, burning epigastric sensation, haematemesis, and achlorhydria. Radiographs showed no peptic ulcer. Symptoms unrelieved by alkalis and gradually disappeared with skin eruptions.
"Surgeon" (1950)	D 8-10	Intestinal paralysis and vomiting. Colon radiologically normal, "the disturbance presumably being in the small intestine."
Donaldson (1948)	D 9-11	Anorexia, nausea, and haematemesis, the symptoms disappearing with the skin changes.
Curtin (1902)	D 10-11	Fever and symptoms resembling appendicitis.
Case 4, present series	D 11-L 1	Intense constipation and local spasm of ascending colon with dilatation distal to this, symptoms being partly relieved by atropine.
Case 5, present series	D 11-L 1	Intense constipation, though taking no drugs. Laparotomy revealed inflammatory changes in ascending colon.
Curtin (1902)	Over kidney and passing to abdomen	Persistent haematuria.
Grossmann (1932)	D 10-L 2	Renal colic. No urinary disturbance or evidence of calculi.
Van der Scheer (1913)	D 12	Polyuria and severe persistent constipation.
Nieuwehuijse (1914)	D 12	Ileus.
Case 6, present series	D 11-L 2	Spasm of ascending and transverse colon and dilatation of distal colon. Inflammatory changes in bladder mucosa, especially on left. Symptoms partly relieved by hyoscine.
Darget (1929)	Inguinal	Cystitis and haematuria. Cystoscopy showed a raised inflammatory area on bladder wall.
Volk, quoted by Schönfeld (1929)	Buttock	Zoster of bladder and haemorrhagic cystitis.
Ford (1946)	Abdominal	Symptoms of bladder irritation.
Watts (1948)	Upper lumbar root zone	Disturbance of bladder function and haematuria.
Siding (1909)	L 1	Rectal and bladder disturbance.
Case 7, present series	D 12-L 2	Transient severe inflammatory changes in bladder mucosa. Spasm of descending colon and rectum and dilatation of transverse colon above (Fig. 3).
Case 8, present series	L 2-3	Inflammation of mucosa of sigmoid colon, spasm of descending colon (Fig. 4). Inflammation of neck of bladder. Symptoms partly relieved by hyoscine.
Dubois (1926)	Buttock	Frequency, dysuria, and eventually urinary retention. Cystoscopy showed vesicles on left side of base and lateral wall of bladder.
Wolbart, quoted by Dubois (1926)	"	Herpes of ureteric orifice.
Satani (1926)	"	Zoster of bladder on same side and suppuration of large intestine.
Rouyer (1903)	Gluteal region	Frequency and dysuria.
Chesterman (1932)	Buttock	Lesions of bladder.
Belgode (1924)	Gluteal and sacral	Uterine cervicitis and enlargement.
Davidsohn (1890)	"	Transient paralysis of bladder and rectum.
Bernhardt (1890)	" " "	" " "
Oppenheim (1911)	" " "	" " "
Tomey (1909)	Sacral	Frequency and disturbance of bowel emptying.
Parsat (1910)	Gluteal region, scrotum, and perineum	Urinary and faecal retention for 14 days.
Frankl-Hochwart (1913)	R. genital area	Dysuria and disturbance of bowel emptying.
Spitzer (1925-6)	Buttock and one leg	Severe urinary disturbance lasting 3 weeks.
Mann (1931)	Sacral	Rectal and bladder disturbance.

Case 1.—Male, aged 42. Ten days before he attended hospital severe pains began in right side of neck and shoulder, followed after three days by rash over right shoulder and front, back, and side of lower part of neck. Three days afterwards he complained of cough, thick mucoid expectoration streaked with blood, and some hoarseness. Examination: Typical painful zoster eruption in distribution of right C3 and 4 segmental zones with hyperalgesia. No abnormal physical signs in other systems. Radiographs of chest normal. Laryngoscopy: redness and oedema of right vocal cord. Bronchoscopy: marked oedema and redness, strictly limited to right side of tracheal mucosa, extending downwards to carina. With fading of the skin lesion the cough, expectoration, and hoarseness gradually ceased.

Case 2.—Female, aged 41. Three weeks before coming to hospital she developed hemigirdle pain in the right lower chest and between the shoulder-blades. Four days later zoster appeared in this region with a sensation of substernal pressure and epigastric aching immediately on swallowing, as though food was stuck. The aching was not improved by taking alkalis. Examination: Typical zoster eruption in right D 6-8 segmental areas. Barium meal: marked spasm in the prepyloric region as shown in Fig. 1. Fractional test meal: high acid curve. Gastroscopy: spasm of pyloric antrum, the mucosa of which was reddened and swollen. Vomiting relieved by belladonna, 12 min. (0.7 ml.) t.d.s.; it reappeared if drug omitted. The skin lesions and digestive disturb-

FIG. 1.—Case 2. Right D 6-8 zoster. Barium meal radiograph showing spasm of pyloric antrum.

ance died down in course of the next three months, by which time the spasm had disappeared radiologically. Fractional test meal now showed some fall in acid secretion.

Case 3.—Male, aged 72. No previous digestive disturbance. He developed herpes zoster of right D 7 and 8 zonal areas. At height of attack he complained of nausea, vomiting, and severe anorexia, which lasted for several months. Skin lesions, followed by post-herpetic pain of two types, a constant ache, and a sharp stabbing pain brought on by movement of trunk; pain varied in severity, but worse in damp and cold weather. Two months after onset two severe haematemeses, each of about 1 pint (570 ml.). A barium meal one month later showed an ulcer crater on the lesser curvature of the incisura (Fig. 2). Despite various antacids the digestive symptoms persisted.

FIG. 2.—Case 3. Radiograph taken during barium meal, showing gastric ulcer on lesser curvature developing with zoster of right D 7-8 zonal areas.

sation and tenderness in region of right hip when he lay on it, and a week later this region became painful. Within a few days a segmental zoster eruption appeared in the painful region, extending from 1½ in. (3.8 cm.) below the umbilicus to groin and round to back in distribution of right D 11-L 1 nerve roots. With onset of rash complete constipation set in. A barium enema showed marked spasm of ascending colon with dilatation of gut distal to this. Constipation partly relieved by administration of atropine by mouth. With healing of rash marked post-herpetic pain remained, but more normal bowel function gradually returned. Two years after onset of herpes bowels still remained sluggish.

Case 5.—Female, aged 62. Developed herpes in right D 11-L 1 distribution. With onset of rash absolute constipation developed and persisted for three weeks, during which time no response to enemata was obtained. Laparotomy performed, but no obstructive lesion found in bowel. The ascending colon was, however, oedematous and engorged, and was excised. Histologically it showed non-specific inflammatory changes in all coats for a distance of 25 cm. Rash faded and the scars healed within six weeks, but pain persisted with some severity for nearly two months. For next 10 years the affected region remained tender and bowel function extremely sluggish. Emptying never occurred without use of purges. One month after development of the herpes her two daughters developed chicken-pox.

Case 6.—Female, aged 60. Two weeks previous to attendance at hospital she developed painful irritation of left lower abdomen followed by a herpetic rash passing to loin and back. Two days prior to attendance sudden severe frequency and burning micturition began, and on day of attendance some haematuria occurred. She was severely constipated. **Examination:** Typical herpetic rash and hyperalgesia in left D 11-12 segmental areas of abdomen and loin. Urine: albumin and blood; catheter specimen: numerous R.B.C. and pus cells; no organisms present. Cystoscopy: marked redness and oedema of bladder fundus, chiefly on left side. Barium enema: marked spasm of ascending and transverse colon and dilatation of descending colon. Treated with tincture of hyoscyamus, 30 min. (1.8 ml.) t.d.s., with some relief of urinary symptoms and constipation. With healing of the skin lesions urinary symptoms and constipation gradually diminished, though both these and pain persisted during the next six months.

Case 7.—Male, aged 50. Two months prior to attending hospital he developed severe left lumbar pain spreading into left loin, iliac fossa, and front of thigh. Three days later zoster appeared in this area. At the same time he complained of difficulty in defaecation and constipation, considerable frequency of micturition, difficulty in emptying the bladder, and burning pain in penis when bladder was full and during micturition. Symptoms at first severe, but diminished somewhat in severity in course of next two months. Visceral symptoms varied with pain. **Examination:** Site of zoster scabs very hyperalgesic and corresponding to left

D 12-L 2 segmental areas. Cystoscopy: marked congestion and submucous haemorrhages in the floor and roof of the bladder mucosa, which bled easily and appeared inflamed. Urine: no organisms, but some pus cells present. Barium enema: markedly spastic descending colon and rectum, with dilatation of transverse colon above (Fig. 3). Cerebrospinal fluid: normal. Repetition of barium enema four weeks later showed much diminution in spasm. Over the next two years he was subject to bouts of pain with inability to empty the bladder.

Case 8.—Male, aged 52. Two weeks previous to attending hospital he developed pain in front of left thigh and knee, extending to outer side of left hip. Four days later a rash appeared in painful area and after another four days he developed severe constipation with a desire to empty the bowels; he passed dark blood-stained mucus and had some difficulty and pain on micturition. **Examination:** Typical herpes zoster and hyperalgesia in left L 2-3 segmental areas. Urine: pus cells but no organisms. Rectal examination: normal. Sigmoidoscopy: swollen reddened mucosa at uppermost limit to which the instrument could be passed. Barium enema: severe spasm of descending colon. Cystoscopy: neck of bladder intensely red and oedematous. Intestinal and urinary symptoms considerably relieved by administration of tincture of hyoscyamus, 30 min. (1.8 ml.) t.d.s. Pain, skin lesions, and intestinal disturbance gradually disappeared in the next three months.

FIG. 3.—Case 7. Left D 12-L 2 zoster. Barium enema radiograph showing spasm of descending colon.

Comment

After reference to the course of the afferent visceral fibres shown in the Table it will be observed that the visceral disturbance in cases of herpes zoster occurs particularly in those viscera, or parts of viscera, supplied with afferent fibres by the posterior nerve roots corresponding to the zonal skin areas affected. As in the skin and deep tissues, so the effects on the viscera are to produce vasodilatation, oedema, haemorrhages, and inflammatory changes, and to predispose to vascular thromboses. The affected gut exhibits local hypermotility and spasm. The evidence suggests that, apart from the parasympathetic and sympathetic, the viscera receive a third type of nerve supply which may affect their activity. The bipolar cell bodies lie in the posterior root ganglia, and their peripheral axons pass to the viscera without relay through the autonomic ganglia. They are, in fact, the so-called visceral "afferent" fibres. This perhaps explains to some extent the frequently reported variable and uncertain effects on the viscera of stimulating the rami communicantes of the spinal nerves and the sympathetic chain in which such fibres run. It further raises the problem of whether "antidromic" centrifugal impulses are normally conducted by the "afferent" unmyelinated fibres.

Summary

In cases of herpes zoster the inflammatory skin lesions are thought to result from disturbance of the ganglion cells of the posterior or trigeminal root ganglia or of the "afferent" fibres of the posterior nerve roots or the peripheral nerves. Similar nerve fibres originate or end in the viscera. Evidence is adduced which seems to indicate that, accompanying the segmental skin lesions, there occurs disturbance of the viscus, or part of the

viscus, innervated by the corresponding nerve roots, which results in inflammatory lesions and spasm in the case of the hollow organs. This suggests that, in addition to the sympathetic and parasympathetic pathways, there exists a third nerve pathway by which visceral activity may be altered.

In a booklet entitled *Health Services in Britain* (H.M.S.O., 3s. net) the Central Office of Information has added another useful publication to its series of "Reference Pamphlets." Starting with water supply and sewerage, the booklet proceeds to describe the other public health services, the National Health Service, and industrial health. There are additional sections on the health services in Scotland and Northern Ireland, on the Medical Research Council, and on professional training in Britain; a bibliography of Government publications; and a useful list of the names and addresses of health departments and organizations. Some statistics are given of the National Health Service. About 97% of the population of Great Britain uses the Service; 98% of general practitioners, the "great majority" of specialists, 94% of dentists, and almost all chemists are taking part in it. The cost of the Service amounts to about 34% of the total national resources, and four-fifths of the gross cost (£570m.) falls on the Exchequer to be met from general taxation.

INFLUENCE OF HYDROCHLORIC ACID ON GASTRIC SECRETION AND EMPTYING IN PATIENTS WITH DUODENAL ULCER

BY

J. N. HUNT, M.D., D.Sc.

Physiology Department, Guy's Hospital Medical School, London

There are at least three possible ways of accounting for gastric hyperfunction in patients with duodenal ulcer. They are: (1) an increased number of cells which secrete acid (Meyers, 1948; Guiss and Stewart, 1948; Hunt, 1950; Cox, 1952; Card, 1952; Hunt and Kay, 1954); (2) an increased vagal drive to the gastric mucosa (Dragstedt, 1956); and (3) a failure of the duodenal mechanisms which inhibit gastric activity; this hypothesis embraces both gastric secretion and emptying (Shay, 1944). The present paper is concerned with the last of these possibilities.

Methods

The main purpose of the present experiments was to examine the influence on gastric secretion of low concentrations of acid added to test meals. Such acid might be expected to have three effects: it should stimulate duodenal receptors which slow emptying and thus prolong gastric distension by the meal. Since gastric distension is a stimulus to secretion in man (Hunt and Macdonald, 1952; Macdonald and Spurrell, 1953) such slowing of emptying should increase gastric secretion; on the other hand, acid should depress secretion via the duodenal inhibitory mechanism or possibly by inhibiting the release of gastrin (Woodward, Lyon, Landor, and Dragstedt, 1954). Thus whether added acid increases or decreases gastric secretion will depend upon the balance between the increased stimulus of distension and the inhibition of secretion from the duodenum. It has been found that in most normal subjects adding sucrose to test meals delays emptying and reduces secretion, but in two the addition of sucrose caused an increase of secretion. On further examination it was found that in these two subjects increasing gastric distension produced an unduly large increase in gastric secretion (Hunt, 1954).

For the present experiments, which were mainly concerned with inhibition of secretion, it was decided to use a solution of glucose as the control meal to which acid could be added as a variable. By slowing the emptying of the meals with glucose it was hoped to minimize the effect of the added acid on emptying. A further advantage of adding glucose to both meals is that it minimizes (Bandes, Hollander, and Glickstein, 1940) the absorption of water from the stomach which occurs to some extent in man (Hunt, 1949), so that phenol red added to the meal may be used as a reliable marker to determine the volume of original meal remaining.

The methods used have been described (Hunt, 1954). In essence the technique involves giving a test meal containing a dye which is not absorbed in the stomach. After 30 minutes the gastric contents are recovered, and from the amount of dye remaining the volume of the original test meal in the stomach at the time of recovery may be calculated. Further, the volume of the gastric contents which has passed into the duodenum may be assessed, together with the total amounts of acid, chloride, and pepsin secreted. From the amounts of acid and chloride secreted the outputs of hypothetical parietal component and non-parietal secretions may be found. Twenty-seven volunteer students were studied and 18 tests were made in 16 patients with a diagnosis of duodenal ulcer without pyloric stenosis. The patients were under treatment in the medical and surgical wards, and the

majority were not having pain during the period of the tests, nor did any of them have pain during their test. The control meal was 750 ml. of solution containing 100 g. of glucose per litre; the experimental meal was similar except that 20 mEq HCl per litre of meal was added, a level of acidity which may be exceeded for 12 hours out of 24 in the gastric contents of normal subjects (Atkinson and Henley, 1955). By giving the meal down the tube and by not taking up the tube during the digestive period the slowing of emptying resulting from the stimulation by acid of receptors lying between the lips and the cardia was avoided (Hunt, 1956). Saliva was aspirated during the tests.

Results

Gastric Emptying.—Table I shows that no marked difference between the rates of gastric emptying in normal subjects and patients with duodenal ulcer was found. Moreover, the slowing of the emptying of the meal by added acid was equal in the two groups.

TABLE I.—Influence of 20 mEq HCl/litre of Test Meal on Gastric Emptying of a Solution of Glucose (100 g./litre)

	27 Normal Subjects		18 Tests in 16 Patients with Duodenal Ulcer	
	Glucose Solution	Mean Change with Acid	Glucose Solution	Mean Change with Acid
Mean volume of meal remaining in stomach at 30 min. (ml.)	489	+36.8	439	+37.7
S.E. of mean	±9	±9	±23	±13
Mean volume of gastric contents at 30 min. (ml.)	566	+10.8	542	+23
S.E. of mean	±9	±9	±21	±9

Gastric Secretion.—Table II shows that the patients with duodenal ulcer as a group secreted twice as much acid, chloride, and pepsin as did the normal subjects. Adding acid to the test meal reduced the secretion of acid in the

TABLE II.—Influence of 20 mEq HCl/litre of Test Meal on Gastric Secretion in Response to a Solution of Glucose (100 g./litre). All Data Refer to a Digestive Period of 30 Minutes

* Because of very large changes occurring in some subjects the effect of acid was determined by comparisons of amount secreted with added acid $\log \frac{\text{amount secreted with added acid}}{\text{amount secreted with control meal}}$.

This gives an equal weight to halving and doubling the outputs of pepsin in each subject.

normal subjects by an average of one-fifth but produced no other significant mean change in the measurements of these quantities in either group.

Because the chloride of the gastric secretion has its origin in at least two types of cell it is often helpful to describe the gastric secretion of electrolytes in terms of the hypothetical acid or parietal component and the non-parietal secretions (Hollander, 1938; Fisher and Hunt, 1950), although with some reservations (Hunt, 1957). The data expressed in these terms show that the hypersecretion in the patients with duodenal ulcers involves not only the acid-secreting parietal cells but also the sources of the non-

parietal secretions. The addition of acid to the test meal decreased the mean secretion of parietal component and increased the output of non-parietal secretions in the normal subjects, but produced no significant mean changes in the patients with duodenal ulcers. It will be seen from Fig. 1,

FIG. 1.—Relation between changes in outputs of acid and chloride on adding 20 mEq H⁺/l. of test meal (glucose 100 g./l.).

in which the change in the output of acid has been plotted against the change in the output of chloride for each subject, that the changes in the outputs of these two electrolytes on adding acid were considerable and correlated with each other in much the same way in both groups. This relationship is masked when only the mean data are considered.

Discussion

Gastric Emptying

It has so far proved impossible in this laboratory, using various test meals, to provide any convincing evidence that as a group patients with duodenal ulcers have stomachs which empty more rapidly than normal subjects. This could be the result of our normal subjects being younger or more

FIG. 2.—Relation between slowing of emptying of meal in response to 20 mEq HCl/litre of test meal (glucose 100 g./l.) and amount of acid secreted in response to meal in 30 minutes.

physically active than the patients, but it does not seem a probable explanation, since these factors have not masked the hypersecretion of acid and pepsin which is associated with duodenal ulcer.

In the data based on these experiments the magnitude of the influence of added acid on gastric emptying depends upon the gastric secretory response to the control meal, a finding which confirms that of Shay and Gershon-Cohen (1934).

In Fig. 2 the change in the volume of the meal remaining after adding acid to the test meal has been plotted against the secretion of acid in response to the control meal for each subject. For the normal subjects there is a tendency, significant at the 1 in 20 level, for the added acid to be more effective in slowing emptying in those subjects who secreted little acid in response to the control meal. Moreover, the subjects were unselected, whereas Shay and Gershon-Cohen (1934) chose subjects with hyperchlorhydria and achlorhydria in arriving at their conclusion. It is clear that the mechanism for the slowing of emptying responds effectively to such low concentrations of acid as 20 mEq/l. even under conditions chosen to minimize the influence of acid by adding glucose to the control meal.

The Shay (1944) hypothesis also suggests that in patients with duodenal ulcer the threshold of the mechanism which delays emptying is raised during the activity of the ulcer and returns to normal during remission. From what has been said above it is clear that comparisons of the reactivity of the mechanism which slows gastric emptying in response to acid must take into account the amount of acid secreted in response to the control meal. The line fitted to the data for normal subjects in Fig. 2 shows that a group of patients with a mean secretion of 6 mEq H⁺ would not be expected to show any slowing of emptying by added acid. When the points are considered individually it may be seen that the normal subject who secreted 12.5 mEq H⁺ showed no slowing of emptying by added acid. Since 12.5 mEq is the mean amount of acid secreted by the patients with duodenal ulcer, amount of acid secreted by the patients with duodenal ulcer, in these patients as a group if the mechanism were normal. In fact, the slowing of emptying was equal in the normal subjects and the patients with duodenal ulcer, a finding which implies that the mechanism which slows emptying in response to acid is overactive in patients with duodenal ulcers.

It is remarkable that the single-withdrawal method used here, which confirms that acid is more effective in slowing emptying in normal anacid subjects than it is in those secreting much acid, fails to confirm Shay's findings in patients with duodenal ulcers. It is possible that the discrepancy arises because Shay was principally recording "emptying time," which depends not only on the rate of emptying in the main part of the digestive period but also upon the final rapid emptying demonstrated by Hunt and Macdonald (1954), whereas the present data refer only to the first 30 minutes of the digestive period.

Gastric Secretion of Acid

The second part of the Shay hypothesis postulates that the gastric hypersecretion of patients with duodenal ulcer results from the failure of the duodenal inhibitory mechanism to slow gastric secretion as the gastric contents become more acid. In confirmation of this it will be seen from Table II that adding 20 mEq HCl/l. of test meal did depress the secretion of acid by about one-fifth in the normal subjects but that the mean depression of secretion in patients with duodenal ulcer was negligible.

A more detailed examination of the data on secretion, set out in Fig. 3, gives a somewhat different impression from that obtained by studying the mean data of Table II. It will be seen that for the normal subjects the greater the amount of acid secreted in response to the control meal the greater was the reduction in the secretory response when acid was added to the test meal (see also Hunt, Macdonald, and Spurrell, 1951). The data for 11 out of 18 tests in patients

with duodenal ulcer conform to this normal pattern, even though in one patient the secretion was five times greater than the mean for normal subjects. In 6 patients out of 16 with duodenal ulcers there was either a very small fall or an increase in secretion on adding acid to the test meal. No explanation of this increase in secretion is offered. It was not,

FIG. 3.—Relation between amount of acid secreted in response to a test meal of glucose solution (100 g./l.) and inhibition of secretion by acid added to test meal (20 mEq/l.). For explanation of A, B, and C, see text.

apparently, the result of increased distension by the meal containing acid, for acid did not especially delay emptying in these six patients.

One patient, noted in Fig. 3 by a special symbol, was tested three times. After six weeks of strict medical treatment his gastric secretion of acid was slightly augmented, although he felt extremely well at the end of this period and was entirely free from pain. In tests at the beginning (A) and end (B) of this six-weeks period, adding acid to the test meal increased secretion. Six months later he was readmitted to hospital and did not respond to strict medical treatment, although at this time his gastric secretion of acid was less and adding acid to the test meal did reduce secretion (C).

Gastric Secretion of Pepsin

The finding that the mean output of pepsin was unaffected in normal subjects when the mean output of acid fell was unexpected, for in previous experiments in which sucrose was used to inhibit secretion (Hunt *et al.*, 1951) the secretion of acid and pepsin fell together. Even when the present data for individual subjects were examined there was no correlation between the changes in the secretion of acid and pepsin. It is possible that the experimental conditions were responsible for concealing a change. Pepsin is partly inactivated at pH 5, so that with the control meal there was probably some inactivation of pepsin during the initial part of the digestive period until the pH fell. When acid was added to the meal this putative inactivation would not occur, so that a small fall in output of pepsin might be masked. In addition the secretion of pepsin may have been inhibited by the glucose in the control meal leaving very little possibility for further inhibition.

Significance of Failure of Inhibitory Mechanism

It is clear that the failure of the duodenal inhibitory mechanism is only an inconstant and minor factor in causing gastric hypersecretion in these patients with duodenal ulcer, for marked hypersecretion was found in some patients in whom the inhibitory mechanism was obviously effective. In addition it is known that, as compared with normal subjects, patients with duodenal ulcers have about 75% greater maximal parietal secretory capacity (Hunt and Kay, 1954) and about 75% more parietal cells (Cox, 1952), findings which can account for the majority of the gastric hypersecretion of acid in such patients.

Summary

The influence on gastric activity of adding 20 mEq HCl/litre of test meal containing 100 g. of glucose per litre has been investigated in 27 normal subjects and 16 patients with duodenal ulcer. The test meal contained a marker which allowed the volume of meal remaining and amounts of acid, chloride, and pepsin secreted to be calculated.

These experiments have not revealed any convincing evidence of abnormally rapid gastric emptying in patients with duodenal ulcers.

In normal subjects the less the secretion of acid in response to the control meal the more effective was the added acid in slowing emptying. The mean slowing of emptying by added acid in patients with duodenal ulcer was equal to that in the normal subjects. When the increased secretory response of the patients with duodenal ulcer is borne in mind this finding indicates that the mechanism which slows emptying in response to acid in patients with duodenal ulcer is more reactive than it is in normal subjects.

In response to the control meal the group of patients with duodenal ulcer had about twice the mean normal outputs of acid, chloride, and pepsin.

The added acid caused a mean fall in the output of acid in the normal subjects. In the patients with duodenal ulcer there were 10 out of 16 in whom the addition of acid reduced the output of acid. In the six others there was some augmentation of the output of acid.

The significance of these findings in the genesis of gastric hyperfunction in patients with duodenal ulcer is discussed.

It is a pleasure to thank many clinical colleagues for permission to investigate their patients with peptic ulcers, the patients themselves, and the students who have co-operated in these studies. I am also indebted to the Society of Apothecaries for the award of the Gilson Scholarship, out of which part of the expenses of this research was defrayed.

"The Australian Department of Health has issued a permit for the importation of the European rabbit flea, which it is hoped will intensify the spread of myxomatosis. The fleas are being collected from Europe this month, the time of the year when they are most plentiful. They will be bred under strict quarantine conditions. Tests will be carried out to ensure that the flea will not be harmful to Australian native animals; experts in wild life will determine whether the flea represents a hazard to such animals as the koala and other marsupials or to certain domestic animals and birds."—*New Scientist*, March 14.

POST-PARTUM BLOOD PICTURE IN SINGAPORE

BY

JEAN A. ROBERTSON, M.B., Ch.B.
D.Obst.R.C.O.G.

From the Department of Physiology, University of Malaya, Singapore

Previous investigations carried out by Wadsworth (1952a, 1952b, 1954) in Singapore showed that healthy people of all races living in a tropical climate had normal packed red-cell volumes, red-cell counts, and haemoglobin levels. The poorer classes of the population were not included in those investigations, but Millis (1954) found only one case of anaemia among 106 infants of the poorest and worst-fed section of the Singapore population, and it was of interest to find out whether there was any great degree of anaemia among those most likely to be affected—mothers in the lower-income groups.

Material and Methods

A total of 212 mothers were investigated in the free post-natal wards of the Kandang Kerbau Hospital, Singapore, where the inmates are all from the lower income groups. All patients had normal full-time deliveries without any haemorrhage before or after delivery, and in each case the puerperium was proceeding normally. They were unselected in respect of race, age, or number of pregnancies, and they represented a typical cross-section of non-paying patients in the hospital. There were 174 Chinese, 36 Indians, and 2 Malays. Their ages ranged from 16 to 46 years, and the number of previous pregnancies from 0 to 11. The climate of Singapore is uniformly warm and humid (Wadsworth, 1954); there is no malaria, very little hookworm, and less poverty than almost anywhere else in Asia and Africa.

All samples of blood were taken from an antecubital vein, using minimal stasis, on the second, third, or fourth day after delivery. The blood was placed in a dry stoppered bottle containing an ammonium-potassium oxalate mixture (Heller and Paul, 1934), and examination of the blood was made within two hours of collection. Haemoglobin estimations were made in all cases and haematocrit estimations in 192, there being slight haemolysis in 20 samples.

Estimations of the haemoglobin concentration were made with an M.R.C. photometer (King *et al.*, 1948a, 1948b). Pipettes used were of N.P.I. standard, and special care was taken to ensure that glass cells were scrupulously clean. Blood was thoroughly mixed before dilution, and errors were eliminated so far as possible by making frequent checks with the calibrated neutral glass standard. The packed red-cell volume was estimated by Wintrobe's method, and the samples were centrifuged for 45 minutes at 3,000 r.p.m.

Results

The mean haemoglobin level was 11.85 g./100 ml. (S.D. 1.85), and the mean packed red-cell volume was 35.3% (S.D. 4.77). The distribution of haemoglobin values is shown in Fig. 1 and the distribution of packed red-cell volumes in Fig. 2. Of the haemoglobin values observed, 95% were above 9 g./100 ml., and 86% of the packed red-cell volumes were over 30%. There were only a few isolated cases of moderately severe anaemia. The lowest levels of haemoglobin were 4 g./100 ml. in one patient, 5 g./100 ml. in two patients, and 6 g./100 ml. in one patient. Two patients had packed cell volumes of less than 20%.

No difference was observed between different age groups, nor was any difference found between primiparae and multiparae, and there was no correlation between the results observed and the number of pregnancies. There was, however, a gradual decrease in haemoglobin levels between the second,

third, and fourth days. Samples of blood examined on the second day after delivery had a mean of 12.17 g./100 ml. (S.D. 1.65) while samples examined on the fourth day had a mean haemoglobin of 10.97 g./100 ml. (S.D. 1.82). This conforms with the observations of Tysoe and Lowenstein (1950), who found that minimal haematological values were obtained on the fourth post-partum day. Indians appeared to have lower haemoglobin levels and packed red-cell volumes than Chinese, but this could have been due to the fact that a larger proportion of Indians than Chinese

Fig. 1.—Distribution of haemoglobin levels, 212 patients.

Fig. 2.—Distribution of packed red-cell volume, 192 patients.

after delivery and an average haematocrit value of 36%. In New Zealand, McGeorge (1935) found haemoglobin levels 15% below normal one to three days after delivery. In Britain Meyer-Wedell (1943) found a mean average haemoglobin level of 65% in the first four days of the puerperium. In Canada, Tysoe and Lowenstein (1950) found a mean haemoglobin concentration of 11.3 g./100 ml. and a mean packed cell volume of 34% on the fourth day after delivery. In spite of a few cases of moderately severe anaemia, the haematological levels in the present series are identical within the normal errors of estimation and sampling, with those quoted above, and it would appear that there is no great prevalence of anaemia among the poorer mothers of Singapore.

In Africa, Berry (1955) found a prevalence of severe anaemia before and after delivery, and he attributed this to the multiple deficiencies, parasitic infestation, and diseases of the liver. The climates of Singapore and Lagos are very similar, but there is no severe malnutrition in Singapore and no prevalence of serious disease. The present results confirm, therefore, that anaemias observed elsewhere in the tropics were not a result of the climate but of poor food or illness. At health (Wadsworth, 1952a, 1952b, 1954; Berry, 1955). At the same time, the high incidence of mild anaemia and the occasional existence of moderately severe anaemia observed during the present investigation show that the problem of post-partum anaemia should not be treated with complacency even in comparatively well-fed populations.

Summary

The haemoglobin levels and the packed red-cell volumes of working-class mothers in Singapore were estimated two to four days after delivery. The mean

haemoglobin level was 11.85 g./100 ml. and the mean packed red-cell concentration 35.3%, a finding which conforms closely with observations made in countries with a high standard of living and a temperate climate. This confirms that tropical anaemias are due to other causes than a warm climate.

My thanks are due to Professor E. M. Glaser for his help and encouragement with the investigations and to Professor B. H. Sheares for access to the maternity wards of the Kandang Kerbau Hospital.

Medical Memoranda

Isoniazid Allergy

Isoniazid sensitivity is a rare occurrence. I have treated more than 500 patients with this drug and have never encountered marked allergic manifestations. This is also the experience of most chest workers in Europe and North America (Carr *et al.*, 1953; Castle, 1953).

Collins (1952) had a case in which a widespread purpuric rash developed after 28 days' treatment with the drug. This eruption subsided when therapy was stopped and reappeared when it was started again. Since then several papers have appeared in the French literature describing a purpuric rash (Levi-Valenski *et al.*, 1953) or bullous dermatitis (Martin, 1953), and in Germany erythroderma (Keller, 1955) and capillary haemorrhages (Merk and Weinreich, 1954; Walther and Winter, 1954) have also been recorded. Indeed, Gernez-Rieux *et al.* (1954) have reported fatalities in two patients treated with intravenous isoniazid. One death was attributed to anaphylactic shock and the other followed massive intestinal haemorrhage. Since then, Kalbian (1954) has reported pyrexia and malaise occurring in a patient following the oral administration of isoniazid.

The following account of isoniazid allergy is presented in view of the drug's extensive use in antituberculous work, the extreme rarity of the condition, and the interesting clinical manifestations of the hypersensitivity.

CASE REPORT

A man aged 45 was found to have tuberculous infiltration in the right apex and first and second right intercostal spaces. A 1-cm. cavity was visible tomographically in the 4 and 5 cm. cuts; acid-fast bacilli were recovered from his sputum on direct smear, and crepitations were audible on auscultation over the posterior segment of the right upper lobe. A diagnosis of active pulmonary tuberculosis was made. He was placed on absolute rest in bed and a course of intramuscular streptomycin, 1 g. daily, P.A.S., 12 g. daily, and isoniazid, 200 mg. daily, each of the latter in three divided doses, which were administered orally.

After 24 days he complained of rawness and burning behind his xiphisternum, with some nausea, abdominal distension, and discomfort on swallowing at the level of the lower end of the sternum. The following day his malaise

and nausea after meals were more marked and he complained of anorexia and frontal headaches. Nothing abnormal was detected on physical examination of his pulmonary, abdominal, or nervous systems. A barium-meal examination was negative and his symptoms were attributed to oesophageal reflux. He was propped up in bed and "aludrox" prescribed. On the twenty-sixth day of treatment he was observed to have a pyrexia of 101° F. (38.3° C.) and a generalized erythematous rash of the face, neck, trunk, and limbs. Three small petechial haemorrhages were noticed on his soft palate and also on the right pillar of his fauces. He complained of photophobia, slight lacrimation, and both eyes were severely injected.

During the next two days the anterior and posterior cervical chain of glands on both sides of the neck became enlarged and extremely tender. There were also swollen tender glands in the supraclavicular regions, in both axillae, and in the inguinal regions, and both epitrochlear glands were similarly involved. His spleen was palpable two fingerbreadths below the costal margin. There was puffiness of his face, ears, eyelids, and neck. He had a considerable sacral pad, and a moderate degree of oedema of his ankles was present. He experienced some discomfort and tightness of his chest on deep breathing, a moderate degree of bronchial spasm was audible on auscultation throughout both lung fields, and he complained of rawness and dryness of his pharynx, trachea, and bronchi. His sedimentation rate had risen from 7 to 22 mm. per hour; his total white-cell count mounted from 6,600 to 14,000 per c.mm. and his eosinophils gradually increased to 30% during the next five days. Serum electrolytes, proteins, and prothrombin time were within normal limits.

A diagnosis of drug allergy was made as soon as the rash appeared and all drug therapy was discontinued. Despite negative intradermal testing with streptomycin, 0.1 g., and a patch test with 20% P.A.S. solution, it was assumed that drug sensitivity was most probably attributable to streptomycin allergy, as isoniazid hypersensitivity had never been encountered previously. Five weeks later, when the erythematous rash had cleared, the entire skin had desquamated, and the adenopathy and splenomegaly had subsided, isoniazid alone was very cautiously recommenced. On the first day 50 mg., and on the second 100 mg., of isoniazid alone, were administered. Within 36 hours of the first tablet being ingested, the patient again complained of nausea, malaise, headaches, a generalized pruritus, with erythema of the face, trunk, and limbs, and a much milder generalized adenopathy of all the glands which had previously been involved. Once again his face, ears, lids, and sacrum became oedematous. His total white count rose to 13,200 per c.mm. and his eosinophils once more increased to 12%. The drug was promptly withdrawn and in nine days the symptoms and oedema had subsided.

COMMENT

This is a case of severe isoniazid hypersensitivity having features rather similar to a case of P.A.S. allergy reported by Mann (1953). Antihistamines, both orally and by direct application, were of no avail in easing this patient's profound pruritus, but considerable relief was obtained from the topical application of 2½% hydrocortisone acetate.

Sudden Death from an Asymptomatic
Pheochromocytoma

The following case is recorded because it serves to illustrate the diversity of clinical picture produced by pheochromocytoma. The condition may be associated with symptoms due to paroxysmal or established hypertension with its concomitant complications. Between attacks the patient may be asymptomatic and not hypertensive (Mackeith, 1944) or, rarely, the tumour may produce no hypertension whatsoever. Cases are on record where the tumour has been found incidentally at necropsy, especially in elderly subjects, and has produced no disability during life. The present case is thought to be worth describing, since the tumour was apparently quite symptomless until it produced the sudden and dramatic death of the patient.

CASE REPORT

A married woman aged 42 was admitted to the Bradford Royal Infirmary in August, 1955, with a 24-hour history of vomiting. She had always enjoyed good health except for

a very transient episode of vomiting four years previously, and she was regarded by her relatives as an unusually robust, active person. On August 19 she went to work in a local mill and while there developed sudden severe vomiting. She was taken home and went to bed. The following day, as she felt very ill, her doctor was called and he recorded her temperature as 104° F. (40° C.) but could find no evident cause for her condition. Further examination revealed a mentally alert, restless, anxious, and dyspnoeic patient. Her skin was pale and grey and she was sweating profusely. There was pronounced blanching of the extremities and some diffuse cyanotic mottling of the skin. There was a tachycardia of 150 a minute, B.P. 140/100, and the fundi were normal. The heart did not appear enlarged. The patient died quite suddenly 15 minutes after admission.

At necropsy a large tumour of the right suprarenal gland was found (see Fig.). This weighed 665 g. and on section was cystic. It contained necrotic areas and a large amount of recent blood clot. There was no left ventricular hypertrophy. Histologically the tumour was found to be a pheochromocytoma.

COMMENT

The interesting feature in this case was the absence of any previous disability and the excellent health of the patient. The episode of vomiting which occurred four years previously may or may not have been caused by the tumour.

No previous clinical information is available, as she had never had occasion to visit her own doctor. Clinically the appearances were suggestive of a Waterhouse-Friderichsen syndrome. The suddenness of death suggested it was in some way related to the massive haemorrhage into the tumour, and this may also have produced the pyrexia.

I thank Dr. C. L. Davidson for permission to publish, and Dr. M. Golliker, who kindly performed the post-mortem examination.

W. B. VALLANCE, M.B., Ch.B.,
Medical Registrar, Bradford Royal Infirmary.

Mercury Dermatitis in a Tattoo: Treated with
Dimercaprol

A number of cases have been reported of mercury sensitivity arising in the red areas (cinnabar) of tattoos. In some cases the use of mercurial applications elsewhere has led to the development of sensitivity and the red areas of the tattoo have subsequently become swollen (Unna, 1930). Other cases are reported in which the sensitivity has developed spontaneously (Ballin, 1933; Sulzberger et al., 1944). A case is described here of a patient who had no other contact with mercury and who in addition to the local eczematous response developed a widespread eruption. The condition quickly responded to injections of dimercaprol.

CASE REPORT

A man aged 28 was tattooed eight years ago on the right forearm and showed at this time no abnormal reaction. The design showed a red heart pierced by a blue stiletto and intertwined with a blue scroll bearing the caption "True Love—Maisie." A few dots of red were present in the scroll and also represented blood near the tip of the stiletto. Later he married, but not Maisie. His wife objected to the tattoo, and on one occasion asked him to have the name altered. For other reasons family stress developed, and shortly after the onset of the eruption his wife left him.

The patient was first seen at the out-patient department in May, 1955. There was no previous history of skin disorders. His father and mother had unspecified rashes, but his two brothers and a sister had been free from skin eruptions. Two months before his first attendance the red areas of the tattoo became swollen and irritable. Treatment with zinc cream was given, but the whole area became red, oedematous, and vesicular, and after three to four weeks an eczematous rash developed over the face, trunk, and limbs. A diagnosis of mercury dermatitis was made and the patient admitted to hospital. After two days the condition was slightly worse and intramuscular injections of dimercaprol were begun, with a dose of 400 mg. on the first day, 200 mg. a day for five days, and then 100 mg. a day for three days. The condition improved rapidly and by the end of the course was clear except for scaling and a little swelling of the red areas of the tattoo. He was discharged home whilst awaiting surgical removal of the tattoo, and 7 to 10 days after the last dimercaprol injection the red areas again became more swollen and started weeping. After a few days the whole tattoo area was swollen, the red areas had become ulcerated, and a widespread eczema again developed.

He was readmitted to hospital, and after a period of four days in which no improvement occurred dimercaprol injections were restarted. A dose of 400 mg. was given on the first day; 300 mg. on the next day; 200 mg. a day for two days, and 100 mg. a day for two days. By the end of the course the condition had again subsided, although the red areas of the tattoo were still prominent. Seven days later these areas again became raised and weeping, and the whole area was swollen. Once more dimercaprol injections were recommenced and 150 mg. a day was given for the next 10 days. Improvement occurred in a few days, and

by the end of the 10 days the whole area was quiet except for the slightly raised and still ulcerated red areas. Three days later the tattoo was excised and grafted, since when there has been no further trouble.

It is of interest that for a few days when an in-patient he developed sore and scaling lips. This ceased when his temperature was taken with a thermometer not kept in biniodide of mercury.

Investigations.—Urine: Normal; specimens before and after the second course of dimercaprol showed no appreciable mercury content. Blood: W.R. and Kahn, negative; cytology within normal limits except for a neutrophil leucocytosis (total neutrophils 9,000 per c.mm.) when first admitted to hospital. Histology: During the second attack a piece of ulcerated red tattooed skin was excised. This was examined by Dr. R. L. Bishton, who reported: "The floor of the ulcer consists of necrotic material overlying inflammatory granulation tissue which extends deep into the dermis. The cellular reaction is very intense, and is composed of lymphocytes and monocytes with a few plasma cells. Although there are collections of blackish pigment particles no foreign-body giant cells are seen. No vascular lesions are observed and there is no tissue necrosis in the dermis itself. Patch tests: These were performed one day after stopping the last course of dimercaprol. 2% ammoniated mercury, 1% biniodide of mercury, 1% perchloride of mercury, and sulphide of mercury (cinnabar) powder all showed a well-marked positive reaction after 12 hours, which was greatest with the biniodide.

COMMENT

In this case there was no history of recent contact with mercury which might have sensitized his skin. The family tendency to "rashes" and the coincident considerable marital stress may well have played a part in the development of this allergic reaction.

The results of the patch tests are of interest. In the past some of these cases have shown a positive response to various mercury salts, but not cinnabar (Unna, 1930; Madden, 1939; Sulzberger et al., 1944). However, Sulzberger (1937) and Novy (1944) describe similar cases in which the patch tests were also positive to cinnabar. Commenting on the inconsistency of these findings, Rook and Thomas (1952) suggest that the hypersensitivity may be to a derivative compound. The very marked sensitivity to biniodide of mercury was obviously the cause of the eczematous reaction on the lips due to contact with a thermometer kept in biniodide of mercury.

It seemed clear that dimercaprol quickly reduced the reaction on all three occasions. The two relapses which occurred after courses of dimercaprol both started 7 to 10 days after it was discontinued. A single dose is said to be effective for only about four hours (Miles Weatherall, 1948). Presumably dimercaprol will only neutralize the mercury in close contact with the tissue fluids and not that towards the centre of the depots of cinnabar. It may be that the interval of 7 to 10 days was necessary for cinnabar in the depots to diffuse again into the tissue fluids or possibly to undergo some chemical change as suggested by Rook and Thomas.

We thank Dr. D. M. M. Thomson for his help in the clinical management of the case; Dr. C. D. Evans for his help with the paper; and Mr. D. C. Bodenham, who carried out the skin excision and graft.

Reviews

SURGICAL HANDICRAFT

Pye's Surgical Handicraft: A Manual of Surgical Principles, Minor Surgery, and other matters connected with the work of Surgical Dressers, House Surgeons, and Practitioners. Edited by Hamilton Bailey, F.R.C.S., F.A.C.S., F.R.S.Ed. Seventeenth edition. (Pp. 800+xvi; illustrated. 52s.) Bristol: John Wright and Sons Ltd. 1956.

Pye's Surgical Handicraft was first published in 1884. Mr. Hamilton Bailey has edited every edition since 1938, and in this, the seventeenth edition, he has enlisted the help of more than 50 distinguished contributors. The result is an authoritative and reliable account of all the methods, techniques, and tests which pertain to the duties of the house-surgeon or surgical registrar. Many of the chapters are masterpieces of judicious compression, notably the ten pages on burns by Mr. A. B. Wallace, a short section on rectal operations by Mr. Gabriel, the 20 pages on eye conditions by Mr. Williamson-Noble, and the 70 pages in which Sir Reginald Watson-Jones gives a volume of information on fractures and dislocations. Mr. Bailey himself has written many articles full of practical wisdom, and we would particularly call attention to his suggestion that the practitioner should pass a gastric aspiration tube as a first-aid method of treatment in cases of perforated peptic ulcer. There is an interesting introductory tribute to Mr. Pye with an accompanying photograph. This is a book which the house-surgeon should buy. Anyone who says he cannot afford it must have a distorted sense of values.

WIRE BRUSH SURGERY

Wire Brush Surgery in the Treatment of Certain Cosmetic Defects and Diseases of the Skin. By James W. Burks, Jr., M.S., M.D. (Pp. 154+xvi; illustrated. 51s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1956.

The removal of superficial lesions of the skin by means of a revolving wire brush, similar in action to the dentist's drill, seemed at first a rather crude suggestion. The late Dr. Kurtin, however, developed this technique to a point where dermatologists could no longer disregard its usefulness. This small volume from Dr. Burks, himself a dermatologist, is a lucid exposition of the potentialities of this development in plastic surgery, with valuable details concerning equipment and techniques, and with good illustrations.

The procedure was originally employed for the amelioration of the deep, pitted scarring of the face which may follow such ills as smallpox and acne. These cosmetic blemishes may be of serious significance to the adolescent, especially the female, and may, as Burks puts it, "scar the soul." Wire brush surgery has now been employed to remove tattoo marks, rhinophyma, naevi, keratoses, and superficial epitheliomata. It has been effectively used in the treatment of active acne with cystic lesions, "marsupialization" of which lesions is said to be followed by ready healing. Hidradenitis suppurativa of the axillae has also been treated with success.

The cosmetic results, while not giving a perfect skin, are very satisfactory in the majority of patients, whether coloured or white, and untoward effects such as keloidal scarring or infection are rare. Radiodermatitis, deep scars, keloids, and virulent coccal infection of the skin are contraindications, since regeneration is dependent upon blood supply and the presence of appendages. It is possible to exercise very exact control of the extent and depth of treatment, and most valuable histological studies of the process of regeneration have been conducted. Epithelialization begins three days after treatment and is complete in eight days.

I had the privilege of seeing Dr. Burks performing this treatment recently in New Orleans and of observing the

results of treatment. It is now widely employed by dermatologists in America and elsewhere and is being adopted by plastic surgeons in Great Britain. There is no doubt that it is a valuable addition to the armamentarium of the plastic surgeon in the treatment of many skin lesions, especially on the face.

J. T. INGRAM.

ENDOGENOUS UVEITIS

Endogenous Uveitis. By Alan C. Woods, M.D. Illustrated by Annette Smith Burgess. (Pp. 303+xvi; illustrated. £5.) London: Baillière, Tindall and Cox Ltd. 1956.

It often happens in medicine that someone makes the study of one aspect of a subject his life's work and the advances thereby gained in medical progress are usually great. But it rarely happens that the investigator is equipped with an unusually acute intellect, both integrative and critical, that he has had the enthusiasm to concentrate over many years on a subject of great complexity, and that these qualities have been sustained by the resources in material and personnel of one of the best medical schools of the world. The occurrence of such a fortunate combination is an event; and this volume, which epitomizes the life-work of Alan Woods, of Johns Hopkins Hospital, is indeed an event. More than 40 years ago he was publishing papers of great originality on uveitis; and to-day he stands unique in the world as an authority on the subject. We who have this book in our hands are fortunate.

The subject of endogenous uveitis is a relatively narrow one within the compass of inflammations of the uveal tract, and the author has further restricted it by omitting all pyogenic inflammations of the inner eye. Nevertheless the subject that remains is immense and much of it is still obscure. The endogenous inflammations are divided into two categories on a clinico-pathological basis which are generally known as infective and allergic, but for which Woods uses the terms introduced by him into American literature—granulomatous and non-granulomatous. There are objections to those terms, but names matter little so long as we know what we are talking about and that is made abundantly clear. The book is divided into four chapters—the pathogenesis, the clinical picture, the aetiological diagnosis, and the treatment of the various manifestation of these two types of disease. This arrangement has much to be said for it, for, though the reader has to cover all four chapters to obtain a comprehensive picture of (say) tuberculous uveitis, the subject is presented to him in the sequence in which it unfolds itself in the clinic. The great value of the book is that the views expressed are those of the author himself rather than being a compendium of the conflicting ideas of many authorities; and, since his views have been largely responsible for moulding ophthalmological thought on this subject over the last quarter of a century, it is good to have them clearly and consecutively summarized. The reader's appreciation of the book is much enhanced by the clarity of the writing, the excellence of its publishing, and by the beauty of the illustrations.

STEWART DUKE-ELDER.

ESSENTIALS OF DERMATOLOGY

Essentials of Dermatology. By Norman Tobias, M.D. Fifth edition. (Pp. 651+xv; illustrated. 64s.) Philadelphia, Montreal: J. B. Lippincott Company. London: Pitman Medical Publishing Co. 1956.

Five editions of this book have appeared in fifteen years. Its success is understandable, for here is readily accessible a great deal of information useful to general practitioners and senior students. The section on nursing at the end of each chapter makes it, furthermore, valuable as a book of reference in a nurses' library. In this new edition more space has been given to the common dermatoses. One is a little shaken to read that "since the cause of psoriasis is unknown, the physician may satisfy the patient's curiosity by explaining that the disease is a 'form of birthmark,'" and that "amputation is advisable in those cases of indurated

leg with chronic indolent ulcers and tissues of lowered vitality which do not respond to vein ligation or skin grafts." Nevertheless, the reader will find in summarized form much sound information about the appearance, aetiology, differential diagnosis, and treatment of all but the rarest of skin disorders.

The busy general practitioner uses a book of reference such as this mainly to attempt to diagnose some unrecognized condition which he has seen and to determine its treatment. Because observation plays such a large part in the diagnosis of these conditions the illustrations in a dermatological textbook are important. Here there are 211 black-and-white figures and five coloured plates. Though many are excellent, some, including those of erythema scarlatiniforme, erythema multiforme, necrobiosis lipoidica, and morphea, might mislead readers unfamiliar with their appearance. Treatment is dealt with clearly and succinctly. The chief difficulty for the British reader is that many proprietary preparations are mentioned with names which are unfamiliar on this side of the Atlantic. There is, however, a valuable chapter on "dermatologic therapeutics" which contains a great deal of practical information. The book is well produced and should prove even more popular than its previous editions.

S. T. ANNING.

ANATOMY FOR SURGEONS

The Thorax, Abdomen, and Pelvis. Anatomy for Surgeons, Volume 2. By W. Henry Hollinshead, Ph.D. (Pp. 934+xiv; illustrated. £7 7s.) London: Cassell and Co. Ltd. 1956.

This magnificent volume presents its subject from an entirely original aspect. The author describes himself as consultant in anatomy to the 600 physicians of the Mayo Clinic and Foundation, and it is obvious that the consultation has been very real and that it has played a large part in the wide outlook and the clarity of detail which characterizes every page. We are sure that there is no surgeon, we might even think no physician, who will not learn some new fact, perhaps of vital importance, from pages devoted to his own particular field.

Anatomy is now a vast subject, and to have covered every region with such scrupulous care is a great achievement. We can only refer to two regions where anatomical progress has been of vital importance to the surgeon. With the work of Blalock and his colleagues the heart and great vessels have become of peculiar interest, and the elaborate description which readers will here find comes at just the right moment for those who are working in this new field. In a very different region, every abdominal surgeon will appreciate the importance of an exact knowledge of the anatomy of the bile ducts and of the variations which may occur in their course and in their blood supply, and here they are set out in the fullest and clearest manner. The book is finely produced and superbly illustrated both by complete drawings and well-devised diagrams. There could be no better foundation for the advanced surgery of the present day.

HENRY SOUTTAR.

ANATOMICAL TECHNIQUES

Anatomical Techniques. By D. H. Tompsett, B.Sc., Ph.D. Foreword by Sir Cecil Wakeley, Bt., K.B.E., C.B., LL.D., F.R.C.S. Historical Introduction by Miss J. Dobson, B.A., M.Sc. (Pp. 240+xvi; illustrated. 35s.) Edinburgh and London: E. and S. Livingstone Ltd. 1956.

This book is designed to act as a guide to the production of anatomical teaching specimens. The first ten chapters are devoted to the technique of dissection and mounting; they put into print, largely for the first time, much information which was previously handed down by word of mouth from one generation of prosectors to the next. The section on anatomical illustration gives detailed instructions, and, though many professional artists might well criticize the

methods used, it is an honest attempt to obtain the best results from readers who might well have a minimum of natural talent. In the chapters on casting techniques Dr. Tompsett explains a craft which he has for some years pioneered in Great Britain. He sets out the details of each particular method clearly and concisely and shows a very real understanding of the pitfalls which are apt to beset the beginner.

Adequately illustrated with line diagrams and many colour plates, this book is a charming combination of the ancient traditions of the Royal College of Surgeons and the newer cult of "Do it yourself." It is to be recommended to all who are concerned with making anatomical and biological teaching material.

D. BROWN.

ACCIDENTS

The Accident Syndrome: The Genesis of Accidental Injury. A Clinical Approach. By Morris S. Schulzinger, M.A., M.D. (Pp. 234+xxiii. 50s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1956.

This book is based on the author's experience of some 35,000 accidents treated in a general medical practice in Cincinnati, Ohio, between 1930 and 1948. This extensive study was concerned with accidents arising in the home, in industry, and from transport; to some extent the sample is selective in that the more serious injuries would have been admitted direct to hospital. It is well known that there is a high accident rate in the U.S.A., and the book reminds us that in 1951 there were 96,300 accidental deaths in that country and 9,600,000 disabling injuries from accidents.

The book reveals some interesting contrasts to the accident picture in Great Britain. For example, it shows a cyclical pattern of distribution of accidents with the highest incidence in the summer months, whereas in this country it is in the winter months; it shows that males have a significantly higher accident rate than females, except in the first year of life, and that three-quarters of the accidents occur to individuals before the age of 35. It surprisingly pays little attention to accidents to the elderly. The author devotes much space to the consideration of accident proneness, but he prefers to maintain that the majority of accidents are solitary experiences of large numbers of individuals—predominantly the young, the male, and the maladjusted. He draws a clear picture of what he means by the "accident syndrome"; he refers to the universal risk, the abnormal environment, the maladjustment and irresponsibility, the trigger episode followed by the reaction of the individual, and the concluding accident with or without injury.

This book is full of information and includes an extensive bibliography. It is clearly written and easy to understand, although some of the charts are not very clear. It could prove a useful book of reference, but to those conversant with safety measures in Britain it would have more value if it devoted more space to the methods of accident prevention in the United States.

C. A. BOUCHER.

Public speakers no doubt soon get used to the sight of reporters below the platform industriously scribbling down their words—words which, in cold print, hardly ever seem adequate to their theme, however compelling when chosen, rehearsed, and uttered. And they must inure themselves, too, to the reproach of reporters not taking down anything, dismayed and bored by words for which no market exists anywhere. This worm's-eye view of public life has been put to good use in *British Hustings, 1924-1950*, by Mr. Arthur H. Booth, chief reporter of the Press Association. The author's many years of reporting at political meetings, including the election tours of all Prime Ministers during the period, have enabled him to record here an experience of party political strife that is both penetrating and judicious. Since politicians have taken to organizing the medical profession, doctors may be particularly interested in this at times revealing book on their new lords and masters. It is published by Frederick Muller Ltd. for 21s.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY MARCH 23 1957

WHAT IS THE CASE ?

The case the medical profession has against the present Government is quite simple. The case is that of a breach of contract, of a broken promise, of a failure to deal directly and simply with a body of men and women who entered the National Health Service in 1948 on what was in essence a gentleman's agreement—an agreement, moreover, that was publicly underwritten by both Government and profession. Mr. Aneurin Bevan—not the initiator but the executor of a scheme continuously modified from 1942 onwards—once said something to the effect that those working in the Health Service should be given an opportunity to behave. Like any other collection of men and women, doctors are subject to the usual frailties of human nature. *Humanum est errare*. But in the main practising doctors have put their best foot forward and have, in spite of the frustrations and pinpricks of officialdom—in spite of the blunderings of bumbledom—done a conscientious job of work during the past eight and a half years. They have looked after their patients, because that is what they were trained to do, and wanted to do. And the people of this country seem to approve of the result.

But the behaviour of Governments—and most regrettably of the present Government—has made doctors deeply disturbed not so much about their present condition as about the future of the profession to which they belong. The present case of doctors versus Government is not only the case for a 24% increase of pay. According to the Spens-Danckwerts formula this claim is at the least one which has the backing of justice and good faith to support it. It has been presented with sound statistical and judicial evidence behind it. Our negotiators have not put it forward in the spirit of a bargainer demanding his pound of flesh. They have asked that if the case is disputed to the point of disagreement it should be submitted to arbitration. They see an ex-Minister of Health, Mr. Iain Macleod, pleading for arbitration in the case of the dispute with the ship-

builders and engineers, and at the same time the present Minister of Health and the Prime Minister denying arbitration to the medical profession. And the doctors, through Dr. Wand, Chairman of the B.M.A. Council, have agreed in advance to accept the verdict of an independent adjudicator. Why does the Government seek for such a reasonable solution in the one case and avoid it in another? Such behaviour is unworthy of intelligent men who assume the mantle of statesmen. It seems to be the behaviour of men who put expedient before principle, of men who appear to discount a small section of the community they govern as politically expendable material. We would repeat to Mr. Macmillan what he himself said at Leicester this week: "*Surely this is a time when we should accept some form of arbitration rather than to have recourse to self-destructive struggles . . . the umpire is better than the duel.*"

If we say, *J'accuse*, is the accusation justifiable? Look at the record! The G.P. Spens Report was published in 1946 and the Consultant and Specialist Spens Report in 1948. Both reports were publicly accepted by profession and Government. Mr. Aneurin Bevan—for whom it would be idle to say the profession had any great affection—agreed as recently as 1950 that the Spens Report for General Practitioners remained the basis for remuneration until some other basis had been found as a result of consultation. This agreement and this confirmation had no statutory backing. They were not embodied in the letter of the law. And the medical profession did not seek to secure this, because it believed that in this delicate process of the nationalization of a profession a Government of decent men would behave decently. But look at the record! When the profession's claim—based upon a previous Government's acceptance of the Spens recommendations—was put to the Minister of Health, Mr. Turton, in July last year, he said the Government could not accept the premises upon which it was based. Mr. Turton contended that the Spens formula applied only at the point of entry of the profession into the N.H.S. He then hedged by asking for a legal justification—for the letter not the spirit of the law. And when our negotiators complied with this, they were met not with a request for discussion and negotiation but with a curt suggestion that they should test it in the courts. When Mr. Vosper took over office from Mr. Turton he said in January this year that the Government could not consider the claim on its merits. Then hard on the heels of this was the statement that the Government would recommend the setting up of a Royal Commission to review medical remuneration in the light of its relations to other professions and (as it finally

came to light) those in connected occupations. In other words, doctors' pay was not to be related to their own merits or to the Spens recommendations, but to the merits and incomes of others. All this was done without any consultation with the medical profession. Faced with the indignation of our negotiators Mr. Vosper said that the Government was prepared to *instruct* the Management Side of Whitley Committee B to negotiate an immediate increase for junior hospital staff—a move which was announced in the House of Lords by Lord Salisbury but not by Mr. Macmillan in the House of Commons. And then—within a fortnight—Mr. Macmillan brushes aside all custom, convention, and understanding between Government and profession, and arbitrarily announces from the floor of the House of Commons that junior hospital staff are to have a 10% increase of pay as from April 1 this year. Of course everyone welcomes at least some increase for these of our colleagues. But has the 10% been arrived at by discussion and negotiation, or, in the failure of agreement, by arbitration? No. These familiar processes of a free democracy have been swept aside by an arbitrary dictatorial decision of the Prime Minister. And as it happens to have been a decision which alleviates the position of those affected it seems to have been passed by with little appreciation of its implications. What would have been the reaction if the decision had been to reduce the pay of junior staff by 10%? There would have been no difference in principle. Having started with a *non possumus*, Mr. Macmillan then said that the work of the Royal Commission did not preclude some interim adjustment for doctors included in its terms of reference. Next he makes an award himself to junior hospital staff, saying that he will make a further statement "in due course" about an interim increase for the other doctors covered by the Commission's terms of reference. Surely this is not the time for a series of one-sided statements. "Surely," in Mr. Macmillan's most recent words, "this is a time when we should accept some form of arbitration. . . ."

Who are these other doctors covered by the terms of reference of the Royal Commission. They are those taking *any part* in the National Health Service of Great Britain. The G.M.S. Committee of the B.M.A. was dismayed last week to learn from its chairman, Dr. A. Talbot Rogers, joint chairman of the Negotiating Committee, that our colleagues in the Public Health Service are excluded from consideration by the Royal Commission. Quite apart from the fact that Medical Officers of Health (many of whom act only part-time in this capacity) *do take some part* in what one might describe as the obvious N.H.S.

services, they are all included in the provisions of N.H.S. Act Part III. But it appears that Sir John Hawton, Permanent Secretary to the Ministry of Health, explained to Dr. Rogers that the apparent inclusion of the Medical Officers of Health in terms of reference of the Royal Commission was just a mistake. This is intolerable and must not be tolerated.

It is extremely difficult to steer one's way through the fog of evasion, inconsistency, and misrepresentation of our present governors, our employers. But the issue is really quite simple. The present Government refuses to negotiate, refuses to admit the moral obligation to face up to the recommendations of the Spens Committees, and refuses the profession's request for arbitration—a method of settlement of dispute it is trying to enforce on the workers in the shipbuilding industry. It sets its inconsistent face against all custom, understanding, and convention which the profession has so far understood to be behind its dealing with the Ministry of Health—now, like so many other things, in the discard. The profession can understand honest disagreements honestly arrived at, and is willing and anxious to resolve them by discussion, negotiation, and, in the event of an impasse, arbitration. But it will not submit to dictation. And it is hard to see how else one can describe the present series of manoeuvres.

In a timely contribution to this week's *Supplement* Dr. W. N. Leak makes an analysis of the present situation which should be carefully studied by everyone who really cares about his profession, and wants to see it manned in the future by men and women who will worthily maintain a great tradition of service to the country in which they live. The Royal Commission, as Dr. Leak puts it, "seems to be a business committee to assess the financial result of doctors' pay without any bunkum about professional standards or traditions. . . ." The issue, as we have said, is simple. There are two questions which could be put to the Government. The first is, "Do you accept the recommendations of the two Spens Reports?" The second is, "If you think these recommendations are unrealistic or not adapted to the conditions of to-day, will you discuss with the profession an alternative set of recommendations on which we can both reach agreement?" The Royal Commission is designed to evade answers to either of these questions—and Dr. Leak adduces cogent reasons why this is so. What is at stake is the future of the medical profession, and its relation with an employer who lamentably fails to understand he is dealing with human beings who in 1948 really believed that in this country a man was as good as his word.

WITHDRAWAL FROM THE N.H.S.

The plan for withdrawal of general practitioners from the National Health Service is published in this week's *Supplement*. It has been drawn up by the General Medical Services Committee under the chairmanship of Dr. A. Talbot Rogers, and will be presented to the special conference of Local Medical Committees at its meeting on April 30. If this plan has to be put into effect withdrawal will initially take place in certain selected areas. It is not recommended that withdrawal shall be total at the outset. If the special conference accepts the plan, the British Medical Guild will take steps to obtain and hold resignations of all general practitioners in the Health Service. Practitioners in the areas selected will be advised to resign from the N.H.S. on October 2, and during that month will be asked to treat their former N.H.S. patients free of charge. If the Government still declines to agree to a satisfactory settlement or to arbitration, then after November 1 standard token fees will have to be charged. The British Medical Guild will have funds from which to give financial support to general practitioners in the selected areas. These and other details are fully set out in the *Supplement*.

The step recommended by the G.M.S. Committee is indeed grave. No one can pretend to welcome such a serious move. But doctors should make it plain to their patients that such a move has been forced on them by the Government. It is the only way in which the gravity of the present situation can be brought home to Parliament and people. It is the only way in which the profession can show its complete disapproval of an employer who refuses to negotiate a claim made under the Spens recommendations, and refuses to agree to arbitration if a satisfactory settlement cannot be reached. Discussions, memoranda, interviews, exchange of letters—all have been without avail. As the Government rejects a reasoned case and a reasonable plea for negotiation or arbitration, action of the kind proposed is all that is left.

OPERATIONS FOR VARICOSE VEINS

All the modern forms of surgical treatment for varices have a long ancestry. Injection treatment is based on the method which Hippocrates is reputed to have used in about 400 B.C.: many small punctures were made in the veins to obliterate them by scarring and thrombosis. The Roman Celsus described the operation of excision in his book written in A.D. 30, and Galen in the second century advocated stripping out the diseased veins with a hook. Ligation came later, and Paul of Aegina gave careful instructions for its performance in A.D. 690. All four methods— injection,

ligation, excision, and stripping—have their uses and their places in modern treatment, but the popularity of all of them has varied. Enthusiasm for one particular method and its use to the exclusion of others has often led to its application to unsuitable cases. Poor results have followed, and the method has been abandoned for another which held sway for a time with similar ultimate result.

The more recent history of the treatment of varices clearly shows the advantages or shortcomings of each method. Ligation of the great saphenous vein in the thigh was popularized by Trendelenburg in the late nineteenth century, and the operation became known by his name. He tied the vein in the middle of the thigh, but the operation was later improved by choosing the point of termination of the vein at the femoral vein for ligation. This was not always enough to give good results, because blood sometimes flowed back into the varices of the leg through incompetent communications with the deep veins at a lower level. Surgeons therefore performed more radical operations in which large reaches of the superficial veins were excised. This was often time-consuming and laborious for the surgeon and a major operation for the patient. When the American surgeons W. L. Keller,¹ C. H. Mayo,² and W. W. Babcock³ introduced their rapid methods of extensive ablation of veins by stripping, excision was soon abandoned. An even quicker method was introduced soon after, when injection treatment was introduced and became the widespread practice. Until the second world war injections combined with ligation remained the standard practice, but about that time it became apparent that the results were not always good and the method was subjected to scientific study by phlebography. A. M. Boyd and D. J. Robertson⁴ and J. B. Kinmonth and D. J. Robertson⁵ showed that the flow of injected fluid was often uncertain and that it might damage valves in the important communicating and deep veins: this would make their valves incompetent or even cause thrombosis and embolism from the deep veins. About the same time T. T. Myers, of the Mayo Clinic, introduced a more efficient flexible stripper which could be passed with greater ease and efficiency through more tortuous veins.

Stripping combined with ligation is now the established operation, and there have recently been reports⁷⁻⁹ of good results in curing varices. There

has also been a satisfying freedom from post-operative embolism, probably owing to early ambulation and elevation of the limbs after operation. The incidence of embolism is one-half per cent. or less, which is no higher than for other surgical operations.⁷ Although the results from this modern combination of stripping and ligation are probably better than at any time in the past, perfection has not been reached. Improvement may lie in more accurate placing of the ligatures. The chief cause of formation of varices or of their recurrence after operation is incompetence of the valves in the veins which perforate the deep fascia to join the deep veins. This allows the high pressure in the deep veins to be transmitted to the superficial. A popular name for these incompetent perforating or communication veins is "blow-outs." They may occur in various places in the limb, and their distribution and anatomical variations have been described by R. S. Sherman.¹⁰ The most important and most anatomically constant is that at the sapheno-femoral junction, and this is readily dealt with. Those in the lower leg are more difficult to find, for they may vary in position. F. B. Cockett¹¹ has described those above the ankle which are most often at fault. They frequently escape when the great saphenous vein is stripped, and so a special effort must be made to find them should there be evidence that they are incompetent. The technique of stripping has reached a high degree of efficiency. It is in the methods of locating incompetent communications that most room for improvement lies.

"QUARTERLY JOURNAL OF MEDICINE"

Fifty years ago the first number of the *Q.J.M.* appeared. It then set a standard which, maintained ever since, has made it one of the finest medical periodicals in the world and indispensable reading in all teaching and clinical centres. The originator of this project, as of much else beneficent in British medicine, was William Osler. He joined forces in 1906 with John Rose Bradford, A. E. Garrod, H. D. Rolleston, W. Hale White, and R. Hutchison—now Sir Robert, happily still with us as the one surviving member of that great band of physicians. These men, who were to become jointly the first editors of the *Q.J.M.*, approached a number of their colleagues in order to form an association of physicians, and in the current number of the *Q.J.M.*, a jubilee issue, Sir Russell Brain records their endeavours and those of other leading physicians of the day to launch the new association and its journal. The first meeting was held on May 23-24, 1907, when the then President of the Royal College of Physicians, Sir Richard Douglas Powell, was voted into the chair and became the first president of the Association of Physicians of Great Britain and Ireland, as it was named. W. Hale White (later Sir William Hale-White)

became treasurer, and W. P. Herringham (later Sir Wilmot Herringham) general secretary. The objects of the association were defined in the simple words—"the advancement of internal medicine, and the promotion of friendship among physicians."

To the first object the *Q.J.M.* has been an invaluable ally. Arrangements were made at the 1907 meeting for its publication in conjunction with the Clarendon Press, Oxford, which has continued to publish it ever since. The idea in starting it was to publish papers which, "though scientifically important, were not suitable for the Journals, nor for the clinical or pathological societies." In practice this has usually meant that the papers were thorough and scholarly reports of investigations or series of cases, and of greater length than is acceptable to most journals. The emphasis to-day as formerly is rather on clinical medicine than the abstruser weapons of biochemical or mathematical attack. In the friendly informality that typifies the meetings of the Association, in fulfilment perhaps of its second aim, Sir Russell Brain sees the enduring impress of Osler's personality. He "overcame the medical isolation of the different parts of the British Isles, which had previously existed, and brought the physicians of Great Britain and Ireland together." The *Q.J.M.* may be seen likewise as bringing together, through the variety and excellence of the papers it publishes, all physicians who care for the advancement and sound practice of medicine.

COMEDO FORMATION

Comedones, the primary lesion of acne vulgaris, occur so frequently about puberty that they may almost be considered a physiological phenomenon. It is therefore surprising that the mechanism of their production is still a matter of controversy. Possible theories with their historical background have been well summarized recently by Lipman Cohen.¹ They may be divided roughly into two groups: those emphasizing obstruction to the outlet of the pilo-sebaceous follicle, and those based on some weakness of the forces which empty it. One of the oldest theories, suggested by Unna, was that the fundamental cause was hyperkeratosis of the follicular orifice, and H. W. Barber suggested that this might occur under the influence of androgens.² J. P. O'Brien in his work on prickly heat drew attention to the keratin ring which he showed obstructed the orifice of the sweat duct; he suggested that a similar mechanism might help to close the follicular orifice.³ Others have paid more attention to the sebum. This is almost certainly increased in quantity, but there is less agreement about its being altered in quality. It has been suggested that it is abnormally viscid, that it contains irritants which stimulate hyperkeratosis, or even that imperfectly involuted sebaceous cells block the ducts. But there is no convincing evidence so far for any of these theories.

² Barber, H. W., in *Modern Trends in Dermatology*, ed. R. M. B. MacKenna, London, 1948.

³ O'Brien, J. P., *Arch. Derm. Syph. (Chicago)*, 1952, 65, 206.

⁴ Grant, R. N. R., *Clin. J.*, 1951, 80, 260.

Unna and Sabouraud believed the so-called acne bacillus was important, but infection is now considered only a secondary phenomenon. Among the various writers favouring weakness of the *vis a tergo* several have pointed out that comedones arise at the site of lanugo hairs, and it has been suggested that these, possibly as a result of imperfect growth, may be unable to keep the mouth of the follicle open. R. N. R. Grant¹ observed the frequency with which the succeeding hair could be seen penetrating the orifice at the base of the mature hair; exacerbations of the acne were found to coincide with a fall in the proportion of follicles containing replacement hairs. Failure of the hair to pierce the follicular opening might be due to inadequate rate of growth or less commonly to the hair becoming curled within the follicle. In general those follicles which produced more sebum produced less hair. One other factor which has been suggested is weakness of the arrector pili muscle, which is unable to contract strongly enough to extrude the sebum. Probably several of these factors combine to produce the comedo, and the corollary is that treatment directed against one alone is unlikely to be successful.

UNIVERSITY TEACHERS' SALARIES

Last week the Chancellor of the Exchequer announced that a further review of the salaries of academic staff at universities was now necessary if the standard of recruitment was to be maintained during the forthcoming period of expansion in the universities, and he proposed to ask Parliament to increase the grant to universities by, at first, £3m. a year, so that new rates of salary for full-time staff could be paid from August 1, 1957. The details of these new scales are given at p. 711. It is just two years ago that the Full-time Non-professorial Medical Teachers and Research Workers Group Committee of the B.M.A. drew the attention of the Central Consultants and Specialists Committee to the difficulties of staffing medical schools because of the low salaries offered to medical teachers and of anomalies in the application of existing scales.¹ During the early part of last year many letters were published in the *Supplement* expressing the dissatisfaction of medical teachers with their remuneration, and the Council of the B.M.A. appointed a special committee to go into the matter.² Last summer a deputation from this committee, led by the Chairman of Council, had an interview with representatives of the University Grants Committee and received a sympathetic hearing.

While the increased rates of pay announced by the Chancellor will be welcomed by medical teachers as a contribution towards meeting higher costs of living, many will feel that the rises are too small and come too late. Further, there is no certainty that all the universities will put the new rates into effect: some have not yet been able to pay the present permissive scales³ of salary. Even without taking into account the medical profes-

sion's claim for increased remuneration, the proposed increases in university salaries will still allow too large a gap between pay in the universities and pay in the Health Service, and the medical schools will continue to fight a losing battle in trying to attract medically qualified teachers to preclinical posts.

HORMONE-DEPENDENT CANCER

The revival of castration^{1, 2} and, later, the introduction of adrenalectomy³ for the control of malignant disease of the breast and prostate have led to the conception of hormone-dependent cancer. At first a simple hypothesis appeared satisfactory: to remove the glands secreting a specific stimulus to a target organ which was the site of a hormone-sensitive neoplasm should result in regression of growth not only of the target organ itself but of the neoplasm. The results of treatment soon showed that such a simple explanation could not stand close scrutiny, and indeed that it ignored the profound readjustments and adaptations which occurred in the body after endocrine ablation. Even after castration alone the function of the pituitary is grossly altered and other structures elaborate hormones which even if not exactly chemically identical cause a physiological response indistinguishable from the primary hormone. It has long been known that oestrogen production often returns in women after the menopause, and sometimes never entirely ceases. The site of production was thought to be the adrenal glands, which had been shown to elaborate oestrogen in other circumstances. Further work on the effects of oophorectomy and adrenalectomy on the secretion of oestrogen has more recently become possible because of improved chemical methods of assay, and elsewhere in this issue R. D. Bulbrook and F. C. Greenwood describe their observations on a series of patients. They found that oophorectomy often failed to abolish oestrogen production, and also that adrenalectomy even after oophorectomy might fail to remove oestrogen entirely from the body, though in some cases it might remain absent for long periods of time. The variability of oestrogen excretion is great after adrenalectomy, and even when apparently absent for weeks or months oestrogen may well return either spasmodically or more permanently. In a second paper Greenwood and Bulbrook extend their observations to the effects of hypophysectomy on urinary oestrogen in cases of breast cancer and show that even after this operation oestrogen may continue to be secreted.

These observations are clearly of great importance in the study of hormone-dependent cancer and underline the necessity for further work along the same lines. It may be wrong to assume that, because production of oestrogen does not cease after oophorectomy and adrenalectomy or after hypophysectomy, the surgical ablation of these glands has been incomplete; in fact, evidence is now accumulating that this is not

necessarily the case. Other sources of oestrogen must be sought, and such sources may indeed be autonomous. Again the production of hormones in the tumour itself is a problem that has not yet been solved. Regression of cancer can also occur despite continuing oestrogen production, and therefore other factors in both the adrenal and pituitary glands may be of equal or possibly greater importance in determining the degree of hormone dependence. The intermittent character of oestrogen production also shows the necessity for prolonged and continuous observations before any firm conclusions can be drawn not only about dependence on oestrogen but also about the nature of other factors on which the growth of cancer may depend. At present much of the information on the secretion of oestrogen after surgical ablation of endocrine glands has of necessity been collected from patients suffering from malignant disease. It would be unwise to accept such evidence as necessarily representative of normal patterns, for some endocrine abnormality may be determined by the nature of the disease present at the time.

RENAL FAILURE AFTER BURNING

Severely burnt patients may develop renal failure, but it is uncertain how often this contributes to a fatal outcome. Despite modern methods of treatment, between a half and two-thirds of fatalities occur within the first four days after burning and are attributed in the main to "shock." Later deaths may be due to infection or what is loosely termed toxæmia. The toxæmic deaths tend to occur between four or five days and two weeks after burning,¹ and it is possible that renal failure may be a contributory factor or even the main cause of death in some of these. Pathological changes in the kidneys certainly occur very commonly in patients dying after burns. S. Sevt² in reviewing the necropsy material at the Birmingham accident hospital found significant renal lesions in 54 out of 86 patients dying after burns. Fifty-one of these showed the changes of tubular necrosis, but only a small proportion of them appear to have died because of renal failure. The tubular changes were of two main types—namely, distal or diffuse tubular necrosis, occurring in about two-thirds of cases, and proximal tubular necrosis in about one-third. The former type occurred at all ages and showed essentially the same histological picture as that described following crush injuries, incompatible blood transfusions, abortions, and variously named lower nephron nephrosis or acute tubular necrosis.³⁻⁷ The latter type, proximal tubular necrosis, occurred more commonly in elderly

patients, the majority of whom had nephrosclerosis with or without hypertension. It appears likely, as Sevt suggests, that the lesion is caused by a disturbance in the blood supply to the cortex. There would seem to be no satisfactory way of distinguishing between the two types on clinical grounds.

It is of interest that some patients may, after burns, develop renal failure without oliguria.⁸⁻¹⁰ The same clinical picture has been described by P. E. Teschan and others¹¹ after battle injuries in Korea. The histological changes are the same as in the more ordinary cases of acute tubular necrosis, but the kidneys behave as though, in the commoner type of failure, they were in the period of diuresis immediately following the oliguria. It is as though they had jumped from the onset phase to what is known as the early diuretic phase, without any prolonged period of anuria or oliguria. There are at this time dangers of water and mineral depletion, because the kidney's ability to retain these substances is impaired. It seems likely that more cases of this high-output renal failure would be discovered in other conditions, if patients who have been injured were observed more carefully. Not only should the volume of the urine be measured but also its specific gravity. Fixation of the specific gravity at about 1010 would suggest the need for further investigation, and an estimation of the level of urea in the blood would establish the presence of renal abnormality.

FIRST GASTROENTEROLOGICAL DEPARTMENT

The first gastroenterological department to be set up in this country was opened at the Central Middlesex Hospital on Friday last week by Sir Gordon Gordon-Taylor, who told the many visitors who witnessed this notable event that he had performed a gastrectomy probably before many of them were born. The director of this new department is Dr. F. Avery Jones, whose contributions in gastroenterology have received worldwide recognition. He is being assisted by Dr. T. D. Kellock, Dr. Richard Doll, and Dr. E. N. Rowlands. The new department contains four laboratories, an endoscopy theatre, an x-ray set, a library, and offices. It is a most efficiently and attractively designed unit situated in close proximity to the two wards where gastroenterological patients are treated. The building of this new unit in a hospital where so much pioneer work has been done on disorders of the alimentary tract has been made possible by the generosity of the Nuffield Foundation; the equipment has been provided by the Medical Research Council and the North-west Metropolitan Regional Hospital Board. It may be noted that the major contribution for this new enterprise has come from bodies outside the National Health Service, and this in itself is a reminder that there is still plenty of room for financial support of State hospitals from outside the Government. The Nuffield Foundation has once again put the profession in its debt by giving financial support to an institution and men best fitted to make the fullest use of it.

DOMICILIARY GENERAL PRACTICE IN PREVENTION AND TREATMENT OF ILLNESS

BY

R. N. THEAKSTON, M.A., L.M.S.S.A.

Hutton-le-Hole, York

Fifty years and more ago the farming community was prevented by bad roads and poor communications from travelling far from home. The local market town might be visited once a week in good weather only. In times of sickness the doctor generally went out to the patients, and a wide range of procedures were performed with a high standard of skill in their homes. In spite of keeping a number of horses, the doctor's area was limited to that over which he could travel in bad weather.

Better roads, motor-cars, and public transport have opened up the countryside and widened the range of travel for patient and doctor alike. Health insurance legislation from 1911 onwards has put the patient under an obligation to attend at a surgery unless prevented by illness. Although at first rather less than a third of the population were covered by insurance, the encouragement of surgery attendance enabled the doctor to draw his patients from a wider area. The tendency has therefore been for fewer doctors to serve a country district now than formerly.

In 1948 the National Health Service made free medical service available to the whole population. Surgery attendance whenever possible was emphasized in the instructions printed on the back of medical cards, and accommodation that had previously been adequate had to undertake the reception of three times the numbers.

Overcrowded waiting-rooms would have been unavoidable even if attendances had not been increased by the service being free of charge. A surgery attendance is usually made because of some minor trouble, among which the upper respiratory infections form probably the biggest group. Attendance may be required for routine treatment or supervision, including antenatal and post-natal examination.

Waiting-rooms probably increase the spread of a great deal of what is termed minor illness, the cost in lost working time being very heavy. Attendance for treatment or supervision often involves rearrangement of household work, or discomfort, or expense in travelling, which discourages regular attendance and prevents regular supervision of, for instance, diabetics and the elderly.

There seems no reason why improved communications and modern equipment should not be used in a small and dispersed practice to revert to the older custom of mainly domiciliary work. The method would have to be within the framework of the National Health Service, and able to pay its way.

In outlying parts of the Colonies, and in other European countries, it is quite common for the well-equipped doctor to travel to the patient. During war-time it was quite normal for a G.D.M.O. based on a hospital to do a daily round by jeep or pickup truck, attending scattered groups of men. At the same time he was available if required in an emergency by any particular group.

Description of Practice and Office Routine

My district can conveniently be described in the form of two equilateral triangles lying respectively above and below a common base, formed by the main road, which runs east to west, and carries the only daily bus service. The total distance between the northern and southern apices is 15 miles (24 km.), and the base is 12 miles (19.3 km.) broad. The lower triangle consists of flat country intersected by narrow lanes; the upper triangle is formed of open moorland ridges which separate the deep valleys that run from north to south. There is no roadway over the moor from valley to valley, access being only from the southern ends. The ridges run together to shut off the northern ends. I live in a village of some 200 inhabitants, which forms the hub of my district.

Surgeries and chemists are available in the two market towns, $3\frac{1}{2}$ and $8\frac{1}{2}$ miles (5.6 and 13.6 km.) away. A bus goes to each of them once a week, on market day, and only those living near the main road are able to use more than a weekly service. The low roads are never completely blocked, but in bad winter weather the high roads may be inaccessible to traffic for several days at a time. There is one telephone in each of the dales, but elsewhere public or private instruments are accessible.

Time spent on office work has been reduced to a minimum by keeping accurate records and using proper equipment. N.H.S. folders (E.C.5 and 6) are filed away and used as envelopes for hospital or specialist's letters. Complete notes and summaries of hospital reports are kept on perforated Copeland Chatterson cards, which give writing space equal to a quarto sheet and fit the typewriter. Sixty of these cards occupy not quite an inch in thickness, whereas 15 E.C.5 or 6 folders have to be firmly compressed into the same thickness. Correspondence and recorded work are typed; on-the-spot notes are taken in shorthand. An alphabetical index of people on my list is kept up to date by pasting in additions and erasing departures as they occur.

Cards in current use are kept separate, and reviewed at the end of each month. I retain the cards that will still be needed, and return the others to the main file. While doing this monthly review, I fill in a nominal list, showing people seen and visits made. The cards held back give the names of those who still need attention, and will form the nucleus of the following month's work. These names are entered on loose-leaves having squares for each day of the month. I make a rough plan for the week's work, adding or altering as necessary from day to day, but in the main being able to arrange for routine work in any district to be done on the same day. This is specially useful for planning my regular visits to the elderly or chronic sick.

Transport

All my journeys can be done in a small light commercial van. I bought a chassis and put on a body to suit myself, so that I can comfortably carry equipment and a passenger if necessary. The overall cost was under £400, and I get over 40 miles to the gallon (14 km. per litre) on commercial petrol. It is easy to manoeuvre, and is reliable, having been designed for frequent stops and starts. Weather conditions have never prevented its use, but in suitable weather I sometimes go on foot, on a motor-cycle, or on skis.

I plan the day's round so that I do not have to retrace my steps, and leave time for delays or for diversion in response to additional calls that come in after I have left home. My patients understand this, and co-operate so well that almost all messages reach me during the advertised "surgery hours." It is also well known that I visit certain people at regular intervals, or certain districts on the same day each week, and I get quite a lot of messages asking me to call when next visiting as the matter is not urgent. New calls generally include an often very accurate indication of

the problem for which advice is being sought, so that I can take the necessary medicine with me.

Distance and accessibility are important in planning the journey, especially in winter-time. Some roads may not be cleared until later in the day in mid-winter, or it may be better to hope for a slight thaw to improve conditions. If possible I find it better to go to the distant places first, so that on the way back I have more chances to pick up additional messages, which are telephoned to places ahead of me. These messages are usually passed on very well, and it is unusual for me not to get the message until I arrive home.

When I started I thought I might be strained by a large number of extra calls or by having to cover a greatly increased monthly mileage. For the preceding four years I had been working from a surgery in the market town $3\frac{1}{2}$ miles (5.6 km.) away, and not dispensing. I was now undertaking to visit at home, and to dispense for three-quarters of all the people on my list. The average distance covered has not been increased by as much as 100 miles (160 km.) a week, and the number of visits made each month amount to only about 10% more than before, if visits and surgery attendances are added together. This supports my idea that, in country work, visits are often made to a village from which have come some of the visitors to the day's surgery. A surgery may not therefore save a lot of working time.

The scheme has been running smoothly for four and a half years, and I get very few seemingly trivial calls out of normal hours. A large number of calls ask me not necessarily to go that day, but to include the visit with others that I had intended to make in that village on the next day. I am probably helped in two ways. The countryman often finds a journey inconvenient, and is accustomed to acting with consideration when asking others to travel; and it is understood that I will go if required, attendance not depending on an arbitrary definition of "seriousness."

Most people are now able to use the telephone properly. In difficulty, someone is usually willing to telephone for the caller, but in a few cases I have had to instruct patients, either by giving them simple written instructions to keep by them when they go to the box, or in one case by taking an elderly man into the box and giving him a practical demonstration. Many messages come by hand or through the post.

Domestic and Public Hygiene

As my list is drawn from a predominantly farming community I am probably responsible for a higher proportion of elderly people and lower proportion of children than I would be if I lived in or near a town. In other respects the composition is similar to that of any ordinary general practice. I think that the conditions of work and of life account for an intelligence that is lower than average and a poor standard of personal hygiene, although there is much to be deplored in the local standards of domestic and public hygiene.

Many cottages and farms have no inside supply of piped water and no indoor sanitation; quite a high proportion have no piped supply at all, and draw their water from an open beck which is draining from the moor or hillside.

Although more than three-quarters of the houses in my own village have either an inside or an outside water-closet, the entire domestic and farm drainage passes either directly or through a septic tank into the beck which runs down the centre. Fish are rarely found nearer than half a mile (800 m.) downstream. The habit of dipping sheep may to some extent have a disinfectant action. Until two years ago the entire water supply was collected into a brick storage-tank partly from underground springs and partly from open drainage from manured meadows, or open cow or sheep pasture.

A knowledge of domestic conditions is of the greatest help in dealing with the cause or the treatment of illness, and there is no better way of knowing these conditions than by habitually visiting families at home.

Care of Aged and Infirm

The care of aged and infirm people, or the supervision of the chronically ill, may be more of a problem in the country than in a town. Families are smaller and young people are leaving the countryside in greater numbers to find better-paid work in the towns, so that neighbourly help is much more difficult to get than it used to be, and any "home help" scheme is defeated by being understaffed.

Four excellent district nurses share the work of a very wide area, and the M.O.H. is 9 miles (14.5 km.) away, but it is easy to miss cases that need help unless visits can be made at fairly frequent intervals. Many of the elderly are not able to travel to a surgery some miles from their home, and in such cases a doctor is often not asked to help until urgent illness compels his attendance. Chronically sick people, such as diabetics, can generally get to a surgery quite easily, but they put off the journey if they can, unless they feel unwell.

I keep a list of old people that I think ought to be watched, and visit many of them at regular fortnightly or monthly intervals. Others I see from time to time, very often when fine weather takes me walking in their direction. These old people have become accustomed to what I call "social calls," and do not think it incumbent on them to produce a symptom that will ensure another visit or justify a bottle of medicine. Several of them do have a regular supply of one of the harmless mixtures, not because I think the mixture has any physiological action, but because it makes the patient feel better, and therefore has a therapeutic effect. The majority are as easily and effectively helped by explanation of the cause of their symptoms or signs.

Diabetics and chronic sick are visited regularly, and know at what intervals to expect me. They do not phone when nearly out of insulin, for instance, because they know that enough has been given to last until my next visit. Diabetics are all members of the Diabetic Association, and I discuss with them points of interest in the *Diabetic Journal*; they all use "clintest" sets and test at variable but regular intervals, recording results on a calendar so that I can see them. At intervals I take blood, and have blood estimations done in hospital when I go up for my weekly anaesthetic session. In acute illness, especially when serious, I make a point of saying when I shall next call—if the family do not have to send for me in the meantime.

Maternal and Infant Welfare

I think of maternal and infant welfare as being two aspects of the same and most important part of my work, for in this branch I can concentrate from the beginning on prevention and education. Home visiting makes this most rewarding and professionally satisfactory, and the frequency of visits depends more on the type of home than on clinical necessity.

I like to know as soon as a woman thinks she is pregnant, and encourage home confinement whenever conditions are suitable. If I am told in time, I do a full physical examination at about 10 to 12 weeks, including a pelvic examination and an estimation (Sahli) of haemoglobin percentage. This routine applies to all cases, whether a first or subsequent pregnancy. Thereafter I visit monthly to 30 weeks, fortnightly to 36 weeks, and weekly or more often till confinement. The blood pressure and urinalysis are recorded at each visit up to 36 weeks, after which urinalysis is done only weekly unless otherwise indicated. The abdomen may not always be examined at each visit until the 30th week, but after that time it is examined at each visit. A full examination at the 30th to 32nd week is combined with a sample of venous blood, taken into a "venule" and sent for grouping, reports of rhesus factor, and a report on blood film. Haemoglobin is estimated on the spot, by Sahli's method. Compound vitamin capsules and iron are given at the latest from the 30th week in the form of "capsules abidec" and

"tabs. fersolate," one or two of each daily. When necessary, the father's blood group and rhesus factor are also determined.

I am told when labour begins, and try to visit as soon as possible. I may then decide to go and do some neighbouring visits, so long as I am sure to be able to be present for the latter half of labour. It is understood that nurse delivers the baby and acts as midwife unless she wants me to take over, so that I can concentrate on general management and upon giving analgesia.

General management may include the use of oxytocin in amounts of two or three units at a time when the os is fully dilated, if there is evidence of fatigue; or the use of pethidine in doses sufficient to slow rapid progress. Analgesia is by pethidine combined with trichlorethylene; the pethidine is put up for me by the hospital dispensary in amounts of 50 mg. in 5 ml.; trichlorethylene is given from a Friedman set that I have altered so that I can control the proportion of vapour in air up to approximately 5%. My technique is not suggested for general use because I have specialized training and a hospital appointment in anaesthesia.

Should any repair be needed, I try to leave the patient for 24 hours. This allows her to recover and gives time for oedema to subside; I then give intravenous thiopentone (nurse always being present) and suture the repair in comfort.

Post-natal visits are made daily, on alternate days and finally weekly until about six or eight weeks after confinement, when I do another complete physical examination similar to the one done at 10 to 12 weeks. Thereafter I visit up to 10 months at monthly intervals.

The infant is vaccinated at 6 months, by which time any upset is much less alarming. At 7, 8, and 9 months a combined injection of the Wellcome preparation is given to immunize against pertussis, diphtheria, and tetanus. So I follow the progress of the infant for the first 10 months of its life, and am by then well able to anticipate its future development.

A result of this system is that every child that I have attended in this way since I came here nine years ago has been successfully vaccinated against smallpox and properly immunized against diphtheria and pertussis, and also against tetanus since 18 months ago. Pertussis has not occurred in any child that I have immunized since I came here. Immunization against tetanus is of importance in this district where there have been two deaths in children under 7 years of age in the past eight years.

If home conditions are not suitable I arrange for confinement in the maternity hospital 30 miles (48 km.) away, but in all other respects the antenatal and post-natal supervision is conducted as before.

Neurosis

From correspondence in the medical press it is concluded that neurosis takes up about a third of the general practitioner's time; I should say that this is roughly true for the calls made upon my time. The common factor is anxiety, of which the manifestations are boundless; serious mental illness is rare. In case of serious illness I arrange a domiciliary consultation with a psychiatrist, and have so far had no trouble about getting the patient admitted voluntarily. The nearest duly authorized officer is 30 miles (48 km.) away, and he shares with one colleague the work over an enormous area.

The home background is of such importance in elucidating the cause of neurosis that I find the problems far less perplexing during a home visit than I used to do when I tried to deal with such cases in my surgery—with a door between me and a crowded waiting-room. During the first few visits I get a good idea of the background, and the patient gets over much of her shyness. I next make an appointment to visit, with nurse whenever possible, first

thing in the morning, in order to examine the patient in bed after a night's rest. If there are doubtful points, I follow them up by a special investigation or reference to an out-patient clinic.

Whatever the result, this is reassuring to the patient, who is satisfied that she has been thoroughly examined. She is not affronted, therefore, if told that her symptoms do not indicate definite organic illness, and is prepared to listen to an attempt to explain the relationship between psyche and soma. I do not try to hurry things, and as there is always some evidence (if only slight) of physiological dysfunction, I institute appropriate medical treatment while leading up to an attempt to explain the influence of anxiety.

In many cases, with the patient's consent, I ask their vicar or priest to call. Sometimes I discuss the problem with him; at other times I ask for his help and leave him to adopt his own approach. I find this very happy co-operation of the greatest help to those patients who let me take this line, and the results are better than in those cases where a conventional method is used.

If I am unable to make headway I refer the case to an out-patient clinic without delay, so that the patient has no time to feel that her case is hopeless or that nothing is going to be done to help her. Out-patient treatment entails at least a 30-mile (48-km.) journey in each direction; thus the patient is away from home for most of the day if she is having a course of shock therapy. I have insufficient experience to draw conclusions from my small number of cases, but my impression is that active therapy is not a great help. I think that if ordinary measures fail to get improvement it is better to try to get the patient to live with her neurosis. Family and friends are very helpful if the problem is explained to them, and this sort of explanation, combined with regular visits of the "social call" type, can maintain a remarkably stable outlook.

Whatever the form of treatment, the patient has ultimately to face the ordinary problems of home and family, and, although there is improvement while she is away having treatment, there is nearly always a relapse soon after her return to ordinary life.

Minor Surgery

The scope of the work undertaken need not be limited because it is done in the patient's home. All my equipment is portable and easy to transport from place to place, and very few modifications have been made to suit my present needs. In any case, so much country work has to be done in the home, where facilities are limited, that items like a battery-operated headlamp and a portable sterilizer are in everyday use.

Until quite recently it was customary to do a great deal of minor surgery in the home or at the doctor's surgery—some of it not really minor, as removal of tonsils and adenoids was considered quite reasonable. Although these procedures were generally done well, they can now be done so much better in hospital out-patient clinics that it is not justifiable to do them elsewhere. I arrange for cases to be taken into minor operations clinics at the local hospital, and to be brought back home soon afterwards. All the rest of the treatment is done at home, and when completed a note to that effect is sent to the hospital for filing with the clinic notes.

For instance, a patient requiring Trendelenburg's operation for varicose veins will be given written instructions about pre-operative preparation (diet, bowels, etc.) and sent by ambulance so that she reaches hospital by 9.30 a.m. The arrangement is that she is put down for the first part of the list, so that the operation has been finished by lunch-time. She is brought back home at about five in the evening, and is put to bed, where I see her that evening. I decide when she may get up and attend to the dressings and stitches. Two notes are sent to hospital: the first when all the stitches are out, the second about a month later, when I pay a final

visit and assess the result of treatment. I rarely find that I must keep the patient in bed for more than a day or two, and when in bed she can attend to innumerable household matters that require her decision or instructions. The result is that I have no difficulty in persuading people to go up for a minor operation, and they avoid the inconvenience of elastic stockings or similar appliances.

Extensive dental extractions are often more satisfactorily done at home than in the dental surgery, which is 9 miles (14.5 km.) from most of my patients. Domestic arrangements are made, and generally one of the nurses meets us at the house. I give an injection of atropine as soon as I get there, and nurse then prepares the patient while the dentist and I get our equipment ready. I give thiopentone and attend to the patient's head, so that I make sure of a proper airway and can keep the back of the mouth free from blood. After the extraction I wait until I am satisfied that the patient is completely conscious. The subsequent treatment is of course done at the dentist's surgery.

Dispensing

Three-quarters of my patients live more than two miles (3.2 km.) from a chemist, and I dispense for them on the tariff basis. Other doctors in the locality do not dispense, but it would be rather pointless for me to give my patients an E.C.10 to take to a distant chemist when I am trying to conduct a domiciliary practice. I simplify the monthly returns of E.C.10's, both for myself and for the pricing bureau, by typing them in different colours. By using the tabulator I can deal with three prescriptions at a time on my machine. Group A are typed in blue, and group S in red; sorting at the end of the month could hardly be made more simple, and every prescription is legible. Dispensing seems to give me more control over treatment, and I am able to give out as much medicine as I think necessary at one time, which is more economical than giving an E.C.10 for as much as might become necessary if the response is not as rapid as usual. That my monthly return of items dispensed shows a fairly steady decline over the four and a half years is, I think, one indication of the success of advice and education during visits. I use almost no placebos, but I do use a number of expensive chemotherapeutic and antibiotic agents, and a good deal of insulin; in spite of this my costs work out at considerably less than the national average per head. I have no difficulty in collecting the 1s. prescription charge, and am generally given it without having to ask. I think that most of my patients now know that this charge is a form of tax, and none of them think that it is one of my perquisites.

Conclusion

Home visiting restores a great deal of the old family doctor relationship, and it becomes an advantage to find out a little about taxation, official returns, welfare services, and a number of things which are outside the medical curriculum. But advice about such things can often be more efficacious than several bottles of medicine. Whether he likes it or not, a country doctor has an important part to play in the affairs of his parish or district, and the value of his help is greatly increased by an intimate knowledge of the homes and lives of his neighbours.

Summary

A country practice in a sparsely populated area, poorly supplied with bus services, is described.

All the work is done by visiting the patient's home, and a central surgery is not used. Drugs are dispensed for three-quarters of the small list, and specialist services are readily available at a hospital 30 miles (48 km.) away. It is claimed that the pressure of work is not increased by excluding a central surgery, and that the scope of the work is not limited by the absence of surgery facilities.

APARTHEID IN MEDICAL EDUCATION

REPORT BY DEAN OF FACULTY OF MEDICINE, NATAL UNIVERSITY

On March 11 the Government of South Africa introduced a Bill for university apartheid.* It provides, among other things, for the separation of the Faculty of Medicine, intended mainly for the training of Africans, from the University of Natal. At the request of the president of the Natal Coastal Branch of the Medical Association of South Africa and other interested persons, a report on the matter has been prepared by Professor I. GORDON, professor of pathology and dean of the Faculty of Medicine of the University of Natal, and this report, thanks largely to a donation from Mrs. FLORENCE A. E. POWELL, who in the past has contributed generously to the development of the Medical School, has now (March 4) been published.

The report is in the form of a quarto brochure of some 50 pages and contains as much printed matter as would fill some 25 columns of an average English newspaper; it is arranged in four sections and gives the whole history of the Medical Faculty from approximately 1922, when the first tentative efforts were made in Durban to train Africans to be doctors.

Background to the Bill

Section I of the Report is essentially historical and calls for little remark, except in that it includes an extract from a message from the present Minister of Education, Mr. J. H. VILJOEN, sent to the University when it was appealing for funds in 1952. In the course of the message the Minister stated, "University education should not be, and is not, State Education," and a little further on the message refers to "... this praiseworthy undertaking in respect of which great credit is due to the University of Natal. . . ." Section II, also largely historical, takes up the tale in 1953, November, when the Government appointed a commission of inquiry in regard to the provision of separate training facilities for non-Europeans at the universities. All too often this Section is punctuated by the phrase "heard unofficially."

The commission in its findings strongly recommended that the Faculty be left on its present basis within the University of Natal. However, the Government refused to accept the findings and appointed an interdepartmental committee to formulate an effective scheme for separate development. In March, 1956, the dean of the Faculty of Medicine first heard unofficially that the Cabinet had decided to transfer the control of the Faculty of Medicine away from Natal University to the University of South Africa. Vigorous efforts to secure an opportunity to present the complicated situation in the University of Natal at Durban, where the medical school existed, to the interdepartmental committee were unavailing. Towards the end of that year (November, 1956) the principal of the University, Dr. E. G. MALHERBE, heard, also unofficially, from the Secretary for Education of the Government's intention to place the Faculty under the control of the Department of Native Affairs, subsequently altered to Department of Education. But it was not until the end of January, 1957, that the first public information became available in the form of a reply by the Minister of Education to a question in Parliament.

Protests from Universities and Branches of Medical Association

Protests rapidly followed this announcement. On February 7 the Faculty and heads of departments of Natal University held an emergency meeting and passed a resolution of emphatic protest at the Government intention. On February 11 the students of the Faculty likewise protested. Two days later the Natal Coastal Branch of the Medical Association of South Africa added their protest, and pointed out that the Branch would find it impossible to co-operate

*See *British Medical Journal*, March 16, p. 655.

in any way with any authority other than the University of Natal in the staffing of the Medical School.

A day or so later the Cape Western Branch of the Medical Association of South Africa passed a resolution of support for its colleagues of the Coastal Branch. Convocation of Natal University added its voice of censure on the Government's intended action; so did the senior members of the University's academic staff, and within a day or so the 10 full-time professors in the Faculty of Medicine of Capetown University added their support. But at the end of February the Minister of Education told a parliamentary correspondent in Capetown that he did not think the Government could change its attitude.

Press comment and many letters relating to the negotiations are given in a fourth section of the Report in the form of 12 appendices. These give detail and add considerable edge to the protests.

Dean's Verdict

Section III, and it is the smallest section, is headed, "Comment on the Government's Intended Action," and as it bears no name or other indication of origin it must be assumed to be the considered opinion of the compiler of the Report, Professor Gordon. It states: "A feeling of frustration and of being regarded as political agitators has become common among responsible South Africans who have found themselves in disagreement with the Government. This sense of frustration is a tragic consequence of recent developments in the country which indicate that decisions are made without consultation and despite objectively defined arguments against the carrying out of predetermined policies. . . . The excision of our Faculty from the other more established Faculties of the University will have the effect of changing what is now a broadly based medical education to a narrowly defined and predominantly technical training. Thus a school which has been initiated and developed in accordance with modern educational trends in Medicine will at one stroke be profoundly modified. . . .

"It should be clearly understood that the University of South Africa, as presently constituted, acts only by providing extramural education for those in the country who wish to advance themselves by part-time studies through correspondence courses. . . . Consequently the functions being delegated to the University of South Africa by the Government subverts the full academic role which universities now have in South African medical education. . . . Apart from these considerations, it will be readily recognized that it is not possible to train good doctors unless the academic staff are able to work in an appropriate 'milieu.' The only 'milieu' possible in this country is that of a University which has effective and accessible inter-Faculty and inter-Departmental contacts. By separating a Faculty of Medicine from other University Faculties and by leaving its staff in isolation, there must inevitably be a fall in academic standards. No formula constituting a single Faculty as a University or constituent college of a University can hide this fact. . . .

"Apart from the interference with freedom of University action, this exclusion of European students from the Faculty of Medicine has important implications for the growth of Medicine in Africa. The European constitutes a minority of the people of South Africa, and an even smaller minority in Southern Africa. Medical services will increasingly be developed among the millions of Africans in this subcontinent, as well as among minority groups such as the Indian and coloured peoples. European doctors constitute the majority of those at present providing these services. Denying them the right to be admitted to a Faculty of Medicine, such as that at Durban, can only deprive them of an experience which would assist them in their future practices."

And the comments end with the observation: "Those concerned with initiating and developing the educational experience provided are deeply conscious of the wrong being done to their students. . . . It is clear that the future of Medicine in Africa will be determined by Faculties of Medicine in countries other than South Africa."

Correspondence

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

Immunological Tolerance

SIR,—In your interesting leading article on immunological tolerance (*Journal*, March 9, p. 570) you quote Professor P.B. Medawar's view that transplantation immunity and red-cell immunity could hardly be more unlike. While Medawar's views naturally command respect, I should like to point out that in this context they are not universally accepted. It is only fair to point out that Medawar made it clear that he was contrasting the orthotopic skin graft with red-cell immunity. This is important, since not all tissues evoke the same type of homograft response.

Medawar based some of his arguments on the following grounds: (1) The antigens are different. Red-cell antigens are cytoplasmic, while those concerned with skin grafting are nuclear. The last statement is based on experiments by Medawar and his colleagues on cells subject to ultrasonic disintegration. In this case only the nuclear fraction was found to induce immunity to subsequent skin grafts. The interpretation of this result is not yet clear. For example, we do not yet know how far these nuclear preparations have been freed from other cell constituents. Further, it is very likely that several chemically distinct iso-antigens differentiate the skins of different individuals. (2) If free serum antibodies are essential in homograft reactions they are not gamma globulins. This statement rests entirely upon the observation that skin homografts will regress in foetal sheep at a time prior to the formation of gamma globulin. This might have some weight if the foetal sheep had been critically examined for their ability to form antibodies, particularly iso-antibodies. It has been argued that the skin homograft reaction is like tuberculin sensitivity, free antibodies being unnecessary. It is indeed likely that sensitivity of the delayed type is important in homograft reactions, but it is probably insufficient, at least in man. Patients with agammaglobulinaemia can neither form antibodies nor destroy skin homografts. They can develop sensitivity of the delayed type. In my opinion this makes it seem very probable that circulating antibodies do play a vital role in the destruction of skin homografts in man. The alternative is to invoke some unspecified secondary effect of the lack of gamma globulin. (3) The homograft reaction has not been reproduced *in vitro*. Nor has haemolytic disease of the newborn. (4) The immunity produced by a living tissue homograft is semi-permanent, while that produced by a single injection of foreign red cells is not. We have clinical evidence that "immunity" developed against a single transfusion of Rh-positive cells may last for over 20 years.

Red-cell immunity is not a simple entity even within a single species, the reactions to incompatible cells varying with the antigenic systems involved. Transplantation immunity probably embraces an even wider diversity of response. Those engaged in its study will be very unwise to neglect possible processes common to many types of iso-immune reactions.—I am, etc.,

Intramedullary Nailing

SIR,—Mr. E. N. Wardle (*Journal*, March 2, p. 520) is naturally at liberty to criticize any method of treating a fractured femur with which he does not agree, but he is a little unfair to the operation of intramedullary nailing in inferring that the four deaths in our series (*Journal*, January 26, p. 208) were due to the operation. If he consults the article again he will see that the four patients who died were over the age of 70 years, and three of them died four weeks or more after the operation, one from secondary carcinoma and the others from bronchopneumonia. The fourth death was from pulmonary embolus and could

possibly be attributed to the operation. We are unaware of the mortality rate in the aged for non-operative methods. Perhaps others can enlighten us.

We have not met the muscle-stripped type of fracture mentioned by Mr. Wardle, though eight of our cases were in the upper third of the femur, but our alleged "indiscriminate employment" and "lack of any sense of proportion" would doubtless guide us to insert a nail.

Since our article was written thirteen months ago we have treated a further twelve cases, and are still undeterred by Mr. Wardle's comments. In our view, the absence of cumbersome splints and traction apparatus, the early ambulation, the shorter stay in hospital, the good alignment and absence of shortening, and the good knee movements outweigh the disadvantages of an operation. And we can assure Mr. Wardle that the prettiness or otherwise of the radiological appearances has not been a factor in our enthusiasm for this method of treatment.—We are, etc.,

Anaemia in Rheumatoid Arthritis

SIR,—Your leading article on the pathogenesis of anaemia in rheumatoid arthritis (*Journal*, March 2, p. 509) deals with a subject of great theoretical and practical interest. I want to add that recently we have been acquainted with the fact that salicylates not infrequently can cause gastro-intestinal bleeding, and we have seen that this has been followed by considerable anaemia.¹ Perhaps some of the confusing circumstances with some cases of anaemia in rheumatoid arthritis can be explained when this fact is taken into consideration.—I am, etc.,

Hillerød, Denmark.

Pathogenesis of Rheumatic Endocarditis

SIR,—After reading Dr. R. Lannigan's letter (*Journal*, March 2, p. 517) I still believe that the hypothesis of thrombus deposition and incorporation adequately explains the occurrence of clearly defined areas of homogeneous eosinophilic material in valves affected by rheumatic heart disease. In Aschoff nodes such clearly defined "clumps" are not found: when fibrin-staining material is present it is in small fragments or fibres, as in the reticular type described by Gross and Ehrlich.¹ As it happened, only the myocardial Aschoff nodes showed fragments of fibrin-staining material in my series; none of those present in valves did so. Furthermore, only an Aschoff node with a homogeneous, dense, clearly defined area of fibrinoid material would be comparable in appearance to the lesions found deep in valves.

In the literature I reviewed² there are two views about the nature of this eosinophilic material: (1) that it is always degenerated collagen; (2) that it is partly degenerated collagen and partly incorporated fibrin (or fibrin and platelets). I was driven to postulate that it was always thrombus by the difficulty of finding either in the literature or in my own observations any clear-cut criteria whereby one could distinguish incorporated partially organized thrombus from degenerated collagen. In fact the concept of fibrinoid necrosis of collagen seemed superfluous for the explanation of the origin of this type of lesion in valves. Small fragments or fibres of eosinophilic material, even if contiguous with collagen fibres, could be due to almost completely organized thrombus rather than fibrinoid necrosis of collagen, and there must be a stage in organization of thrombus when this appearance occurs.

The main reason for labelling a lesion "degenerative" is because it appears to be very deep in the valve. In recently affected valves no lesion can be very deep, because the valve cusp itself is so thin. In older, thicker valves single sections may give a very erroneous idea of the depths of a lesion, owing to the puckering and pocket formation that occur in these valves. Isolated lesions that appear at

first to be deep in a valve may actually turn out to be formed in the apex of such a pocket. I do believe that a further study of serial sections should be carried out with a view to seeing whether eosinophilic "clumps" genuinely occur deep in the valve at levels equidistant from endothelia on the two surfaces of the valve cusp, and well away from the apex of any pockets or fissures there might be.

As Dr. Lannigan states (quoting Talalajew),³ mucoid material (which shows metachromasia with toluidine blue) has been held to be a pre-fibrinoid change. Nevertheless, it does occur in organizing thrombi, it does occur in relation to organizing vegetation; therefore a proportion of that found in valves must arise from this latter source. Certainly its occurrence cannot *per se* be accepted as evidence of a pre-fibrinoid change, especially as an almost completely organized vegetation will give appearances mimicking fibrinoid degeneration.

I agree that repeated attacks of subclinical rheumatism contribute to valvular deformities. The problem, really, is whether subclinical rheumatism acts by leading to thrombus deposition or by fibroblastic proliferation with or without preceding oedema—or by both mechanisms. The difficulty of accepting oedema of the valve cusp as a factor in the early acute stages of the disease is that one would expect such a cusp to rupture, or become frayed.—I am, etc.,

Rapid Serum Cholesterol Estimation

SIR,—The investigation of serum cholesterol levels in coronary-artery and associated diseases is now a fairly well established procedure. The following technique (which uses reagents commonly found in a clinical laboratory and takes approximately five minutes to perform) may be of value as a screening test. It is adapted from the method of Sols.¹

To 0.2 ml. haemolysis-free serum in a centrifuge tube is added 5 ml. acetic anhydride and the contents well mixed. The tube is stoppered with a cork pierced by a short length of narrow-bore glass tubing and placed in boiling water for exactly three minutes. After immediate cooling the tube is centrifuged one minute and the contents decanted into a similar tube. 0.15 ml. concentrated sulphuric acid is then added with vigorous shaking so that the temperature rises. After about 30 seconds the colour is read in the usual manner with a red filter in a photo-electric colorimeter. For the standard, which keeps a month, 19.3 mg. cholesterol and 8.8 ml. of water are added to 200 ml. acetic anhydride and the flask placed in boiling water for 20 minutes. Shake from time to time. Cool and make up to 250 ml. with anhydride. 5 ml. is treated with acid, as is the serum extract, but the tube should be left for 45 minutes at 20° C. before reading. The figure obtained corresponds to a serum cholesterol of 200 mg.%.

Standardization is, of course, only necessary at infrequent intervals dependent on reagent and colorimeter stability. Laboratories carrying out cholesterol determinations as a regular routine may find it more convenient to use the routine technique to standardize this screening test rather than prepare the standard as above.—I am, etc.,

Living with a Colostomy

SIR,—The leading article on care of patients who have colostomies (*Journal*, February 2, p. 274) is indeed timely, and can go a long way to alleviate the suffering of thousands of unfortunate individuals. The colostomy patient often finds that he is friendless, and, due to complaints from his fellow workers, frequently loses his job, particularly if he has not perfect control. This most affects executives and office workers, who are usually in close proximity to their fellows.

I find Clayton-Jones's advice on the home management of a colostomy¹ quite ideal for the patient. It gives him great confidence to know that he need not be ostracized, and from a practical point of view I have found this advice gives complete control of the colostomy in nearly all cases. Points of paramount importance are that a patient can take what is virtually a normal diet; the colostomy working is controlled and the faecal odours are absorbed; wash-outs are unnecessary and the patient ceases to be unwelcome in his home environment. Lastly, the taking of pure methyl cellulose, as advocated in the article, reduces the quantity of dressings to one-third, and this is a great saving on the cost of prescriptions.—I am, etc.,

Derby.

Toxic Effects of Methylpentynol

SIR,—Our article on the toxic effect of methylpentynol (*Journal*, December 22, 1956, p. 1467) was intended only in part to emphasize the undesirable features of the drug's effect. Although methylpentynol is prescribed both as a sedative and a hypnotic, Lasagna,¹ in a most stringent analysis, noted that its hypnotic effect (0.5 and 1.0 g. doses) was indistinguishable from placebo. An acceptable maximum sedative dose is 2.0 g. per diem, and 0.1–1.5 g. has been given daily by mouth for six months without ill effect.²

Our series was presumably composed of persons most susceptible to the action of central nervous system depressants, and as such represents one extreme of individual and biological variability. Consequently it would be fair to suppose that a reasonable proportion of subjects would exhibit no adverse features on a maximum dose level. As drug response increases in approximately arithmetical progression for a corresponding geometric progression in dose,³ those individuals manifesting sensitivity to the drug might have remained "symptom free" on dose levels of 0.25, 0.5, or 1.0 g. daily. This seems to be so, and there are data to substantiate it.⁴

In answer to criticism of our use of the serial sevens, we would reply that it is merely one aspect of a more comprehensive appraisal of the mental status. One bat does not make a belfry, and it would be equally presumptuous to suppose that the serial sevens test isolated from its context is anything more than meaningless. Finally, our results were not presented as a denigration of the drug. Methylpentynol has few serious effects. It is habit-forming in certain persons,⁵ but then, almost certainly, so would have been alternative drugs; only one case of exfoliative dermatitis has been reported in the world literature during four years⁶; and there is very meagre evidence to incriminate it as a potential hepatic toxin.⁷—We are, etc.,

EDWARD MARLEY.

Type Distribution of Coxsackie Viruses in Japan

SIR,—After the discovery of the immunological multiplicity of Coxsackie viruses¹ many papers appeared on the identification and classification of antigenic types of Coxsackie viruses isolated in many areas of the world.^{2–10} Here I present the results of typing of 157 Coxsackie viruses isolated in Tokyo for the past six years. The serological identification was carried out by means of neutralization

reaction in suckling mice, using 16 representative types kindly supplied by Dr. Gilbert Dalldorf, New York. Of 157 strains, 6 were isolated in 1951, 2 in 1952, 3 in 1953, 23 in 1954, 109 in 1955, and 14 in 1956. As the result of typing, 1 strain falls in A1, 38 in A2, 43 in A4, 35 in A5, 24 in A6, 3 in A8, 12 in A10, and 1 in B1 types of Dalldorf's classification.¹¹ An A1 virus was isolated from the patients suffering from mild febrile disease occurring in the summer of 1951 (51 cases were observed),¹⁰ and a B1 virus was isolated from an epidemic myalgia (Bornholm disease) patient in 1952 (32 cases were studied).¹² Of 109 strains isolated in 1955, 80 were isolated from herpangina patients, and the remaining 29 were from contacts with or without grip-like symptoms; 12 of 13 strains were also recovered from herpangina patients in 1956; 82 viruses isolated from herpangina patients belonged to A2 (28 strains), A4 (18 strains), A5 (29 strains), A6 (14 strains), and A10 (3 strains). Thus group A Coxsackie viruses isolated in Japan from herpangina patients were limited immunologically to only 5 of 19 types of A viruses. This finding is consistent with that of other countries, which showed that the viruses from herpangina were divided into 7 types—i.e., A2, A3, A4, A5, A6, A8, and A10.^{13–15} It is problematic whether other types than the 7 types mentioned above are able to cause herpangina in children or not. In my opinion, every type of group A Coxsackie virus can induce herpangina. With respect to the frequency of isolation, A4 was the most widely distributed type in Japan in 1951–6. In Sweden also, A4 virus is isolated most frequently.⁵ It seems to be true that type distribution of Coxsackie viruses does not differ in Japan from other areas in the world.—I am, etc.,

Tokyo, Japan.

Underfeeding of Babies

SIR,—A mother brought her 3-month-old baby to my out-patients recently because he was perpetually crying. The details she gave me about the quantity of dried milk he was receiving made me suspect that he was underfed, but the mother vigorously denied this and claimed, rightly as it turned out, that his inguinal hernia was the real cause. Apparently she had had breast-feeding troubles earlier and had been an in-patient with her baby at a well-known paediatric centre. There she had been strongly reprimanded by the sister for giving the baby too much milk, and this had made her decide not to tell the truth next time she was asked about feeding details. She confessed all this to me and admitted that in fact the baby was taking twice as much milk as she had led me to believe.

I thought it worth while recording this in case there are still some doctors who try to prevent mothers from giving young babies as much milk as they want, and to remind paediatricians that ward sisters sometimes give advice which would not meet with our approval.—I am, etc.,

Stock, Essex.

IAN G. WICKES.

Test for Handedness

SIR,—It is sometimes useful to determine whether a person is naturally right- or left-handed, and the following simple test, noted many years ago in a book on shooting, seems a little known. The person points with a finger, quickly, at a suitable slim object, and then at once, without any change of position, closes one eye to see if the finger is "on" and then opens it and closes the other. One eye wins at this test repeatedly and that is the dominant eye. Useful if shooting, the test can be useful in medicine if, as seems to be the case, dominant eye goes with dominant hand.—I am, etc.,

Manchester, 13.

M. Q. BIRKBECK.

Tibial Traction

SIR,—In further reply to Dr. Winifred L. Turner's letter (*Journal*, February 9, p. 344) deprecating tibial traction and advising femoral traction in fractures of the shaft of the femur, an opportunity arises to correct a very widely held misapprehension which Dr. Turner exemplifies.

The object of traction is twofold: to maintain alignment of the femoral fragments, when either femoral or tibial traction would serve, and, secondly, to overcome the shortening produced by the pull of the muscles spanning the fracture. All these muscles, with the exception of the lower fibres of adductor magnus, and a few fibres of adductor longus (Fig. 1),

FIG. 1.—Anterior view of right knee and fracture, showing only muscles whose pull must be overcome by tibial traction acting through the ligaments. FIG. 2.—Anterior (a) and posterior (b) views of right knee showing muscles whose insertions are pulled on directly by tibial traction. Split up into three views for the sake of clarity.

are inserted below the knee-joint. Tibial traction, therefore, pulls on these muscles direct, and the strain transmitted through the ligaments of the knee-joint is extremely slight, merely drawing the flail-like lower fragment of the femur into alignment with virtually no resistance.

Femoral traction, to achieve the same effect, can only work by thrusting the loose lower femoral fragment down on to the tibia, whence the force can be transmitted to the insertions of the quadriceps, semimembranosus, semitendinosus, gracilis, sartorius, biceps femoris, much of gluteus maximus, and tensor fascia lata (Fig. 2a, b, and c). The diagrams demonstrate that no lower fragment or ligaments are needed at all to pull on any of these muscles with tibial traction. Similar considerations apply in the leg, where no muscle is inserted into the lower three-quarters of the tibia or into the talus.

If we want to rest a joint we apply traction to it, and this has been proved beneficial in tens of thousands of cases

of arthritis of every kind. Joint cartilage, on the other hand, atrophies under continuous compression, and this is inevitable with femoral skeletal traction.

As Mr. Richard Harrison (*Journal*, March 2, p. 523) indicates, the causes of stiff-knee after femoral shaft fractures are largely inherent in the fracture, but their incidence is reduced if thigh muscle exercises are instituted from the first, and, perhaps most important of all, if it is recognized that there may be a time factor, which is as yet undetermined but probably lies for adults in the vicinity of 12 to 14 weeks, beyond which maintenance of immobilization of the knee-joint may be followed by irreversible stiffness. Femoral traction, however, will ensure knee stiffness within a very much shorter time. The diagrams are based on illustrations from *Buchanan's Manual of Anatomy*.¹—I am, etc.,

Canterbury.

Intelligence and Cleft Palate

SIR,—In your leading article (*Journal*, February 23, p. 454) you discuss the relation between cleft palate and lowered intelligence as found recently by Illingworth and Birch.¹ The *Proceedings of the Royal Society of Medicine* record a paper read on December 9, 1930.² This began from the other side and examined the occurrence of developmental anomalies of all kinds in a large number of mental defectives. The field of study was the whole of the records of 2,464 idiots and imbeciles admitted to the Fountain Hospital between 1912 and 1930 and actual examination of a further 564 patients of those grades who were still present in 1930. In the earlier group 11 cleft palates were recorded, or 0.44%, and in the later group there were 3, or 0.53%. Tredgold³ quotes Langdon Down as finding 0.5% in aments and Ireland as finding 1.0% in idiots, whereas Grenzer reported only 0.06% in 14,466 "presumably normal" children. This compares with the 0.1% which Fogh-Andersen⁴ seems to have expected from normal children.

Without access to the detailed methods of these observers it is not easy to compare their conclusions. It seemed to me, 26 years ago, "that there are more physical anomalies in mental defectives than in the mentally normal," but that "the difference between the two is probably less marked than we have been given to believe."⁵—I am, etc.,

Lewes, Sussex.

Psychiatry in Africa

SIR,—The *Journal* reaches me three weeks after publication, but I write to reply to Dr. A. Stewart Henderson's comment (*Journal*, February 2, p. 283) on Dr. A. Lambo's paper (*Journal*, December 15, 1956, p. 1388) in the hope that your columns remain open on this topic. Dr. Lambo's article was timely and informative, and answered some questions about the incidence of psychiatric illness which have interested psychiatrists everywhere. It has already received favourable comment in this country.¹

Dr. Henderson first appears not to understand a statement in which it is clear that Dr. Lambo quotes the native medicine-men as claiming greater success in the neuroses than in the psychoses. Having done so, Dr. Henderson is able to take offence at the thought that our "scientific disciplines" are "bettered by primitive magic in Africa." The remainder of Dr. Henderson's letter displays his concern that treatment by magic should be called "effective" and "scientifically sound." If this is so, he asks, what reasons have we to train Africans in psychiatry?

I think Dr. Henderson's real difficulty is with the word "magic," which seems to offend his scientific orientation. Yet is it not true that much of medicine has been based upon magical principles in the past, and do we not still

Are not the following facts acceptable: (1) that B.C.G. in a statistical sense, in some instances and in the early stages will reduce new infections to a benign state (whether first or reinfections); (2) that B.C.G. will not prevent clinical infection in all instances or even approximately all instances; (3) that the thought that B.C.G. should not be given to those with positive tuberculin tests is generally accepted; (4) that both historic evidence and experimental evidence indicate that overdoses of tuberculin should not be given to reactors; (5) that mass inoculation does superimpose B.C.G. on some tuberculous persons; (6) that the consequences of such mishaps, if serious, would be charged to an acknowledged ineffectiveness of B.C.G. rather than made a true and proper responsibility of B.C.G.; (7) that it would take few such instances to offset the good accomplished, since we are really weighing a relatively small amount of good against relatively small risks; (8) that a missed diagnosis because of masked tuberculin response, an unnecessary risk because of the assumed virtues of B.C.G., or a withdrawn measure of safety because of the time, expense, or assurance with B.C.G. should properly be charged against the benefits of the use

We had not read the paper "Subacute Bacterial Endocarditis: Its Changed Aspects," by Drs. L. Biro and G. Gottsegen.² This omission has been rectified. The material described by the authors is certainly large: 1,012 patients alleged to have subacute bacterial endocarditis. Unfortunately the data presented in this paper are not comparable with those found in English and American literature for several reasons. The survey was based on questionnaires which had been sent out to Hungarian hospitals: "the

answers were based on no equally exhaustive case records, and not every institute answered each question." No mention is made of the organism isolated in patients with a positive blood culture. Positive blood cultures were obtained in only 13.7% of the patients, and there is no mention of the criteria on which a diagnosis of subacute bacterial endocarditis was made in the patients with a negative blood culture. 10% of the patients in the latter group had a normal temperature. During the period 1945-8 only 57%, during the period 1949-51 only 87%, of the patients received antibiotic therapy. Of the 627 patients who had penicillin, only 106 received 1 mega unit or more. 174 necropsies were performed, but in only 55% was evidence of subacute bacterial endocarditis found. The data are set out in a most unusual way. For instance, "Results of treatment in patients treated with antibiotics": 1945-8, number of cases 193, recovery 32 (17%), deaths 60 (31%); 1949-51, number of cases 513, recovery 150 (35%), deaths 124 (27%). What happened to the 52% and 38% in the two groups respectively is not disclosed (table IV). We assume that your correspondent is referring to his table V when he mentions "the more serious prognosis of abacteraemic subacute bacterial endocarditis." This table gives the "relationship of haemoculture results and prognosis": 1945-8 haemoculture positive: recovered 13 (33%), died 4 (10%), total 39 (100%); haemoculture negative: recovered 19 (13%), died 48 (33%), total 145 (100%). 1949-51 haemoculture positive: recovered 25 (48%), died 17 (33%), total 52 (100%); haemoculture negative: recovered 115 (31%), died 86 (23%), total 374 (100%). The total figures analysed in this and the previous table quoted represent only a fraction of the total number of cases (1,012) included, and there is no record of the fate of the patients who have apparently been included in the table but neither died nor recovered. It will perhaps be evident, from the examples quoted, why we find ourselves unable to compare Dr. Gottsegen's data with those obtained by us and other writers here and in America. We pointed out in our paper that our figures are small and it would be dangerous to draw too many conclusions from the percentages of deaths and recurrence, even though our figures agree with those of other writers. Our findings regarding the dental state of patients with subacute bacterial endocarditis due to *Str. viridans*—namely, that they all had teeth—are, however, so definite that the possibility of this being due to pure chance is remote. We have found nothing in Dr. Gottsegen's paper which in our opinion invalidates our observations, particularly when it is doubtful whether the clinical and pathological criteria necessary for a diagnosis of subacute bacterial endocarditis are the same in this country and in Hungary.—We are, etc.,

Compound Aspirin and Steroid Tablets

SIR,—Your correspondent Mr. J. A. Braun (*Journal*, March 2, p. 523) has forgotten two important tests in his communication. In addition to the "cotton pellet" test and the "granuloma pouch" test I should like to submit the "national pocket" test and the "relative dangers" test in the appraisal of compound aspirin and steroid tablets. If, in fact, the results of the "cotton pellet" and "granuloma pouch" tests can be accepted it would appear that the anti-inflammatory effects of these tablets are simply additive and not synergistic (that word so beloved by the pharmaceutical advertiser). There can surely be no contradiction to the mixture of the ingredients of the compound aspirin and steroid tablet in the patient's stomach, and this would facilitate modification of the dosage to suit individual requirements. When the "national pocket" test is applied it will be seen that the country's economy will also benefit. The basic price of 100 aspirin tablets (5 gr.—0.3 g.) is 6d., that of 50 1-mg. prednisolone tablets 15s., and that of 100 compound aspirin and steroid tablets containing 5 gr. (0.3 g.)

of aspirin and 0.5 mg. of prednisolone is 22s. 7d., plus 6s. 9d. purchase tax—that is, 29s. 4d. From whatever viewpoint—except from that of the drug firms—the result of this test is obvious.

The application of the "relative dangers" test to prednisolone and aspirin makes the latter a sure winner. With aspirin there is no risk of hypertension, tuberculous flare-up, mental disorder, or masked pyogenic infection, to mention but a few of the disadvantages of steroid therapy, and gastric irritation leading to perforation or haematemesis must be extremely rare. It is assumed that the dangers associated with compound aspirin and prednisolone treatment will be less than when full doses of the steroid are used. On the other hand, the combined tablet can be expected to be used mainly in general practice, where the safeguards and routine checks advocated for patients on steroid therapy will inevitably be less rigid. In the end, because of the smaller doses of steroid used, we shall be lulled into a false sense of security and the dangers may be out of all proportion to the benefits anticipated.—I am, etc.,

Plymouth.

BERNARD J. PECK.

Prophylactic Value of Tetanus Antitoxin

SIR,—The article by Dr. Leon S. Kind (*Journal*, March 2, p. 498) once more brings up the larger question of the rationale of this form of therapy as practised in casualty departments. Usually any patient with a breach of continuity of the skin receives 1,500 units of tetanus antitoxin if an adult and 750 units if a child (unless they are known to be sensitive to it, to have asthma, or to have been actively immunized) as a routine, irrespective of the wound, with the object of preventing tetanus. My copy of Conybeare's *Textbook of Medicine* says on the subject of tetanus prophylaxis: "The value of antitetanic serum as a prophylactic measure is universally recognized. At least 3,000 units should be injected subcutaneously as early as possible after all wounds, particularly if these have occurred on a road or cultivated ground. Even a graze on the skin or small puncture wounds are potentially dangerous. Further injections should be given at weekly intervals until the wound is completely healed. Failure to give prophylactic serum can only be regarded as criminal negligence." Besides being mostly impractical, I suggest that in the light of modern knowledge this advice may be harmful.

Prophylactic A.T.S. is given, and may be justified, on the following grounds: (1) It combines with and neutralizes exotoxin from the established case of infection with *Clostridium tetani*. (2) A single dose delays the appearance of signs and symptoms, thus increasing the incubation period. This is beneficial, since it is known that the mortality is indirectly related to the length of the incubation period,² due to the time available for host resistance, in the full pathological sense, to be built up. (3) Forensically, combined with a patient's or doctor's request. (4) Traditionally. Abusive letters and returned patients to the casualty officer, who resists the easy way out, testify to this attitude.

Prophylactic A.T.S. when given may be harmful or useless on the following grounds: (1) A.T.S. is a horse protein which itself acts as an antigen when injected into humans, who react by producing antibodies, which are probably active in seven to ten days. Further antigens—that is, A.T.S.—may now be ineffective, when the toxin production of the clostridia in the tissues may be just getting under way.^{1,4} This condition is aggravated every time the patient receives A.T.S. prophylaxis. There is no doubt as to the efficacy of full therapeutic doses of antitoxin in the treatment of the disease in those who have not previously received A.T.S. (2) Sensitization to the horse serum of the A.T.S., a corollary of (1). I see at least one case a week with generalized urticaria from this cause, but not one case a year of tetanus. Deaths from anaphylaxis have occurred. (3) Doses as above are inadequate to have even the desired beneficial effect. 1,500 units of A.T.S. for children and 3,000 units for adults should be a minimum initial dose, which must be repeated in a week to protect adequately a person developing the disease, since the fall in blood antitoxin level is rapid in the unimmunized and the incubation period is prolonged for this time by the initial dose.^{5,6} Casualty departments give only single doses. (4) Most cases of tetanus come from trivial injuries or unrecognized

trauma which never find their way to a casualty department for treatment. We are not protecting those who are going to get the disease.

Other reasons, such as cost and delay in treatment (half an hour between test and immunizing doses, consent for minors where parents cannot be contacted, etc.) are valid in busy centres to a lesser extent.

Tetanus is not a common disease, and it has been suggested that this is because passive immunization with antitoxin, while not preventing infection, may suppress signs and symptoms, leading to a subclinical attack and active natural immunity. This is difficult to prove. On the other hand, for reasons above, the use of antiserum does not lower the incidence of tetanus in a community.² How prevalent must a disease be to justify measures taken against it on the scale of those taken against tetanus, in terms of cost, inconvenience to the patient, and possible dangers, assuming that the measures achieve what is claimed for them? Presumably gas gangrene is below that figure, yet *Cl. welchii* is as ubiquitous as *Cl. tetani*. Diphtheria antitoxin is not used in a comparable way for a comparable pathology. Should not all operative cases receive A.T.S. because of the danger of exogenous spores in catgut or powder, or endogenous reinfection from latent infection of bones? Why is it more criminally negligent of the doctor to "let" a patient die of tetanus than of diphtheria or poliomyelitis?

I suggest the following as a more rational procedure for antitetanus measures: (1) The active immunization with tetanus toxoid, along with pertussis vaccine and diphtheria toxoid, using a single dose triple antigen, of all babies possible. With appropriate booster doses this gives lasting immunity, covers the exceptional conditions of war, and obeys the first principle of medicine, prevention. (2) Use of tetanus toxoid as a booster or initial dose in the casualty department. This takes care of the delayed case, reactions are rare and mild, test doses are not required, and no serum is used in toxoid manufacture. (3) Abandoning indiscriminate routine use of tetanus antitoxin as an immunizing measure, and reserving its use for the treatment of suspected or established cases of the disease on clinical grounds. This would even apply to grossly contaminated wounds or compound fractures, thus keeping the best curative measure at its most potent for combating one of the few remaining infectious diseases with a distressingly high mortality.—I am, etc.,

London, N.14.

Crash Helmets

SIR,—To motor-cyclists suffering from head injuries I often pose the question: "Were you wearing a crash helmet?" Two recent replies have been brilliantly nonsensical: "No. You see, I only have a small motor-bike," and: "I remember deciding not to put it on, as it had stopped raining." I suppose a stupid question deserves a stupid answer. There may be even better to come, such as, "I only have a small brain," or, "I don't think they suit me." I shall continue to pop the question.—I am, etc.,

St. Andrews, Guernsey.

J. R. DICKSON.

The Silver Lining

SIR,—In 1954 Drs. T. H. Wilson and G. Wiseman, working in the department of physiology, University of Sheffield, introduced their technique for studying intestinal absorption by the use of sacs of everted small intestine. In doing so my colleagues had the temerity to turn an organ inside out in order to study its physiological function. In admiring their courage and ingenuity, I had also credited them with being pioneers in finding a biological use for the sac of everted mammalian intestine. The letter by Dr. Julian Huxley (*Journal*, March 9, p. 581) makes it clear that Drs. Wilson and Wiseman have not got this distinction, and were

in fact anticipated by more than 100 years. Furthermore, it would have to be admitted that the use described by Dr. Huxley can fairly be said to be a more penetrating investigation of the reliability of the everted intestinal sac. *Vixere fortes ante Agamemnona*.—I am, etc.,

Senna and Morning Sickness

SIR,—In Professor A. S. Duncan's article (*Journal*, February 23, p. 439), in which he describes the value of "senokot" standardized senna as a laxative during pregnancy and in the puerperium, he mentions its use in morning sickness. For some time I have prescribed senokot to pregnant patients with constipation and have been interested to have been told that in many cases their morning sickness has disappeared. Recently I have given senokot to those with severe morning sickness and have the impression it is more effective than the usual drugs given. It would be interesting to hear of any actual series or similar cases. I should be grateful for any explanations of the mechanism of how senokot acts to help these patients.—I am, etc.,

Littlehampton.

ROBIN BEST.

Treatment of Acute Appendicitis

SIR,—I was much interested in the recent correspondence in your columns about acute appendicitis at sea. A good many years ago, while whaling in the Weddell Sea, we got news in the factory ship that a whaler was coming in with two whales and that a Norwegian seaman had been taken seriously ill with acute abdominal pain. The gunner thought this was due to acute appendicitis. His diagnosis was correct.

The seaman was a very big, well-built Norwegian. He had a pulse, I believe, of about 120. He had an ominously low temperature of 99° F. (37.2° C.) which I did not like. He was blue and cold, and very ill. There was a *B. coli* odour in his breath and he was exquisitely tender in the right iliac fossa, both on rectal examination and on palpation. I decided, rightly I think, that the only course here was immediate operation. I told the captain and the gunner manager that I saw nothing else for it, and so instruments were boiled up and the officers' mess prepared. The surgical equipment was adequate. I intended to operate under a spinal anaesthetic. The chief engineer and the chief steward were to assist. The scene was so like that depicted in *Doctor at Sea* that this might have been an identical case.

Myself and my two assistants had a very large tot of rum each, but the patient said he felt too ill to have some—he must have been ill, because he had a magnificent swallow. When the sheets were raised from the instruments and basins on another table, and before I could get the man into position for a spinal puncture, he took one look at the shining instruments and fled. Nothing on earth would beguile him out of the fo'c'sle, until a direct order from the captain landed him in the sick bay, which happened at the time to contain several skulls of sea leopards, etc. He was very ill indeed for some days, lost weight rapidly, and suffered from extreme toxæmia with a temperature swinging from normal to 103 and 104° F. (39.4 and 40° C.). A large abscess formed in the right iliac fossa and got bigger and bigger as sweats and physical deterioration increased. I told the captain that all I had to do was to put a knife in the swelling and insert a drain, and he would probably recover. The patient refused. One night I thought that he was dying, and in the early hours of the morning I was awakened by his feeble thumping on the bulkhead, and on going to him he asked for a bed-pan. He then evacuated an enormous quantity of the most foul-smelling pus per rectum—and proceeded to make an uninterrupted recovery. He ate enormously and actually rejoined the crew of the whale-catcher, only to be drowned the following year when his boat capsized in the pack ice.—I am, etc.,

Lanark.

JOSEPH BRYANT.

Obituary

J. G. HAMILTON, M.D.

Dr. J. G. Hamilton, the distinguished American medical scientist, died on February 14 in San Francisco, at the age of 48. He was professor of medical physics, experimental medicine, and radiology at the University of California, and was one of the first to study the use of radio-isotopes in man.

Joseph Gilbert Hamilton was born in Waverley, Mass. Educated at the University of California, he first graduated in science and then went on to study medicine, proceeding to the degree of M.D. in 1936. Until 1942 he worked as instructor in neurology and medicine in the medical school of the University of California at San Francisco. At the same time he was carrying out research in physics at the radiation laboratory at Berkeley, where he became professor of medical physics in 1950. This appointment was combined with the chair of experimental medicine and radiology at the medical school. Among his many public appointments he served as chairman of the radiological study section of the National Institute of Health and of the National Research Council's committee on radiology. He was a consultant to the U.S. Atomic Energy Commission, and during the war he directed part of the biological research undertaken in connexion with the Manhattan Project.

As a doctor with a training in physics, Hamilton was quick to grasp the value of artificial radio-isotopes in the study of biological problems. Within a few years of E. O. Lawrence's invention of the cyclotron at Berkeley, he had studied the metabolism of many radioactive elements in animals and humans. In 1938 he gave the radioactive elements, sodium, potassium, chlorine, bromine, and iodine, to normal humans by mouth, and followed their absorption from the intestine by measuring the rate of appearance of radioactivity in the hand. In his report of his results he pointed out that the rate of absorption of a radioactive element would give a measure of the rate of absorption of the naturally occurring stable isotope. In the following year, with Dr. Mayo H. Soley, he applied this principle to the study of the uptake of iodine by the human thyroid, and he also compared the uptake of a test dose of radio-iodine in thyrotoxic patients and normal people. This is the earliest report of the use of a radio-isotope as a diagnostic test.

In 1940, Hamilton, Soley, and Eichorn, making use of Hamilton's earlier observation that radio-iodine is selectively concentrated in the thyroid, gave radio-iodine to patients before an operation for removal of the thyroid. Autoradiographs were then made from thin sections of the thyroid. By this method they were able to localize the areas in which the radio-iodine was concentrated in pathological thyroid glands. Other workers had already used autoradiography for studying the deposition of radium in human bone, but Hamilton's work on the thyroid gland was probably the first attempt to use this technique for localizing an artificial radio-isotope in humans.

Hamilton's other important contribution to this field of study was his demonstration that the selective concentration of radio-iodine within the thyroid could be used to destroy the thyroid by irradiation without damaging

other tissues. With J. H. Lawrence he applied this discovery to the treatment of patients suffering from Graves's disease, and in 1942 they reported that they had successfully treated three patients with radio-iodine.

Hamilton continued his researches until shortly before his death. After he had developed leukaemia, from which he died, he visited this country to lecture on his work on the metabolism of astatine, a radioactive halogen. Although his work was confined to physiology and clinical medicine—he took no part in the application of radio-isotopes to biochemistry—he helped to establish many of the principles that have since become commonplace in the applications of nuclear physics to these branches of biological science. In this he was a pioneer.

A. A. GUILD, M.D., M.R.C.P.

Dr. A. A. Guild, consultant physician and physician superintendent of Lambeth Hospital, died at St. Thomas's Hospital on March 9. He was 40 years of age.

Alexander Alan Guild was born on May 22, 1916, and was educated at Edinburgh Academy and at Gonville and Caius College, Cambridge, returning to Edinburgh for his clinical training. At Cambridge he gained first-class honours in the Natural Sciences Tripos and was a college prizeman, and at Edinburgh he was medallist in pharmacology and therapeutics and in public health and obtained a Murchison scholarship in clinical medicine in 1941, the year in which he graduated M.B., Ch.B. Having completed a resident appointment at the Edinburgh Royal Infirmary, he joined the R.A.M.C., serving with the 159th Field Ambulance, first as medical officer and later as company commander, from 1942 to 1945. He was with the 78th and 4th Divisions in North Africa, Sicily, Italy, Palestine, and Greece. Appointed A.D.M.S. Land Forces (Greece) in December, 1945, he became deputy to the D.D.M.S. (Greece) in 1946, being demobilized in the latter year with the rank of lieutenant-colonel.

After the war Dr. Guild took the M.R.C.P.Ed. in 1947 and in the following year was admitted to the London M.R.C.P. In 1948 he was appointed clinical tutor to the university medical unit of the Western General Hospital, Edinburgh, under Professor L. S. P. (now Sir Stanley) Davidson, and medical registrar to Dr. W. I. Card. He was appointed senior registrar in 1949. Two years later he was appointed consultant physician and physician superintendent of Lambeth Hospital, where he remained until his death. He was joint author of the section on diseases of the nervous system in Davidson's *Principles and Practice of Medicine* (1952). He proceeded to the M.D. in 1953.

A colleague writes: Guild devoted his life to the art of medicine and took infinite pains in the treatment of the patients under his care. A man of wide culture, he was keenly interested in art, music, and architecture; he also maintained his connexion with the Territorial Army. He was a capable administrator and a loyal colleague. It is tragic that he died at such an early age, and he will be sadly missed at Lambeth Hospital. He leaves a widow and two young children, to whom we all extend our deepest sympathy.

J. F. MAHONEY, M.D.

Dr. J. F. Mahoney, who until recently was health commissioner of New York and formerly director of the venereal disease research laboratory at the U.S. Marine Hospital, Staten Island, died in New York on February 23. He was 67 years of age. He will be remembered as one of the pioneers of the penicillin

treatment of syphilis. John Friend Mahoney graduated in medicine at Marquette University, Milwaukee, in 1914. In that year he joined the U.S. Public Health Service, and in due course he became director of the venereal disease research laboratory at the U.S. Marine Hospital, Staten Island. He was also lecturer in dermatology at Columbia University, New York, and assistant professor of clinical syphilology and dermatology. It was in 1943 that he published a preliminary report with R. C. Arnold and A. Harris on the effect of penicillin in the treatment of syphilis. As a result of this successful clinical research he received many honours, including the honorary life membership (Wellcome prize) of the American Social Hygiene Association, and, in 1946, the Lasker Award of the American Public Health Service. At the time of his death Dr. Mahoney was director of the Bureau of Laboratories in New York City's Department of Health.

H. S. STANNUS, C.B.E., M.D., Ph.D., F.R.C.P. D.T.M.&H.

The obituary of Dr. H. S. Stannus was printed in the *Journal* of March 9 (p. 589).

Dr. J. B. DAVEY writes from Pietermaritzburg, Natal: By the passing of Hugh Stannus the profession has lost a man of outstanding ability and great charm. I came to know him in 1904 when home on leave from the British Central Africa Protectorate (later Nyasaland) and Stannus was considering an offer of appointment in that country. He had already held a number of house appointments at his old hospital, St. Thomas's, at the Bethlem Royal Hospital, and, for two years, at the Hertford Hospital in Paris. Into his fourteen years' service in Nyasaland he packed an immense amount of original work, both medical and anthropological, in addition to setting a very high standard in the execution of his official duties. Of a most inquiring mind and possessed of keen powers of observation, he recorded original investigations into such varied subjects as dietary deficiencies, congenital defects, yaws, leprosy, and trypanosomiasis, the customs, ceremonies, and industries of the African population, the diseases of domestic animals, and entomology. In 1911 he took the London M.D. and was awarded the university gold medal for a thesis in which some of these investigations were recorded. There is no doubt that he would have reached the highest positions in the Colonial Medical Service had not ill-health compelled retirement in 1919. After taking up medical work in London he continued to show an active interest in tropical medicine and contributed many papers on the subject to medical societies and journals. When his long service as medical adviser to the Board of Inland Revenue was recognized by a C.B.E. last year the award gave great pleasure to his numerous friends. In his younger days he possessed powers of physical endurance of a high order. He was a strong swimmer and walker, a keen big-game hunter, a vigorous hockey player, and an accomplished dancer. His interests were manifold, and anything he took up he pursued with great zest. He introduced the first motor-cycle to Nyasaland, and, later, was an enthusiastic motorist in England and on the Continent. Always full of new ideas, he was a most stimulating companion. On many questions he held strong views and was apt to express them with some pungency, and of slovenly work he was strongly critical. To those privileged to be admitted to his circle he was a most loyal friend and generous to a fault, and by them he will be sorely missed.

Dr. E. C. ASPINALL died in Birmingham on January 20 after a short illness. He was in his 63rd year. Eric Charles Aspinall was born at Wigan on February 20, 1894. After serving in the R.A.M.C. in the British Expeditionary Force

in the first world war he took up medicine, graduated M.B., Ch.B. at Birmingham University in 1924, and then acted as house-physician to the late Sir Leonard Parsons. In 1925 he joined the late Dr. W. B. Featherstone in Erdington as partner in a general medical practice and continued actively as senior partner in the same practice until 10 days before his death. He was medical officer to the Josiah Mason Orphanage, and he succeeded his senior partner as medical officer to Oscott College. At the time of his death the college had been served by the same practice for 67 years.

E. B. writes: Eric Aspinall was a family doctor of the best type. He was a bachelor, and his work was his hobby, but he interpreted his work in a very broad sense, and was a wise counsellor to his patients in their daily problems. To his close friends, of whom he had many, the memory of his funeral, through the lined streets of Erdington to the packed and overflowing parish church, will always linger as an inspiration.

Dr. E. B. SUNDERLAND died at his home at Haverhill, Suffolk, on January 29 at the age of 67. Edward Benjamin Sunderland, who was born on December 7, 1889, came of a Lincolnshire family. In 1914 he qualified M.R.C.S., L.R.C.P. from University College Hospital, where he later held the resident appointments of house-physician and obstetric house-surgeon. Soon afterwards he joined the R.A.M.C. and saw active service in the Gallipoli campaign. After the first world war he settled in practice, first in King's Lynn and later in Haverhill, where he remained for thirty years. He built up a good practice in Haverhill. His patients liked and respected him, and his clinical judgment was always sound. He was a man of few words and did not suffer fools gladly, but he was nevertheless most sympathetic where sympathy was required. He had many outside interests, including tennis, shooting, and fishing. He was well known in sporting circles for his achievements at the spaniel field trial championships, and he was a first-class shot. The sympathy of his many friends will go out to his widow.

Dr. W. DE W. WISHART died at Georgetown, British Guiana, on February 18 at the age of 84. After winning the British Guiana Scholarship in 1890 William de Wever Wishart became a medical student at Edinburgh University, where he graduated M.B., C.M., with first-class honours, in 1895. After graduation he held the appointment of house-physician at the Victoria Hospital for Consumption, Edinburgh. He took the D.P.H. of the Irish Royal Colleges in 1910. He was appointed the first medical officer of health for the city of Georgetown, and retired a few years ago. A member of the British Medical Association for over 60 years, he was a past president of the British Guiana Branch and had served on its council. He was appointed M.B.E. in the 1946 New Year Honours.

Dr. F. G. FRANCE, who was in general practice at Bromley, Kent, for some 30 years, died at his home there on February 22 at the age of 58. Francis George France was born at Ludlow on November 29, 1898, and was educated at Ludlow Grammar School and Bromsgrove School. During the first world war he joined the Welch Regiment and served in France, where in 1918, at the age of 19, he received severe shrapnel wounds in the chest which produced an arteriovenous fistula that was to prove a severe handicap for the rest of his life. As soon as he had recovered from his wounds he entered St. Bartholomew's Hospital as a medical student and qualified from there in 1924 by taking the London Conjoint diploma. He then became house-physician at Brompton Hospital, and while there obtained the London degrees of M.B., B.S. He was later resident medical officer at the Leicester Royal Infirmary. He entered general practice at Bromley in 1926, working first as a partner, and then as the successor, of Dr. D. R. McArthur in one of the two oldest-established practices in the area. He became an honorary physician at Bromley Hospital, and served there for many years, both before and during the

second world war. He relinquished this position on the re-organization of the hospital consultant staff to include visiting consultants from London, which took place shortly before the commencement of the National Health Service. On his retirement from the hospital he was given the title of emeritus physician of Bromley Hospital. In spite of the severe handicap of the disability resulting from his wounds, he was an active general practitioner caring for a widely scattered practice, and much beloved by his patients and his friends. A fine classical scholar, he continued throughout his life in practice to obtain enjoyment from his reading of the classics and of English and French literature. He was a founder member of the Bromley Chess Club and later its president, and he played chess for his county. He leaves a widow, two daughters, and a son. His elder daughter and his son have followed him in a medical career, both of them training at his own hospital, St. Bartholomew's.

P. S. writes: May I, who knew Dr. France during his last seven years, say how greatly he was admired by his friends and patients? Despite increasing disability he was a supremely happy man. He was the ideal family doctor, well informed technically, but above all liked, respected, and consulted as a man as well as a doctor. He devoted most of his leisure to books and read well and widely, being especially a student of Marcel Proust. He had travelled a great deal in France and the Mediterranean, which he loved. He was a superb host, and the combination of his warm personality, cultured conversation, and wide general knowledge made one feel a unique sense of civilization when at his table.

Dr. H. J. DEAN, formerly medical officer of health for the Willenhall and Short Heath urban district councils, died on February 23 at Reading, where he had been living in retirement for nearly a quarter of a century. He was 84 years of age. Henry James Dean was born on February 27, 1872, and received his medical education at the London Hospital, qualifying L.S.A. in 1893. Some three years later he entered general practice at Middleton, Lancashire, and while there obtained the diploma of L.R.C.P.I. in 1900. He moved to Willenhall, Staffordshire, in 1902, and was in partnership with the late Dr. J. T. Hartill before going into independent practice. In 1906 he took the L.R.C.S.Ed. and six years later the L.M.S.S.A. At Willenhall he held a number of appointments, becoming police surgeon, medical officer to the Post Office and to the Board of Education, certifying factory surgeon, and medical referee to the Ministry of Labour. For some twenty years he was also medical officer of health to the Short Heath and Willenhall urban district councils. He retired to Reading in 1933, but came out of retirement during the second world war to serve as chairman of the local medical board. He is survived by his widow and daughter.

Dr. JOHN WYLLIE died in Leeds on February 24 at the age of 55. John Wyllie was born on June 6, 1901, and was a medical student at Glasgow University, where he graduated M.B., Ch.B. in 1926. In the same year he joined a large practice at Hunslet, Leeds, as an assistant, and after a time became the partner of a very popular triumvirate, Drs. William Rodgers, W. J. B. Fergus, and Wyllie. He remained at Hunslet until his death, and endeared himself to the warm-hearted people there by his self-sacrifice on their behalf. Dr. Wyllie took a keen interest in local affairs. During the second world war he was in charge of a first-aid post, and it was as a result of discussions he had there with the then vicar of Hunslet, now Bishop of St. Albans, that he decided to found a much-needed boys' club in the district. The club is now one of the finest in the country, and Dr. Wyllie became the first chairman of its management committee, remaining in that position until shortly before his death. He was made a justice of the peace in 1949 and was very highly and affectionately regarded by all his associates on the bench: his interest in the youth movement led to his appointment to the juvenile panel, on which he served with distinction. He will not

be forgotten in Hunslet, where he was a family friend to many, carrying on his work in spite of grave physical disability until only a month or two before his death. One of his many interests was colour photography. A devoted husband and father, he had two daughters, one of whom is training as a nurse and the other in social welfare. His widow also survives him.

Dr. C. W. DE V. PRITCHARD died at St. Mary's Hospital, London, on March 9. He was born in South Africa of British and Huguenot stock, his father, W. H. Auret Pritchard, being one of those concerned in the early development of Johannesburg and the gold mines. His grandfather, Captain the Hon. Charles Pritchard, was a pioneer in the development of Cape Colony, and as a boy was often in the company of Napoleon on St. Helena. The family inherited many of the Emperor's personal possessions, which, some few years ago, were placed in a museum. Educated at St. John's College, Johannesburg, where he captained in cricket and football and won championships in swimming and long-distance running, Charles William de Villiers Pritchard studied medicine at Edinburgh and took the Scottish triple qualification in 1922. Subsequently he held appointments at the Larbert Mental Hospital, Edinburgh Royal Infirmary, and the Tavistock Clinic, and for a few years he had a consulting practice in Wimpole Street. But his main interest was in archaeology and travel, taking him to various parts of the world, where he collected many proofs of his adventures. He married Miss A. G. Seldon, who made her debut as Audrey Segnitz in Covent Garden opera in the early thirties. He was himself a polished amateur actor. During both world wars he served in the Royal Navy. His brother, Dr. Percival V. Pritchard, is medical officer of health for Gosport.

The obituary of Mr. S. S. BARTON was printed in the *Journal* of March 2 (p. 525). Dr. K. E. SCHMIDT writes: This is a small tribute to a man who to many like myself has been a guide, philosopher, and friend. A great personality indeed has gone from us and the world seems a much poorer place without him. He was not only an outstanding gynaecologist, beloved by his patients, blessed with that gift of inspiring confidence, optimism, and security, but was a poet (two books of his poems were published) and a painter of no mean achievement. The Cambrian Academy has not only lost one of its most outstanding members but also the founder of the Saxon Barton Prize. Mr. Barton had convictions and was not shy of making them known, nor did he leave anybody in doubt as to whether he liked a person or not. Somebody approved of by him was always worth knowing. To his juniors and students he was an inspiring teacher, encouraging initiative, responsibility, and, above all, work. He had a highly developed and kind-hearted sense of humour, and together with Mrs. Barton was a most generous and stately host in the manner of an era almost gone. Any meeting or assembly gained in status by his presence. A picnic and excursion with him into the North Wales hills was an experience. We will miss him very much indeed, and to him go our thanks for the privilege of his friendship. To Mrs. Barton and his sons goes our sympathy in their tragic loss.

Medical Notes in Parliament

APPEAL COSTS IN HEALTH SERVICE

The question of an award for costs in an appeal to the Ministry of Health from the decision of an executive council was raised in the House of Commons on March 14 by Mr. WILLIAM WELLS (Walsall, North, Lab.).

The case arose out of the death of Miss June Anne Evans, aged 17, of Walsall, in January, 1955. On January 4, Mr. Wells stated, she complained of severe pains and was vomiting. Dr. A was called and diagnosed gastro-enteritis. On

January 8 the symptoms became more severe, and Dr. A was again diagnosed gastro-enteritis. The following day was a Sunday, and the girl's father called at the surgery. Dr. B, who was standing in for Dr. A, visited the girl with Miss C, a medical student, who was allowed to conduct the whole examination, and who said there was no sign of appendicitis, which the parents had suggested. The father was dissatisfied with the conduct of the examination, and the next day called in a third doctor, who ordered the patient's immediate removal to hospital, where she died after an operation, the following day from peritonitis, a perforated appendix, and a perforated small intestine.

Her father made a complaint to the Walsall Executive Council. This was heard on June 3, and the executive council decided that there had been no breach of the doctor's terms of service. They also found that "the practice of allowing advanced students to accompany qualified medical practitioners in their day-to-day work is not only recommended but encouraged both by the Medical Committee of the Ministry of Health and the General Committee of the B.M.A., and has been accepted as a desirable and necessary procedure for a number of years." This finding, Mr. Wells said, could scarcely have been more misleading to all concerned. It was no part of the parents' complaint that a medical student had been present, nor even that the student had conducted an examination. The essence of the complaint was that the doctor rested content with an examination by the student, and took no trouble to verify what she had ascertained, so that at this critical stage of the illness diagnosis was conducted by an (at the time) unqualified person. The Walsall Executive Council misapprehended the essence of the complaint in this crucial finding, and that led to a false and misleading conclusion on the facts.

The father exercised his right to appeal to the Minister, who held that there had been a lack of proper medical attention in the visit on January 9, when the examination was conducted by Miss C. No order was made about costs, and Mr. Wells subsequently wrote to the Minister on the father's behalf, suggesting that it followed from the fact that the appeal had been allowed that the costs should to some extent at least follow the event. In a reply from the Minister on March 27, 1956, it was stated that it was an established practice to make an order for costs against one of the parties to an appeal only in quite exceptional circumstances—for example, where a case was pursued unreasonably; that it had never been held that a respondent was acting unreasonably in defending himself against an appeal seeking to reverse a decision that he had not failed to comply with his terms of service; and that "the doctor could not properly be penalized in this way, especially since the appeal was allowed only in relation to treatment on a particular day of Miss Evans's illness, and this was in effect allowed only in part."

To say that the appeal was allowed only in part, Mr. Wells complained, was certainly illogical and possibly evasive. The executive council itself, in a letter to him, had expressed the view that "on the Minister's decision the complainant's appeal was allowed, and therefore he should be recompensed for expenses incurred in exercising his right of appeal." The father had pursued the matter with success, and in plain justice and equity should be recompensed for the costs he had incurred in so doing.

Government Reply

Mr. J. K. VAUGHAN-MORGAN, Parliamentary Secretary, said that the result of the appeal to the Minister, which was issued after consultation with the Medical Advisory Committee, was that the doctor responsible should be reprimanded on the ground of a breach of the terms of service "in that her deputy failed on January 9 to render all proper and necessary treatment." The implication was that examination by the medical student without participation by the doctor was not adequate, but that the executive council had been right in taking the view that Dr. A had paid adequate visits and made adequate examinations.

It had been argued by Mr. Wells that, on the analogy of the normal rule in legal proceedings, costs should follow the event. But in so far as the procedure on appeal to the Minister related to complaints of infraction of obligations to the State, and was not an attempt to obtain restitution, the analogy with civil proceedings was not complete. The general principles of the award of costs by tribunals fell

within the terms of reference of the Committee on Administrative Tribunals and Inquiries, and were therefore in some measure *sub judice* that Committee.

Except perhaps for repayment of expenses they had incurred, usually small, complainants were not themselves hoping to obtain money under this procedure. They could, and often did, conduct appeals without incurring legal costs, and they would be deterred by the prospect of responsibility for the practitioner's legal costs if they were not successful. A rule that "costs follow the event" might seem on balance to work against complainants. Executive councils had occasionally been authorized or required to contribute to the costs of parties, usually associated with some form of mistake, unreasonableness, or undue severity on the part of the council. The executive council's finding in this case as a whole was supported in large measure and overturned on one point only. Thus it could not be regarded as widely wrong. It was a case in which costs following the event might have led to the award of a proportion of costs—perhaps, but not necessarily, one-third—of the fees incurred by Mr. Evans. In the light of practice in other cases this was not an occasion for payment by the executive council.

Tetanus Infection in N. Staffs

Dr. BARNET STROSS (Stoke-on-Trent, Central, Lab.) asked the Minister of Health for as full a statement as possible on the infection of five patients operated on recently in the North Staffordshire Royal Infirmary, of whom two had died from infection by tetanus. Mr. D. VOSPER stated on March 15 that tetanus had been diagnosed in five patients who were operated on between February 21 and 26. The symptoms appeared in the first case on February 26. Further cases developed symptoms on February 28, March 1, and March 3. The theatre suite in question was closed from February 28, and would not again be brought into use until any necessary measures had been taken to prevent any risk of further infection. All those operated on between February 21 and 26 were given a protective dose of tetanus antitoxin on March 1 and 2 except six patients who had been discharged, and their family doctors were advised to take the same action.

Poliomyelitis Vaccine

Mr. ERIC FLETCHER (Islington, East, Lab.) asked the Minister of Health on March 18 what were his proposals regarding the distribution of vaccines against poliomyelitis. Mr. VOSPER: A batch of vaccine was distributed last week and further batches would be distributed as they became available. They would be used in the first place for vaccinating children registered last year. There might on occasion be delay in this procedure, but the stringent safety precautions were in the interests of the parents and children concerned. Mr. FLETCHER asked for the Minister's assurance that he was completely satisfied with the safety of the vaccines that were to be distributed. Mr. VOSPER stated that he was completely satisfied.

Dr. REGINALD BENNETT (Gosport and Fareham, Con.) asked the Minister what evidence he had of the transmission of poliomyelitis in untreated sewage or water contaminated with it. Mr. VOSPER said he was advised that untreated sewage contained large amounts of poliomyelitis virus when infection occurred in a community, and that polluted water was assumed to be a constant risk. But there was no definite evidence in this country of the transmission of poliomyelitis from these sources.

University Salaries

Mr. K. ROBINSON (St. Pancras, North, Lab.) asked the Chancellor of the Exchequer on March 12 if he was aware of the concern that was felt by the Committee of Vice-Chancellors and amongst university teachers at his failure to announce any improvement in the salaries of university teachers, following the protracted negotiations that had recently taken place; and if he would now make a statement.

Infectious Diseases

The largest fluctuations in the number of notifications of infectious diseases in England and Wales during the week ending March 2 were decreases of 190 for whooping-cough, from 3,190 to 3,000, and 57 for scarlet fever, from 890 to 833, and a rise of 1,743 for measles, from 21,317 to 23,060.

The largest increases in the incidence of measles were 368 in Kent, from 433 to 801, 259 in Yorkshire West Riding, from 1,429 to 1,688, 244 in Staffordshire, from 627 to 871, 171 in Surrey, from 1,079 to 1,250, 157 in Cumberland, from 413 to 570, 145 in Lincolnshire, from 269 to 414, and the only large decreases were 112 in Northumberland, from 1,073 to 961, and 98 in Cornwall, from 169 to 71. The largest variation in the local returns of scarlet fever was a fall of 20 in Lancashire, from 130 to 110. The largest decreases in the incidence of whooping-cough were 50 in Durham, from 204 to 154, 44 in Kent, from 203 to 159, and 42 in Warwickshire, from 122 to 80. 7 cases of diphtheria were notified, being 5 more than in the preceding week; 2 of the cases were notified in Plymouth C.B.

3 cases of paratyphoid fever were notified in Lancashire, St. Helens C.B., and in Staffordshire, Kidsgrove U.D.

30 cases of acute poliomyelitis were notified. These cases were 9 fewer for paralytic and the same for non-paralytic as in the preceding week. The largest returns were Hertfordshire 5 (Barnet U.D. 2), London 3 (Lewisham 2), Middlesex 3, and Buckinghamshire 3.

The number of notifications of dysentery, 1,291, were 5 fewer than in the preceding week. The chief centres of infection were Lancashire 277 (Ashton under Lyne M.B. 54, Accrington M.B. 31, Stretford M.B. 25, Fylde R.D. 24, Urmston U.D. 23, Blackburn C.B. 19, Liverpool C.B. 18, Bolton C.B. 10), Yorkshire West Riding 245 (Rotherham C.B. 50, Leeds C.B. 38, Sheffield C.B. 36, Bradford C.B. 25, Dewsbury C.B. 16, York C.B. 16), London 85 (Woolwich 14 and the remaining 71 cases were scattered through 22 boroughs), Bedfordshire 77 (Luton M.B. 76), Warwickshire 58 (Coventry C.B. 32, Birmingham C.B. 18), Nottinghamshire 56 (Nottingham C.B. 23, Arnold U.D. 12, Mansfield M.B. 11), Durham 55 (Blaydon U.D. 13, Gateshead C.B. 10), Northumberland 50 (Blyth M.B. 32, Newcastle upon Tyne C.B. 10), Staffordshire 44 (Kidsgrove U.D. 16, West Bromwich C.B. 11), Middlesex 43 (Hayes and Harlington U.D. 18, Enfield M.B. 10), Surrey 33 (Surrey M.B. 19), Essex 31 (East Ham C.B. 18), Carmarthenshire 30 (Kidwelly M.B. 20), Wiltshire North Riding 27 (Middlesbrough C.B. 27), and Wiltshire 20 (Calne and Chippenham R.D. 13).

In Scotland the number of notifications of dysentery, 398, was 16 less than in the preceding week. The largest returns were Glasgow 161, Edinburgh 73, Lanark county 35, Stirling county 29, and Aberdeen 20.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending March 2 (No. 9) and corresponding week 1956.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES In Countries and London	1957					1956				
	Eng. & Wales	London	Scot.	N. Ire.	Eire	Eng. & Wales	London	Scot.	N. Ire.	Eire
Diphtheria	7	1	8	0	3	6	1	7	0	8

STILLBIRTHS	183	19	27			247	26	29		

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenza pneumonia.
‡ Includes puerperal pyrexia.

Medical News

Dame Dehra Parker.—The resignation of Dame DEHRA PARKER, Minister of Health and Local Government in Northern Ireland, was announced on March 14. The resignation is on the grounds of ill-health. Dame Dehra Parker, who was a member of the original Parliament of Northern Ireland, has held office as Minister of Health and Local Government since 1949. She will remain an M.P., and will resume her parliamentary duties as soon as her health permits. At the time of going to press the name of the new Minister had not been announced.

Mass Radiography in Glasgow.—The Glasgow mass radiography campaign is meeting with great success. By the end of last week—the first of the campaign—142,000 persons over the age of 14 had been radiographed. The health department had set itself a target of 250,000 for the five weeks of the campaign—which if achieved would constitute “a world record”—but now hopes to reach this figure in two weeks. If this happens the campaign will nevertheless continue for the full five weeks. The “possible” population for mass radiography in Glasgow is put at about 800,000.

Sims Commonwealth Professors.—Professor M. L. ROSENHEIM, professor of medicine at University College Hospital Medical School, London, and Professor R. M. JAMES, professor of surgery at Toronto University, have been appointed Sir Arthur Sims Commonwealth travelling professors for 1958. Professor Rosenheim is to visit Australia and New Zealand, Professor James parts of Africa. The appointments were made by the council of the Royal College of Surgeons of England at its meeting on March 14.

“British Medicine” on New York City Radio.—The New York Academy of Medicine is running a series of weekly broadcasts on British Medicine. The series is being given in the Academy’s postgraduate radio programme “For Doctors Only” which is broadcast by the city’s own wireless station on a private wavelength. The programme is addressed to “the medical profession of Greater New York.” Recordings for the series were made in Britain by the B.B.C., and the following speakers contributed: Lord COHEN OF BIRKENHEAD on “Continued Education of the Doctor,” Sir DAVID CAMPBELL on “The General Medical Council,” Professor A. A. MONCRIEFF on “Paediatrics,” Sir CHARLES DODDS on “Synthetic Oestrogens,” Mr. T. HOLMES SELLORS on “Cardiac Surgery,” Professor C. F. W. ILLINGWORTH on “Peptic Ulcer,” Professor J. MCMICHAEL on “Digitalis Therapy,” Dr. J. J. R. DUTHIE on “Cortisone and Rheumatoid Arthritis,” Sir JAMES PATERSON ROSS on “Vascular Surgery,” Professor L. J. WITTS on “Anaemia,” and Professor B. W. WINDEYER on “Surgery, Radiotherapy, and Chemotherapy of Advanced Malignant Disease.” Each contributor spoke for 20-30 minutes. The series began in February and will continue until the end of April.

Mental Health Research Fund.—The Fund’s annual meeting was held at the Royal Society of Medicine on March 19. Mr. IAN HENDERSON, chairman of the Fund, was able to record a year of satisfactory achievement, thanks largely to the “very welcome priming of the pump” last year by the £75,000 grant, spread over six years, from the Ford Foundation. During the calendar year 1956 £25,110 was allocated in fellowships and grants, and applications for worth-while projects were stated to be increasing as the Fund became better known to research workers. After the report Sir FREDERICK ARMER, chairman of the Board of Control, addressed the meeting. The Fund, whose address is 39, Queen Anne Street, London, W.1, exists to stimulate public interest in the possibilities of research in the field of mental health, to attract qualified research workers into this field, and to provide money for research.

British Universities.—In the autumn term, 1956, there were 13,035 students in the medical faculties of British Universities. This is a small decline from previous years, and is matched by a similar though proportionately somewhat larger decline in the new entry to medicine. Out of a total student body of 88,701 in Britain that term, medicine claimed 14.7% compared with arts 42.9%, pure science 21.9%, and technology 13.9%. In 1938-9 medicine had 23.8% of the students, and in 1953-4 16.4%. Commenting on these figures, the University Grants Committee in its recent report *University Development* (an interim report on the years 1952 to 1956) states: “The trends which were in evidence five years ago have continued, science and technology gaining at the expense of arts and medicine.” On the quality of university students the Committee writes: “In our last report we said that in general the proportion of outstandingly good and outstandingly weak students was lower, and of good second-class students was higher, than it was before the war. This remains the general position.”

Public Health and Nuclear Radiations.—On March 15 Lord SALISBURY opened an exhibition called “Atoms and Health” at the Royal Society of Health’s headquarters in London. The exhibition demonstrates the sources of nuclear radiation, both natural and artificial, and the steps the U.K. Atomic Energy Authority is taking to protect the general public and workers in nuclear industry. The exhibition will remain open daily (Monday to Friday, 10 a.m. to 5 p.m.) until May 31 at 90, Buckingham Palace Road, London, S.W.1.

London University.—Two readers at the Postgraduate Medical School of London, Dr. J. V. DACIE and Dr. T. RUSSELL FRASER, have had conferred on them the title of professor in the University of London. Dr. Dacie receives the title of professor of haematology; Dr. Russell Fraser the title of professor of clinical endocrinology. Both titles are in respect of their posts at the Postgraduate Medical School. Mr. J. D. S. FLEW, dean of University College Hospital Medical School, and Mr. H. DAVSON, D.Sc., a member of the scientific staff of the Medical Research Council, have been made fellows of University College, London.

R.C.P. and the Harveian Tercentenary.—The Royal College of Physicians of London has announced its plans for the Harveian Tercentenary in June. The College’s commemoration will be from June 3 to 8, coinciding with the Tercentenary Congress (see *British Medical Journal*, December 1, 1956, p. 1296). The principal events will be a memorial service at St. Paul’s Cathedral (12 noon, June 3); a reception at the College (8.30 p.m., June 4); four showings of a revised edition of the late Sir Thomas Lewis’s film illustrating experiments from Harvey’s *De Motu Cordis* (5-5.45 p.m. on June 3, 5, 6, and 7); and an exhibition of Harvey’s life and work (2-5 p.m., June 5; 10 a.m.-5 p.m., June 6 and 7; 10 a.m.-1 p.m., June 8). Admission to the film and exhibition is free to all the College’s fellows, members, and licentiates, and to members of the Tercentenary Congress.

Cardiovascular Research in Australasia.—The Life Insurance Medical Research Fund of Australia and New Zealand invites applications for grants-in-aid to institutions and research fellowships. The Fund limits its support at present to research on cardiovascular function and disease. Fellowships for work in Australia or New Zealand are at the rate of £1,800-£2,000 a year, travelling fellowships at £2,000-£2,250 a year plus approved travelling expenses. Applications should be submitted by July 1 to the medical director of the Fund (Dr. JOHN H. HALLIDAY), 87, Pitt Street, Sydney, New South Wales, from whom further details may be obtained.

Guigoz Fellowship.—The International Children’s Centre invites applications for this year’s Guigoz fellowship for work on nutrition. The fellowship, valued at one million French francs, is endowed by the Guigoz Company (makers of dietetic products) to allow a nutritionist or physician to

spend a year in Paris in research on the nutrition of infants and children. Applications must be lodged by May 15. Further details may be obtained from the International Children's Centre, Château de Longchamp, Bois de Boulogne, Paris 16.

Population Control in China.—Abortion and sterilization are now to be made legal in China, according to a report by the New China News Agency in London. This decision is said to have been taken "with the greatest reluctance." The agency was reporting an address by Madame Li TEI-CHUAN, the Minister of Health, made in Peking on March 7. She is quoted as saying that China's population was now rising at a rate of 15 million a year. During the past year, she said, the health departments had made strenuous efforts to popularize birth control, but this work was far from enough.

F.R.S. Edinburgh.—Among the new fellows of the Royal Society of Edinburgh announced this month are the following members of the medical profession: Dr. A. T. DOIG, lecturer in industrial hygiene at the Universities of Aberdeen and St. Andrews; Professor J. W. McLEOD, F.R.S., emeritus professor of bacteriology at Leeds University; and Professor E. W. WALLS, professor of anatomy at the Middlesex Hospital Medical School.

Sir Howard Florey, F.R.S., professor of pathology at Oxford, is to receive the honorary degree of LL.D. of Edinburgh University at a ceremony on July 5.

Dr. Hilary Koprowski, assistant director of viral and rickettsial research at the Lederle Laboratories of the American Cyanamid Company, has been appointed director of the Wistar Institute, University of Pennsylvania. Dr. Koprowski will take up his new appointment on May 1.

COMING EVENTS

Multiple Sclerosis Society.—Recital by Miss MURIEL SMITH at Royal Festival Hall, March 31, at 3 p.m., to raise funds for the Society.

Institute of Laryngology and Otology.—Demonstration on "Bone Structure and Bone Pathology" by Dr. H. A. Sissons, April 1-12. Open to all medical practitioners.

Indian Medical Association.—Annual dinner and dance at the Cumberland Hotel, London, W.1, April 4, at 7.30 p.m. Details from Dr. C. R. AMIN, 38, Newcomen Street, London, S.E.1 (Tel.: HOP 2024).

United Hospitals' Choir.—Mozart's Requiem Mass at the Church of St. George-the-Martyr, Queen Square, London, W.C.1, April 4 at 8.30 p.m. Admission by programme, price 3s. 6d., at the door.

Radioactive Isotopes in Medicine.—British Council course in London and Sheffield for overseas medical practitioners, September 15-28, fee £44. Apply to the local representative of the British Council.

NEW ISSUES

Archives of Disease in Childhood.—The new issue (Vol. 32, No. 161) is now available. The contents include:

THE DIAGNOSIS AND TREATMENT OF COMPLETE ANOMALOUS PULMONARY VENOUS DRAINAGE. W. T. Mustard.
THE OPERATIVE TREATMENT OF THE FUNNEL CHEST. F. Rehbein and H. H. Weiricke.

EVENTRATION OF THE DIAPHRAGM. Eric Goulston.
OESOPHAGEAL RECONSTRUCTION IN CHILDREN USING INTRATHORACIC COLON. Charles E. Sherman, jun., and David Waterston.

ABNORMALITIES IN MECONIUM OF THE FOETUS AND NEWBORN. John L. Emery.

MECONIUM AND FAECAL PLUGS IN THE NEWBORN. R. B. Zachary.

SEPTIC UMBILICAL ARTERITIS. Isabella Forshall.

INTRALUMINAL INTESTINAL CALCIFICATION IN THE NEWBORN. P. P. Rickham.

TISSUE CULTURE AS A POSSIBLE AID IN RECOGNIZING THE ORIGIN OF CYSTIC HYGROMA. John Greve and John D. B. MacDougall.

TENSION EMPHYSEMA IN INFANTS. T. Y. Nelson.

CONGENITAL LUMBAL HERNIA. C. Marshall Lee, jun., and Helmut Mattheis.

UROLITHIASIS IN CHILDHOOD. N. A. A. Myers.

THYROID CARCINOMA IN CHILDHOOD IN GREAT BRITAIN. Keith D. Roberts.

TREATMENT OF PORTAL HYPERTENSION IN CHILDREN. Philip Sandblom and Carl-Axel Ekman.

PAEDIATRIC SOCIETIES IN THE BRITISH ISLES.

BOOK REVIEWS.

Issued six times a year; annual subscription £3 3s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, March 25

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Ophthalmology Lecture by Professor Arnold Sorsby: Cycloplegics and Mydriatics.

Tuesday, March 26

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. D. G. James: Sarcoidosis—The Present Position.

LIVERPOOL UNIVERSITY.—At Physiology Lecture Theatre, 5.15 p.m., Professor B. Uvnäs (Stockholm): Sympathetic Vasodilator System.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Professor R. Cox: Management of Dysphagia Due to Malignant Lesions of the Thoracic and Abdominal Oesophagus.

ROYAL STATISTICAL SOCIETY: MEDICAL SECTION.—At Keene Lecture Theatre, 2nd Floor, Westminster Medical School, S.W., 5.30 p.m., Mr. P. D. Oldham: Arterial Blood Pressure in Population Samples.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5.30 p.m., Thomas Young Lecture by Professor J. Z. Young, F.R.S.: Efferent Optic Nerve Fibres and the Crossing of the Visual Pathway. Some Speculations on the Mechanism of Vision.

WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Dr. T. Rowland Hill: Neurological demonstration.

Wednesday, March 27

BIRMINGHAM MEDICAL INSTITUTE: SECTION OF PSYCHIATRY.—8 p.m., Valdictory Address by Dr. May Pearce: Matrimonial Causes.

CHRISTIAN MEDICAL FELLOWSHIP.—At Royal Empire Society, Northumberland Avenue, W.C., 8.15 p.m., Mr. Harold Dodd: The Doctor as a Person.

HARVEIAN SOCIETY OF LONDON.—At 11, Chandos Street, W., 8.15 p.m., Harveian Lecture by Sir Russell Brain, P.R.C.P.: Some Disorders of the Cerebral Circulation.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. H. Haber: Specific and Foreign Body Granulomas.

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—5.30 p.m., Dr. E. Ann Mower White: Opportunities for Health Teaching in Schools.

Thursday, March 28

BIOCHEMICAL SOCIETY.—At Department of Biochemistry, University College, Gower Street, W.C., 10 a.m., annual general meeting.

CHADWICK TRUST.—At Royal Society of Health, 5.30 p.m., Sir Harold Whittingham: Problems of Hygiene in Civil Aviation.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. B. Russell: (1) Tuberculosis of the Skin; (2) Sarcoidosis of the Skin.

LIVERPOOL MEDICAL INSTITUTION.—8 p.m., symposium: Management of Coronary Thrombosis. Speakers, Dr. E. Noble Chamberlain, Dr. C. S. McKendrick, and Dr. W. P. O'Regan.

LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.—At Common Room, Royal Free Hospital School of Medicine, 8.30 p.m., talk by Dr. Cicely Williams on her work with W.H.O.

LONDON JEWISH HOSPITAL MEDICAL SOCIETY.—At Savoy Hotel, W.C., 6.45 p.m., annual dinner dance.

LONDON UNIVERSITY.—At St. Thomas's Hospital Medical School, S.E., 5.30 p.m., special university lecture in pharmacology by Professor Björk Uvnäs (Stockholm): Mechanism of Histamine Release.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Arris and Gale Lecture by Mr. D. Greer Walker: Facial Development.

ROYAL NORTHERN HOSPITAL.—2.45 p.m., clinical demonstration by Mr. F. P. Fitzgerald: Some Common Fractures and Sprains.

WEST OF ENGLAND CHILD HEALTH GROUP.—At Department of Child Health Lecture Theatre, Bristol Royal Hospital for Sick Children, 8.30 p.m., Dr. R. Lightwood: Home Care of Sick Children.

Friday, March 29

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. P. D. Samman: clinical demonstration.

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. K. Robson: clinical demonstration.

Saturday, March 30

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES.—At Royal Hospital, Sheffield, 2.15 p.m., Mr. St. Elmo Hall: Problems of a Mixed Community.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Ward Platt.—On March 6, 1957, to Patricia (formerly Frodsham), B.M., B.Ch., D.C.H., and Walter Ward Platt, of 45, Hornby Lane, Liverpool, a daughter—Anne Heathcote.

Wolfson.—On February 17, 1957, at Dudley Road Hospital, Birmingham, to Nancy, wife of L. J. Wolfson, F.F.A.R.C.S., a third daughter—Barbara Hilary.

DEATHS

Allan.—On March 6, 1957, in a nursing-home, Edinburgh, Harry Allan, M.B., Ch.B., of 193, Mayfield Road, Edinburgh, late of Penang, Malaya, a daughter—Eric Charles Aspinall, M.B., Ch.B., of The Poplars, Erdington, Birmingham, aged 62.

Foley.—On February 13, 1957, in Sydney, Australia, John Foley, M.R.C.S., L.R.C.P., of Dee Why, New South Wales, aged 62.

Iredale.—On March 3, 1957, in hospital, Jabez Percival Iredale, M.B., B.S., of The Old House, Rushy Heath, Herts, aged 87.

Mennell.—On March 2, 1957, at his home, "Courts of the Mornings," Rake, Liss, Hants, James Beaver Mennell, M.D., aged 77.

Reid.—On March 7, 1957, at 64, Chapel Road, Forest Gate, London, E., Allan George Reid, M.C., M.R.C.S., L.R.C.P., aged 84.

Ross.—On February 28, 1957, at 7, Cannon Street, Accrington, Lancs., Robert Stewart Ross, M.C., M.B., B.Ch., aged 77.

Sperber.—On March 3, 1957, in Accra, Gold Coast, Karel Sperber, O.B.E., M.D., aged 46.

Tivy.—On February 27, 1957, at Downend, Galmpton, Brixham, Devon, Cecil Brian Forsyth Tivy, M.B., M.Ch., aged 76.

Wyllie.—On February 24, 1957, at Highgate Street Lane, Leeds, Yorks., John Wyllie, M.B., Ch.B., J.P.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Hair of the Dog

Q.—An allergic reaction to dog hair has been detected by skin tests in a patient with rhinitis. Must it be assumed that he is sensitive to all breeds of dog? Could he, for instance, keep a poodle, which is said to have a different type of hair from other breeds?

A.—It is accepted that danders from various species of dogs possess qualitative antigenic differences. It cannot, therefore, be presumed that because a patient is sensitive to one breed of dog he is sensitive to all dogs. Skin-testing with the dander from individual species is advisable or even from individual dogs. It must also be remembered that a skin test only indicates the presence or absence of skin-sensitizing antibodies. For proof of clinical sensitivity there must be symptoms on contact with the dog and, in the absence of other allergens, freedom from attacks when removed from contact.

Focal Sepsis and General Ill-health

Q.—What is the current view of the importance of focal sepsis in accounting for general diseases and ill-health? Has the view that toxins from bacteria at the root of the teeth or in the bowel may exact a general baneful effect on the body been completely exploded? If so, are the only arguments for attending to bad teeth local ones?

A.—The final clause of this question is the most easily answered, and the answer to it is emphatically "No." Dental sepsis can cause bacteraemia, which in a predisposed patient may result in bacterial endocarditis. Hobson¹ goes so far as to say that he has never seen this infection in an edentulous patient. It is also a frequent source of lung abscess, the mode of spread probably being embolic: pulmonary actinomycosis may be assumed to originate in the same way.

To pronounce judgment on the commonly held belief that "focal sepsis" can be the underlying cause of states of chronic ill-health, and in particular of chronic multiple arthritis and other painful or disabling conditions involving joints or muscles, is much more difficult. It is more difficult still to confirm or deny that this may be the cause of some forms of insanity and other such obscure conditions. Although much less has been heard lately of this belief, there are doubtless practitioners at the present day who would support it by adducing histories of cures or alleviations by treating such foci surgically or otherwise. A rational judgment on a theoretical basis might be as follows: Of evidence that bacterial toxins from the bowel, in the absence of intestinal lesions, can produce disease elsewhere there is none. Toxic absorption from any closed focus of sepsis can reasonably be supposed to be capable of causing degenerative changes elsewhere, but the focus in the only closed dental lesion, an "apical abscess," is very small. In extensive gingivitis (pyorrhoea) the material swallowed might cause a gastritis, and other consequences could follow from that. That arthritis is the result of dental sepsis could only be proved by finding a micro-organism derived from the primary lesion in the joint itself: it is true that this is not often attempted, but there is almost no evidence that bacteria are ever present in such lesions. It can of course be assumed, although it cannot be proved, that the arthritis is an allergic response to bacterial products. It is scarcely necessary to add that this field of medicine has been the happiest of all hunting-grounds for

purveyors of vaccines made from harmless mouth and throat bacteria. If these vaccines have done any good, only the most credulous will believe their effect to have been specific.

Adrenal Apoplexy

Q.—What treatment is advised for a suspected case of adrenal apoplexy under field conditions? How should a case be treated where full facilities are available, as in hospital?

A.—The essentials of treatment are to restore the depleted body stores of salt and water, combat hypoglycaemia, and provide the deficient adrenocortical steroids. In hospital 500 ml. glucose in saline is infused intravenously over 2-4 hours, and to this is added 200 mg. hydrocortisone (40 ml. of concentrate in 50% alcohol or as the hemisuccinate salt). During the next 2-4 hours 500 ml. physiological saline containing 100 mg. hydrocortisone is given. Thereafter 500 ml. dextrose in saline and 500 ml. saline, each containing 100 mg. hydrocortisone, are given alternately until a total of 2,500 ml. fluid has been infused in 24 hours. An intramuscular injection of 5 mg. deoxycortone acetate in sesame oil is given as soon as the infusion has been started. If the blood pressure does not begin to rise after four hours 2-4 mg. noradrenaline is added to the infusion solution. Penicillin by intramuscular injection is given twice daily in a dose of 500,000 units procaine penicillin. Sedatives and morphine must on no account be given until 200 mg. hydrocortisone has entered the body. As soon as the patient can swallow and no longer vomits, cortisone is given by mouth in divided daily doses starting at 200-300 mg. and gradually reducing to 37.5-50 mg.

The outcome will probably be unsatisfactory unless intravenous treatment is possible. In these circumstances, if the patient is not vomiting, glucose and half-strength normal saline, flavoured with fruit juice, should be given by mouth, together with 100 mg. cortisone four-hourly until improvement occurs. Penicillin and deoxycortone acetate are given as described above, and 0.3-0.5 mg. phenylephrine hydrochloride ("neo-synephrine") injected subcutaneously every one or two hours to maintain the systolic blood pressure over 90-100 mm. Hg. The underlying cause of the adrenal insufficiency should be treated with the most specific chemotherapeutic or antibiotic agent available.

Local Analgesics in Rhinology

Q.—What is the maximum safe dosage of amethocaine hydrochloride for topical application in the nose and throat? I have recently had a fatality following the application of amethocaine flakes. Should the use of this drug in rhinology be abandoned in favour of some other local analgesic, and, if so, which is recommended?

A.—The toxicity of cocaine and other local analgesics varies considerably in different individuals, so that what may be a safe dose in one can cause rapid, severe, or even fatal collapse in another. The maximum safe dose depends not only on the above but on the rapidity of absorption by the mucous membrane of the respiratory tract and the gastric mucosa. Thus the pure substance, or concentrated solution, is very much more dangerous than the same total dose in a dilute solution applied over a prolonged period. Especially is this true of the synthetic analgesics, which are not vasoconstrictors. A safe topical application of amethocaine hydrochloride would be 40 to 50 mg. But to make doubly safe it is wise to dilute the solution to 0.5%, to use only about 3 ml. at a time, and to allow five minutes to elapse between applications. Lignocaine hydrochloride is considered to have a higher margin of safety, and is therefore preferred by some, but there is no need to abandon the use of amethocaine if used with due care. No local analgesic is devoid of fatal risk.

Albinism and Blindness

Q.—A couple have two children, the first a blind albino and the second quite normal. There has been only one other albino in the family so far as is known, and he was the great-grandfather of these two children. What is the risk of further children being albinos?

A.—The risk of a further child being an albino is very probably the 1-in-4 risk for conditions due to a recessive gene. The complete forms of albinism behave regularly as if due to a recessive gene. The association with blindness, if the blindness is total in this child, is unusual. Albinism leads to a loss of the appreciation of form which intensifies the effects of any coincidental cause of poor vision such as refractive errors, but is not known to be associated with any form of blindness.

Infra-red Apparatus

Q.—What points should be looked for in assessing the value of the various types of infra-red apparatus the public can buy on medical prescription, and what technical data should one expect to be given by the manufacturers? What is the value of the domestic gas or electric fire as a simple home substitute for such apparatus? Is the infra-red bulb, such as is used by poultry keepers in rearing chicks, another possible inexpensive substitute?

A.—The following points should be looked for in assessing an infra-red apparatus for home use: The lamp should be stable so that there is no danger of it falling upon the patient. The element should have an output of not less than 500 watts and should be within a parabolic reflector. A guard should be fixed to the reflector to prevent accidental contact with the element. The apparatus should be adequately earthed. The manufacturers should state the output of the lamp at any given voltage.

Domestic gas and electric fires are rich in infra-red rays and are an effective substitute. It is, however, usually difficult to maintain a comfortable and relaxed position in front of such appliances while irradiating a small area of the body. The infra-red bulbs used by poultry keepers in rearing chicks have too small an output to be useful for therapeutic purposes.

Anaesthetizing the Eyelid

Q.—What is the best way of anaesthetizing an eyelid for the removal of a meibomian cyst?

A.—A preliminary drop of 4% cocaine should be instilled into the eye, and then another drop after the lapse of two or three minutes. Then the affected eyelid should be injected with 4% novocain. An interval of two minutes should be allowed to elapse after the injection before the operation is started. There are, of course, various effective substitutes for cocaine and novocain.

NOTES AND COMMENTS

Threadworms.—Professor R. S. ILLINGWORTH (Sheffield, 10) writes: I would be grateful if your expert writing on threadworms ("Any Questions?" February 23, p. 474) would (a) supply the evidence for the statement that "heavily infected children may show some anaemia with loss of appetite and malnutrition," (b) explain how the worms cause "... catarrhal inflammation" by "mechanical irritation of the intestinal mucosa."

OUR EXPERT replies: The statements that (a) "heavily infected children may show some anaemia with loss of appetite and malnutrition" and (b) "catarrhal inflammation may result from mechanical irritation on the intestinal mucosa" were taken from *Textbook of Clinical Parasitology*¹ and *Clinical Parasitology*.² Froehlich has observed by speculum haemorrhagic points on the rectal mucosa caused by the worms (cited in Brumpt's *Précis de Parasitologie*). The statement (a) is supported by my own observation of the symptoms shown by one of my children who

contracted a very heavy infection of *Enterobius*. The symptoms rapidly disappeared after appropriate anthelmintic treatment and to been administered by my wife, without my knowledge and to my intense disgust, as I had hoped to use the case to carry out some further investigations on the biology of the parasite. With regard to statement (b), the worms are sometimes present in very large numbers. They live on the surface of the mucous membrane, and the associated catarrh is due presumably to their active wriggling movements. The worms have often been reported as the cause of "appendicopathia" by French writers.

Gustatory Sweating after Sympathectomy.—Mr. HERBERT HAXTON, F.R.C.S. (Manchester, 13), writes: Your expert ("Any Questions?" February 16, p. 416) appears to be unaware of all my investigations of this phenomenon.¹ I found that in all cases with gustatory sweating after sympathectomy the syndrome could be temporarily abolished by injections of local anaesthetic in the stellate ganglion, and, furthermore, thermoregulatory sweating is not completely absent in the head and neck. Some degree of sympathetic activity is thus essential for the syndrome. It is, of course, a cholinergic phenomenon, but it seems likely that the acetylcholine is liberated at cutaneous sympathetic nerve endings. I am aware of no reliable evidence that parasympathetic nerve endings, such as are mentioned by your expert, exist in the skin. The only effective treatment for a severe case is removal of the stellate ganglion, or section of the cervical sympathetic chain, after preliminary injection of a local anaesthetic has confirmed that the phenomenon can be abolished in this way.

REFERENCE

1. Haxton, H., *Brain*, 1948, 71, 16.

OUR EXPERT replies: I was quite familiar with Mr. Haxton's paper. Several excellent papers have been written on this subject, much of the interest of which lies in the physiological puzzle which it presents and the uncertainty about its exact cause and treatment. Mr. Haxton stresses two points in his paper: (1) "in all cases ... the syndrome could be temporarily abolished by injections of local anaesthetic"—in that case why does he consider it necessary to recommend preliminary injection of local anaesthetic before sympathectomy? (2) In his letter Mr. Haxton writes: "In all cases ... thermoregulatory sweating is not completely absent," but in his paper he says "there is always absent or reduced thermoregulatory sweating." Other workers (for example, Wilson¹) have also reported absence of thermoregulatory sweating. Its presence (and by inference the presence of intact sympathetic fibres) is not essential for the syndrome, which could be produced by sprouting from other nerves. Recent work by Murray and Thompson² is interesting in this respect. It follows that no one can be dogmatic about the cause or treatment of the syndrome and that thorough investigation is necessary before embarking on surgical treatment.

CLINICAL AND SOCIAL PROBLEMS OF
PEPTIC ULCER*

BY

F. AVERY JONES, M.D., F.R.C.P.

Physician, Central Middlesex Hospital

These two lectures aim to give a perspective of peptic ulcer as it exists among the community and a commentary on clinical problems of diagnosis and management.

It is well known that the pattern of peptic ulcer has changed greatly in the past century. Acute gastric ulcers in young women were formerly the main cause of hospital admissions for haematemesis and melaena, or acute perforation, but to-day such patients are rarely seen. The frequency of true chronic gastric ulcer has probably altered little since 1920, but that of juxta-pyloric (including duodenal) ulcers, affecting predominantly young and middle-aged men, had increased more than twofold in the twenty years between the two world wars (Illingworth, Scott, and Jamieson, 1944).

Has the prevalence of duodenal ulcer continued to increase since 1938? Evidence from the national mortality rates and hospital admissions for acute perforation suggest that this is so. The experience for acute perforations at the Central Middlesex Hospital, serving a population of 300,000 persons in North-west London, is recorded in Table I. Admissions for duodenal ulcer

TABLE I.—Acute Perforations

Years of Admission	G.U.	D.U.	G.U.:D.U. Ratio
Male			
1938-40	21	77	1:3.7
1941-3	27	81	1:3.0
1944-6	29	102	1:3.5
1947-9	26	142	1:5.4
1950-2	21	177	1:8.4
1953-5	15	134	1:8.9
	139	713	
Female			
1938-43	11	10	1:0.91
1944-9	12	15	1:1.25
1950-5	18	39	1:2.17
	41	64	

have increased, but there has been no increase and even a slight fall in admissions for perforated gastric ulcer, with consequent change in the G.U./D.U. ratio.

It is probable that this experience in North-west London reflects the national trend, for it fits in with the 1938-48 survey of perforations admitted to 40 British hospitals (Avery Jones, 1955b) and also with the continuing experience at Glasgow (Jamieson, 1955).

When the Registrar-General's figures for peptic ulcer are examined it will be found that for some years there

*The first of two Lumleian Lectures delivered before the Royal College of Physicians of London on April 10 and 12, 1956.

has been little change in the total number of deaths from peptic ulcer in Great Britain, but these figures may be misleading and must be interpreted separately for patients over and under the age of 65. Above this age, deaths from both gastric and duodenal ulcer have increased, but since 1948 there has been a drop in the death rate attributed to senility and it is possible that the apparent increase in mortality from peptic ulcer in the elderly reflects a greater precision in diagnosis. Under 65, the mortality of gastric and duodenal ulcer must be considered separately. Deaths from gastric ulcer have decreased. The risk to life from the complications of peptic ulcer has diminished greatly since the introduction of antibiotics and relaxant anaesthetics, and this is the most likely explanation for this fall in mortality. The death rate from duodenal ulcer in those under 65 has remained almost unchanged. This is very surprising in view of the known improvement in treatment, and it raises the possibility that the apparently stationary mortality for duodenal ulcer may be hiding an increasing prevalence. These trends, noted by Doll (1952) up to 1948, have continued since then (Table II).

A continuing rise in incidence of peptic ulcer has also been reported elsewhere. In Denmark, Alsted (1953)

found peptic ulcer more than doubled in Denmark between 1940 and 1948. In Stockholm, Tomenius (1955) recorded almost a 50% increase between 1938 and 1952.

Present Prevalence

What is the present prevalence of peptic ulcer in this country, and what is its economic importance? With these questions in mind several studies were organized.

One of the problems in medical practice is to get a complete view of any medical problem. The consultant at the hospital and the general practitioner tend to see two different groups, for the severe cases are concentrated in hospital practice. An unbiased overall view was obtained from a survey of 6,047 members of the public, done in collaboration with Dr. Richard Doll and the assistance of a research almoner, Miss M. M. Buckatzsch (Doll, Jones, and Buckatzsch, 1951). In men, the incidence of peptic ulcer (active and inactive) was found to rise to a maximum little short of 10% in the age group 45-54. In women, the highest incidence was 6%, and was not found until the age of 55. The incidence in the older age groups of women reflects partly the prevalence of acute gastric ulcers among girls at the beginning of the century.

An impressive incidence may be demonstrated, but such large absolute figures do not indicate the degree of suffering and disability. Of the total number of persons with diagnosed ulcers in the survey—those who have had definite ulcer-like symptoms or complications of ulcer—approximately a quarter had had an episode of dyspepsia followed by some years of freedom from dyspepsia, or with perhaps only slight symptoms; in rather more than a half there were recurrent symptoms at varying intervals, but with some care and discretion these had caused little or no loss of time from work. The remaining quarter had had a great deal of pain or had suffered from troublesome complications, and if operation had not already been done the patient had earned it.

Incidence of Peptic Ulcer at Necropsy

Another approach to the question of incidence was made with the assistance of Dr. Donald Teare, who during 1952-3 recorded the presence of peptic ulcer and scars in coroner's necropsies. These were mainly patients who had died suddenly from either violence or natural causes. It was thought that such cases of sudden death would give a true

TABLE III.—Necropsy Incidence

Sex	Age	Total	Active		Scar	
			No.	%	No.	%

	65+	896	9	1.0	16	1.8
		1,370	12		29	

picture of the incidence of ulcer among the general population, and the picture would not be complicated in some groups by the presence of a preceding illness which might perhaps cause or exacerbate the ulcer. The survey covered 3,223 necropsies, and the proportions in different age groups are shown in Table III. Between the two sexes the incidence of gastric ulcer is remarkably equal, but duodenal ulcer is between two and three times commoner in men, and reflects clinical experience. The incidence of gastric ulcer increases steadily with age, but duodenal ulcer generally occurs more commonly in the 45-64 group than in the over-65 group. This accords with our population study and also with clinical studies from Norway (Knutsen and Selvaag, 1947).

This difference in trend with age would fit in with the hypothesis that duodenal ulcer has increased in incidence, but the generation over 65 have not been exposed in youth to the ulcerogenic influences to the same extent as in the younger generations.

In general, necropsy studies show that gastric and duodenal ulcers are approximately equal in incidence, although clinical practice suggests that duodenal ulcer is in appreciable excess. This may be due perhaps to gastric ulcers having a greater tendency to develop terminally with other illnesses. This factor can be excluded in those who have met a sudden death in an accident and in those who have committed suicide without a known preceding organic illness. Such cases have been analysed in this necropsy series (Table IV), and it is interesting to note that in men duodenal ulcer was twice as common as gastric ulcer.

TABLE IV.—Violence and Suicide

Age	No.	Ulcers and Scars			
		G.U.	D.U.	Total	%

65+	43	6	2	8	18.6

Liability to Develop a Peptic Ulcer

Which members of the community are more liable than others to develop peptic ulceration? It is by studying the difference in incidence that clues may be found towards the aetiology of peptic ulcer. There are differences in the frequency of association with other diseases. There are striking differences in relation to possible environmental influences, as demonstrated by studies on geographical distribution, social class pattern, and occupation. There are also important differences relating to constitutional factors such as blood groups and gastric secretory activity. Finally, there is the significance of the anxiety factor with its interplay between environmental stress and temperament.

Hospital practice certainly suggests that chronic bronchitis and emphysema has a special tendency to be associated with peptic ulceration. This association has been noted previously by Weber and Gregg (1956) and by Latts, Cummins, and Zieve (1956), who found more than three times

TABLE V.—Presence of Peptic Ulcers and/or Scars

	Persons Total		Persons G.U.		Persons D.U.		Persons G.U. + D.U. and J.U.	
	Obs.	Exp.	Obs.	Exp.	Obs.	Exp.	Obs.	Exp.
Violence and suicide	27	36.7	14	19.3	13	16.7	—	0.7
Cardiovascular	231	222.8	139	137.2	89	81.0	3	4.6
Chronic bronchitis	51	35.5	27	21.8	20	12.9	4	0.8

	463	463.0	283	283.1	171	170.9	9	9.0

the expected number of ulcers at necropsy among those who were noted to have hypertrophic pulmonary emphysema. Further information has been collected on this point. In the coroner's necropsy survey, a higher incidence of both gastric and duodenal ulcer was found among persons in whom death was associated with bronchitis (Table V) ($\chi^2=10.2874$; $N=4$; $0.02 < P < 0.05$).

Environmental Factors

Environmental factors are associated with varying incidence of peptic ulcer, and this is considered in relation to geography, social class pattern, and occupation.

Geographical Incidence

Between different populations there appear to be striking differences in the incidence of gastric and duodenal ulcer, but our knowledge is based more on varying G.U./D.U. ratios and clinical impressions than on comparisons of absolute incidence from population surveys. In considering G.U./D.U. ratio it is of interest that only from one centre, a fishing community in North Norway, has an excess of gastric over duodenal ulcers been reported (Schanke, 1946). Elsewhere there is an excess of duodenal over gastric ulcers.

Within Great Britain there are striking differences, with a much lower G.U./D.U. ratio in Scotland than in London. Tidy (1944) found a disproportionate rise in the male mortality from duodenal ulcer in Scotland up to 1937. Striking differences in incidence of peptic ulcer have been reported in Nigeria (Konstam, 1954), in Malaya (Kouwenaar, 1930), and in India (Dogra, 1940). Dogra made a very careful clinical study of the peptic ulcer problem throughout India. He found peptic ulcer was fifteen times as common in Madras (South) as in the Punjab. Everywhere duodenal ulcer greatly exceeded the incidence of gastric ulcer, the D.U./G.U. ratio being 30:1 and the male/female ratio 18:1. In Southern India duodenal ulcer was a disease of the poor agricultural and labouring classes and affected all castes and creeds, but was rare in the upper classes.

On a brief visit to India I had the opportunity of discussing the ulcer problem with many doctors, and the geographical difference was certainly very striking between Travancore and Karachi, but peptic ulcer seemed comparatively common in Calcutta and Bombay. Duodenal ulcer in Southern India tends to stenose and not to bleed or perforate, and those working there do not think this can be explained only by inadequate transport facilities, but clearly this factor plays a part. The stenosed patients might come a hundred miles to the hospital, but not those who bleed or perforate. It seems difficult to correlate ulcer with the use of spices, but there may well be some other dietary factor.

Social Class Incidence

There are marked social-class differences in the incidence of peptic ulcer. Duodenal ulcers are evenly distributed throughout the entire population, but there is a noticeable deficiency of gastric ulcers in the professional groups and a striking excess among the labouring classes (Doll *et al.*, 1951). It is possible that these social-class differences may be one factor in producing the geographical differences in the ratio of gastric and duodenal ulcer. Between different countries, however, this social-class distribution may not be generally applicable and needs testing. It may be untrue for Southern India, where duodenal ulcer is particularly a disease of the very poor.

Occupational Incidence

From the occupational survey (Doll *et al.*, 1951) an increased incidence of duodenal ulcer was found among doctors and amongst men in responsible positions in industry, foremen, and business executives. There was also a residual group of unskilled workers with an increased incidence, but this may have been due to a sheltered employment chosen by ulcer subjects. Better diagnosis undoubtedly contributed

towards the high incidence among doctors, as there was a disproportionate number with melaena only as a presenting symptom, which led to a barium-meal examination being carried out. This would, however, suggest that the figures in other groups have been underestimated rather than overestimated. No confirmation was found for the widely held belief that bus drivers were particularly prone to the disease. Agricultural workers were found to have a remarkably low incidence due to a deficiency of duodenal ulcer.

Constitutional Factors

Constitutional factors concern sex, age, blood groups, hereditary factors, and gastric secretory activity, and these reveal interesting differences in peptic ulcer incidence.

Sex Incidence

Peptic ulcer is essentially a disease of men, approximately 80% of the cases being male. During the reproductive years of life women have a relative immunity which is particularly marked during pregnancy and which seems to decline at the time of the menopause (Clark, 1953). The overall peptic ulcer population, both in-patient and out-patient, at the Central Middlesex Hospital showed that the sex ratio varies with the type of ulcer (Jones and Poliak, 1945), and it is interesting to note that the acute ulcers which were diagnosed gastroscopically after haematemesis and melaena showed an approximately equal sex ratio. From further analysis of this and other data, Avery Jones and Doll (1953) have demonstrated that the sex ratio is nearly constant for each site irrespective of age, and they also concluded that the gastric and duodenal ulcers are between one and a half times as fatal in men as in women. This is at least in part explained by a lower tendency for acute perforation to occur in women, as shown by the very high male/female ratios in studies on this complication.

Age

The incidence of peptic ulcer varies in different age groups, but this must be distinguished from the expectation of developing an ulcer. From the age of onset of the observed ulcers in the population survey and the number of man-years lived in each age group, it was possible to calculate the annual expectation of developing an ulcer; this is almost constant, and is probably at its maximum between 35 and 64, giving a rate of 3.2 ulcers per 1,000 men. The impression that ulcers occur more often in young men is due to a failure to take into account the relative size of the population at risk.

Blood Groups

A most interesting recent discovery concerning peptic ulcer has been the correlation of this disease with blood groups. The possible presence of appreciable differences in health in persons differing in such innate attributes as blood groups was predicted by Fisher (1930), but the first convincing evidence of any such difference within the ABO system was the demonstration by Aird, Bentall, and Roberts (1953) when they showed the increased susceptibility to gastric cancer of group A persons compared to those in groups O and B, the difference in incidence being 22%. This was followed by a similar survey for proved cases of peptic ulcer in which group A and B persons were found to be less liable than group O, group A having a relative liability to peptic ulceration of 72% and the liability to duodenal ulceration being less than that to gastric ulceration (Aird *et al.*, 1953). These results were confirmed by Clarke *et al.* (1955), whose figures combined with those of Aird's showed an appreciable distinction between duodenal and gastric ulcer.

The blood-group substances are mucopolysaccharides. They are distinguished from each other by their antigenic properties. There does not appear to be a specific antigenic blood-group substance for blood group O, but those who belong to group O have a mucopolysaccharide called H substance which appears to be present to a less extent in people who belong to other blood groups. These mucopoly-

saccharides are present in small quantities in red corpuscles and in much greater amounts in body tissues and fluids, and usually in the salivary and gastric secretions.

There are two possibilities: their effect may be indirect or humoral and related to genetic control of gastric acidity; or their effect may be direct and cellular and concerned with varying tissue resistance to an exogenous ulcerogenic or carcinogenic factor, with blood group A protecting against ulcerogenic factors and blood group O protecting against carcinogenic agents. Aird (1955) has suggested that a protective action like this may be more important than is suggested by the relatively small differences which are found between the different groups. It might be, for example, that all the blood-group mucopolysaccharides protect against both cancer of the stomach and peptic ulcer but that groups O and B protect more efficiently against cancer than A, and that A and B protect more effectively against ulcer than O. Important studies are at present in progress by Clarke and his co-workers on the correlation between duodenal ulcer and the presence of mucopolysaccharides in the saliva. It appears that non-secretors have a 45% greater liability to develop duodenal ulcer (Clarke *et al.*, 1956).

Hereditary Factors

Another point of interest is the tendency for peptic ulcer to run in families. There is no doubt that the prevalence of ulcer is greater among the relatives of ulcer subjects than among the general population. There have been a number of reports of excess incidence of ulcer in the near relatives of ulcer subjects compared with controls, but the difficulty has been to overcome the objection that the patient with an ulcer is more likely to be interested in searching out similar cases in his family than the patient who is suffering from some entirely different disease. Using the population survey as a control, Doll and Buch (1950) have demonstrated an excess incidence among close relatives of ulcer subjects. There is also evidence for the independent inheritance of gastric and duodenal ulcers (Doll and Kellock, 1951). Thus relatives of gastric ulcer patients tend to have gastric ulcers, and this appears to hold for the site of the ulcer in different generations as well as the same generation.

The interpretation of this hereditary pattern is still in doubt. Is it due to hereditary altered tissue resistance or susceptibility or, as suggested by Kirsner and Palmer (1952), should the attention be directed to environmental factors and "hereditary habits" rather than to hereditary tendencies? More information is certainly required about the role of hereditary habits, and studies of twins will be needed to solve this aspect of the problem.

Hypersecretion of Acid

It seems likely that hypersecretion is one of the constitutional factors related to duodenal ulcers. Hypersecretion of acid may be due either to a great amount of acid produced from the same mass of secretory cells as in a normal person subjected to the same stimulus or, alternatively, it may be due to a greater mass of secretory cells which are responding to nervous hormonal stimuli with the same intensity as in a normal stomach. Work by Kay (1953) has thrown important light on this point. By increasing the dose of histamine stimulus to the stomach and neutralizing the systemic effects with an antihistamine, he demonstrated that the volume of the gastric response increased with increasing doses up to four times the normal body-weight dose, but thereafter more histamine produced the same volume as with four body-weight doses. It is a reasonable assumption that at this dosage level the total secretory cell mass is operating and the volume of gastric juice represents the maximum secretory capacity of the stomach. With this test there is clear evidence of hypersecretion in patients with duodenal ulcer.

Hunt and Kay (1954) next demonstrated that with the same body-weight dose of histamine the same percentage response was obtained in relation to the maximum secretory

capacity in both normal and duodenal ulcer subjects. Therefore there is no greater reactivity of the gastric mucosa in duodenal ulcer subjects than in normal persons, suggesting that the duodenal ulcer subject with hypersecretion has a greater secretory cell mass than the normal individual. Further confirmation of this view came from Cox (1952), who from measurement of the stomach at necropsy demonstrated that those with duodenal ulcer are particularly concentrated amongst the larger stomachs, and a correlation clearly exists with the number of parietal cells as judged by cell counts.

There may be two components to this greater secretory cell mass. It may be hereditary in the same way as an individual's limbs or trunk may vary in size, or there may be hyperplasia as the result of long-continued nervous or dietetic overstimulation.

Support for the hereditary component comes from Dr. L. Cooke, who, using basal-secretion studies, has found that the near relatives of duodenal ulcer subjects have a significantly increased incidence of hypersecretion as indicated by this test.

With gastric ulcer there is a tendency to hyposecretion, best demonstrated when ulcers associated with pyloro-duodenal stenosis are excluded (Daintree Johnson, 1955). The nocturnal fall in pH (unlike that in normal subjects) raises the possibility that the lower acidity is due to a greater secretion of the non-parietal alkaline component of gastric juice. Alternatively, it may reflect the greater incidence of gastritis in the body of the stomach in patients with gastric ulcer.

Anxiety and Personality

So far, various environmental and constitutional correlations with peptic ulcer have been studied but no reference has been made to the role of anxiety and personality. Here there is a close interplay between environmental stress and constitutional nervous factors determining the reaction of the individual to those stresses.

All clinicians are agreed that acute anxiety is a most significant factor in precipitating complications in peptic ulcer and that a chronic anxiety state tends to lead to intractability of the ulcer. It is not merely a question of acute anxiety, but with this there is the ability to "bottle up" an emotional tension—"worrying inwardly." It is sometimes difficult to appreciate the degree of frustration or resentment that may be hidden. In practice it is impossible to say how much of a relapse is due to nervous tension and how much to other concomitant aggravating factors, particularly physical fatigue from insomnia or over-long hours of work and increased smoking as a reaction to the stress. Fatigue is probably as important as anxiety in promoting exacerbation of ulcer symptoms, a point frequently confirmed by doctors who themselves suffer from peptic ulcer. Those who are more exposed to sustained anxiety by their work, such as doctors or those responsible for maintaining industrial output, will have a higher proportion of clinically manifest ulcers than those who lead protected, quiet lives.

Anxiety, frustration, resentment, fatigue, smoking, and irregular meals may determine whether or not an acute ulcer, initiated by other factors, will become chronic. They spell intractability, complications, and surgery. They are not the primary cause but important aggravating factors.

This recognition of the anxiety factor is not the same as postulating that peptic ulcer develops particularly in a section of the community with a particular personality pattern (Kellock, 1951). The thesis that peptic ulcers tend to develop especially in those who are oversensitive, overactive, and overconscientious rests on very insecure evidence. The anxiety factor promotes chronicity and complications, but the personality of ulcer subjects corresponds with the rest of the population.

Why has pyloro-duodenal ulcer become more prevalent in the past thirty years in this country? It is difficult to believe that life has become so much more worrying. The changing incidence of ulcer must mean that it is associated

somewhat with our mode of living. Perhaps it may prove to be correlated with the great increase in tobacco consumption.

Integration

It does not seem possible to integrate the many aetiological considerations into one neat explanation, and it is probable that peptic ulcer is the end-product of a variety of mechanisms. Furthermore, the independent behaviour of gastric and duodenal ulcer in relation to social class, occupational incidence, and hereditary and epidemiological factors does suggest that different mechanisms may be operating, although there may well be many factors common to both sites.

How can all the differences in incidence be related to the causation of peptic ulcer? First, there must be environmental factors which account for the changing incidence in this century and the varying incidence in different parts of the world. Secondly, there must be hereditary constitutional factors which help to determine the incidence and site of ulcers. These must include the secretory cell mass of the stomach and the blood groups. Some members of the community may have a special liability to duodenal ulcer by virtue of their specially generous endowment with parietal cells or because of their blood group.

From the pathological viewpoint there is less difficulty in explaining acute than in explaining chronic ulcers. Probably acute gastric lesions—small superficial ulcers—are very common and widely distributed over the stomach and duodenum, and normally heal rapidly. From the frequent presence of mucosal fragments in gastric aspirations such small lesions are known to occur (Hawksley and Cooray, 1948). Such small lesions may be part of the normal life-cycle of the epithelium or could be due to some cytotoxic factor analogous to aphthous ulcers in the mouth. It is also possible that local ischaemia from vascular spasm could cut off adequate supplies of carbon dioxide from actively secreting parietal cells, and this could lead to an intracellular necrotizing concentration of alkalis. Davis (1952) has produced experimental ulcers this way.

The real problem in peptic-ulcer pathology is, why do some ulcers become chronic? This may be due to, the presence of anti-healing factors, which could be either humoral or exogenous. The healing process could be modified by adrenal overactivity from mental or physical stress or by administration of cortisone or corticotrophin. This could operate either on cellular repair mechanisms or by modifying the physical character of mucus as suggested by Hirschowitz, Streeten, Pollard, and Boldt (1955). An impaired mucous barrier might allow cytotoxic factors within the stomach more ready access to the damaged mucosa. It is quite conceivable that anti-healing factors could be present in food and might determine the striking differences in geographical distribution. Tapioca root is the staple diet in Southern India and also in Southern Nigeria, where duodenal ulcers are so prevalent. Could the appreciable amounts of hydrocyanic acid in the root act as an anti-healing factor? Another possible anti-healing influence might arise from vascular constriction. In chronic ulcers the blood supply at the base of the ulcer may become so diminished by vascular occlusion that healing is no longer possible (Key, 1950). An earlier phase might be functional vasoconstriction from tobacco smoking.

Daintree Johnson (1955) believes that stasis in the stomach could be correlated with the development of gastric ulcer. Stasis in a jejunal loop or in the duodenum might also play a part as an anti-healing factor. Possibly the volume of secretion, and especially pooling, of gastric juice may have a greater anti-healing effect than the mere level of acidity. Stasis plus hypersecretion may be a particularly potent combination. In this connexion it is interesting to recall the observation of Zollinger and Ellison (1955), who found an association between the presence of non-insulin-secreting adenoma of the pancreas and sustained hypersecretion leading to stomal ulcer. Another mechanical factor might be

the force of the jet of gastric juice passing through the pylorus and impinging on the duodenal cap, and this in turn could be correlated with nervous tension reflected on gastric motor activity.

Gastric and duodenal ulcers can occur in lower animals but only rarely in the natural state. Natural selection would tend to eliminate animals prone to develop ulceration from unusual environmental factors. In man new personal habits, new foods, new drinks, new methods of cooking and food preparation, and changing feeding habits have come under the guise of civilization. The forces of natural selection have become blunted by medical science, and a disequilibrium now exists between man and his environment, and one of its manifestations is peptic ulcer.

[The second lecture, with a list of references, will appear in our next issue.]

REVIEW OF 464 CASES OF CARCINOMA OF LUNG TREATED BY RESECTION

BY

JOHN HAMILTON GIFFORD, M.B., C.P.H.

AND

J. K. B. WADDINGTON, M.B., F.R.C.S.Ed.

From the Thoracic Surgical Unit, Broadgreen Hospital, Liverpool

In his Lister lecture of 1947 Graham reported the first substantial series of cases of carcinoma of the lung treated by pneumonectomy. Since then numerous papers have recorded the results of individual surgeons or groups of surgeons in different parts of the world.

In Great Britain, Sellors, Cruickshank, and Billimoria (1947) reported a series, followed by Brock (1948), Mason (1949), Taylor and Waterhouse (1950), Price Thomas (1952), Sellors (1955), Bignall and Moon (1955), and Belcher (1956).

At the present moment surgical treatment, where possible, is generally accepted as the most satisfactory treatment for bronchial carcinoma. This involves removal of between a quarter and a half of the respiratory mechanism, and the ability of the patient to withstand the operation depends on the function of the remaining lung tissue and his cardiovascular system. In a heavy industrial and climatically severe region such as Liverpool, inflammatory and degenerative changes in the two systems, especially in the 40 to 60 age group, are likely to be more pronounced than in the districts where sedentary occupations and light industries predominate. That such changes will affect the results of surgery is only too obvious, and it is against this background that we have investigated the results of surgery in the Liverpool Region. As a regional centre, the thoracic unit undertakes most of the surgical treatment of cases in the area apart from the few that gravitate elsewhere. We have based the figures on the known incidence of the disease in this area as revealed by the Cancer Control Organization.

The basis for selection, and the operability, operative mortality, and survival rates vary from author to author, so that a true comparison of results is not readily available. To provide some measure of comparison we have

FIG. 1.—Carcinoma patients admitted to unit, thoracotomies performed, and tumours excised, expressed as percentages of patients registered each year by the Cancer Control Organization. (Proportions of patients treated by lobectomy or pneumonectomy represented by black and shaded columns respectively.)

FIG. 2.—Proportion of thoracotomies in which resection was possible for each year from 1941 to 1954.

FIG. 3.—Annual operative mortality from pneumonectomy and lobectomy.

adopted the same criteria as Bignall and Moon (1955) and Belcher (1956) for the operative mortality, survival rate, and histological groups.

In December, 1955, we reviewed all the cases of bronchial carcinoma admitted to the Liverpool Thoracic Surgical Unit between 1941 and 1954. Figures are available for the cases registered each year by the Liverpool Cancer Control Organization from 1945 onwards, and these are quoted at the top of Fig. 1. The Organization covers substantially the same region as the Liverpool Thoracic Unit and gives a reliable figure for the known incidence of the disease for the area.

A total of 2,156 patients suffering from bronchial carcinoma were admitted to the unit, of which 7% were women. Of these, 714 were explored (33%) and from 464 (21%) the growths were removed.

Fig. 1 shows the annual percentages of registered patients who were admitted to the unit, were subjected to thoracotomy, and from whom the growth was excised. The relative proportions of lobectomies and pneumonectomies by which the tumour was removed are also shown (calculated to nearest 0.1%).

The proportion of notified cases admitted to the unit increased steadily from 22% in 1945 to 45% in 1954, whilst in the same period the numbers explored rose from 6.1% to 20.8%. Thus the thoracotomy rate increased from an average of 6.4% between 1945 and 1949 to 15% in the period 1950-2 and 20% in 1953-4. This is the natural result of earlier diagnosis, M.M.R. services, and improved clinical facilities, aided more recently by external diagnostic endoscopic clinics at which the obviously inoperable cases were eliminated.

Similarly, the numbers of patients from whom the growths were excised increased from 1.6% in 1945 to 13.9% in later years; there has therefore been approximately a ninefold improvement in the chance of a patient having his tumour removed.

Between 1941 and 1948 the average ratio of operable to inoperable growth was 3:4, but from 1949 onwards this averaged 7:3. Whilst the number of resections has increased from year to year, the relative proportions of pneumonectomies and lobectomies altered considerably, and, whereas pneumonectomy was the more usual operation prior to 1951, that year marked a change of policy, and in subsequent years the numbers of lobectomies increased considerably.

Not only does pneumonectomy carry a higher operative mortality than lobectomy, but the loss of a whole lung deprives the patient of a larger volume of functioning lung tissue, and this may lead to respiratory insufficiency

amounting in some cases to respiratory crippledness. With this in mind, it has been the policy to perform lobectomy in all possible cases, provided the basic criteria for effective removal of the tumours were fulfilled.

The proportion of thoracotomies in which removal of the tumour has been possible is shown in Fig. 2. This had increased since 1945, and though in later years it showed slight variations, during each of the last six years approximately 70% of the growths were removable. No doubt this figure could be improved by rejecting doubtful or borderline cases, but by so doing many patients would be deprived of the benefits of surgery.

Material.—The percentage of patients in quinquennial age groups was: under 45 years, 14.8%; 45-49, 18%; 50-54, 24.5%; 55-59, 23.7%; 60 and over, 19%. Of the 464 patients in whom resection of the tumour was possible, 448 were followed to death or for a minimum of one year.

Operative Mortality

Operative mortality is defined as the number of patients undergoing operation who died of any cause within two months, expressed as a percentage of the whole.

Of the 464 patients undergoing operation, 101 (21.7%) died within two months. Prior to 1948, 31% died, but as the number of operations and experience increased so the mortality fell to 21.5% for the years 1949 to 1954. The respective mortalities for pneumonectomy and lobectomy were 25.9% and 14.7%, showing that the former carried a higher operative risk.

Only 33 women underwent operation, and of these 12% died—a proportion much less than that for men.

Fig. 3 shows the annual variation in operative mortality for pneumonectomies and lobectomies. With the exception of peaks in 1943 and 1952, the mortality for the former declined from 50% in 1942 to 21% in 1954. Lobectomies showed more variation from year to year, but after 1950, when they were performed more often, the mortality became more uniform, with an average of 12.4%.

Comparison with Other Series.—Table I shows the operative mortality recorded by various authors. The mortality in the Liverpool series is strictly comparable only to that of Bignall and Moon, to whose criteria for operative mortality we adhered in calculating the operative deaths. As might be expected, the operative mortality for pneumonectomy has decreased from 53% in Graham's series (Table I) to 11% in Brock and Whytehead's series of "Radical Pneumonectomies," and, although Bignall and Moon reported no deaths from lobectomy, the average mortality for this operation ranges from 4.5 to 9% in the hands of different surgeons.

To determine, if possible, how operative risk could be reduced, we investigated the cause of death in all cases (Table II). The deaths are grouped into "early," occurring within 48 hours of operation, and "late," occurring after 48 hours but within two months, and we found that 42 patients (41.6% of deaths) died within 48 hours.

Accidental or technical difficulties accounted for 12.87% of deaths, coronary thrombosis or congestive failure caused 24.75%, pulmonary embolism and cerebral thrombosis accounted for 2.97% and 2.97% respectively, and a further group due to pulmonary oedema, insufficiency, or infection totalled 31.68%. No fewer than 62.37%, therefore, were due to pulmonary deficiency or vascular lesions of brain, heart, or lungs.

Putting this group into a category of "cardio-pulmonary failure" (C.P.F.), we have in Table III related the proportion of C.P.F. deaths to the total early and late deaths occurring after right and left pneumonectomies and lobectomies.

Whilst the numbers of right and left pneumonectomies were similar, there was a marked difference in the mortality

for the two sides, the right being nearly twice that of the left (33% against 17.3%). The numbers of lobectomies differed somewhat, and the contrast between the two sides was not so pronounced, but, even so, 16.3% of patients who had right lobectomies died, compared with 11.7% of left. When only the C.P.F. deaths are considered the contrast is even greater.

Bignall and Moon also found a higher mortality for right-sided operations (right 12%, left 8%), but thought chance played a part in the difference.

In our series the contrast was more marked, and we believe that the difference is too great for chance to be the only factor.

Table IV shows the proportion of operations and deaths due to pneumonectomy and lobectomy as they are distributed in quinquennial age groups. Deaths after lobectomy increased with age, but deaths after pneumonectomy showed

TABLE I.—Operative Mortality of Other Reported Series

Author	Resection	Mortality Rate
Graham (1947) ..	Pneumonectomy	53%
Rienhoff (1947) ..	"	22.3%
Sellers <i>et al.</i> (1947) ..	"	15%

TABLE IV.—Effect of Age on Operative Mortality

Age Group	Whole Series (464)	Pneumonectomies. Deaths (81)	Lobectomies. Deaths (20)
Under 45 ..	15%	8.6%	0%
45-49 ..	18%	17.2%	10%
50-54 ..	24%	28.4%	20%
55-59 ..	23%	16%	30%
60+ ..	19%	29.6%	40%

considerable variation, being most frequent in the 50-54 and 60+ groups. Only 16% fell into the 55-59 group, and it is significant that this particular age group had the highest number of survivors of the operative phase and the best two-year and five-year survival rates.

Survival Rate

The survival rate has been calculated from the formula:

$$\frac{\text{Actual survival}}{\text{Possible survival}} \times 100$$

The fate of 347 patients who survived the arbitrary two months after operation has been reviewed. At the time of review 204 were known to be dead, and, except in those cases where the patient died in hospital and necropsy was possible, the cause of death was obtained from the practitioner who attended during the terminal illness.

The cause was unknown or unspecified in 15 (7.3%), but of the remainder, 152 (74%) died of recurrence or metastasis. Bronchopleural fistula (or sequelae), coronary disease, and pulmonary insufficiency accounted for 8.8%, 3.8%, and 2.4% respectively.

Malignancy was the cause of death of 76% of those who had lobectomy and of 74% of those who had pneumonectomy, 64% and 60% respectively within two years. The proportion of patients dying of malignant disease increased each month to a peak at 18 months, and, whilst four patients died of metastases five years after their pneumonectomy, no patient died of metastases later than three years after lobectomy. As is shown below, the peak at 18 months corresponds with the time at which nodal involvement began to affect survival rates.

The two-year survival rates for pneumonectomies and lobectomies were similar (44% and 45%), but the five-year rate for pneumonectomies (30%) was much more favourable than that for lobectomies (12.5%). Nevertheless, the lobectomy patients have probably survived in greater comfort.

Of the patients alive and well at the time of the survey, 10 had lived for five years, 9 for six, 3 for eight, 2 for nine, and 1 for ten years after pneumonectomy; a total of 25 out of the first 136 patients operated on since 1941 (100 of these survived operation).

Factors Affecting Survival

Table V shows little difference in the two-year and five-year survival rates for patients treated before and after 1948, so that the year of operation seems to have little effect on survival.

Position of Tumour

The tumours were distributed more or less equally between the right and left lungs (170 and 177), and the two-year survival rates were very similar. The five-year rates, however, were much better for right-sided tumours (34% against 22%). The distribution of individual histological types of tumour was even throughout all lobes and both lungs except the left lower lobe, which had 41% undifferentiated types, some 7% more than the average for both lungs. Nodal involvement occurred in 38% of left-sided tumours compared with only 28% of right-sided lesions. This factor, the higher proportion of undifferentiated tumours in the left lower lobe, and cross-lymphatic spread probably accounted for the poorer five-year rate for left-sided tumours.

The survival rates for individual lobes and their histological types were calculated (Table V, Figs. 4 and 5). The left upper lobe was most often involved and the right middle lobe least often. The latter was involved in only 12 cases, and none lived as long as three years after operation.

Of all lobes, the right lower carried the best prognosis, probably by reason of a slightly higher proportion of squamous tumours (Table VI, Fig. 4), a low rate of nodal

involvement (25%), the earlier incidence of symptoms, and the fact that, except in basal segmental tumours, it has been the practice to perform a middle and lower lobectomy in nearly all lower lobe tumours.

Nodal histology was known in 281 cases and survival time of these was from time of operation to time of survey.

The prognoses for left upper and lower lobe tumours, were similar, and were worse than for right-sided tumours, the reasons for this being a higher rate of nodal involvement (30% left upper, 49% left lower), a longer delay in the appearance of symptoms, and cross-lymphatic spread.

FIG. 4.—Survival rates in upper and lower lobes in both lungs.

FIG. 5.—Survival rates in the three histological types of tumour.

Age and Sex

The best two- and five-year survival rates were found in the 55-59 quinquennium (53% and 45% respectively), the worst in the over-60 group, 33% of whom survived two years, but none to five years (Table V).

We found that whereas under 50 years of age the distribution of squamous tumours equalled the sum of the undifferentiated and adenocarcinomas—that is, the more malignant types—over this age squamous tumours amounted to 57% of the whole. Nodal involvement by tumour cells occurred in only 29% of patients in the 55-59 group compared with 45% under 45 years and 34% for all other ages. The higher proportion of squamous tumours and the low incidence of nodal involvement probably explains the good survival of the 55-59 group of patients.

In this series 81% of the patients over 60 died of "metastases" compared with 74% for the series as a whole, despite the fact that squamous tumours predominated. It is possible that some of these patients were labelled "metastatic deaths" when in fact death was due to vascular lesions associated with arteriosclerosis.

There were 33 women in the series, four of whom died from the operation. The two- and five-year survival rates were 38% and 25%, compared with 45% and 29% for men (Table V). Adenocarcinomas and undifferentiated carcinomas predominated—65% compared with 44% for men (Table VI)—and though the average age was lower the degree of nodal involvement was much the same. The poorer prognosis would appear to be related to the predominance of the more malignant types of tumour and possible delay in diagnosis, since bronchial carcinoma is less often anticipated in women.

Histological Type of Tumour

All biopsies, tumours, and lymph nodes were examined by the same team of pathologists from 1946 onwards, so that a uniform appraisal of cell types can be expected, and where a "mixed" tumour occurred the predominant cell type dictated the group into which it was placed (F. Whitwell, personal communication).

The histological type of tumour was known in 347 patients who survived the arbitrary two months' operation phase, and the broad classification into squamous, undifferentiated, and adenocarcinomas was adopted.

Table VI shows the distribution of cell types of the tumours in the two lungs, all lobes, main bronchi, type of operation, sex, age groups, nodes, and all survivors.

Squamous tumours occurred in 55% of all cases and behaved consistently in all lobes, with two- and five-year survival rates of 54% and 38% (Tables V and VI). The proportion of squamous tumours was rather lower than in the series recorded by Bignall and Moon, but the survival rate was similar. Nodal involvement occurred in 28% of all squamous tumours.

Undifferentiated tumours occurred in 34% of the patients, compared with 26% in Bignall's series, and, though the overall two-year rate was the same (35%) (Tables V and VI), the five-year rate was considerably less (19% compared with 26%). The prognosis for this type of tumour varied considerably from lobe to lobe, ranging from a two-year rate of 27% in the right upper lobe to 48% in the right lower lobe, with intermediate percentages of 44% and 31% for the left upper and lower lobes. The five-year rate was much better in the right lower and upper lobes (33% and 28%) than in the left (12% and 9%). Nodal involvement occurred in 43% of these tumours.

Adenocarcinomas behaved very differently in this series compared with those recorded by Belcher and by Bignall and Moon. They occurred in 9% of cases (10% of survivors), compared with 13% and 18% respectively. They were commoner in women, more frequently on the right side than the left, and in most cases were associated with hypertrophic pulmonary osteoarthropathy. Nodal involvement occurred in much the same proportion as in undifferentiated types of tumour—namely, 45%. The prognosis compared very unfavourably with the two series mentioned above, 31% surviving two years and 20% for four years; none lived five years (Table V).

Comparing the survival rates of lobectomies in our series, the two-year rate was only 31%, compared with 69% in Belcher's series of lobectomies.

We therefore found that squamous tumours had the best prognosis and adenocarcinomas to be by far the most malignant, both features contrasting strongly with the findings of Belcher and of Bignall and Moon.

Mediastinal and Hilar Nodal Metastases

In this series the involvement of hilar and mediastinal nodes by tumour cells has been investigated from the histological aspect rather than the surgeon's assessment of nodal involvement at operation. With few exceptions, deliberate clearance of mediastinal nodes has been practised since 1947, and most specimens have been examined histologically for evidence of involvement. Full reports were available for 215 specimens removed two years and 53 five years prior

to the time of review. No evidence of metastases was found in 184 cases, and the survival rates for two and five years were 60% and 33% respectively. Metastases occurred in 97 specimens (Table VII), the two- and five-year rates being 26% and 8%.

* Survivors in this group taken from time of operation to survey in December, 1955. Percentages corrected for histological type, age, sex, duration of symptoms, and extent of operation related to those with nodal involvement.

The two-year rates are identical with those of Bignall, and, though the five-year rates are lower, they show the same ratio of 4:1 in favour of those without metastases. Since his figures were based on the surgeons' assessment of nodal involvement, it would appear that macroscopic appearances compare closely with histological findings.

After correcting for any of the five other major factors which might affect survival—namely, sex, site, duration of symptoms, extent of operation, and histological type—the two-year rate for patients without evidence of metastases was still 60% and slightly lower at five years (29% compared with 33%). The different survival rates of those without compared with those with metastases is therefore very striking (Table VII).

When the one- and two-year survival rates were compared it became apparent that between these periods the effect of nodal involvement became manifest (Table VII). When no metastases were present the rate fell only from 73% to 60%, whereas in those cases with metastases, the rates fell from 67% to 26%. This corresponds to the period in which the highest number of deaths from metastases occurred—that is, 18 months. The advantage of metastasis-free nodes over involved nodes from two years onwards is approximately 2.5:1 up to four years, and at five years the ratio is better

at 3.7:1 (all figures corrected as before). Whilst nearly all the recorded metastatic deaths occur early, the results of finding no evidence of tumour deposits at operation are even more marked at five years than earlier.

The effect of nodal involvement on the survival rates of the three main histological types is shown in Tables VI and IX. Squamous tumours showed a survival rate (to the maximum period after operation) of 57% if the nodes were free from metastases. Even in the 28% of squamous tumours where nodes were involved, the survival rate was still as high as 40%.

Adenocarcinomas and undifferentiated tumours without nodal involvement had survival rates of just over 40%—that is, no better than squamous tumours already showing involvement. Forty per cent. showed nodal involvement and the survival rate was 20%.

Table VIII shows the relationship between the site of tumour and the state of the hilar nodes. Left lower lobe

tumours had nodal involvement in 49% of cases, probably accounting for the left lung showing metastases in 40% compared with 30% in the right side. The right middle and lower lobes had 78% and 75% free from metastases, and the left and right upper lobes occupied intermediate positions. The diminished survival rate for left lower lobes is thus accounted for without taking into consideration the assumption that lymph paths cross over to the right side (Rouvière, 1932).

The proportions of each histological type of tumour showing nodal involvement increased every year up to and including 1953, with the exception of adenocarcinomas. Since their numbers are small and we have found them similar in other respects, they are best considered along with the undifferentiated tumours (Table VII), and this combined group showed the greater increase of nodal involvement. Prior to 1951 the incidence of nodal involvement in the combined group was 26%, compared with 23% for squamous tumours, but in 1953 it increased to 64%, compared with 36% for squamous types. While, therefore, nodal involvement in squamous tumours increased only from 23% to 36%, the combined group actually reached nearly twice this figure.

Why this should happen is not clear; the duration of symptoms was shorter each year, suggesting that the tumours were being operated on at an earlier stage (see below). It is unlikely to be due to keener histological search, since the incidence decreased in all instances in the last year (1954), and although it could have been due to acceptance of patients with greater clinical likelihood of nodal involvement followed by retrenchment in 1954, when results in 1953 were found to be less satisfactory (see above), this is very unlikely. No satisfactory explanation is therefore forthcoming.

Duration of Symptoms Prior to Operation

The expectation of survival did not, as might be first supposed, bear a direct relation to the period for which symptoms had been present at the time of operation.

Like Bignall and Moon (1955), we found the best chance of survival among those with longer histories (over nine months), which had two- and five-year rates of 59% and 33%. Those with histories of less than six months had intermediate rates of 46% and 30%, whilst for those with symptoms of six to nine months the rates were the worst at 36% and 19% respectively (Table IX).

TABLE IX.—Duration of Symptoms Related to Histological Type of Tumour, Condition of Nodes, Two- and Five-year Survivors

Adenocarcinoma plus undifferentiated	60	41	17	59	7	33

Nodal involvement remained remarkably constant in relation to the length of history, so that this factor was not in this instance responsible for the influence on survival (Table IX). Contrary to Bignall's finding, however, in our series the percentage of squamous tumours in the groups paralleled the survival rates closely, and the six-to-nine-months group was the only one with more adenocarcinomas and undifferentiated tumours. Also unlike him, as already noted, we found that the effect of duration of symptoms was as great on the five-year rates as on the two-year.

The tumour site had a similar distribution among the under-six-months and six-to-nine-months groups, but with fewer left lower lobe tumours in the over-nine-months group. Hence site has no effect on the two shorter periods, but may have contributed a little to the improved chance of survival in the longest group.

It would appear from our series that the superior survival rates in the patients with long or short histories compared with the intermediate group is mainly due to the inclusion of more patients with squamous tumours (Table IX).

We agree with Bignall that patients coming to operation early stand a better chance of having the tumour removed before metastases have occurred and that those with long histories have slower-growing types of tumour, and we likewise found the incidence of metastases was highest in those with histories of intermediate length.

The average duration of symptoms for patients coming to operation in succeeding years showed a steady reduction (Table VII). In 1953 this was two and a half months, or 40% of the pre-1951 figure, probably due to earlier diagnosis and more expeditious handling on the part of the practitioner, aided by improved thoracic surgical services generally.

Despite the reduction of the duration of symptoms, the two-year survival rate for any given year remained constant around 45% (Table VII), whereas with earlier diagnosis it should have improved. The survival rate has not been affected either by variation in the average age of patients operated on or by the proportions of total and subtotal operations performed (Table VII), since, though the latter varied from year to year, the two-year survival rate is the same for both types of operation (Table V). A practical answer to this is that the proportion of patients with involved nodes increased steadily from 25% pre-1951 to 47% in 1953, but fell again to 27% in 1954. The significance of this cannot be appreciated, as at the time of this review in December, 1955, the two-year survival rate for the patients treated in 1954 could not be calculated.

A similar effect might have resulted from an increased proportion of the more malignant types of tumour, but Table VII shows that, though it fluctuated, the proportion actually fell from 50% in 1952 to 38% in 1953. To offset this, squamous tumours showed more evidence of metastases in 1952 and 1953 with over 30% involvement, compared with just over 20% in 1951 and earlier. In 1954 it was 24%.

It would thus appear that the advantage gained by early operation was offset by the annually increasing frequency of nodal metastases up to 1953.

Extent of Operation

The two-year survival rates after pneumonectomy and lobectomy were practically equal with 45% and 44% respectively. The five-year rates (Table V), however, differed considerably with 29% and 12.5%. Squamous tumours were found equally after both types of operation, but adenocarcinomas slightly more often after lobectomy, at the expense of undifferentiated types. This might be expected, since adenocarcinomas tend to be peripheral and circumscribed (Table VI).

Nodal involvement was found after 39% of pneumonectomies and 27% of lobectomies; and in patients surviving pneumonectomy or lobectomy for two years nodes were found to be involved in 38% and 33% respectively. Of the patients living five years after pneumonectomy, only 25% were found to have nodes involved originally. The survival rates after both operations were similar up to three years, but, later, patients who had undergone pneumonectomy survived better; and, knowing that all those dying of carcinoma after lobectomy did so within three years, we have the impression that some of these might have lived longer with a pneumonectomy if this had been functionally possible.

The ultimate fate after lobectomy and pneumonectomy would seem to depend on the surgeon's appraisal of nodal involvement, especially in lower lobe tumours. There is, of course, a clear difference in operative risk and mortality for the two operations.

Discussion

Apart from purely symptomatic measures, the two main methods of treating bronchial carcinoma are radiotherapy and surgical excision. Bignall (1956) showed that, of 207 patients with and without mediastinal nodes treated by radiotherapy, 29% survived one year and 8% survived two years. Of 463 patients who received no treatment, only 8% survived one year and 6% two years.

We have shown that in the Liverpool Region, of 448 patients treated surgically over a period of 14 years, 53% lived one year and 35% lived two years, notwithstanding the fact that 30% of the survivors of the operation were found to have metastases in mediastinal or hilar lymph nodes. There is little doubt that, at the moment, surgical excision is the method of choice.

We have already shown that the proportion of registered cases treated successfully by surgery increased from 1.6% to 13.9% in 10 years and that the two-year survival rate remains in the region of 44%; therefore, roughly 6.2% of all patients with carcinoma of the lung have a chance of living two years with existing standards of diagnosis and surgical treatment, irrespective of the duration of symptoms.

Belcher (1956) has already emphasized the need for a conservative approach to lung resection in carcinoma cases to preserve adequate lung function, even to the extent of performing palliative lobectomy in cases with poor pulmonary function. The latter type of operation reduced the two-year survival rate from 52% to 33%.

Study of our operative results shows that pneumonectomy is twice as lethal an operation as lobectomy and that on the right side is even more so than that on the left. Robinson *et al.* (1956) found, despite an overall younger age group, that in tuberculous patients 31% died after right pneumonectomy compared with 7% after left pneumonectomy. They noted

that resection on the right side for all types of operation was three times as lethal as on the left side. We felt the marked difference between the two sides was due solely to the relative volumes of the two lungs and to the subsequent effects of mediastinal displacement on the heart and remaining lung after right-sided resection.

Accepting the need for conservative resection, the problem at operation is how little lung can be removed and yet give a hope of a five-year cure?

Provided the anatomical situation of the tumour makes lobectomy a reasonable operation, the decision between performing a total or a subtotal operation must depend on nodal involvement as assessed at the time of operation. The upper lobe tumours present less of a problem than lower lobe lesions in that those with mediastinal nodal involvement have already metastasized and pneumonectomy will be no more radical a procedure than lobectomy. Study of 21 patients who had upper lobectomy and died of metastases showed that with two exceptions all were dead within two years—that is, within the period when nodal metastases usually affect prognosis. There is no reason to believe that these would have survived any longer after pneumonectomy even if they survived the major operation.

Lower lobe tumours are more difficult, especially on the left side, where we found 50% with nodal involvement compared with 25% on the right. Of the patients dying of metastases after lower and middle lobectomies, 22 had tumours in the lower lobes and four in the middle lobe. All the latter died within 12 months, and with two exceptions all those who had lower lobectomies were dead within 23 months. They thus survived about the same length of time as the patients after upper lobectomy. It is conceivable that right pneumonectomy might save a few more patients with lower lobe tumours, but, in view of Rouvière's (1932) work on lymphatic drainage from the left lower lobe, it is doubtful whether left pneumonectomy would have eliminated metastases, particularly if the subcarinal nodes were involved. It would be good fortune if no cancer cells had passed through to the right side by the time the node showed involvement.

We found, despite the reduction in the duration of symptoms, that the two-year survival rate has remained constant, about 45%, and concluded that this was due to increasing nodal involvement, particularly by squamous tumours. The proportion of lobectomies performed since 1951 (except 1953) has been over 40%, and the fact that the two-year rate has remained steady despite an annual increase of nodal involvement suggests that adequate gland removal has been obtained with the less extensive operation in most cases. We feel, therefore, that when the site of tumour and nodal involvement permits of lobectomy this operation is preferable because it preserves lung function and usually provides an adequate removal of the tumour and attendant lymph nodes.

Summary

The fate of 2,156 patients suffering from bronchial carcinoma admitted to the Liverpool Thoracic Surgical Unit has been studied and related to the known cases registered by the Cancer Control Organization.

714 patients were explored and 464 tumours resected; 448 patients were followed to death or survival for a minimum of one year.

347 survived the arbitrary operative phase and 45% and 28% survived for two and five years respectively.

The cause of operative deaths has been analysed and 62.37% found to be due to "cardio-pulmonary failure."

Right-sided operations were more lethal than left, especially for pneumonectomy, and more so when deaths were due to cardio-pulmonary failure.

The quinquennial age group 55 to 59 years made up 24% of all survivors; they had the lowest mortality after

pneumonectomy and had the best two-year and five-year survival rates of 53% and 45% respectively.

Patients with growths in the right lower lobes had the earliest symptoms, the lowest incidence of nodal involvement, and the best five-year survival rate for both squamous and undifferentiated tumours.

Left lower lobe tumours had the highest nodal involvement and the highest proportion of undifferentiated tumours, but the survival rate was similar to the left upper lobe.

Adenocarcinoma appeared to be the most malignant type of tumour, though nodal involvement was no higher than with undifferentiated types.

Despite earlier operation in relation to symptoms, the two-year survival rate has hardly changed, probably owing to the increasing incidence of nodal metastases.

We thank all members of the Liverpool Thoracic Surgical Unit for the use of their case notes; the medical practitioners for their co-operation; Drs. J. S. Fulton and M. A. Stewart, of the Cancer Control Organization, and Mr. F. Ronald Edwards and Dr. O. F. Thomas for their advice and criticism; Mr. G. Wilkins for the preparation of the figures; and Mrs. D. Anthony and Miss J. Peet for undertaking work outside their normal secretarial duties.

COMPRESSION OF MEDIAN NERVE IN CARPAL TUNNEL AND ITS RELATION TO ACROPARAESTHESIAE

BY

HUGH GARLAND, T.D., M.D., F.R.C.P.

J. P. P. BRADSHAW, M.D., M.R.C.P.

AND

J. M. P. CLARK, M.B.E., F.R.C.S.

From the Departments of Neurology and Orthopaedic Surgery, the General Infirmary at Leeds

The purpose of this paper, which is based on a study of 53 patients with acroparaesthesiae, is to present information concerning the diagnosis, prognosis, and treatment of this condition and to discuss its underlying mechanism.

Schulze (1893) introduced the term "acroparaesthesiae" to describe nocturnal attacks of pain and paraesthesiae that affect the hands of middle-aged women. Wilson (1913) reported the syndrome, often with partial thenar atrophy and objective sensory loss over the digits, in association with cervical rib. Walshe (1945), however, stated that muscular wasting does not occur and the objective sensory loss is exceptional, though when the pain and paraesthesiae are maximal there may be some blunting of cutaneous sensibility over the digits. The most constant feature was, he considered, tenderness over the extensor muscles of the fore-

arm and sometimes over the thenar and adductor muscles of the thumb. He concluded: "... that traction and compression of the lower trunk of the brachial plexus and possibly also of the subclavian artery are the essential mechanical factors underlying most, if perhaps not all, cases of acroparaesthesia in women, that these factors are caused by sagging of the shoulder girdle, and this, in turn, is a natural consequence of an atonic supporting musculature." More recently, Walshe (1951) reaffirmed this contention and discussed the importance of structural and functional abnormalities of the thoracic inlet.

Brain, Wright, and Wilkinson (1947) described the cases of six women, three of whom had acroparaesthesiae, with signs indicative of a lesion affecting the median nerve in the carpal tunnel. At operation they were found to have swelling of the median nerve proximal to the transverse carpal ligament, and in some, where it lay beneath this structure, there was evidence of direct compression of the nerve. Relief of symptoms and improvement of the neurological deficit followed a decompressive operation. McArdle (1951) was the first to suggest that this mechanism was responsible for the production of acroparaesthesiae, and Kremer, Gilliatt, Golding, and Wilson (1953) reported the complete relief of all symptoms in 37 out of 40 cases submitted to surgery; re-exploration of the three who did not obtain benefit showed that the transverse carpal ligament had not been fully divided in two, whilst the last had a cyst attached to the flexor tendons within the carpal tunnel. Gilliatt and Wilson (1953) provided further evidence of a median-nerve lesion in their patients by the study of ischaemic paraesthesiae and sensory fading. Occlusion of the brachial artery was effected by a pneumatic cuff inflated to above arterial pressure. Patients with acroparaesthesiae developed intense tingling in the median distribution within 30 to 60 seconds, and if ischaemia was maintained a number were found to have cutaneous sensory loss in the same territory within 10 minutes.

In spite of this work Ford (1956) writes of acroparaesthesiae: "The fact that there is never any evidence of nerve root damage, even after symptoms have been present for many years, seems to be very strong evidence against the possibility that the symptoms are neurogenic." He preferred to call the condition the "tired arm syndrome," and suggested that it arose from an accumulation of metabolites in fatigued muscle.

Material and Methods

Patients were accepted for the present series who complained of attacks, lasting from minutes to hours, in which they experienced various combinations of pain and paraesthesiae in the digits and palm of one or both hands. Radiation of pain to the forearm and arm was recognized as a variant of the syndrome. Some patients had no objective neurological deficit, others had motor and sensory signs distal to the wrist. The finding of any other neurological abnormality, such as an alteration in the state of the deep tendon reflexes, necessitated rejection from the series.

Fifty-three patients fulfilled these requirements, and between the years 1949 and 1956 inclusive were diagnosed consecutively as suffering from acroparaesthesiae or compression of the median nerve in the carpal tunnel. Of these, 38 attended the department of neurology in the General Infirmary at Leeds, and 15 were seen in private consultant practice by one of us (H.G.).

Details of the treatment and the follow-up are described below. In addition to the routine questioning and exami-

nation, ischaemic sensory tests were carried out on eight patients before treatment and on 43 during the course of the follow-up. A pneumatic cuff was wrapped round the arm and inflated to a pressure of 220 mm. Hg, which was in all instances above arterial pressure. The patient was asked to describe any sensory symptoms affecting the digits or hand that might follow this procedure during the next two minutes. In the greater number the occlusion of the brachial artery was maintained for up to 10 minutes, and sensation over the volar surface of the digits and palm was tested with a pin at two-minute intervals. At the end of this time, if no abnormality was detected, two-point discrimination was tested over the tips of the digits before the cuff was released.

Clinical Features

The number of cases diagnosed in each year is shown in Table I. It can be seen that the annual incidence has steadily increased since 1953. The 53 patients (46 women and 7 men) were between the ages of 18 and 76. In about

a half of them symptoms began during the fifth and sixth decades, and there was a second, but smaller, peak in the age distribution between the 25th and 30th years. Possible predisposing factors included the following.

Occupational Stress.—Thirty-eight of the women patients, who were either housewives or were engaged in domestic work, related the onset of symptoms to a period of increased activity. Many had noticed improvement after a holiday and had relapsed when they resumed their duties. Tasks which were especially prone to provoke symptoms included heavy lifting, polishing, washing, and knitting. Four men first made complaint after a change of work to a postman, wirewinder, gardener, and pneumatic driller respectively.

Trauma.—In three patients the onset occurred immediately after a fall upon the outstretched hand; one sustained a Colles fracture, one a posterior dislocation of the lower third of the ulna, whilst the last had no bony injury. Another had lacerated her wrist by pushing it through a window.

Arthropathy of Wrist.—Radiographs of the wrist were taken in eight cases and were normal in four. A gross osteoarthritis of the wrist-joints affected three elderly patients, which was most marked on the side of the neurological symptoms; one other had extensive rheumatoid arthritis of the hands.

Pregnancy.—Symptoms came on during pregnancy for the first time in one patient and a relapse ensued in another.

Symptoms

The duration of symptoms was from six weeks to fifteen years. The right hand was first affected in 34 patients, and with one exception all were right-handed persons; in 18 the condition became bilateral within a matter of months. Symptoms began in the left hand in 10 and in five remained unilateral; four patients were left-handed, two sustained an injury to the left wrist, and one held a pneumatic drill in the left hand. In nine both sides were affected simultaneously.

Method of Presentation.—In 45 cases the first intimation that anything was wrong came as a nocturnal attack of either pain, paraesthesiae, or both, referred to the digits and palm. Most often this awakened the patient in the small hours of the morning, and lasted for 10 to 30 minutes. With the passage of time these episodes became more frequent and more severe until there was a more or less continuous background of discomfort throughout the day. In the other eight cases the symptoms began

insidiously and were both persistent and steadily progressive, though punctuated at intervals by diurnal and nocturnal attacks similar to those described.

Pain.—Thirty-six patients complained of pain in the digits and a greater or lesser portion of the adjacent palm. The little finger was involved in only three, all of whom were poor witnesses of fact. In the remainder the distribution was the first four digits (16), the first three digits (13), the first two digits (1), the index and middle fingers (2), and the index, middle, and ring fingers with sparing of the thumb (1). The pain was described as "bursting" or "burning," and it radiated centripetally in 13 to involve the forearm and in six the arm. The seven who had digital paraesthesiae without pain complained of dull ache in the forearm and arm.

Paraesthesiae.—Forty-one patients complained of a disagreeable "pricking" or "tingling" sensation and 22 of "numbness" in the digits. Eight of these did not have digital pain, but when pain and paraesthesiae occurred together the site of reference was, with minor variations, the same and always within the distribution of the median nerve.

Other Complaints.—Ten patients, all of whom had suffered for more than six months, complained of slight weakness of the hand, and three of these had noticed wasting of the thenar eminence. Five others stated that during the height of an attack their fingers turned "white," and another had noticed excessive sweating of the median two-thirds of the hand.

Physical Signs

In eight patients the hands were objectively normal. Careful examination in the remainder revealed a slight-to-moderate neurological deficit, and when symptoms were bilateral there was seldom any major difference between the physical signs on the two sides.

Motor System.—Eighteen patients had wasting of the thenar muscles. Fasciculation was not seen, nor was there any tenderness of muscles of the thenar eminence, forearm, or arm. The scapular muscles were normal and drooping of the shoulder-girdles was not evident. Relative weakness of the abductor pollicis brevis was detected in 36, and opposition of the thumb, as judged by internal rotation of the first digit, seemed to be defective in many.

Sensory System.—A slight alteration of cutaneous sensibility was found in 29; this consisted of relative hypalgesia, hypaesthesia, and impairment of two-point discrimination in 21, while 7 stated that a pin-prick felt abnormally sharp. Delimitation of minimal sensory change over the palm was often difficult owing to the thickness of the skin, but the incidence with which various digits were affected is shown in Table II. It will be seen that in all cases the abnormality was within the cutaneous distribution of the median nerve.

TABLE II.—Frequency and Distribution of Cutaneous Sensory Impairment

Designation of Affected Digit					No. of Patients
1	2	3	4	5	
1	1	1	1	0	3
1	1	1	1	0	18
1	1	1	0	0	6
0	0	1	1	0	2

Special Investigations

Electromyography.—In six patients electrical examination was made of the first dorsal interosseous, thenar, and hypothenar muscles and extensor muscles of the fingers and forearm. In two the findings were normal, in four there were changes indicative of denervation of muscles supplied by the median nerve below the wrist.

Compression of Wrist.—Digital pressure was applied to the volar aspect of the wrist over the transverse carpal ligament in five patients and was maintained for three minutes. This manoeuvre provoked an attack of acroparaesthesiae in three and in two was without effect.

Occlusion of Brachial Artery.—The methods of studying ischaemic paraesthesiae and sensory fading have already been described. Six out of eight patients tested in this way developed intense paraesthesiae, and, of this number, four exhibited cutaneous sensory impairment within the distribution of the median nerve.

Radiographs of Cervical Spine.—Plain radiographs of the cervical spine were taken in six patients, and were normal in five. One was found to have bilateral cervical ribs.

Treatment

Most of the earlier patients were advised to have surgical treatment, and 53 operations were done on 35 patients. One of these had been submitted previously to a two-stage removal of bilateral cervical ribs, from which she had obtained no benefit.

Operative Technique.—Under a general anaesthetic the transverse carpal ligament was exposed through an incision passing along the longitudinal palmar crease at the base of the thumb and up to the transverse crease in front of the wrist to the region of the pisiform bone. This gave a palmar flap large enough to expose the transverse carpal ligament, which was approached through a small longitudinal incision through the palmar fascia in the midline and divided. In some patients the skin incision was extended proximally along the ulnar border of the forearm in order to inspect the median nerve at this site.

Operative Observations.—No abnormality was seen at 29 operations, but at 20 the median nerve was swollen to about twice its normal diameter for between 1 and 3 inches (2.5 and 7.5 cm.) proximal to the transverse carpal ligament; after division of this structure the swelling subsided within a few minutes. In nine of these, and in two where the nerve was not swollen, the median nerve was flattened over that portion of its length where it lay behind and adjacent to the transverse carpal ligament; distal to this ligament the normal convexity of the nerve reappeared (see Figure). In

Compression of the median nerve in the carpal tunnel. The anterior carpal ligament has been divided, showing constriction of the median nerve beneath the ligament with swelling of the nerve proximal to the point of compression. (By kind permission of Sir Reginald Watson-Jones, who performed the operation at the London Hospital. Photographed by R. F. Ruddick.)

eight operations this abnormality persisted, but in three the nerve regained its normal rounded appearance by the end of the procedure. All of these patients had suffered from symptoms for more than six months, many for several years, and all had a moderate neurological deficit. One case requires further description.

Case 1.—In September, 1950, a woman aged 47 had sustained a laceration to the volar surface of the right wrist which had severed some of the flexor tendons and "nicked" the median nerve just above the annular ligament. Primary suture of the tendons and of the nerve was carried out, but in March, 1954,

the wound was re-explored on account of local pain, and a small lateral neuroma of the median nerve was excised. The results of this procedure were initially satisfactory, for power was preserved and the pain relieved, though there was some sensory loss over the territory of the median nerve in the hand. In October she began to have nocturnal attacks of burning pain and paraesthesiae in the median four digits of both hands, but worse on the right side. These became more severe and more frequent until November, 1954, when she was admitted to hospital. Both carpal tunnels were explored; on the left no abnormality was found, on the right silk sutures were removed from the median nerve, which appeared to be otherwise healthy.

Medical Treatment.—Eighteen patients were advised to rest the affected hand as much as possible and to avoid those tasks which were known from experience to provoke symptoms. No other treatment was given.

Results in Surgically Treated Cases

A follow-up of 33 of the 35 patients submitted to surgery had been carried out by one of us (J.P.P.B.) up to the time of writing. The intervals between operation and final assessment were from two months to seven years; 24 were followed up for more than six months, 13 for more than a year. Two patients were followed-up for only three months, and thereafter postal information was obtained from one, and one was untraced. Of the 18 patients who had bilateral operations, 10 obtained complete relief of all symptoms in both hands and three on one hand alone. The latter include one with slight weakness of a hand, one who has persistent aching pain in the forearm and arm, and one who complains of pain in the wrist (Case 1). Three patients, two of whom were elderly valetudinarians, have slight and intermittent tingling of two or more digits on both sides; the case of the third of these follows:

Case 2.—In December, 1955, a woman aged 52 experienced attacks of burning pain, tingling, and numbness affecting the median four digits of both hands which came on at night. In April, 1956, examination showed slight weakness of the abductor pollicis brevis and a minimal hypalgesia over the cutaneous sensory distribution of the median nerve on both sides. Both transverse carpal ligaments were divided and the patient became symptom-free for two months. Thereafter she developed tingling in the ulnar two digits of both hands and difficulty in walking. In September, 1956, examination showed painful restriction of all cervical movements, cutaneous sensory loss in the dermatomes C8-T1 on both sides, and a mild spastic paraplegia. A diagnosis was made of cervical root and cord compression from cervical spondylosis which was demonstrated on plain radiographs.

Of the 17 patients who had a single operation, 11 became symptom-free. The remainder enjoyed a great measure of improvement, but three complained of slight weakness of the hand, two experienced occasional and mild paraesthesiae of two or more digits, and one had pain in the region of the fifth metacarpal which came on after a fall.

With two exceptions, Cases 1 and 2, all were well satisfied with the result, all returned to a normal life, and none had more than minimal symptoms. Indeed, one who did not obtain complete relief of symptoms had returned to his work at the coal-face within seven weeks of an operation on his right wrist.

Before treatment 19 had sensory impairment; 29 had weakness, and of these 10 had wasting of the thenar eminence. After operation sensory loss was found in two and relative weakness in three, two of whom also had some wasting of the thenar eminence. No patient without physical signs before operation developed a neurological deficit after treatment. From the clinical aspect it remains to be said that about half complained of pain and swelling at the site of operation for a few weeks, but this was seldom troublesome and never persistent. Eight experienced aching or tingling in the scar which was precipitated by local pressure or by cold. Cheloid formation did not occur.

Ischaemic paraesthesiae were studied in 29 patients on both sides and the results were normal in 21. Eight, six of whom had been followed up for less than four months, complained of paraesthesiae in the territory of the median

nerve on one side within two minutes. Ischaemic sensory fading was tested in 22 of the above 29 on both limbs, and no abnormality was found in 19; two developed sensory loss in the median territory on the treated hand and one on the untreated hand within 10 minutes.

Results in Medically Treated Cases

A complete and personal follow-up was done on 17 of the 18 patients after intervals of one month to six years; 14 were followed for more than six months and 10 for more than a year. One other was followed for three months only, and since that time has remained untraced. One of the 18 had suffered from increasingly severe nocturnal attacks of acroparaesthesiae for two years and had obtained no benefit from rest; bilateral operations were done at another hospital, and since that time she has been symptom-free; she now has no objective deficit, and ischaemic sensory tests are normal.

Of eight patients who had bilateral symptoms, three have symptomatic relief, but any attempt to return to normal work or household duties results in a relapse, one has improved, and four continue to have nocturnal attacks three or four times a week. Of the nine who had unilateral symptoms, five are symptom-free so long as they avoid tasks which involve flexion and extension of the wrist; three continue to have nocturnal attacks of severe pain and tingling.

Of the eight with an initial sensory deficit, five regained normal sensation, but in three impairment of sensation appeared during the period of observation. Normal muscle bulk was restored in three out of seven who had partial thenar atrophy, but the wasting increased in four. Weakness of the abductor pollicis brevis improved in four out of seven but appeared for the first time in two others.

Ischaemic paraesthesiae were studied in both hands in 14 patients and the results were normal in six; paraesthesiae in the territory of the median nerve appeared in six on both sides and in two on one side within two minutes. Ischaemic sensory fading was studied in 10 of the above 14 patients on both sides; sensation in the territory of the median nerve became impaired in two on both sides and in six on one side within 10 minutes.

None of these patients were able to lead unrestricted lives and seven continued to suffer from frequent nocturnal attacks of pain and paraesthesiae.

Discussion and Conclusions

All the evidence obtained by the present analysis of 53 patients with acroparaesthesiae suggests that the underlying mechanism is compression of the median nerve in the carpal tunnel. The dominant symptoms of pain and paraesthesiae are almost invariably referred to the cutaneous territory of the median nerve, and, though there may be no objective neurological deficit, when such exists it provides additional support for this localization of the lesion. The centripetal radiation of pain is an observed but unexplained fact. When electromyography and ischaemic sensory tests are carried out there is additional support for the contention, and to this must be added the operative findings and the symptomatic relief which follows surgical treatment. For these reasons we cannot agree with Ford (1956) that acroparaesthesiae results from the accumulation of metabolites in fatigued muscle, nor yet with Walshe (1945, 1951) that the condition is determined by structural or functional abnormalities of the thoracic inlet. Indeed, it is notable that the one patient who had bilateral cervical ribs obtained no benefit from their removal, whilst she became free from all symptoms after surgical division of the transverse carpal ligaments.

Garland (1955) has remarked on the predominance of women in all series of median nerve palsy whilst in other peripheral nerve palsies the greater number are men. This may be related to the smaller size of the carpal tunnel in women and to occupational factors. Brain *et al.* (1947)

have shown that pressure within the carpal tunnel is greatest when the wrist is extended, and this posture is especially associated with such household tasks as polishing, knitting, and scrubbing; indeed, it is these activities that provoke symptoms in patients with acroparaesthesiae. The occasional onset or relapse in pregnancy may be aggravated by narrowing of the carpal tunnel by fluid retention. The mechanical nature of the malady is emphasized further by the frequency with which the dominant hand is first affected, and when this does not obtain other factors such as osteoarthropathy of the wrist, trauma, or the nature of employment may be incriminated. These contributory factors are especially common when men are affected.

When surgery is employed it is most inadvisable to adopt the straight longitudinal incision along the midline of the volar aspect of the forearm. This crosses the joint flexure at right angles and pays no attention to the tension lines in skin. Nearly all the patients are women, and it is a surgical solecism to inflict a scar which will in all likelihood produce a cheloid. It is also a cosmetic impropriety to place such a scar in a position which is readily visible. A skin incision has been described which gives an adequate exposure, leaves a featureless scar, and does not in any way interfere with the function of the wrist or hand.

Most often there are no abnormal findings at operation, but in about a third of the cases the median nerve is swollen for a few inches above the transverse carpal ligament and, since this is immediately reversible, is probably determined by oedema. Less frequently there is evidence of direct compression of the median nerve by the transverse carpal ligament, and it is likely that the flattening of the nerve is caused by the duration and extent of the compression.

An analysis of patients treated by surgery shows that there is invariable immediate and dramatic relief of symptoms and that this is maintained; there is then a diminution or disappearance of any pre-existent neurological deficit as judged by clinical examination and the results of ischaemic sensory test. All returned to normal activity. Minor disadvantages include pain and swelling of the volar aspect of the wrist and aching pain provoked by pressure on the scar or by cold. The former does not last for more than a few weeks, but, because it is at times troublesome, it is best to avoid operating on both sides for bilateral symptoms at the same time unless they are very severe. Two separate operations were done on a number of patients and, after the first, symptoms disappeared on the treated side alone. All of these returned of their own accord for the second operation and this seems sufficient answer to those who maintain that the rest enforced by surgery is responsible for the cure.

It must be admitted that rest by itself often gives relief from all symptoms and leads to the disappearance of a pre-existent neurological deficit. However, none who were treated in this way were able to lead unrestricted lives, and some, despite prolonged inactivity, obtained no benefit and developed a progressive objective disability. In addition, ischaemic sensory tests showed a persistent abnormality in the majority. We consider, therefore, that surgery provides the optimum treatment unless the history is short, the symptoms relatively mild, or the patient is able to afford the luxury of prolonged unemployment.

Summary

The clinical features of 53 cases of acroparaesthesiae are described; dominant symptoms consisting of pain and paraesthesiae are almost invariably referred to the territory of the median nerve in the hand, and in the majority there is a slight objective deficit compatible with a median nerve lesion at the wrist.

Electromyography and ischaemic sensory tests lend support for localization of the lesion at the wrist.

The great predominance of female patients may be explained by the smaller size of the carpal tunnel in

women and to occupational factors. In men the onset may be determined by osteoarthropathy of the wrist, trauma, or a change of employment.

Division of the transverse carpal ligament gives immediate and lasting relief of symptoms and improvement of any neurological deficit that may have existed.

In about one-third of the patients there is direct or indirect evidence of compression of the median nerve in the carpal tunnel at operation.

Rest may alone relieve symptoms, but relapse occurs in the majority of patients when they resume a normal life. Some achieve no improvement and develop a progressive neurological deficit.

SICKLE-CELL-THALASSAEMIA DISEASE IN SOUTH TURKEY

BY

M. AKSOY, M.D.

Physician, Mersin State Hospital, Turkey

AND

H. LEHMANN, M.D., Ph.D., F.R.I.C.

Senior Lecturer in Chemical Pathology, St. Bartholomew's Hospital, London

When both the genes controlling the formation of normal adult haemoglobin (haemoglobin A) are replaced by alleles responsible for the sickle-cell haemoglobin variant (haemoglobin S), sickle-cell anaemia (S.C.A.) results. If only one A gene is thus replaced, normally no disability results, the AS heterozygote being a symptomless carrier of the sickle-cell trait (S.C.T.) (Neel, 1947, 1949; Beet, 1949; Pauling *et al.*, 1949). The thalassaemia gene is not an allelomorph of those responsible for the formation of haemoglobin A and its variants, but its effect is a suppression of haemoglobin A formation. If an AA homozygote inherits two thalassaemia genes a severe anaemia results—thalassaemia major. If he is heterozygous for the thalassaemia gene the condition is very much less severe or even symptomless—thalassaemia minor (Gatto, 1942; Wintrobe, 1942; Dameshek, 1943; Valentine and Neel, 1944; Chini, 1946; Silvestroni and Bianco, 1946a).

If, however, an AS heterozygote inherits a single thalassaemia gene, suppression of haemoglobin A formation with a subsequent preponderance of haemoglobin S may produce a state which resembles S.C.A. This modified S.C.A. is called sickle-cell-thalassaemia disease (S.C.Th.D.) or microdrepanocytic disease (Silvestroni and Bianco, 1946b, 1952, 1955; Powell *et al.*, 1950; Gatto and Purrazzella, 1951; Wasserman *et al.*, 1952; Sturgeon *et al.*, 1952; Neel *et al.*, 1953; Humble *et al.*, 1954; Singer *et al.*, 1955; Edington and Lehmann, 1955).

MARCH 30, 1957

The cells are small and hypochromic, and there are many target cells among them. The resistance towards lysis by hypotonic saline solution is increased (Caminopetros, 1938). Haemoglobin A may be virtually absent, or may be so decreased that it is difficult to establish its presence by the usual electrophoretic techniques.

Foetal haemoglobin (haemoglobin F) is usually present in S.C.Th.D., whereas it is not found in S.C.T. This haemoglobin is under a genetical control which is independent from that of haemoglobin A and its variants, and also from that of thalassaemia. The persistence of haemoglobin F at high concentration beyond the age of 4 months—at which time it has normally disappeared—is a common feature of thalassaemia major, and F is also often found—though at relatively low concentration—in thalassaemia minor (Liquori, 1951; Rich, 1952). When haemoglobin F is demonstrated in an AS heterozygote it usually indicates the inheritance of a thalassaemia gene, and the observation helps towards establishing the diagnosis of S.C.Th.D. Target cells at considerable frequency can be an indication of the presence of the thalassaemia gene. Before they are accepted as such, other conditions associated with target cells must be excluded. The most important are other haemoglobinopathies and severe cirrhosis of the liver. In milder disorders of the liver they may be found occasionally but rarely occur in large numbers, and when they are found in patients with liver disease they coincide with a strikingly increased diameter of the red cells.

We record the occurrence of S.C.Th.D. among the Eti-Turks in Southern Turkey, and in addition report that we have found that the heterozygous possession of a sickling and a thalassaemia gene can express itself either as a severe anaemia closely resembling S.C.A. or as a mild anaemia, or, lastly, that it can fail to give rise to any symptoms. In this latter case it can be discovered accidentally in the course of a survey or when a family of a known S.C.Th.D. patient is studied.

One of us (Aksoy, 1955) found that there was a high sickling incidence in the Eti-Turks, a small Arabic-speaking population enclave near Mersin, in Southern Turkey. We found that in some instances a child suffering from S.C.A. had only one sickling parent. The investigation of such families led to the discovery of the thalassaemia gene among them, and resulted in an alteration of the diagnosis of S.C.A. to one of S.C.Th.D.

Methods

Haemoglobin was determined on a Hellige haemoglobinometer. Reticulocytes and platelets were estimated in a wet preparation, using Dameshek's platelet solution (see Wintrobe, 1951). Osmotic fragility was determined according to Daland and Worthley (see Ham, 1951). The sickle-cell test was performed by incubation of cells with sodium metabisulphite (Daland and Castle, 1948). Foetal haemoglobin was determined according to Singer *et al.* (1951). Target cells were accepted as a possible indication of the presence of the thalassaemia gene only when they were found at considerable frequency, and after the exclusion of other possible causes such as cirrhosis of the liver. Electrophoresis of the haemoglobin was performed on solution freed from stroma by shaking with toluene and subsequent centrifugation. (For details of electrophoretic technique see Lehmann and Smith, 1954.)

Case 1

A 40-year-old housewife, known to be anaemic for several years, was admitted to Mersin State Hospital because of

lassitude and gastric discomfort. Some months prior to admission she tired easily and suffered from moderate osteoarticular pains. She also complained of palpitation on exertion and of irregular fever.

Physical examination revealed a well-developed and well-nourished but pale woman—height 5 ft. 7 in. (170 cm.), weight 11 st. 11½ lb. (75 kg.). The sclerae were subicteric. The spleen was barely palpable, liver not enlarged. A systolic murmur was heard over the apex. Blood pressure was 125/85 mm. Hg. There was no adenopathy. X-ray examination of the skull showed moderate thickening of the diploe and mild trabecular striation on frontal and parietal bones. There were no abnormalities of long bones and hands. The sickling test was positive. The electrophoretic pattern of the haemoglobin was AS; haemoglobin F was absent. The haematological findings are summarized in Tables I and II. The direct and the indirect Coombs test were negative. Features suggesting the presence of a thalassaemia gene were the appearance of the red cells, target cells, and lowered osmotic fragility. A family study revealed thalassaemia minor in one sibling and in one daughter, the husband being normal. It was concluded that this was a mild case of S.C.Th.D.

Details of Family Study (see Fig. 1).—The daughter in whom thalassaemia minor was diagnosed was 17 years old:

Case 2

A 12-year-old boy came to the out-patient department of Mersin State Hospital because of lassitude, irregular fever, and malaise. He had a history of infective hepatitis. He developed normally until 2 years of age, when irregular fever, anaemia, and malaise appeared. Malaria was diagnosed, but treatment with quinine, mepacrine, liver extract, and iron gave no relief. Latterly complaints became more severe.

Physical examination revealed a normally developed well-nourished pale boy. The sclerae were subicteric; spleen not palpable; liver enlarged two fingerbreadths below costal margin. Striking frontal bossing was present. X-ray examination of skull showed considerable thickening of diploe and mild striation of frontal, parietal, and occipital bones; there was, however, no "hair-on-end" appearance and the outer table had not disappeared. Long bones showed coarse striation around elbow-joints. The sickling test was positive and the blood smear showed sickle cells. The electrophoretic pattern of the haemoglobin was AS; haemoglobin F was 1.3% (not significant). The haematological findings are summarized in Tables I and II. Features suggesting the presence of a thalassaemia gene were the appearance of the red cells as a whole, 18.2% target cells, and a lowered osmotic fragility. A family study revealed one other sibling with S.C.Th.D. (Case 3) and the presence of the thalassaemia gene in the father, both parents being S.C.T. carriers.

Case 3

A 10-year-old girl, sister of Case 2, was first seen in 1954 suffering from lassitude, irregular fever, malaise, and anaemia. She was treated for malaria. Physical examination revealed a normally developed well-nourished though pale girl. The sclerae were slightly subicteric; spleen three fingerbreadths and liver two fingerbreadths below costal margin. Mild frontal bossing was present. X-ray examination of skull showed moderate thickening of diploe and mild trabecular striation around elbow-joints. The sickling test was positive. The electrophoretic pattern of the haemoglobin was AS; haemoglobin F was 7.8%.

The haematological findings are summarized in Table I. Features suggesting the presence of a thalassaemia gene were the appearance of the red cells as a whole, 9.6% target cells, a lowered osmotic fragility, and the presence of haemoglobin F.

Details of Family Study of Cases 2 and 3 (see Fig. 1).—Both parents and one sibling were AS heterozygotes. All had less than 1% foetal haemoglobin. The appearance of the father's blood film suggested the possession of the thalassaemia gene (8.6% target cells), but there was no anaemia. The thymol turbidity and the gamma-globulin content of the serum were not raised; the pseudocholinesterase was within normal limits. It was concluded that the father was a symptomless heterozygote for the thalassaemia and the sickling gene. The ABO, rhesus, MNS, Lutheran, Kell, and Duffy blood groups of the parents and their three children were determined by Dr. A. E. Mourant and Miss E. W. Ikin at the M.R.C. Blood Group Reference Laboratory; there was no evidence of non-paternity.

Case 4

A 13-year-old girl was brought to the out-patient department of Mersin State Hospital because of palpitation, lassitude, and irregular fever. She had been ill from childhood and there had been bone pains with irregular fever now and then, but there had been no swelling of joints.

Physical examination revealed a normal stature and a somewhat mongoloid facies. The sclerae were subicteric, and there was pallor with a brown-yellow tint to the skin. There were no leg ulcers or adenopathy. The spleen was two fingerbreadths and the liver one fingerbreadth enlarged below the costal margin. Pulse rate was 180 a minute, regular. A systolic murmur was heard over apex and pulmonary artery area. The second pulmonary sound was accentuated. Blood pressure was 110/80 mm. Hg. There were no abnormalities over the lung. X-ray examination of the thorax showed mild left ventricular enlargement, and prominence of the pulmonary artery. E.C.G. showed sinus tachycardia, P-mitrale, left ventricular strain, and heart in vertical position. Frontal bossing was present. X-ray films of the skull revealed thickening of the diploe, mild trabecular striation on parietal bone, and some osteoporosis of frontal bone. The sickle-cell test was positive, and the peripheral blood smear showed some sickled cells. The electrophoretic

pattern of the haemoglobin (Fig. 2) showed most of the haemoglobin to be in the S position (80% as determined by densitometry); there was, however, a "trailing" of haemoglobin extending forward to the haemoglobin A position with a slightly greater density towards the A position than in the intervening area. Foetal haemoglobin was 5.9%. The haematological findings are summarized in Table I.

In this case the differential diagnosis was between S.C.A. and S.C.Th.D., as all the features suggesting the presence of a thalassaemia gene could equally well be found in S.C.A.

Fig. 2.—Separation of haemoglobin variants by filter-paper electrophoresis. Father, AA. Mother, AS. Daughter (Case 4), sickle-cell-thalassaemia disease.

However, electrophoresis revealed that the amount of non-sickle-cell haemoglobin exceeded the 5.9% haemoglobin F found by chemical estimation, and this suggested the diagnosis of S.C.Th.D. A final proof was brought about by family study, which showed thalassaemia minor in the father (a non-sickler) and in one sibling.

Details of Family Study.—The father, a non-sickler, had thalassaemia minor; Hb, 13.1 g./100 ml.; R.B.C., 4,850,000 per c.mm.; 16.8% target cells; P.C.V. 44%; osmotic fragility, 0.4-0.2% NaCl. X-ray examination of skull showed mild thickening of frontal, parietal, and occipital bones, and striation on parietal bones. The mother was a symptomless sickle-cell-trait carrier. Several siblings had died, one sister at the age of 18 years from anaemia resembling in its features that of Case 4. Two siblings showed no abnormality, but one brother aged 15, a non-sickler, showed evidence of thalassaemia minor (7.8% target cells, osmotic fragility 0.4-0.2% NaCl, mild changes in skull and long bones revealed by x-ray examination).

Case 5

A 23-year-old man was admitted to Mersin State Hospital with dyspnoea, orthopnoea, cough, and abdominal discomfort. He was diagnosed some three years previously in one of the medical clinics of Istanbul University as having sickle-cell anaemia. All his life he had suffered from irregular fever, bone pains, joint swellings, anaemia, and lassitude. The osteoarticular pains were intolerable, and every antirheumatic treatment was ineffective. Three years ago he had leg ulcers which lasted for about one year. Five months before admission his liver became noticeably enlarged and he had dyspnoea. He improved after rest. One week prior to admission he had three to four days' fever, and the yellow discoloration of his sclerae increased; there was abdominal discomfort and cough.

Physical examination revealed an underdeveloped boy rather than man—height 5 ft. 1 in. (154 cm.), weight 7 st. 11 lb. (49.5 kg.)—with a somewhat mongoloid facies. He was pale and icteric. He was orthopnoeic and sat rigidly because of abdominal pain and distension. His temperature was 101.2° F. (38.4° C.). There was a mild inguinal adenopathy, and four scars of leg ulcers were noted. The area of cardiac dullness extended into the lung fields, the pulse rate was 84 a minute and regular, and a moderate friction rub was noted at the left sternal border. Blood pressure was 105/55

mm. Hg. The epigastrium was distended. The spleen was enlarged to two fingerbreadths below the costal margin, and the liver was tender and extended to the iliac crest. X-ray examination of the thorax disclosed an enormous enlargement of the heart; there was no characteristic shape. On screening no pulsations were seen over the heart. X-ray films of the skull showed thickening of the frontal, parietal, and occipital bones and mild striation on the parietal bone. The long bones showed coarse striation around the elbow-joint and the femur; the elbow joint had a "honeycombed" appearance. There was osteoporosis of the pelvis, femur, and tibia.

The sickle-cell test was positive, and the peripheral blood film showed some sickle cells. The electrophoretic pattern of the haemoglobin was AS; the foetal haemoglobin was 1.9% (just significant). The haematological findings are summarized in Tables I and II. Features suggesting the presence of a thalassaemia gene were the appearance of the red cells as a whole, 27.8% target cells, traces of foetal haemoglobin, and a lowered osmotic fragility.

Treatment with ouabain, salicylates, antibiotics, mercurial diuretics, low-sodium diet, and oxygen therapy resulted in prompt improvement. The pyrexia subsided and on the fifth day the friction rub was no longer heard. A mild systolic murmur became audible, and the heart silhouette measured radiographically showed a 3.5 cm. diminution in size. Salicylates and antibiotics were discontinued after two weeks. Treatment with digitalis and mercurial diuretics was continued, and the size of the liver diminished to about four fingerbreadths below the costal margin.

Details of Family Study (see Fig. 1).—As in Cases 2 and 3, both parents were AS heterozygotes. Two of the three siblings investigated were also AS heterozygotes. The father, aged 50, showed no other abnormalities in his blood. The mother, aged 40, however, had numerous target cells (10.5%) in her blood smear. Liver-function tests were not carried out. The serum thymol turbidity was not raised, and there was no obvious evidence of liver disease or of any other condition except thalassaemia which could be responsible for this high incidence of target cells. It was concluded that she was a symptomless heterozygote for both the sickling and the thalassaemia gene.

Discussion

The community of the Eti-Turks is small, and it is remarkable that we should have seen no fewer than five cases of S.C.Th.D. over a period of six months. The Eti-Turks resemble in this respect other communities living around the Mediterranean shore. It is well known that thalassaemia minor by itself may be completely symptomless. This variable effect of one thalassaemia gene is well reflected in the varying severity of the S.C.Th.D. seen in our series. Contrary to the findings of the other writers, none of our five patients had a lowered M.C.V., and the M.C.H.C. was significantly lowered in only two. Nucleated red cells were always present in four, and three showed sickled cells in the peripheral smear. Foetal haemoglobin was absent in two, present in traces in one, and significantly raised in two. All had a lowered osmotic fragility of their red cells—a feature both of S.C.A. and of thalassaemia major—but the conspicuous changes seen in the x-ray films of the skeleton were similar to those seen in thalassaemia major rather than to the milder ones of S.C.A.

In addition to the five patients, two individuals were discovered who were heterozygous for the thalassaemia and sickling genes but did not seem to suffer from S.C.Th.D. This suggests that the same thalassaemia gene does not suppress the haemoglobin A formation equally in different members of a family, and that its penetrance may possibly depend on the particular A gene an individual carries.

Summary

Five cases of sickle-cell-thalassaemia disease were seen in four Eti-Turk families. In addition two individuals were discovered who were heterozygous for the thalassa-

Fig. 1.—Family trees of five patients with sickle-cell-thalassaemia disease.

aemia and sickling genes but were not anaemic. The incidence of the haemoglobinopathy among the Eti-Turks is equalled only in Sicily.

A STUDY OF THE SURVIVAL RATE OF CASES OF SICKLE-CELL ANAEMIA

BY

G. F. JACOB, M.D., D.T.M.&H.

Pathologist, Uganda Medical Service

It is now generally accepted that the phenomenon of the sickling of red cells at reduced oxygen tensions is due to the presence of greater or lesser amounts of an abnormal haemoglobin within the cells. The production of this haemoglobin is controlled by a gene which is allelic to the gene controlling normal haemoglobin production. The heterozygous inheritance of this sickle-cell gene produces the harmless sickle-cell trait, while the homozygote is manifest as sickle-cell anaemia. This anaemia is characterized by haemolysis with intermittent crises and is usually fatal in childhood. This death in childhood of the homozygotes must remove abnormal genes from the population, and the immediate question arises of how, in the face of this recurrent gene loss, the gene frequency can be maintained at the high levels at which it is found in many African tribes.

The answer seems to lie in the interaction of three main factors. Firstly, recurrent mutations must play some part, though it is highly improbable that they could provide the sole replacement of all the genes lost by childhood deaths. Secondly, it is now well established that the heterozygote sickler enjoys some advantage over the normal in respect of falciparum malaria, though the magnitude and exact mechanism of this effect are not yet clear. Thirdly, there is the fact that while most subjects with sickle-cell anaemia die in childhood, some few do survive to adult life and contribute abnormal genes to the next generation. This paper presents some evidence on this third factor as found in a single African tribe in Uganda.

The older literature on the natural history of sickle-cell anaemia has become largely invalidated by the recent discovery of other genetically controlled abnormal haemoglobins and by the description of microdrepanocytic disease. Both this latter disease and the anaemia often resulting from the double inheritance of two abnormal haemoglobins may produce a clinical picture closely similar to sickle-cell anaemia. In East Africa, however, other abnormal haemoglobins have not been found among the African tribes (Jacob, 1955; Roberts and Lehmann, 1955) and thalassaemia has never been detected. The same situation appears to obtain in the Belgian Congo. A high degree of validity can therefore be attached both to clinical reports in children and to simple electrophoretic surveys in adults directed towards defining the survival rate of cases of sickle-cell anaemia in these two areas. Nevertheless, published work has produced somewhat variable estimates of survival rates.

In Kenya, Allison (1954) examined 70 adult sicklers of the Luo tribe by paper electrophoresis and found two cases with the pattern of sickle-cell anaemia. He calculated that these two represented a 35% survival rate to adult life. He later suggested that the survival rate in Africa was more likely to be in the region of 20% on the basis of figures collected from the Musoma tribe of Tanganyika (Allison, 1956). In a survey of the Baamba tribe in Uganda, Lehmann and Raper (1956) found no case showing the electrophoretic pattern of sickle-cell anaemia in a random sample of 478 adults. They conclude "that the survival of sickle-cell homozygotes plays no significant part in the maintenance of the high sickling rate in the Baamba." Workers in the Belgian Congo have expressed the same opinion on the basis of clinical observations in children. The Lambotte-Legrands (1955) state that the great majority of patients die in childhood, and Vandepitte (1955) estimates that only about 1% survive to adult life. It was therefore decided to undertake an electrophoretic survey of adults of the Baganda tribe in an attempt to obtain a more exact figure for the survival rate to reproductive age.

Method

Blood samples were obtained from specimens which had been sent in to the laboratory for routine Kahn tests from the antenatal clinic and from the male V.D. clinic of Mulago Hospital. A few samples were also obtained from mothers bringing their children to the paediatric clinics. Specimens from the Baganda tribe only were examined. In all cases a sickling test was done by the *E. coli* method, and all which were positive were subject to paper electrophoresis by the method already described (Jacob, 1955). An attempt was made to see all cases showing the pattern of sickle-cell anaemia at their next clinic attendance.

Results

Altogether 3,362 specimens were examined, of which 545 were from sicklers and were subjected to electrophoresis. The source of the specimens can be seen from the Table. Cases 291, 316, and 543 of this series of 545 sicklers showed the pattern of sickle-cell anaemia. These samples were all from the antenatal clinic, and further details are as follows.

Sources of Blood Specimens

Source of Blood	Non-sicklers	Sicklers	% Sickling
Antenatal clinic	2,090	396	15.9
Male V.D.	651	126	16.2
Mothers in paediatric clinic ..	76	23	23.2
Total	2,817	545	16.2

Case Reports

Case 291.—A woman aged 18, who had had one abortion and was three months pregnant when seen, gave a history of recurrent fevers throughout childhood which had gradually decreased in severity. The attacks occurred about once a month, and she stated that during them she ached all over, her fingers and toes often swelled, and her eyes often became yellow. She never felt really well between the attacks. It was not possible to obtain a proper family history from her. On examination there was no bossing of the skull, and the spleen was palpable. Her conjunctivae were slightly yellow and the mucous membranes a little pale. There were no joint swellings. The haemoglobin was 8.1 g. per 100 ml. (M.R.C. grey-wedge photometer); red blood cells, 3,400,000 per c.mm.; P.C.V., 32%; white blood cells, 9,400 per c.mm. Stained blood film: the differential white count was within normal limits and the polymorphs showed no shift to the left; the red cells showed some hypochromia and moderate polychromasia; occasional irreversible sickle cells were seen. There were no normoblasts and no malaria parasites. The bilirubin was 2 mg. per 100 ml. Alkali-resistant haemoglobin (Singer *et al.*, 1951), 13.0%. The solubility of haemoglobin was 0.79 g. per litre of 2.24 phosphate buffer (Itano, 1953).

Case 316.—This patient, aged 28, was 34 weeks advanced with her first pregnancy when seen. She did not return to the clinic for the result of her Kahn test, and only clotted blood was available. A film made from the clotted blood showed considerable polychromasia. The bilirubin was 2.8 mg. per 100 ml.; alkali-resistant haemoglobin, 12.0%.

Case 543.—A woman aged 30, who was 28 weeks advanced with her first pregnancy when seen, gave a vague history, but it appeared that she had had recurrent fevers throughout childhood, occurring about once every two months, and accompanied by pains in the limbs and by yellow eyes. She was unable to give any family history. On examination her skull showed slight bossing, her mucous membranes were pale, and the conjunctivae slightly yellow. There were no joint swellings and the spleen was palpable. The haemoglobin was 6.5 g. per 100 ml.; red blood cells, 2,200,000; P.C.V., 24%; white blood cells, 4,300; normoblasts, 15,600 per c.mm. A blood film showed large numbers of normoblasts in varying stages of maturity. There was very marked polychromasia, and irreversible sickle cells were present. The polymorphs showed a shift to the left and occasional myelocytes were seen. The bilirubin was 2.3 mg. per 100 ml.; alkali-resistant haemoglobin, 8.0%. The urine had a considerable excess of urobilinogen. This woman had a stillbirth at home at 36 weeks. She was subsequently admitted to Mulago Hospital with peritonitis. She refused to allow any further blood examinations, and on her death, a few days later, her relatives refused permission for a post-mortem examination.

Discussion

All three women showed the pattern of sickle-cell anaemia on paper electrophoresis and had evidence of a haemolytic process. It could be maintained, however, that they were not true cases of sickle-cell anaemia—in other words, homozygotes for the sickle-cell gene—since it was not possible to prove that they had inherited a single sickle-cell gene from each parent. This proof is theoretically necessary, as both microdrepanocytic disease and sickle-cell haemoglobin D disease produce an electrophoretic haemoglobin pattern on paper indistinguishable from the true case of sickle-cell anaemia. Nevertheless, as in other published reports from East Africa, a high degree of validity can be attached to the diagnosis in the absence of other abnormal haemoglobins and of thalassaemia. Collateral evidence in favour of accepting these as true cases is obtained from the Mulago Hospital records, which show that other young adults with sickle-cell anaemia have been seen in whom the diagnosis has been firmly established by the finding of sickling in both parents.

In order to determine what proportion of the expected number these three cases represent it is assumed that the sickling rate is static. It is further assumed that a system of random mating occurs. It can then be calculated from the sickling rate of 16.2% that this population at birth should have included 22 cases of sickle-cell anaemia. Since only three of these cases were seen in adult life it can be presumed that approximately 86% have died in childhood.

This figure of 14% survival rate lies between the estimates made by Allison (1956), on the one hand, and by Lehmann and Raper (1956) and the workers in the Belgian Congo on the other. The difference might be explained on the basis of the smaller samples of Allison and of Lehmann and Raper; and the Congo workers, relying on clinical diagnosis, might have missed just those mild cases which might be expected to survive to adult life. It seems possible, however, that the different estimates represent a true variation in survival rate. A subject with sickle-cell anaemia may die of the disease *per se* in a crisis, but he may die from many other diseases, such as pneumonia and typhoid, to which he is likely to be less resistant owing to persistent anaemia. The prevalence of these other diseases are therefore likely to affect the survival rate in any one area. The Bwamba forest, in which Lehmann and Raper worked, is certainly more unhealthy than the conditions under which the Baganda live in and around Kampala, and, though accurate vital statistics for these areas are not available, it is certainly clear that the general childhood death rate is by far the higher in the Bwamba forest.

The fact that the heterozygote (sickle-cell trait) is in some degree protected from falciparum malaria has already been referred to. Allison (1956) has stated: "It will be clear that the main factor determining the frequency of the gene in any population is environmental—that is, mortality from falciparum malaria." If the survival rate of the homozygote is truly variable in different areas, and if this variability is due to the relative prevalence of other diseases, then malaria is only one of the many environmental factors concerned in the maintenance of the sickle-cell gene. A study of the maintenance of the sickle-cell gene in any area must include both a study of the childhood mortality from malaria and of the survival rate of the homozygote to reproductive life; only general qualitative inferences may be drawn from such a study, and quantitative inferences are likely to be invalid.

Summary

A study of 3,362 adults of the Baganda tribe has been made. Paper electrophoresis of the haemoglobin solutions revealed three cases of sickle-cell anaemia.

The sickling rate of the whole series was 16.2%, and it is calculated that these three cases of sickle-cell anaemia represent a 14% survival to adult life.

It is suggested that the survival rates of subjects with sickle-cell anaemia may vary in different parts of Africa.

The Central Council for Health Education has produced a pegboard triptych screen display unit for use by local authority health departments. Printed displays in colour are available, with supporting leaflets and posters, for making a compact exhibition of a size to fit an ordinary table. The council hopes also to produce a series of "Make It Yourself" displays on various topics for the triptych screens. Further details and prices will be provided on application to the medical director, Central Council for Health Education, Tavistock House, Tavistock Square, London, W.C.1.

CANCER OF PHARYNX TREATED BY SURGERY

BY

RONALD W. RAVEN, O.B.E., T.D., F.R.C.S.
Surgeon, Westminster (Gordon) Hospital; Surgeon, the
Royal Marsden Hospital, London

An assessment of the results obtained in the treatment of patients with cancer by various methods should be made at intervals to determine the benefit the patients derive and to evolve the most satisfactory techniques with our present knowledge of the disease. It is an impossible task, with the available treatments, to save all, but many are enabled to live on for many years with freedom from the disease. Some are treated so that they can live with the disease in comfort for variable periods, and this amelioration is an important object of our work. We must endeavour not to leave a patient any worse off after treatment than he was before it was given. When the results of surgical treatment for cancer are assessed an answer should be sought to these questions: Are distressing symptoms relieved? Are complications caused by the disease, which may be mortal, avoided? What is the length and quality of the patient's life after the operation?

The object of this paper is to present the late results of the surgical treatment of 24 patients with carcinoma of the pharynx who were operated on during 1948 to 1952 and followed up in October, 1956. The interval that had elapsed after operation is adequate for an assessment of results.

The operative techniques used in the treatment of these patients and the earlier results obtained were described in previous papers (Raven, 1952, 1953, 1954).

Carcinoma of Oropharynx

A man aged 62 had an ulcerating carcinoma involving the tonsils, faucial pillars, soft palate, and the base of the left side of the tongue. The left upper deep cervical lymph nodes were enlarged and hard. Operation: partial palato-glosso-pharyngectomy and radical neck lymphatic dissection were performed on July 22, 1949. Histological examination showed a squamous-cell carcinoma of the oropharynx with metastases in cervical lymph nodes. Follow-up, October, 1956: patient has had no recurrence; swallows well; and works regularly (Fig. 1). Survival period, seven years three months.

FIG. 1.—Photograph of patient alive seven years three months after left partial palato-glosso-pharyngectomy and radical dissection of neck lymph nodes for extensive carcinoma of oropharynx and cervical lymph-node metastases. No recurrence.

Carcinoma of Hypopharynx

Case 1.—Woman aged 67 with a carcinoma of the hypopharynx for which a gastrostomy had been performed elsewhere. Operation: laryngo-oesophago-pharyngectomy in two stages. First stage performed on March 28, 1949;

second stage on July 5, 1949. Description of carcinoma: the carcinoma fills the hypopharynx from the cervical oesophagus to the arytenoid cartilages. Histology: a well differentiated squamous-cell carcinoma which had infiltrated widely, including the capsule of the thyroid gland; no lymph-node metastases. Follow-up, October, 1956: patient has had no recurrence and swallows satisfactorily. Survival period, seven years, seven months.

Case 2.—A man aged 67 with a carcinoma of the hypopharynx which had been treated with irradiation elsewhere. Operation: laryngo-pharyngectomy in one stage, performed on October 17, 1950. On December 3, 1951, excision of right cervical lymph nodes. Description of carcinoma: a deep malignant ulcer in the right pyriform fossa. Histology: a squamous-cell carcinoma; metastases in cervical lymph node. In June, 1954, he developed a second primary carcinoma in the posterior third of the tongue which was treated by radiotherapy and diathermy. Follow-up: died May 5, 1956, from carcinoma of the tongue. Survival period, five years seven months.

Case 3.—A man aged 64 with a carcinoma in the hypopharynx which had been treated with irradiation elsewhere. Operation: laryngo-pharyngectomy in multiple stages; acromio-pectoral tubed pedicle grafts were used for the reconstruction of the hypopharynx; first stage performed on December 13, 1950, and the final reconstruction operation on September 10, 1952. Description of carcinoma: in the left pyriform fossa is a malignant ulcer 3.8 by 1.3 cm. whose medial margin reaches the aryepiglottic fold; a nodule of growth 0.7 by 0.4 by 0.2 cm. projects on the posterior surface of the epiglottis at the level of the centre of the ulcer. At the posterior margin of this nodule is a small perforation which communicates with the base of the ulcer in the pyriform fossa. There is a tumour 1 cm. diameter invading the posterior margin of the left sternomastoid muscle. Histology: a squamous-cell carcinoma; tumour in neck—active, keratinizing squamous-cell carcinoma infiltrating dense fibrous tissue and fibrosed muscle. Follow-up, October, 1956: patient has had no recurrence and swallows satisfactorily. Survival period, five years ten months.

Case 4.—A woman aged 61 with a carcinoma in the hypopharynx. Operation: laryngo-oesophago-pharyngectomy in two stages. First stage performed on January 31, 1951, second stage on March 7, 1951. Description of carcinoma: in the anterior wall of the hypopharynx is a malignant ulcer extending from the cervical oesophagus to just below the arytenoids; it invades the oesophago-tracheal septum and bulges into the trachea at the level of the first three rings. Histology: a keratinizing squamous-cell carcinoma; no metastases in the regional lymph nodes. Follow-up, October, 1956: patient has had no recurrence and swallows satisfactorily (Fig. 2). Survival period, five years nine months.

Case 5.—A man aged 62 with a carcinoma in the hypopharynx. On August 24, 1949, an emergency tracheotomy was performed elsewhere. In October, 1949, he was given teloradium therapy, dose 6,500 r in 46 days. The disease was not controlled. Operation: laryngo-oesophago-pharyngectomy in

FIG. 2.—Photograph of patient (Case 4) alive five years nine months after laryngo-oesophago-pharyngectomy for carcinoma of hypopharynx. No recurrence.

multiple stages; acromio-pectoral tubed pedicle grafts were used for the reconstruction of the hypopharynx. First stage performed on January 24, 1951; the final reconstruction operation on May 21, 1952. The severe degeneration of the skin of the neck with infection and dermatitis which also affected the anterior chest wall before surgical treatment began, necessitated long intervals between the operations. Description of the carcinoma: a malignant ulcer 3.5 by 2.5 cm. involves the right pyriform fossa and passes on to the posterior pharyngeal wall crossing the midline; it infiltrates into the larynx, forming a malignant ulcer 1 by 0.5 cm. between the true and false vocal cords. Histology: an anaplastic squamous-cell carcinoma; metastases in the cervical lymph nodes. Follow-up, October, 1956: patient has had no recurrence, swallows satisfactorily, and works regularly. Survival period, five years nine months.

Case 6.—A woman aged 60 with a carcinoma in the hypopharynx. Operation: laryngo-oesophago-pharyngectomy in two stages. First stage performed on June 27, 1952, second stage on September 16, 1952. Description of carcinoma: this extends from the arytenoids downwards for 7.2 cm. and encircles the wall of the hypopharynx. It penetrates the posterior wall of the trachea, involving an area 2.2 by 1.1 cm. Histology: a well-differentiated squamous-cell carcinoma; metastases present in the cervical lymph nodes. Follow-up, October 1956: patient has had no recurrence; swallows satisfactorily. Survival period, four years four months.

Case 7.—A woman aged 64 with a carcinoma in the hypopharynx. Operation: laryngo-oesophago-pharyngectomy in two stages. First stage performed on September 30, 1952; second stage on November 25, 1952. Description of carcinoma: an ulcerating tumour 6 by 5 cm. in the hypopharynx, infiltrating as high as the epiglottis. Histology: an anaplastic squamous-cell carcinoma; no metastases in the regional lymph nodes. Follow-up, October, 1956: patient has had no recurrence; swallows satisfactorily. Survival period, four years one month.

Discussion

Carcinoma of Oropharynx—A small number of patients have been treated by partial pharyngectomy and its modifications—partial palato-pharyngectomy, partial glosso-pharyngectomy, and partial palato-glosso-pharyngectomy. More time must elapse before the results can be assessed. The case reported above, in which the patient was well and at work seven years three months later, is an encouragement, for he had an extensive oropharyngeal carcinoma with metastases in the cervical lymph nodes—an unsatisfactory lesion for radiotherapy. Surgical treatment is worthy of consideration for a carcinoma in this site, especially when other methods have not controlled it or cannot offer any lasting benefit, as in this case. Patients who are in this situation have everything to lose and their last months are full of suffering. Before an operation is undertaken it must be established that the carcinoma can be removed radically and a satisfactory pharyngeal reconstruction performed.

Carcinoma of the Hypopharynx—There are 23 patients in the series who were treated surgically three or more years ago. The survival periods are computed from the date of the excisional operation for the carcinoma. Thirteen patients died with cancer from 4 to 33 months later; three died from causes other than cancer; and seven were alive for five years or more; the longest survivor has so far lived seven years seven months.

Clinical Condition of the Patients before Operation—The results should be judged against this dark background. The patients suffered severely from dyspnoea, stridor, and dysphagia; one had a palliative gastrostomy and another a palliative tracheotomy. Some had been pronounced untreatable and were awaiting death with the help of sedatives. Others had received radiotherapy, but the disease was not controlled and they presented difficult problems to solve concerning degenerative and inflamed tissues in the

neck. The carcinomas affected extensive areas of the hypopharynx and often infiltrated the cervical oesophagus, larynx, trachea, and thyroid gland. In 50% of the patients metastases were present in the cervical lymph nodes. The only encouraging feature was the splendid spirit of the patients, their will to fight for life and desire that something should be done to enable them to achieve it. This attitude by patients makes it hard to decide not to carry out a radical operation for certain reasons.

Clinical Condition of Patients After Operation—These surgical procedures do not cause mutilation; the patients have a normal neck except for healed incisions and a tracheostomy. The latter must be a pleasure for those who have struggled with stridor and dyspnoea. They can dress normally and swallow everything, and I have not had a case of fibrous stricture formation at the junction of the skin pharynx and cervical oesophagus or elsewhere. They are taught tracheostomy management, and wear a perforated metal shield over it by day and a tube by night. Speech therapy is given, but they do not speak so well as following laryngectomy, although many make themselves understood. Respiratory infections are not more frequent than in others. They are able to work, live almost normal lives, and are amongst the happiest patients I know, for their present comfort is contrasted with the intense suffering of the past. In addition to giving the patients a chance of permanent benefit, radical surgery affords immediate relief from stridor, dyspnoea, and dysphagia.

Some Facts About the Operation—Every patient is studied as an individual problem, for surgical techniques are available for each condition encountered; these include one-, two-, and multiple-stage operations. The length of stay in hospital varies from three weeks for the one-stage operation to eight or more weeks for the two-stage operation. The plastic reconstruction operations when surgery follows radiotherapy take a long time to complete, for lengthy intervals are necessary between the stages, as seen in the case records cited. When the two-stage operation is done the patient is left with a pharyngostomy and an oesophagostomy after the first operation and is fed through a tube passed through the oesophagostomy into the lower end of the oesophagus. I usually allow an interval of about eight weeks to elapse between the two stages for wound consolidation to occur. Occupational therapy helps the patients to pass the time in hospital between the stages in an interesting way. The risk of these operations is small; there was no operative mortality in this series of patients.

Summary

The late results of the surgical treatment of 24 patients with carcinoma of the pharynx who were operated on during 1948 to 1952 are presented and details are given of eight patients who underwent a radical surgical operation with survival periods of four years one month to seven years seven months. Their clinical condition before and after operation is described and some facts are given regarding the operations. This and subsequent experience in a large series of cases shows there is a place for radical surgery in the treatment of carcinoma of the pharynx, and in some cases when radiotherapy has failed to control the disease, for, in addition to giving patients the chance of permanent benefit, distressing symptoms are relieved at once.

In the first nine months of last year there was an increase of 19% in the number of both men and women student-nurses in mental hospitals; in mental deficiency hospitals the increase was 22% for men students and 24% for women. These figures were given last week at Chelmsford by Mr. J. VAUGHAN-MORGAN, Parliamentary Secretary to the Ministry of Health.

ACUTE AMPHETAMINE POISONING AN ACCOUNT OF 3 CASES

BY

RAYMOND GREENWOOD, M.B., M.R.C.P.

Senior Medical Registrar

AND

R. S. PEACHEY, M.B., B.S., B.Sc.

Casualty Officer

King's College Hospital, London

Amphetamine ("benzedrine") and its derivatives, amphetamine sulphate, dexamphetamine sulphate ("dexedrine"), methylamphetamine, and methylamphetamine hydrochloride ("methedrine") are widely prescribed for a number of ills, and their stimulating effect on the central nervous system is becoming well known to the general public. Although the sale of oral and parenteral preparations is controlled under schedule 4, inhalers containing 325 and 330 mg. of amphetamine base or 250 mg. of methylamphetamine can still be bought without restriction for unauthorized use.* In spite of this ready supply only eight cases of acute poisoning with amphetamine or its compounds have been described in this country. All these drugs appear to have similar effects when taken in excess, and the term "amphetamine poisoning" in this account refers to the clinical picture which can be produced by overdosage with any of the group.

The purpose of this paper is to report three further examples of acute amphetamine poisoning. The case reports illustrate the difficulties which may arise when such patients are admitted to the wards of general hospitals, the necessity for adequate sedation in treatment, and the danger of excessive or improper use of a "benzedrine inhaler."

Case 1

A man of 23 attended the casualty department at 7 a.m. on June 7, 1956, complaining of a cramp-like pain over the praecordium, a tingling sensation over the face, and difficulty in breathing. The symptoms had been present for five hours. He denied having taken any drugs or alcohol. His wife stated that on the previous evening her husband complained of nasal obstruction and a frontal headache. At 11 p.m. he began to use a benzedrine inhaler bought the previous day. This seemed ineffective, and so he warmed the inhaler, at first before the fire and later by partial immersion in hot water. He inhaled constantly until 2 a.m., when he became dizzy and complained of inability to breathe and, soon afterwards, of nausea. Benzedrine inhalations were continued until 4.30 a.m. His symptoms persisted and about 6 a.m. his legs became weak, he had precordial pain, his face began to tingle, and he began to sweat profusely. Now very anxious, he called a neighbour and was brought to hospital.

On examination he was anxious and pale, and was sweating profusely. Breathing was shallow and rapid (40 a minute). His pupils were dilated but reacted to light and accommodation. His pulse was regular, 140 a minute, and his B.P. 200/100 mm. Hg. No other abnormal physical signs were present. Blood glucose on admission was 125 mg. per 100 ml. An electrocardiogram showed regular rhythm with auricular premature beats. The pulse was taken every 15 minutes for the next two and a half hours and varied

*Since this paper was written it is understood that all manufacturers in this country have ceased to make inhalers containing amphetamine derivatives.

between 146 and 100. He was given 3 gr. (0.2 g.) of soluble phenobarbitone intramuscularly and admitted to the ward. On further questioning he gave a clear account of previous illnesses but was confused regarding the day and date. He remained quiet and co-operative during the day. In the ward the pulse rate slowly fell from 120 to 90 and the blood pressure from 170/100 to 130/80 mm. Hg. Breathlessness and other symptoms gradually disappeared.

He was visited by his wife at 7.30 p.m., and at 8 p.m., after she had left, he suddenly developed tachypnoea 50 a minute and tachycardia 160 a minute. He sweated profusely and demanded oxygen. He then insisted he could hear his wife talking and accused the nursing staff of denying him permission to see her. He was given morphine, $\frac{1}{4}$ gr. (0.01 g.), subcutaneously and soluble phenobarbitone, 3 gr. (0.2 g.), intramuscularly. At 8.15 p.m. he demanded more oxygen and attempted to get out of the window. He was restrained with difficulty, but eventually jumped out of bed and for a time several nurses were needed to control him. Paraldehyde, 10 ml., was given intramuscularly and he eventually became quieter. At 1.30 a.m. a further 10 ml. of paraldehyde was given, he fell asleep, and the pulse and blood pressure again fell to normal levels.

Next day he could not remember his confusional episode. Dr. I. S. Kreeger, who then examined him, could find no evidence of psychiatric disturbance. He had been a paratrooper with a good Service record. He was happily married and there was no current stress. His wife recalled that her husband had once before used an inhaler for a cold the previous year; but then he had followed the printed instructions and inhaled only occasionally. After three days the patient was discharged, but later he suffered attacks of hyperventilation. These were becoming infrequent when he last attended the out-patient department four weeks later. The urine passed while he was in hospital was found to contain a total of 36 mg. of amphetamine base, which would correspond with an oral dose of 72-130 mg. of amphetamine (Connell, 1957). The benzedrine inhaler, analysed after the patient's admission to hospital, contained only 60 mg. instead of its original 325 mg.

Case 2

A woman of 32 was admitted to hospital at 8 p.m. on July 21, 1956, having swallowed 50 tablets of dexamphetamine sulphate (200 mg.) 12 hours previously. She denied suicidal intent and stated that she had taken the tablets for slimming, but later she admitted to being very depressed by the proposed adoption of her illegitimate son, 2 months old. The father of the child, of whom the patient was very fond, had suggested the adoption but had refused to marry her.

On admission she was aggressive, suspicious, and restless. Her face was flushed, she was perspiring profusely, and her mouth was dry. Both pupils were widely dilated but reacted to light and accommodation. Her pulse was regular at 120 a minute and her blood pressure 180/90 mm. Hg. After a stomach lavage she was sedated with intramuscular soluble phenobarbitone, 6 gr. (0.4 g.) six-hourly. She slept well during the night, and next morning was quite wide awake and co-operative. Her pulse rate was now 80 and her pupils were of normal size; her B.P. was 90/60 mm. Hg. Recovery was uneventful. The above sedation was continued for three days, when she was interviewed by Dr. E. J. Nuffield, who found no evidence of any specific psychiatric disorder other than mild depression. The urine passed in hospital contained 54.7 mg. of amphetamine sulphate, which would correspond with an oral dose of 109-187 mg. of dexamphetamine sulphate (Connell, 1957).

Case 3

A man of 32 was admitted to hospital on July 11, 1956, at 10 p.m. The previous evening he had drunk 12 pints (6.8 litres) of beer and then spent the night at a coffee stall, where he chewed the contents of one and a half benzedrine inhalers (487.5 mg. of amphetamine). He now felt "on top of the world," and drank a further 5 pints (2.8 litres) of beer

at Covent Garden, starting at 6 a.m. During the day he developed substernal pain and palpitation, and at 2 p.m. attended the Royal Eye Hospital, where he was given 3 gr. (0.2 g.) of soluble phenobarbitone intravenously and transferred to King's College Hospital, arriving at 2.45 p.m. After stomach lavage he refused in-patient treatment and left the hospital.

He returned at 9 p.m., having drunk a further 2 pints (1.1 litres) of beer. He was now anxious and sweating, with dilated pupils which reacted normally to light and accommodation. His pulse was regular at a rate of 108 a minute, and his blood pressure 170/120 mm. Hg. His tendon reflexes were brisk. He was given paraldehyde, 8 ml. intramuscularly, and sodium phenobarbitone 6 gr. (0.4 g.), intramuscularly. The latter was repeated six-hourly. He slept uneventfully through the night. His pulse rate rapidly fell to 70 and his B.P. to normal levels. Next day he was quiet and co-operative and was interviewed by Dr. Nuffield, who found no evidence of psychiatric abnormality beyond a history of chronic alcoholism. He went home after three days, having quite recovered.

Discussion

The side-effects of amphetamine compounds when used therapeutically include dryness of the mouth, restlessness, insomnia, irritability, and anxiety, and are relatively unimportant. With larger doses of 10-30 mg. the cardiovascular system is chiefly affected, causing flushing or pallor, palpitation, labile pulse rate and blood pressure, extrasystoles, heart-block, chest pain, and sometimes collapse (Anderson and Scott, 1936). Prolonged use may on rare occasions cause aplastic anaemia (Davies, 1937), and fatal pancytopenia has been recorded with continued overdosage (Mitchell and Denton, 1950). Death, however, is rare in acute poisoning. Only six cases appear to have been reported, and in three of these the role of amphetamine is uncertain. Harvey *et al.* (1949) thought that amphetamine had contributed to the death of a 35-year-old alcoholic who became jaundiced and died after ingesting alcohol together with the contents of two benzedrine inhalers. Post-mortem examination revealed an alcoholic fatty liver with zonal necrosis. The second patient, a student aged 25, after taking an estimated 10 mg. of amphetamine died suddenly during an examination. At necropsy acute gastric and splanchic dilatation was found. Although he was accustomed to taking amphetamine, his death was partly attributed to the drug (Smith, 1939). Amphetamine was held responsible for the death of a one-year-old child from haemorrhagic gastritis after swallowing 40 mg. of amphetamine together with an unknown quantity of ferrous sulphate tablets (Hertzog *et al.*, 1943).

In animals amphetamine is known to cause cerebral haemorrhage (Ehrich *et al.*, 1939; Ivy and Krasno, 1941), and all three patients in whom acute amphetamine poisoning appeared to be the sole cause of death had cerebral lesions. Pontrelli (1942) described the necropsy findings in a 25-year-old soldier who died after taking 100 mg. of amphetamine. The brain, lungs, and liver were congested, the kidneys showed tubular degeneration, and punctate haemorrhages were present in the pleura and pericardium. Gericke (1945) noted subdural and subarachnoid haemorrhages and petechial haemorrhages in the cerebrum, cerebellum, and pons in a 36-year-old man who had swallowed 120 mg. of amphetamine. Pretorius (1953) found acute internal hydrocephalus in a 3-year-old girl who died after swallowing an estimated 40 mg. of dexamphetamine sulphate. Poteliakhoff and Roughton (1956) have described the occurrence of cerebral haemorrhage with recovery in a man of 42 who dissolved the contents of a benzedrine inhaler in "coca-cola" and drank the mixture.

One common and most alarming result of amphetamine poisoning may be the development of an acute psychosis. Of the eight cases of acute amphetamine poisoning recorded in this country, four had visual or auditory hallucinations (Wallis *et al.*, 1949; Carr, 1954; Patuck, 1956; Shanson,

1956). Another patient was repeatedly admitted to hospital with excitement, confusion, paranoid delusions, and on one occasion depression, each admission being preceded by the ingestion of large quantities of amphetamine (O'Flanagan and Taylor, 1950). Watts (1956) reported the case of a 2-year-old child who swallowed tablets of "edrisal," each containing amphetamine, 2.5 mg., aspirin, 160 mg., and phenacetin, 160 mg. He became very restless and talked all night, at times coherently and at other times "like the wanderings of a lightheaded child." In these cases the amount of amphetamine taken, when known, varied from 55 to 115 mg. One patient extracted the contents of two benzedrine inhalers, but the actual amount ingested was uncertain (O'Flanagan and Taylor, 1950). We estimated that our patient who became psychotic had absorbed 265 mg. of amphetamine.

Acute amphetamine poisoning is commoner than published reports suggest. The severe examples present as an acute mental disturbance and are likely to be seen most often in mental observation wards. Connell (1956) has investigated 42 such cases from the physical and psychiatric aspects in the past two years and has followed the urinary excretion of amphetamine in 10 of these patients. Patients, however, who do not show initial overt mental disturbances at an early stage of the illness may be admitted to general hospitals and the need for heavy sedation may not be appreciated. This may well lead to difficulties and dangers, as shown in Case 1, in which the patient developed an acute psychotic state 12 hours after admission.

Since amphetamine is a barbiturate antagonist (Myerson *et al.*, 1936; Reifstein and Davidoff, 1938), large doses of these sedatives are required in the treatment of amphetamine poisoning, not only to control a psychotic patient but also as a prophylactic measure, since there is good evidence that mental abnormality may thereby be prevented. In the converse problem of barbiturate poisoning treated with large doses of amphetamine, mental complications are rare. None occurred in 14 patients given up to 400 mg. of amphetamine intravenously in eight hours (Freireich and Landsberg, 1946). Riishede (1950) treated 132 cases with total doses of amphetamine up to 4,850 mg., given intramuscularly over 84 hours. Although these amounts far exceeded reported toxic doses of amphetamine, only 5% of patients became confused or euphoric and only 2% developed hallucinations.

In the cases reported here, after adequate sedation Case 1 recovered within a few hours, and the initial restlessness and aggressive attitude in Case 2 quickly disappeared. There was no overt disturbance of a psychotic nature in the third patient, who, possibly wisely, had taken considerable sedation in the form of alcohol before admission.

All three showed an increased tolerance to hypnotic drugs. The first patient slept for only eight hours after injections of 3 gr. (0.2 g.) of sodium phenobarbitone, 20 ml. of paraldehyde, and $\frac{1}{4}$ gr. (0.01 g.) of morphine within five and a half hours. The second and third patients were wide awake after receiving a total of 12 gr. (0.78 g.) of sodium phenobarbitone by injection during the previous 12 hours.

These three further examples bring the total number of cases of acute amphetamine poisoning reported in this country to 11. In seven of these the source of the drug was an amphetamine-containing inhaler. Two examples of inhalational poisoning have previously been described in this country (Carr, 1954; Shanson, 1956), and we could find no evidence that our first patient took the drug in any other way. Memory impairment caused by amphetamine has been noted previously (Waud, 1938), and possibly explains why this patient inhaled almost continuously for five and a half hours when he had previously used an inhaler normally. Impairment of memory was certainly present eight hours after he had started to inhale.

Summary

Three examples of acute amphetamine poisoning are described. Two patients took the drug orally and one by inhalation. One patient became poisoned by chewing

the contents of one and a half benzedrine inhalers, an unorthodox but readily available source of the drug.

One case developed an acute psychosis, a common feature of severe amphetamine intoxication which requires heavy barbiturate sedation both for prophylaxis and for treatment.

We thank Dr. Clifford Hoyle for his guidance and for permission to publish these cases. We are also indebted to Dr. P. H. Connell (Maudsley Hospital) for estimating the amphetamine excretion in two of the cases and for much valuable advice.

TRICHOPHYTON RUBRUM INFECTION IN FAMILIES

BY

MARY P. ENGLISH, M.Sc.

Mycologist, Bristol Royal Hospital

Trichophyton rubrum is the fungus most often isolated from patients with mycotic skin diseases attending the Bristol Royal Hospital. Of the 12 species isolated from 204 of these patients seen in the two years since March, 1954, *T. rubrum* was found 43 times.

The infection is usually first noticed as a scaling or macerated area between the toes indistinguishable from tinea pedis due to other fungi. *T. rubrum* differs from other dermatophytes, however, in that it is much more likely to attack the nails, when their discoloured, misshapen, and broken appearance (see Fig.) may cause the patient much mental distress; treatment at this stage is very rarely successful. It is surprising, therefore, that the epidemiology and prevention of the disease have been so neglected.

Literature

Baer *et al.* (1955) showed the ease with which infective particles can be shed from active mycotic lesions of the feet. After they had soaked the infected feet of 73 patients in footbaths for 15 minutes they were able to demonstrate the presence of fungi microscopically in the water from 54 of the baths, and to obtain cultures of pathogenic fungi from 13 of these. Despite this evidence, these authors deny the importance of cross-infection in the spread of the disease, on the grounds that numerous attempts, by themselves and others, to isolate pathogenic fungi from

supposedly contaminated floors have been generally unsuccessful. Recently, however, Gentles and Holmes (1956, personal communication), using a new technique, have been able to isolate from the floors of four pit-head bathhouses the species of fungus predominant in the feet of the bathing miners at each pit.

Numerous surveys have been carried out on the incidence of tinea pedis in many types of community, but little effort has been made to trace the spread of any one fungus. Peck *et al.* (1944), on examining the feet of workers in six factories, found only five cases of *T. rubrum* infection, and all these occurred in the same plant. Gentles and Holmes

Trichophyton rubrum infection of the toe-nails.

(1956, personal communication) produce strong evidence that the habitual use of communal baths is an important factor in the spread of tinea pedis in coal-miners. The infection rate with all species of fungi is 31% of miners using baths against 8% of those who do not. They also found that, among bathing miners, the proportion of the two most important pathogens varied from pit to pit: in eight pits *T. mentagrophytes* was the predominant fungus; in one, *T. rubrum*; and in the tenth the two species were present in almost equal numbers. These figures indicate the importance of cross-infection in a community.

On the other hand, Hopkins *et al.* (1947), investigating fungous infection of the feet of soldiers at a military post, found that the various species occurred in approximately the same ratio in most of the groups examined, and concluded that individual susceptibility to an existing latent infection was more important than exposure to cross-infection. However, three of their 26 groups show considerable variation from the predominant species ratio and four others show slight variation. It is possible that the rapid turnover of personnel in military establishments would often allow insufficient time for any one species to become dominant.

Sulzberger *et al.* (1942) attempted to assess the extent of familial and conjugal infections of the feet and groins by sending questionnaires to over 100 American dermatologists. They concluded that among "a sum total probably aggregating hundreds of thousands of patients with fungous infections" of these areas, only four cases of familial infection were proved, and that therefore such infection was of no practical importance. The authors rightly consider that familial infection is not proved unless the fungi are isolated and shown to be culturally similar; yet they include as relevant the replies of 82 dermatologists who did not attempt cultural methods of proof, as well as those of the six who did. Also, no evidence is offered that any of these dermatologists had, as a routine, examined the family contacts of all their ringworm patients, and unless this was done their data can be of little value.

Referring to family infection by *T. rubrum*, Hyman (1953) does not believe that there is any evidence for its existence, while Lewis (1953) thinks it is fairly common, an opinion

which is supported in this country by Gold (1954). Several case reports of familial infections with this fungus have appeared (Hodges, 1921; Lewis and Spoor, 1953).

In view of these conflicting opinions I have tried to determine the incidence of familial *T. rubrum* infections in normal home conditions by a small survey of families living in the Bristol area.

Methods

The 32 patients from whom *T. rubrum* had been isolated and who were living with their families were asked to take part in the survey. As well as households consisting of parents and children, the families included adult brothers and sisters living together, and couples with no children at home. Two families refused to co-operate, five had left the district, and six were found, for various reasons, to be unsuitable subjects. Observations were made on the remaining 19 families comprising the original patients and their 48 contacts. They were visited on prearranged evenings, with the result that it was usual for the whole household to be present at the interview. The survey was undertaken during the winter of 1955-6.

The Interview.—The feet and hands of all persons present were examined and if there were clinical symptoms scrapings were taken. Personal histories were noted and family circumstances and habits discussed.

Laboratory Methods.—The skin scrapings were examined microscopically in 15% potassium hydroxide solution and cultured on Sabouraud's glucose-agar with added penicillin and streptomycin, cultures being obtained from all but one of the microscopically positive specimens but never from those which were negative. When more than one member of a family was infected, the isolates were compared with regard to growth rate and macroscopic and microscopic characters on six agar media (Sabouraud's glucose; Sabouraud's preserve; cornmeal; cornmeal + 1% glucose; asparagine-glucose; and nutrient + 4% glucose) on which they were grown for four weeks at 29° C. Distinct and persistent cultural differences, however slight, were taken to indicate the possibility of different strains which the patients might have contracted from different sources.

Results

The Spread of Infection.—In 9 out of the 19 families more than one person was infected with *T. rubrum*, and within each of these families the isolates were mycologically of the same type. In addition to the communal strain, variant strains of the fungus, occurring in the same lesions, were isolated from two of the families. Of the 48 contacts examined, 13 (27%) were infected, and in 11 of these the infection was first noticed in the feet. The minimum duration of exposure before any of these contacts showed signs of the disease was one year, but one girl was exposed for 15 years before infection was apparent. A much larger survey would be necessary to discover accurately the proportion of children brought up in infected families who ultimately contract the disease; but eight subjects between the ages of 14 and 35 years had been exposed as children, and six of these had proved infections.

Environment and Spread of Infection.—According to the Registrar-General's social classification, 11 of the families belonged to social classes I and II, the disease having spread in six; five were in class III, with a disease spread in two; and three were in classes IV and V, with a disease spread in one. The numbers are small, but they could indicate that *T. rubrum* mycosis is a disease mainly of the professional classes. Alternatively, it is possible that the working classes are less likely to seek medical advice about such a condition. Social class did not influence the incidence of spread, extension of infection having occurred in about half the families in each group. Two of the families were overcrowded, one being spotlessly clean and the other filthy, and together they accounted for 16 of the persons interviewed; yet, in each, only one contact had contracted the disease.

Seven of the original patients could trace their initial infection to residence or active service abroad, and in four others the disease was first noticed while the patient was using swimming-baths regularly or taking an active part in sports. The remaining eight could describe no special circumstances which might have accounted for the onset of their infection.

Effect of Precautions.—Five families had for three years or more taken precautions against spreading the disease—for example, they avoided walking about with bare feet, exchanging footwear, or using a communal bath-mat; and if they shared a bed they wore socks. The infection had not spread in any of these families after the precautions were instituted. It must be noted, however, that two wives who had taken no precautions had not contracted the disease, though they had been exposed to their husband's infections for 30 years.

General Observations on the Infected Persons

In an analysis of all the 32 infected persons seen during the survey (the 19 original patients and the 13 infected contacts) the following points were observed:

1. There was an almost equal sex incidence (17 males to 15 females).
2. Conjugal infection had occurred in 4 out of the 15 couples seen.
3. One child had contracted the disease before he was 5 years old; five first showed evidence of infection between the ages of 5 and 13, and seven persons when they reached 14 years or over.
4. In 27 patients the initial infection was in the feet; of the other five, the hands alone were involved in four, and one child had only a lesion on the face.
5. The nails were infected in 25 persons (78%); in four the finger-nails only had been attacked, in 15 the toe-nails only, and in six both finger- and toe-nails.
6. Three women and four men had had groin infections. Ringworm of the groin in women has seldom been reported in this country, and a description of these cases will be given elsewhere. One woman described ringworm of the axilla and one had an extensive infection of the arms and legs; four cases of ringworm of the face and body were seen.

7. Dermatophytes other than *T. rubrum* were encountered only twice, each time in association with the latter fungus. One man had a severe infection of the feet and toe-nails from which mixed cultures of *T. rubrum* and *Epidermophyton floccosum* were isolated; he had infected his daughter with the former fungus only. One woman had *T. rubrum* on her hands, contracted while treating her son's infection, and *T. interdigitale* on her feet.

8. Twenty-three patients had been referred for specialist advice, but only one while the infection was confined to the toe-webs. Of the remainder, seven consulted a dermatologist when their finger-nails became involved; five each about groin and toe-nail infections; four about face and body lesions; and one about lesions on the hand. Yet in 18 of these infection of the toe-webs had preceded by many years the more widespread symptoms.

Discussion and Conclusions

This survey indicates the importance of cross-infection by *T. rubrum* in the home. In half the families the malady had spread, and 27% of the contacts who were examined were infected. A number of them were unaware of their infection, and this emphasizes the importance of personal examination of such people rather than merely questioning them or their relatives. In fact, these figures are probably an underestimate of the extent of the disease, for in addition to the verified cases many persons interviewed gave descriptions of typical ringworm of the body in the past and mentioned other members of the family who had left home whose toe-nails were "all yellow and thickened."

Marples and Di Menna (1949), Baer *et al.* (1955), Gentles and Holmes (1956, personal communication), and others have noted the long period of exposure before clinical infection of the feet becomes evident: this, as I have reported, has also been my experience. The evidence indicates that some breakdown in personal immunity must precede the onset of clinical disease. If a person is to become infected, this lessening of immunity must coincide with inoculation with a viable fungus. In contradistinction to the hypothesis that patients become infected after recent inoculation from an outside source, Sulzberger *et al.* (1942) and Sulzberger and Baer (1955) believe that most supposedly normal persons are carriers of fungi, and that this is the starting-point of clinical disease when immunity breaks down. Their theory is not supported by the evidence of familial infection in 11 of my 48 contacts, while only one had contracted the disease (due to *T. interdigitale*) from an outside source: a larger proportion of extraneous infections, or at least of mixed infections with two species, would have been expected. The evidence indicates continual exposure of the contacts to cross-infection in the home and a phase of lowered personal resistance which allowed the fungus to produce clinical disease.

The intractability of *T. rubrum* infections to treatment, their disfiguring nature, and the mental distress which often ensues emphasize the importance of attempting to check the spread of the disease. This is especially so in families with young children, as is shown by the infection rate of six out of eight persons over the age of 14 who had been exposed to infection as children. Precautions should be simple and have the object of preventing the shedding of infective particles in places where others may come into contact with them; for instance, avoiding walking about bare-footed, exchanging footwear, or using a communal bath-mat. The sterilization of footwear and floors is impracticable and is not likely to be performed faithfully by the patient.

In half the patients who had been referred to dermatologists the disease had already reached the nails, and was therefore practically incurable. If more patients with tinea pedis were seen by dermatologists before this stage was reached, and if the fungus concerned was identified, infection of the nails and hands might be delayed or prevented. For should *T. rubrum* be found, the patient could be warned to pay greater attention to his condition than is normally accorded to "athlete's foot."

Summary

The epidemiology of *Trichophyton rubrum* infections has been studied in 19 families in whom one member was known to be infected.

The disease had spread in nine of the families, and 13 (27%) of the 48 contacts were infected. The mycological similarity of fungi isolated from members of the same family has been demonstrated.

Six out of eight persons over the age of 14 who had been exposed to infection during childhood had contracted the disease.

Periods of exposure of from 1 to 15 years were noted before clinical signs of disease occurred, and in five families who had taken precautions for three years or more there had been no spread of infection.

The nails had been attacked in 78% of all the infected persons. In most of these the disease had begun in the toe-webs, but specialist advice had not been sought at this early stage.

Cross-infection with *T. rubrum* in families is important, and simple precautions against spreading the disease are suggested.

I thank Dr. R. P. Warin and Dr. C. D. Evans, whose patients, except for one family, were the subjects of this inquiry, for their enthusiastic support throughout; Dr. Catherine J. Maclaren, who

most kindly interviewed one family of her own patients for me; the families, for their very helpful co-operation; and Dr. M. Hewitt for his invaluable guidance in the preparations for, and conduct of, the survey and in the presentation of the results. I am indebted to the University of Bristol Medical Photographic Department for the photograph.

ATHLETE'S FOOT FUNGI ON FLOORS OF COMMUNAL BATHING-PLACES

BY

J. C. GENTLES, B.Sc.

Lecturer in Medical Mycology, University of Glasgow

During a recent survey of foot ringworm in groups of industrial workers in Great Britain, Gentles and Holmes (1955, 1957) showed that there is spread of infection among users of communal bathhouses. Parasitic fungi were isolated from the floors of some of the bathhouses on a number of occasions (Gentles, 1956). There was some indication that these fungi were not present as saprophytic colonies on the floors, but the evidence was not conclusive (Gentles and Holmes, 1955; Gentles, 1956). Various opinions on the method of spread of infection have been given. Duncan (1949) and J. T. Ingram (1954, personal communication) believed that spread took place by transfer of scales from the feet of the infected to the interdigital clefts of the feet of others. Duncan also believed that the fungi could grow saprophytically on wooden floors, and Riddell (1951) stated that the increase in incidence of the disease amongst users of communal bathing-places was probably due to the lighting up of latent infections rather than to new infections caused by the fungi growing saprophytically on the floors. Peck, Botvinick, and Schwartz (1944) stated that the pH of aged concrete was compatible with growth of the dermatophytes concerned, but they did not show that growth actually took place, and the dermatophytes they isolated from sterilized concrete probably came from infected skin fragments (Gentles, 1956).

Adamson and Annan (1949) isolated *Trichophyton mentagrophytes* from a fragment of skin found on the floor of a bathhouse, and I also made one isolation in this way (Gentles, 1956).

Experiments recently carried out in this laboratory have confirmed that spores of *T. mentagrophytes* can exist for long periods on concrete surfaces and also that this species of dermatophyte can grow on moist crushed asphalt when soap is present. It seems unlikely, however, that the conditions required to enable growth to take place are ever fulfilled in practice. It is customary for floors of most institutions to be thoroughly cleaned at frequent intervals (usually daily) with detergents and disinfectants of various kinds, and these substances almost without exception exert a fungistatic action on

the fungi concerned. In an effort to obtain further information on the question of how infection spreads, the answer to which is important if satisfactory prophylactic measures are to be introduced, it was decided to investigate more fully the condition of shower floors both in the clean state and after they had been used.

Method

The experiment was carried out on two occasions, in May and three weeks later in June, 1956, in the bathhouse of a near-by colliery. The incidence of athlete's foot among those who used the showers at this colliery was estimated in 1953 to be 19% (Gentles and Holmes, 1955; 1957). The sampling of the floor, which is surfaced with asphalt, was carried out with direct samplers (Gentles, 1956). These consist essentially of a velvet pad on a wooden support, and on each of five previous occasions on which they have been used dermatophytes have been successfully isolated. In the laboratory they have proved suitable for location of both fungal spores and skin fragments on asphalt and concrete surfaces.

Three samplers were used on each of the four positions A, B, C, and X (Fig. 1) on the clean floor, and the same number two hours later after some hundred or more men had bathed. Each sampler was applied four times to the part of

FIG. 1.—Diagram of shower bay in colliery bathhouse, showing the relative positions of the four floor areas A, B, C, and X used in the experiments.

the floor surface immediately below the shower nozzle, the area covered by three samplers on each occasion being just under 1 square foot (929 square cm.). The showers were run for a short period before sampling in order to wet the clean floor, as the samplers are not suitable for use on a dry surface. Three petri dishes containing 4% malt extract agar supplemented with cycloheximide (5 µg./ml.), penicillin (20 units/ml.), and streptomycin (40 units/ml.) were inoculated from each sampler.

The dishes were incubated at 28° C. and examined at frequent intervals.

Results

The cycloheximide inhibited the growth of most of the common saprophytic fungi for a period, and dermatophyte identity of the isolates was in every case confirmed by microscopical examination of a slide mount. Only one species of dermatophyte, *T. mentagrophytes*, was obtained. This species is the common cause of foot ringworm in this country, and is also the predominant species in foot infections at this colliery (Gentles and Holmes, 1955). The isolates were all of the interdigitale variety, and subcultures in no way differed from those usually obtained from foot infections with this species.

The Table shows that dermatophytes were isolated from all four shower positions, but only once were they obtained on both May and June samplings from the same shower.

Results Obtained from Sampling the Floors of Four Shower Stalls on Two Occasions

Date of Sampling (1956)	No. of Colonies of Dermatophyte Obtained							
	Shower A		Shower B		Shower C		Shower X	
	Clean*	After Use	Clean	After Use	Clean	After Use	Clean	After Use
May	0	2	0	0	0	0	0	0
June	0	2	0	22	0	1	0	1
Total	0	4	0	22	0	1	0	1

* Sampling was carried out on the clean floors and also after the showers had been used.

Discussion

It is apparent from these results that the distribution of the fungi on the floors is not the same all the time, as would be the case if the fungi were present as saprophytic colonies. It must be assumed under such circumstances that the spread of infection takes place, as Duncan and Ingram have postulated, by transfer of infected skin fragments. Failure to isolate from the clean floors indicates that cleaning of the floors effectively removes the infective fragments and therefore spread of infection obviously takes place only among those groups who use the showers in periods between cleaning. The efficacy of the cleaning in this bathhouse, which is in no way unusual as regards either method or materials, was clearly evident by comparison of the numbers and variety of saprophytic fungi, yeasts, and bacteria in the petri dishes inoculated from the clean floor and in those inoculated from the floor after use. Two comparable series from a shower before and after use are shown in Fig. 2.

In a previous article (Gentles, 1956) it was stated that the parasitic fungi were probably present on the floors in some quantity. These further isolations from a relatively small

FIG. 2.—Photograph showing on the left the series of three dishes inoculated with a single sampler from the floor of shower A after use, and on the right the dishes inoculated with corresponding sampler used on the clean floor of the same shower. A single colony of *T. mentagrophytes* is present on the lower left petri dish slightly off centre in direction of 5 o'clock.

area confirm this view and show that the failure of many previous attempts was due to deficiencies in the methods used (Peck *et al.*, 1944). The large number of isolates obtained at the June sampling from shower B is probably the result of sampling the shower immediately after it had been used by an infected person. The few colonies usually obtained would seem to indicate that the infected fragments may be washed down the drains shortly after being deposited, as Peck *et al.* suggested, but it is also possible that they are carried away on the feet of subsequent bathers. The risk of skin fragments containing parasitic fungi being picked up on the feet of a person using this particular shower would at any rate be very great.

In view of these findings it seems certain that any measures for control of spread of infection must be taken by the individual, either by the use of aids such as sandals to prevent direct contact with the floors, or by application of some fungicidal preparation after bathing.

Summary

The same four shower stalls of a communal bathhouse were sampled before and after use on two separate occasions. It is clearly shown that the presence of dermatophytes as saprophytic colonies on the floor is extremely unlikely, and that the spread of infection almost certainly takes place by transfer of infected skin fragments. There is also evidence that skin fragments containing viable parasitic fungi are deposited, and are on occasion present on the floors, if even for a comparatively short time, in very large numbers. It is pointed out that measures to control spread must be of a personal nature.

I thank the medical services of the National Coal Board for their co-operation; Professor J. W. Howie and Dr. J. G. Holmes for their advice; Miss C. O. Dawson for much valuable assistance; and Mr. F. Lonsdale and Mr. G. Clark for the photography.

Medical Memoranda

A Case of Traumatic Caesarean Section

The case is described of an African woman carrying twins who suffered a traumatic caesarean section with prolapse of foetal parts. Prompt though primitive surgery was performed by the husband, thereby saving the lives of the mother and one child.

CASE REPORT

A pregnant woman of the Tugen tribe was admitted to Rift Valley Province General Hospital on the evening of November 3, 1954, after a journey of some 40 to 50 miles (64 to 80 km.) on foot and by ambulance. Approximately 24 hours earlier she had fallen forwards on to an iron spike in her garden, and sustained a 4-in. (10-cm.) transverse wound of the abdominal wall with prolapse of what was thought to be a foetal elbow. The husband had roughly sutured the wound with strong thread, and the woman had started on her journey to El Dama Ravine Hospital, from whence she was transferred by ambulance.

On admission the patient's general condition was excellent. The abdominal wound appeared slightly septic, and there was considerable tenderness and guarding over the lower abdomen so that it was difficult to determine details,

although a full-term uterus was palpated and the foetal heart sounded clearly and of normal rate. The patient confirmed that foetal movements were still being felt.

At this time it was thought that the story of prolapse of foetal parts was a mistake, since such an injury was thought to be scarcely compatible with a viable child more than 24 hours later. In consequence operation was deferred for 12 hours, when the thread sutures parted to reveal a foetal hand.

At operation the foetal parts were found to be prolapsing through a transverse wound of the uterus situated 1-2 in. (2.5-5 cm.) above the usually selected site of incision for a lower-segment caesarean section. The uterus was not contracted, though the edges of the wound were everted and bleeding very little; about 1½ to 2 pints (850 to 1,140 ml.) of blood was collected from the paracolic gutters and transfused after straining through gauze into citrate solution.

The dead foetus, with the placenta and membranes, was removed without enlarging the uterine wound, and a further binocular twin, which lay in an intact sac, was similarly delivered and found to be alive.

The uterus was repaired by the method usually adopted after lower-segment caesarean section, and the abdomen was closed without drainage. Apart from some superficial wound infection which responded to chemotherapy, and an anaemia which required treatment, the post-operative course was uneventful. A very satisfied mother was discharged with her small son on the twenty-fifth post-operative day.

COMMENT

This case has a number of features in common with the case of self-inflicted caesarean section described by Sandford (1951).

Hysterectomy was not considered, and indeed it is seldom found necessary to undertake this heroic measure in cases of ruptured uterus, since repair is almost always an easier and less shocking procedure, and very often leaves a uterus capable of further normal function or one in which caesarean section may be undertaken at full term in subsequent pregnancies.

Sufficient confidence in the repair persuaded us that sterilization would also have been an unwarranted procedure. There is adequate supervision by a rural health service in this woman's district to ensure that she will receive satisfactory treatment in the event of further pregnancy.

Regarding the latter paragraph, it is of interest that Dr. Sandford's patient, who also was not sterilized, was returned before term with a further pregnancy, and after an unsuccessful trial labour was delivered of a live child by caesarean section, under my care.

My thanks are due to Dr. D. W. F. Charlton, who assisted in the management of this case.

Recurrent Myxoedema and Goitre Attributed to Potassium Iodide

Myxoedema resulting from the administration of iodine to patients free from thyroid gland disorder is rare. It has been described by Léchelle and Troisier (1950), Bareau (1952), Morgans and Trotter (1953), Herbert and Petrie (1954), and Freed (1954). Acute swelling of the thyroid gland complicating treatment with iodides was reported by Edmunds (1955). Cases in which both myxoedema and goitre developed after iodide administration have been described by Bell (1952), Raben (1953), and Turner and Howard (1956).

The patient whose case is described here had four attacks of myxoedema and goitre in five years, and recovered without treatment. It is believed that potassium iodide was responsible for each episode.

CASE REPORT

The patient, a bricklayer aged 41, has been subject to bronchial asthma from the age of 20. There is no history of any other disease. In September, 1950, he was admitted to hospital complaining that for some three weeks he had been tired, cold, and constipated, and was increasing in weight. His voice had become hoarse, his face puffy; and the swelling of the neck had made fastening his collar difficult. Examination showed a well-built man with the characteristic features of myxoedema. The thyroid gland was uniformly enlarged, smooth, and soft, and the neck measured 16½ in. (41.2 cm.) in circumference. The chest was emphysematous. There were no other abnormal physical findings. The serum cholesterol level was 381 mg. per 100 ml., and the basal metabolic rate (B.M.R.) -20%. He improved rapidly without treatment, and in two weeks had lost 17½ lb. (8 kg.) in weight; his neck circumference had become an inch (2.5 cm.) less, the serum cholesterol level had fallen to 236 mg. per 100 ml., and the B.M.R. had risen to +5%. In three weeks he felt well and his appearance was normal.

In June, 1951, the goitre and symptoms of hypothyroidism recurred during the space of a few weeks, and his appearance again became myxoedematous. Without treatment he recovered completely in two months.

In February, 1952, he was readmitted to hospital with pneumonia and frank myxoedema. The goitre and symptoms of hypothyroidism had begun two or three weeks earlier. Without treatment for his myxoedema he improved rapidly. In three weeks the neck circumference was reduced by 1½ in. (3.1 cm.) and he lost 13 lb. (5.9 kg.) in weight. In two months he was free from symptoms and signs of hypothyroidism.

In March, 1955, he was admitted to hospital with symptoms of severe hypothyroidism, present for about two months. He was sleepy, and had a croaking voice. The features were coarse, with thick lips and puffy eyelids. The skin was cold, dry, and rough. The thyroid gland was uniformly swollen and firm, and the neck measured 17½ in. (44.8 cm.). The serum cholesterol level was 440 mg. per 100 ml. and the B.M.R. was -17%. The electrocardiogram showed small QRS deflections and flat T waves. Without treatment he regained his normal appearance, vigour, and body weight in two months. With recovery his serum cholesterol level fell to 180 mg. per 100 ml. and the B.M.R. increased to +4%; the electrocardiogram became normal, and the neck circumference returned to its normal 14½-15 in. (38-39 cm.).

It was evident that the patient was not suffering from primary hypothyroidism, and inquiry showed that the only chemical agent he had taken was a proprietary medicine containing potassium iodide (potassium iodide, 2½ gr. (0.16 g.); caffeine sodium salicylate, 2½ gr. (0.16 g.); ephedrine, 2½ gr. (26 mg.); extract of coffee B.P.C. to 1 dr. (3.5 ml.). A week had rarely passed without his taking a

little of the mixture, but for several weeks before each attack of myxoedema he had taken five or six doses every day. The symptoms and signs of hypothyroidism had disappeared on each occasion within two months of stopping the medicine. Figs. 1 and 2 show the patient during an attack and between attacks of myxoedema respectively.

A mixture containing all the ingredients of the proprietary medicine except potassium iodide was dispensed, and five or six doses were taken by the patient daily for two months without evidence of hypothyroidism developing.

COMMENT

This case, with the evidence in the literature to which reference has been made, suggests that iodides can cause myxoedema in persons free from previous disorder of the thyroid gland.

Iodide administration is occasionally followed by myxoedema in cases of mild thyrotoxicosis, and in patients subjected to partial thyroidectomy for exophthalmic goitre (Haines, 1928; Thompson and Thompson, 1930; Thompson *et al.*, 1930; and Prodger and Brauns, 1943). A patient with simple goitre in whom iodine administration led to myxoedema was reported by Hurxthal (1945) and by Bell (1952).

It is conceivable that iodides may reduce metabolism by interfering with the secretion or action of thyrotrophic hormone, by increasing the rate of breakdown and excretion of thyroid hormone, by acting directly upon the thyroid gland, or by a combination of these actions. Werner *et al.* (1955) concluded that iodides act upon the thyroid cell, and not by interference with the action of thyrotrophic hormone; and Ansell and Miller (1952) found no evidence of increase in the rate of breakdown and excretion of thyroid hormone in rats fed large doses of iodides. With respect to the effect of iodides on the thyroid gland, it has been found in rats and man that high levels of plasma iodide prevent the transfer of iodine from inorganic to organic combination, and prevent the uptake of iodine by the gland (Wolff and Chaikoff, 1948; Stanley, 1949; Childs *et al.*, 1950; Keating *et al.*, 1950). Ansell and Miller (1952) and Goldsmith and Eisele (1956) suggest that high levels of plasma iodide suppress the release of thyroid hormone from the gland. Fawcett and Kirkwood (1953) believe that excess iodide ions act by forming molecular compounds with elemental iodine in the thyroid gland, and thus make it unavailable for iodinating tyrosine.

Raben (1953) has suggested that the goitre resulting from iodide administration is caused by an excessive secretion of thyrotrophic hormone consequent upon prolonged interference with thyroid hormone formation.

Why myxoedema and goitre should be so rarely caused by these actions of iodine is, at present, a matter for speculation.

I am grateful to Dr. C. E. Davies and Dr. T. Hanley for advice and criticism.

P. G. F. NIXON, M.B., M.R.C.P.

The Royal Hospital, Sheffield.

Reviews

ORGANIZATION OF MEDICAL RESEARCH

The Support of Medical Research: A Symposium Organized by C.I.O.M.S. Edited by Sir Harold Himsworth and J. F. Delafresnaye. (Pp. 170+xi. 17s. 6d.) Oxford: Blackwell Scientific Publications. 1956.

By honourable tradition research is a function of the universities, but with the increasing realization of the vital importance of scientific knowledge in the present century, and the increasing cost of the machinery of research, it has been found necessary in many countries to supplement the universities' resources for the purpose by establishing central research organizations directly financed by Government. Inquiries by the Council of International Organizations of Medical Sciences (C.I.O.M.S.) in the spring of 1954 showed that no fewer than 30 countries had set up central organizations for medical research, with functions essentially analogous to those of the Medical Research Council in the United Kingdom. It was a happy idea to arrange a meeting between senior officers of these bodies, so that they might compare their problems, determine their common philosophy, and, not least important, get to know each other well. The meeting, which was held in London in October, 1954, under the chairmanship of Sir Harold Himsworth, Secretary of the U.K. Medical Research Council, was attended by representatives of Australia, Belgium, Canada, Eire, India, Israel, the Netherlands, New Zealand, Norway, Sweden, Switzerland, the Union of South Africa, the United Kingdom, the United States, Yugoslavia, and Western Germany; four other countries—Brazil, Japan, Spain, and the U.S.S.R.—had expressed interest in the meeting but were unable to send delegates, and illness unfortunately prevented the representative of France from attending. In preparation for the meeting the delegates of 16 countries had provided detailed memoranda upon their national organizations for medical research, and these are printed as appendices to the report of the symposium.

The report itself is a remarkable document, having been synthesized by Sir Harold Himsworth and Dr. Delafresnaye, with uncommon skill and to the satisfaction of all present, from the verbatim transcripts of the four days' discussions. It shows what a surprising measure of agreement exists, in countries with widely different political systems, in regard to the respective roles of the universities, the central research organization, and special research institutions in the promotion of research and the recruitment and training of investigators. Perhaps its most important conclusion is that, in order to preserve the intellectual climate essential for good research, the central research organization, even when supported wholly or mainly by Government, must be guided in its activities by experienced research scientists, and must itself, like the universities, with which it should be closely integrated, be left free to pursue its scientific aims without political interference.

The book contains much of interest and value for all who are concerned with the advancement of knowledge in medical science and the education of scientific workers. It should be of particular help to the Governments of countries which have not yet set up a research organization but are contemplating doing so; let us hope they will turn to it for guidance in the principles which should govern their work.

HORMONE RESEARCH

Recent Progress in Hormone Research. Proceedings of the Laurentian Hormone Conference, 1955. Edited by Gregory Pincus. Volume XII. (Pp. 453; illustrated. \$10.) New York: Academic Press Inc. London: Academic Books Ltd. 1956.

It is a common complaint that medical literature increases faster than it can be tabulated or digested. There is urgent need for more research into the best methods of recording,

classifying, and disseminating new knowledge. One fairly successful method is by means of the review which surveys the literature on a limited subject. But many reviews fail because they are mere catalogues of collected and relevant papers without critical selection or appraisal. A recent and more successful method is by publishing the proceedings of a symposium. In this way a critical survey of the present state of knowledge is obtained from an expert, and the general conclusions are extended and discussed by other experts. Properly handled, this proves to be an eminently successful method of presenting recent knowledge.

An excellent example of this is the series of Proceedings of the Laurentian Hormone Conferences. Published once a year under the title *Recent Progress in Hormone Research*, this has now firmly established itself as an important reference work in endocrinology. The twelfth volume records the 1955 conference and fully maintains the high standards of both scholarship and editing which we have come to associate with this series. The subjects covered include reviews of thyroid hormone metabolism, and the biogenesis of adrenal medullary amines and of cortical steroids. There are critical studies of the mechanisms of oxidation-reduction of the steroid nucleus and of hormonal glucuronide formation. An extensive survey reviews knowledge of the effect of steroids on cerebral metabolism in man. Present knowledge of the significance and behaviour of aldosterone is concisely and ably reviewed. All the surveys are by leading experts in their fields.

Long surveys are included of the effects of insulin in peptide formation, on human urinary gonadotropin, and on the hormone control of melanin pigmentation. The role of male sex hormone in reproduction is discussed, and so is the mechanism of action of ovarian steroids. Relatively few of the papers are directly clinical, but this volume contains a valuable review of pituitary syndromes in man and a clinical study of testicular hormone production.

All who seek to keep up with the ever-changing concepts of any aspect of endocrinology will find this series of the greatest value. They should be available in every medical library.

TEXTBOOKS OF HISTOLOGY

Lehrbuch der Histologie und der Mikroskopischen Anatomie des Menschen. Established by Philipp Stöhr, carried on by Wilhelm v. Möllendorff, and revised by Kurt Goerttler. Twenty-seventh edition. (Pp. 558+xii; illustrated. D.M.36.) Jena: Gustav Fischer Verlag. 1955.

Histologie und Mikroskopische Anatomie des Menschen. By W. Bargmann. Second edition. (Pp. 796+xvi; illustrated. D.M.69.60.) Stuttgart: Georg Thieme. 1956.

The first of these books is the 27th edition of a famous textbook on the histology and microscopical anatomy of man. Originated by Stöhr, it was continued for many of its appearances under the guidance of von Möllendorff, and for its latest form Professor Goerttler, of Freiburg, is responsible. All systems and tissues are dealt with thoroughly, not only from the point of view of their static composition, but dynamically and from the standpoint of function. That so much can be encompassed in some 550 pages is largely due to the lavish use of illustrations, some in colour; the majority of these are schematic drawings which enable a clear comprehension of the subject to be obtained. Where necessary, however, photomicrographs and drawings of appropriately stained and illuminated preparations are freely employed. Detailed criticism of the enormous amount of material cannot be attempted; its thoroughness indicates its country of origin, and its content is important to a much wider audience than the student population.

To all concerned with normal microscopical anatomy and who do not already know this book it can be confidently recommended on the grounds of its ability to explain the minutiae of its subject and the ease with which the illustrations can be understood. The book is scientifically highly desirable, easily handled owing to its reasonable size, and, possibly what is much more important to its producers, it

is, as a foreword tells us, acceptable as a textbook in the universities and high schools of the German Democratic Republic.

The second of these books, Dr. W. Bargmann's, is the second edition of a textbook on normal human microscopical anatomy and histology. Its resemblance to Goerttler's *Lehrbuch* in subject-matter, layout, and the use of illustrations is remarkable; even the same diagrams are reproduced from the literature in some cases. This may perhaps be traced to the fact that Dr. Bargmann was a pupil of von Möllendorff, presumably at a time when the latter was busy with an earlier edition of the *Lehrbuch der Histologie*.

It is as little possible to criticize minutely *Histologie und Mikroskopische Anatomie des Menschen* as it is the *Lehrbuch der Histologie*. Dr. Bargmann, single-handed, has produced a monumental work of reference for the microscopical anatomist, lavishly illustrated by all convenient methods. That he has made an effort to reduce the size of his book is shown by the condensation of the two earlier parts into one volume in this edition.

These two books are so similar in every way that the questions must inevitably arise of whom they are intended for and whether there is a genuine need for the two. It is easier to answer the second question than the first by noting the regularity with which the *Lehrbuch der Histologie* has presented new editions and that Dr. Bargmann's second edition appears but five years after his first. An audience for the books will be readily found in all those concerned with normal and pathological microscopy of human tissues. In an attempt to compare and contrast these two books and as some sort of aid to a prospective purchaser, it should be noted that Bargmann's book is larger, heavier, and more expensive than Goerttler's. The production of both is of a high order.

GERIATRICS

Modern Trends in Geriatrics. Edited by William Hobson, B.Sc., M.D., D.P.H. (Pp. 422+vii; illustrated. 72s. 6d.) London: Butterworth and Co. (Publishers) Ltd. 1956.

Many books in geriatrics lose in value because they deal with diseases peculiar to, or of special importance in, old age, but fail to give the essential background for comparison—the changes in mind and body normally associated with ageing. The work under review is free from this fault. The first four chapters dealing with the general problem—the biological and cellular changes, the biochemistry, and the pathology of the elderly—are masterpieces in their execution. A remarkable level of excellence is achieved by the writers of the various contributions which follow. Indeed, it might appear to be invidious to single out any one of them for special praise except that a reviewer is necessarily influenced by his personal interests and experience. The chapters on glycosuria, including the treatment of diabetes mellitus, and those on anaesthesia and therapeutics for the elderly are of outstanding merit.

Each writer has provided a concise, informative, and well-written article in his subject. The result has been the production of a work of exceptional merit which can be read with profit by all medical men even though they may have no special interest in geriatrics.

A. H. DOUTHWAITE.

TEXTBOOK OF MEDICINE

The Principles and Practice of Medicine. A Textbook for Students and Doctors. By Sir Stanley Davidson, B.A., M.D., P.R.C.P.Ed., F.R.C.P.Lond., M.D.Oslo, and the staff of the Department of Medicine, University of Edinburgh, and associated clinical units. Third edition. (Pp. 1,076+viii; illustrated. 35s.) Edinburgh and London: E. and S. Livingstone. 1956.

This textbook has reached its third edition within five years. It is widely used by students preparing for the final examination, and it is easy to see why this is so. The book is essentially practical; its advice on treatment is always lucid

and detailed. It is beautifully printed and light in the hand. It is well planned, and a satisfactory proportion is achieved, not only between the various systems but also in the allotment of space to individual diseases. More than a thousand pages are provided for 35s. For this edition the section on neurology has been rewritten by John Marshall, who has made excellent use of the opportunity. How good also are the sections on haematology (R. H. Girdwood and James Innes), on water and electrolytes (J. S. Robson), and on chronic rheumatic diseases (J. J. R. Duthie). There are sections which could, and probably will, be better done, and the work is not so comprehensive as Cecil's incomparable textbook and the best English texts. It is, however, a more adequate textbook than any of the same size which was available thirty years ago. If these thousand pages contain all the medicine that the final-year student requires to know, are we justified in saying that the medical course demands more of him than he can be reasonably expected to provide?

D. V. HUBBLE.

A TEXTBOOK FOR DIETITIANS

Foundations of Nutrition. By Clara Mae Taylor, Ph.D., and Grace Macleod, Ph.D., and the late Mary Swartz Rose, Ph.D. Fifth edition. (Pp. 620+xi; illustrated. 42s.) New York and London: The Macmillan Company. 1956.

The aim of the fifth edition of this popular book, as of previous editions, has been "to present within a small space some of the fundamental principles of human nutrition, in terms which call for no highly specialized training in those natural sciences upon which the science of nutrition rests." So far as these limitations allow, the whole subject is treated with admirable clarity and facility in 29 chapters which could be grouped under the headings of metabolism, major food components, minerals, vitamins, and dietetics. Little or no chemistry is included, but the reader is given evidence of the reality of vitamins by photographs of their crystals. Moreover, in spite of the human bias of the book, there are only a few illustrations of the effect of nutritional deficiencies in man, which are supplemented by more numerous photographs showing deficiency diseases as produced in experimental animals. In most chapters the history of research is traced back to its early origins, but sometimes the knowledgeable reader may criticize the choice of the most salient references and topics. Thus in dealing with vitamin A no mention is made of the crucial work of H. von Euler on the biological activity of carotene, nor of Wald's classical demonstration that vitamin A is a component of visual purple. To continue in a critical vein, the reader is given no warning on page 235 that the rat's continuously growing incisor teeth, which can be affected by avitaminosis A, are quite different in structure from the molar tooth shown in the adjoining Fig. 62.

Such minor defects, however, will do little to reduce the value of the book to those for whom it is mainly intended. Practical dietitians will receive invaluable help from the numerous pictures showing the amounts of various foods, neatly set out on plates, which provide the same amount of the nutrient under discussion. Expert dietitians have long suggested that the nutrient contents of foodstuffs should not be expressed by weight, nor in international units, but in terms of the standard daily human requirement for the nutrient. This plan has been applied very successfully in this book by expressing nutrient contents as "shares" equal to 1/32 of the daily requirement of a standard man. By comparing the calorie shares of a foodstuff with its shares in other nutrients it is at once apparent where its strengths and weaknesses lie. To quote one example: a portion of wholemeal bread which supplies one share of calories also supplies 1.9 shares of protein, 2.4 of iron, 2.6 of vitamin B₁, and 1.0 of riboflavin. The work concludes with an appendix of 78 pages of tables, new to the present edition, which give, among other data, the contents of numerous foods in calories, protein, iron, calcium, and vitamins A, B, C, and riboflavin.

SATURDAY MARCH 30 1957

STRONTIUM-90 IN MAN

Whenever a nuclear weapon is exploded, or atomic energy is released in a reactor, over 200 radioactive isotopes are produced. All these can be harmful to man, but the main villain of the piece appears to be strontium-90. Its notoriety is due to several reasons. First, it has a high yield: one in every twenty fissions results in the production of an atom of strontium-90. Secondly, it is long-lived: its physical half-life is 28 years. Thirdly, it finds its way from the soil into food. Fourthly, it is a bone seeker. And, fifthly, it is retained in the human body for a long time; the biological half-life is about $7\frac{1}{2}$ years. The last two properties lead to the possibility that the β -rays emitted from radiostrontium may produce bone lesions and sarcomas as well as leukaemias.

Although the hazards from the deposition of strontium in bone have long been recognized, too little has been known about its distribution and metabolism to assess the hazards quantitatively. Recent papers¹⁻³ giving results of a world-wide survey of strontium content in man throw some light on the subject. Strontium-90 is an inevitable by-product of nuclear power production, and by the time most of our power requirements have been met from atomic energy there will be an embarrassingly large quantity of strontium-90 to be disposed of; but this does not present a hazard at the moment, since the strontium is not allowed to escape into the open. Even in a full-scale nuclear war strontium-90 would not be the main radiological poison; its damaging action would be small compared with that of the shorter-lived isotopes strontium-89 and iodine-131. It is the relatively small amount of strontium-90 accumulating from test explosions that causes some worry. Furthermore, strontium-90 does not present a genetic hazard, since it emits only β -rays, which do not penetrate to the gonads. It is the somatic hazard, the probability of inducing bone tumours, that is the main concern.

When a nuclear weapon is exploded in the air the radioactive fragments are carried by the upward draught high into the stratosphere. In the case of a

high-altitude explosion—as the next British H-bomb test is supposed to be—there is very little local fall-out, and practically all the radioactivity is taken up into the stratosphere. The rate of descent from there is very low, about 10% per year, and this allows the radioactivity to spread out over the globe, so that when it does come down, mainly with the rain, it is nearly uniformly distributed all over the world. By the time the active material has descended the short-lived radioactive elements have practically all decayed and only the long-lived ones, mainly strontium-90 and caesium-137, are deposited on the ground. Here strontium, being chemically similar to calcium, enters into the soil-plant-animal-human chain of calcium. The first step in the chain, the uptake of strontium by plants, depends on the root depth and on the calcium content of the soil. The latter varies greatly; differences by a factor of 100 are quite common. Since the uptake of strontium by the soil will be the greater the less calcium it contains, the concentration of strontium-90 per gramme of calcium in the soil, and thus the concentration in plants, may vary enormously. There is also a large variation with depth, most of the strontium being deposited in the top 4 in. (10 cm.) of soil. The consumption of vegetable food is one way of introducing strontium-90 into the body. But since most of the calcium in our diet comes from dairy products the next step in the chain, the uptake of strontium by grazing animals, is the most important one. Fortunately there is a large discrimination factor, of about 7, against strontium consumed by the cow appearing in the milk. Furthermore, there is another discrimination factor, of about 8, in going from food to the deposition of strontium in bone, so that the amount of strontium-90 per gramme of calcium in the human bone is very much smaller than that in the soil.

The concentration of strontium-90 is expressed in terms of so-called sunshine units (S.U.), one such unit being one-millionth of a microcurie per gramme of calcium. A recent survey² has shown that the content of strontium-90 in the human skeleton, resulting from all H-bomb tests carried out until the autumn of 1956, will eventually reach a value of about 2 S.U. This is an average value with a very wide spread. The uptake in different bones in the skeleton varies by as much as a factor of 15, the largest concentration being in the vertebrae and sternum, the lowest in the skull. There is also a big variation with age; children aged 0-4 years take up about five times more than adults, and they have also a greater sensitivity to radiations. Finally, there are large variations in individuals of the same age group, probably due to differences in diet.

The main problem is how to assess the hazard from a given amount of strontium-90 in bone. The maximum permissible concentration of strontium-90 is 1,000 S.U., which is 500 times the average amount which will accrue from test explosions. But such a comparison is misleading, since all maximum permissible levels were established for people occupationally exposed to radiations. When whole populations are exposed the maximum level must be greatly reduced. The assessment of this hazard hinges on a fundamental question: how does formation of bone tumours vary with dose? If a threshold dose exists below which tumours are not formed, then the small doses resulting from test explosions are probably harmless. But if there is no threshold, and tumour formation is a linear function of dose, then even the smallest dose will impart a small but finite probability of a bone tumour being formed. The available evidence is meagre, and, moreover, it entails comparison of strontium with radium, since only after exposure to radium has production of bone sarcoma in man actually been observed. There is growing evidence that the relation between the amount of exposure to radiations and the probability of developing long-term effects is of a linear nature. This was the view accepted by the M.R.C. in its report,⁴ which states that "each unit quantity of radiostrontium absorbed by the bone confers a certain probability of bone tumour formation." The consequence of a linear relationship is that every H-bomb test by causing an increase of the content of strontium-90 in bone will increase the frequency of bone lesions. But much more research work will be required before an accurate assessment of the hazard can be made.

ROAD ACCIDENTS

In Great Britain an average of fifteen people die every day as the result of road traffic accidents and 750 are injured. The daily toll of deaths in the United States is 110, and in 1955 four thousand million dollars' worth of property (including vehicles) was damaged in road accidents there.¹ In a recent number of the *Journal of the American Medical Association*, devoted to an A.M.A. symposium on road accidents, a leading article² states: "This is our number 1 public health problem. We are confronted with a massacre without precedent, without good reason, and without a ready solution. The control methods invoked to date are not adequate." The same could be said of road accidents in Great Britain. Almost all countries publish road accident statistics; most have safety committees; yet little attempt has been made outside the

United States to study the causes of these injuries. No country has seriously studied the type of closely co-ordinated, quick-moving hospital organization necessary to tackle the whole problem or to lessen the death rate. The great majority of people who die from these accidents are not killed outright on the road, but die subsequently in hospitals. Road accidents—indeed, injuries in general—present a challenge as yet inadequately answered by both preventive and curative medicine.

A medical committee taking part in a symposium held last year in New York¹ unanimously recommended that "qualifying medical examinations be mandatory prior to the first issuance of a [driver's] license to an individual and that a periodic qualifying medical examination be given prior to each renewal of the license." Independently the J.A.M.A. leading article² states: "The right to drive an automobile must become a sought-after privilege. . . . Some states still regard driver licensing as a source of revenue rather than a means of protecting the welfare of its citizens." Supporting the need for such examinations is the increasing evidence, from America, that the driver is a major factor in road accident causation. Moreover, industrial firms that have instituted a conscientious medical assessment of fitness to drive before employment have reduced their accident rates by as much as 50%.³

Important research on car design and its relationship to injuries of car users, sponsored by the Chrysler Corporation, the Ford Motor Co., and insurance companies, has been carried out over the last few years in the Cornell University Medical College and the Cornell Aeronautical Laboratories.³ Their factual findings on the internal features of conventional American cars likely to cause injuries correspond to those in Britain.⁴⁻⁶ Cornell lists the conventional American design of the instrument panel as responsible for 16% of all injuries, the steering component 14%, the windscreen and frame 13.5%, and the door components 12%. As a result of these findings their Aeronautical Laboratories have built a prototype safety car to lessen these risks. Other research at Cornell, not yet published, shows that some injuries result from the design and location of the hand-brake. An interesting finding from the Cornell research is the frequency in America of "ejection injuries" to the

⁴ Medical Research Council, *The Hazards to Man of Nuclear and Allied Radiations*, 1956, London.

occupants of cars and their high rates of serious injury and fatality. "In crashes where the velocity of the impact was high, there was a great tendency in frontal impacts for both front doors to open and in lateral impacts for the door opposite the side struck to open. In roll-over accidents, one or both front doors open in 77% of the accidents as compared with 53% in non-roll-over accidents. The resultant ejection of some of the car occupants doubles their risk of serious injury and of death."⁷ Such a high incidence of ejection has not been reported in Britain; that such accidents do occasionally occur here and result in serious injury cannot be doubted. Their much more frequent occurrence in America is probably due to the design of their long straight highways, often tightly packed with cars travelling at high speed; in part they may be due to the large bodies of many American cars. The compact, stoutly constructed, small British cars, with their engine in front, and the absence in this country of high-speed, straight highways, save their users in large measure from this particular hazard. It would be helpful if car manufacturers designed a safer "package" for car occupants. The evidence shows that when the occupant stays in the vehicle after impact he has a much better chance of survival; if he is not thrown violently about against projecting internal fittings, he has an excellent chance of escaping injury altogether.

Our road traffic conditions differ greatly from those of the United States. Here road fatalities in 1956 were shared between pedestrians 42%, motor-cyclists and their passengers 22%, motor-vehicle drivers and car occupants 22%, and pedal-cyclists 12%. In the U.S., where one in every three is said to own a car, the users of cars account for 75% of the total road fatalities and pedestrians for 22%. Yet as the number of motor vehicles on British roads has increased, so have the total injuries (as distinct from fatalities) to their users increased. For 1956 the Ministry of Transport's figures show that the following were killed in road accidents in Great Britain: pedestrians 2,270, pedal-cyclists 650, motor-cyclists 1,250, occupants of other motor-vehicles 1,197; total 5,367. The numbers injured were as follows: pedestrians 61,689, pedal-cyclists 49,169, motor-cyclists 63,883, occupants of other motor vehicles 93,130, horse riders 89; total 267,960.

From the nature of this high-speed machine age, injuries from road accidents will continue into the foreseeable future. Medicine has not yet taken on its full responsibilities in the prevention or treatment of them. The last two decades have witnessed remarkable advances in medical knowledge of the treatment of all types of injury, yet no hospital in this country

has so far been equipped with all the facilities and the staff necessary to meet these treatment requirements in an orderly manner and at the right time. Indeed, most hospitals are at their wits' end to keep pace with the numbers requiring treatment in their old and inadequate buildings. Yet a comparatively small number of hospitals, or self-contained large accident departments, specifically designed with modern, closely co-ordinated equipment, would give medicine a chance to apply its new knowledge and so reduce the present mortality and crippling rate from injuries, and at an economic cost.⁸ Such hospitals should provide reasonable facilities for research teams studying preventive measures to correlate the detailed causes of the accident with the injuries received by the car users, and to include in their study the final result of treatment, the total cost of the accident, and the related cost of hospital treatment and rehabilitation. As the *Journal of the American Medical Association* has stated, this problem remains unsolved. Yet if an all-out attack is mounted at hospitals receiving large numbers of injured it would have purpose and the necessary stimulus to go on until a reasonable solution is reached. But at least one special modern hospital is badly needed to serve as an experimental prototype for future development.

AMPHENONE INHIBITION OF ADRENAL FUNCTION

One of the fascinating features of clinical endocrinology is the stimulus it receives from animal experiments. Amphenone, 1,2-bis-(*p*-aminophenyl)-2-methyl propanone, one of a series of deoxybenzoins, was synthesized by M. J. Allen and A. H. Corwin in 1950.¹ R. Hertz and collaborators^{2,3} were interested in its structural relation to synthetic oestrogens, but noticed that it also produced enlargement of the adrenals (and the thyroid) in the rat, with the deposition of large amounts of inactive lipid material in the cells of the zona fasciculata and the zona reticularis of the adrenal cortex. This was interpreted as being due to inhibition of the synthesis of adrenal steroids, a thesis supported by the abrupt suppression by amphenone of the secretion of 17-hydroxycorticoids after giving A.C.T.H. to the hypophysectomized dog, blood from the adrenal vein being used for corticoid assay.^{3,4}

In contrast to the success they have achieved by hormone-substitution therapy in cases of endocrine deficiency, endocrinologists have been unable to abolish pituitary or adrenal hyperfunction or both, or the function of the normal gland in malignancy, without resort to major surgery. Hertz and colleagues⁵ therefore tried the effect of amphenone in four cases of advanced breast cancer with metastases. They found, as in the rat and dog, that the adrenal corticoids, measured by urinary assay, decreased considerably when the amphenone was

given orally in capsules of 0.125 to 0.5 g. 6-hourly; and that in two fatal cases the adrenals were "extraordinarily enlarged" and full of lipid. Further, the patients did not respond to A.C.T.H. while under the influence of amphenone. In another woman of 35, with carcinoma of the left adrenal with metastases and incomplete Cushing's syndrome, the urinary corticosteroids fell from 24 mg. to 3 mg. a day. In none of the patients was there any appreciable change in the urinary 17-ketosteroids, so that the inhibition of synthesis appears to apply to the adrenal glucocorticoids and not to the adrenal androgens.

Hertz then combined with Thorn and colleagues⁶ to study the effect of amphenone in a woman of 41 with Cushing's syndrome due to an adrenocortical carcinoma. The urinary 17-hydroxycorticoids were reduced by amphenone from 250 mg. a day to 50 mg. or less, but the effect on the raised 17-ketosteroids was much less striking. Accompanying the decrease in 17-hydroxycorticoids was a fall in insulin requirements for the patient's diabetes from 74 units to 13 units and then to nil. The levels of 17-hydroxycorticoids in the plasma showed a remarkable drop of both the free and the conjugated fractions. All this indicates that amphenone specifically interferes with the synthesis in adrenocortical tissue of biologically active 17-hydroxycorticoids from inactive precursors. This is in keeping also with the observations of R. I. Dorfman⁷ that, when added *in vitro* to adrenal slices, amphenone was found to inhibit the production of 17-hydroxycorticoids from suitable precursors.

It next became of theoretical and clinical interest to determine whether amphenone prevents the synthesis of adrenal aldosterone (electrocortin), because this controls electrolyte metabolism, and its secretion is largely independent of pituitary A.C.T.H. A. E. Renold and colleagues⁸ in some metabolic studies at the Peter Bent Brigham Hospital showed that amphenone has this effect. In the first patient, with adrenal hyperplasia, obesity, and diabetes, urinary aldosterone was reduced by amphenone from 20 µg. per 24 hours (normal 1-8) to nil, and a sodium diuresis was noted. The second patient, of great clinical interest, was a 39-year-old nurse, complaining of anasarca for ten years, without evidence of cardiac or renal abnormalities, but with evidence of sodium retention. Urinary aldosterone was greatly raised, being 66-123 µg. per day. Amphenone led to reduction of these values to 8-12 µg. and to a sodium diuresis, with an increase of urinary sodium from 3.0 mEq to 28 mEq. The adrenals were explored and an adenoma secreting aldosterone was found and removed, with restoration of normal biochemical values and clinical cure. Similar investigations into the effect of

aldosterone gave comparable results in a variety of other cases, but no effect was obtained in adrenalectomized patients.

Unfortunately amphenone has toxic side effects. Thus in a series of 24 patients⁹ 18 had drowsiness, 11 gastro-intestinal symptoms (heartburn, nausea, vomiting), 6 morbilliform and pruritic rashes, 6 methaemoglobinemia, and 2 impaired liver function with hepatomegaly in 1. These severe toxic features prevent the therapeutic use of the substance, and its main significance is as a diagnostic tool, including the differentiation of primary and secondary aldosteronism. It is indeed also a spur to search for other substances with similar action but less toxicity. In this connexion it is of interest that Hertz and colleagues⁵ showed that amphenone also inhibits thyroidal ¹³¹I uptake by interfering with the organic binding of iodide, and goitres develop as they do with the thiouracil group of inhibitors of thyroxine synthesis. In nature we find that the synthesis of thyroxine is interfered with at various stages in some forms of genetically determined cretinism; and in genetic virilism, evident at birth or early infancy, there is an apparent inability in the adrenals to convert 17-hydroxyprogesterone to 17-hydroxycorticosterone. Both these defects are usually thought to be due to absence of some chemical link, but it is possible that they are due to the presence of chemical inhibitors. If so, this would give further encouragement to the hope that substances allied to amphenone but without its toxicity will be forthcoming, and, if they are, a new therapeutic era will be opened up.

ATHLETE'S FOOT

According to some American authors¹ expenditure in the United States on the treatment of athlete's foot runs into millions of dollars annually. It is the commonest superficial mycotic disease in Great Britain. What does it cost us?

Two papers published in the *Journal* this week indicate that efforts to control the spread of the disease should be concentrated on communal bathing establishments and the home. For many years athlete's foot has been associated in the lay mind mainly with communal bathing, and this too seems to be the general opinion in the medical profession. The floors and duck-boards in such premises have been suspected as sources of infection owing to their supposed contamination by the exfoliated infective scales of sufferers from athlete's foot. But the many attempts made over the years to isolate by culture pathogenic fungi from presumably contaminated surfaces in bathing premises yielded little positive evidence to support the general belief that

infection was spread by infected epithelial debris. These repeated failures were at least in part responsible for causing some American authors^{2,4} to seek other evidence to account for the onset of athlete's foot. Their view seems to be mainly that the pathogenic fungi concerned are present in a dormant state or in a state of low activity in apparently normal skin, and that infection as perceived clinically requires some biochemical alteration of the skin^{2,3} or a "factor X."⁴ These authors rather discount the role of desquamated infective material in the epidemiology of the disease and accordingly regard the customary preventive measures as superfluous. However, recently evidence for the presence of infective materials in shower baths has been accumulating. A few years ago, with the help of cycloheximide in the culture medium to suppress saprophytic moulds, it was possible for some American authors¹ to isolate fungi which cause athlete's foot from shoes and also from the floor of a bathroom, and last year this was accomplished repeatedly by Mr. J. C. Gentles,⁵ who used a special technique for the purpose as well as incorporating cycloheximide in the culture medium. He records some further results in a paper at p. 746 this week. Some American authors,⁶ whose work is cited by Miss Mary P. English in her article at p. 744, state that spread of infection in families is a rare occurrence. Others,⁴ referring to *Trichophyton rubrum* infection, state that "it is important that the patient realize that the disease is relatively harmless and that transmission to others is unlikely to occur; it does not occur in families." In Britain we think otherwise, and the consensus of opinion may be summarized in the following quotation⁷: "The patient should be warned of the risk of infecting others. Going about barefoot at baths and other places may spread infection." There is no doubt also that if more cases of athlete's foot and their contacts in the home were followed up, as Miss English has done, the results would add further evidence that the infection is transferred among members of a family. On the other hand, no amount of evidence of this kind will explain why only a relatively small number of persons exposed to contamination become infected or what are the factors concerned in the onset of clinical manifestations.

As to preventing the spread of infection, bathers with healthy feet should be encouraged to wear shoes or sandals while bathing at communal baths and to wash their feet thoroughly on returning home. Persons affected with athlete's foot should be discouraged from frequenting such premises, and the ways in which infection is spread should be explained to them. In the home an infected member of the family needs practical advice on minimizing the risk of spreading infection to other members of the family. In particular, towels, bath-mats, and other bathroom paraphernalia such as nail-brushes, sponges, face-towels, and soap should be kept apart for his own use. He should not share slippers with others or walk barefooted about the bedroom floor. In bed, and especially in the conjugal bed, he should wear cotton socks, to be washed at frequent intervals after boiling. It is also worth warning him that the infection (chiefly of the *T. rubrum* type) may spread to

other parts of the body, as for instance the hands and the groin, and that in time the nails may be infected, and he should be advised to report immediately to his doctor any spread of this kind and any spread to other members of the family. He will also need explicit directions for the application of the treatment prescribed, because efficient treatment plays an important part in preventing the spread of infection. These may seem to be counsels of perfection, but in this disease half-way measures bring little benefit.

NEW FELLOWS OF ROYAL SOCIETY

Among the 25 new Fellows of the Royal Society elected last week are several medical men, as well as other scientists whose work has advanced medicine. Professor John McMichael, of the Postgraduate Medical School, is elected for "his contributions to medical knowledge, especially on the mechanisms of heart failure." A paper from McMichael and a colleague on this subject appeared three weeks ago in this *Journal*,¹ as did his classical Oliver-Sharpey lectures on the "Dynamics of Heart Failure" in 1952.² One of the pioneers in cardiac catheterization, McMichael was able to obtain data by this procedure about pressure changes in the healthy and diseased heart. He succeeded Sir Francis Fraser at the Postgraduate Medical School in 1946, having been acting director of the department of medicine there during the war. Professor C. L. Oakley, of Leeds University, has carried out a series of investigations into anaerobic bacteria, especially the pathogenic clostridia, doing much to elucidate their antigenic relationships. His researches have had important practical applications in the development of antitoxins. From 1934 to 1953, when he went to Leeds, Oakley worked at the Wellcome Research Laboratories, and during the second world war played a large part in providing prophylactic sera and vaccines for the armed Forces. In 1956 he became editor of the *Journal of Pathology and Bacteriology*. Dr. E. Lester Smith, now senior biochemist at the Glaxo Laboratories, is well known particularly for his work on vitamin B₁₂, or cyanocobalamin. In 1948 he and his colleagues succeeded in isolating it (as did an independent American team) in pure crystalline form. He has continued to study this and related haemopoietic factors, several of these being isolated in his laboratory for the first time.³ Apart from vitamin B₁₂, Lester Smith has been largely concerned with the extraction and development of penicillin.

Professor Saul Adler was educated at Leeds and went to Jerusalem to become head of an institute of microbiology. Later he was appointed one of the first professors at the newly created Hebrew University. His main contribution has been the investigation of leishmaniasis and its manifestations as oriental sore and kala-azar. In 1933 he received the Chalmers Medal of the Royal Society of Hygiene and Tropical Medicine for his work on the transmission of kala-azar by the sandfly and for his demonstration that while blood was sucked flagellates escaped from the infected sandfly into the

¹ McMichael, J., and Shillingford, J. P., *British Medical Journal*, 1957, 1, 537.
² ———, *ibid.*, 1952, 2, 525, 578.
³ Smith, E. L., *ibid.*, 1951, 1, 151.

victim's blood stream. In addition to leishmaniasis Professor Adler has made notable contributions to the pathology of malaria and trypanosomiasis. Professor B. Mendel, of Amsterdam University, made his first contributions to medical science in Germany. In Professor Warburg's Institute he discovered the inhibition of glucolysis by glyceraldehyde—a finding which became subsequently of considerable importance in the unravelling of the steps of the Embden-Meyerhof cycle. He left Germany at the beginning of the Hitler regime and after a time in Holland went to Canada, where he occupied a post at the Banting Institute in Toronto. Here he showed that the cholinesterase of the human and animal blood is not uniform but that there are two groups of enzymes, the true cholinesterases which act on acetylcholine *in vivo*, and the pseudocholinesterases. He has recently shown that the ali-esterase of animal serum can inhibit the growth of virus, plant cells, and tumour cells.

Professor J. F. Danielli's early work on the physical chemistry of membranes was carried out at University College, London; he used monolayers of steroids as his model. In 1938 he went to the Biochemical School in Cambridge as a Beit Memorial Fellow, his main contributions being on blood capillaries; and during the war he was a member of a team concerned with chemical defence. From 1949 he has been professor of zoology at King's College, London. His main interest in recent years has been cytochemistry, but besides his scientific achievements Danielli has been active in the organization of biologists and was one of the principal founders of the Institute of Biology. Other distinguished scientists elected include Professor E. C. Amoroso, of the Royal Veterinary College, London, an authority on the physiology of animal reproduction, and Dr. Charlotte Auerbach, of Edinburgh University, who is investigating the mutations caused by chemical treatment and ionizing radiation.

REACTIONS FROM ORAL PENICILLIN

The admission of two patients within one month to a hospital in Arlington, Virginia, suffering from severe reactions to orally administered penicillin has recently been recorded.¹ Both were women of middle age; one of them was known to have swallowed a capsule of 250 mg. of penicillin V, and the other had in fact taken a 200,000-unit tablet of penicillin G, but this was not at first known, the patient having been rushed to the hospital in coma by the local rescue squad. (It seems from this and several other reports about this type of emergency that Americans have the benefit of rather more than an ordinary ambulance service.) The features of these reactions seem no less alarming and rather more varied than those due to injected penicillin, though the fully developed picture of shock, with unconsciousness, cyanosis, and a steep fall in blood pressure, takes perhaps a few more minutes to develop. In the meantime there are burning sensations in the mouth and eyes, a sense of suffocation and of impending death, and oedema of the lips and eyelids: this is the sign which should suggest the true cause when no history is available. Both patients recovered after treatment with

¹ Maganzini, H. C., *New Engl. J. Med.*, 1957, 258, 52.

adrenaline, antihistamines, and hydrocortisone. In one of them noradrenaline had to be continued for 7½ hours to maintain the blood pressure, a total of 52 mg. being given.

The author also reviews the literature on reactions to penicillin administered by routes other than parenteral injection. These include, apart from oral administration, the local treatment of nasal sinuses, the application of ophthalmic ointment, the use of contaminated syringes, and the performance of a skin sensitivity test. Many such patients can give a history of previous reactions or of allergic manifestation of other kinds, and the single precaution which should never be omitted is to ask about these. It is also necessary always to be prepared to administer the urgent treatment required if shock develops. Accounts of these cases often do not say why the patient took penicillin; when they do the indication sometimes sounds inadequate. Are such reactions most liable to occur in the sort of patient who keeps penicillin tablets at home and takes one occasionally for a trivial reason? It is at any rate necessary to bear in mind that treatment with oral penicillin is not completely free from this risk. It should consequently not be prescribed because of its ease of administration for patients whose condition does not merit the greater trouble of giving an injection.

ANNUAL MEETING AT NEWCASTLE

More doctors from overseas attended the Annual Meeting of the B.M.A. last year than ever before, and no doubt the increasing attraction of the scientific side of the meeting was partly responsible for this encouraging sign of world-wide interest. In the *Supplement* this week we publish the provisional programme of this year's meeting, to be held at Newcastle upon Tyne from July 10 to 19. The Scientific Sections offer a wide choice to visiting members, and it is good to see that the opportunity has been taken to raise the barriers separating some of the specialties: for instance, the Sections of Medicine, Surgery, Cardiology, and Radiology will meet together to discuss arterial embolism. The subjects for the Plenary Sessions have been well chosen and should give family doctors a chance to contribute their own observations. The experiment begun at Brighton of having round-table discussions is to be repeated, and the scientific and pharmaceutical exhibitions will give the visitor plenty to see and think about. An innovation at Newcastle, and one that is certain to be popular, is a series of closed-circuit colour television programmes, sponsored and produced by Smith, Kline, and French Laboratories. These will consist of clinical demonstrations and surgical operations by members of the staffs of the Medical School, King's College, and the Royal Victoria Infirmary, and the transmission will be to the Gymnasium of King's College, where receiving sets will be provided. The programmes have been arranged to take place at times which do not overlap with other meetings. Thanks to the work of those responsible for the arrangements at Newcastle, the Annual Meeting this year offers an unusually diverse programme, and members who are thinking of attending should reserve their hotel accommodation as soon as possible. A list of hotels is given in the provisional programme.

Correspondence

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

ABO Blood Groups and Duodenal Ulcer

SIR.—The very important paper by Dr. C. A. Clarke and his colleagues (*Journal*, September 29, 1956, p. 725) established an association between duodenal ulceration and secretion of substances with ABO specificity, ulcers being considerably commoner in non-secretors than in secretors. At the same time they set out to discover whether the associations of duodenal ulceration with group O and with non-secretion observed in the general population also hold within sibships of brothers and sisters. I greatly appreciated several discussions with them during the progress of this interesting work, and they have also kindly given me a copy of the full basic data. Two points have struck me, which I think ought to be made, and after consultation with Dr. Clarke and his colleagues it was agreed that I should put them forward, thereby allowing the Liverpool workers to devote a letter to some new features which they have noted.

The first point is a matter of clarification. It was found that in 112 sibships containing both O's and non-O's the propositus with ulcer who brought the sibship to notice belonged to group O in 59 instances. The expected number on the null hypothesis, that within sibships O's and non-O's are equally likely to develop ulcers, was 54.9095. The difference was only 0.804 times its standard error and so not significant. It was therefore correctly concluded that "the analysis of our sibship data gives no evidence to support the hypothesis that a group O individual is more likely to have a duodenal ulcer than are his A, B, or AB sibs." But neither do the data contradict the hypothesis that the incidence of ulcer in persons of group O relative to non-O's is as high within sibships as it is in the general population.

The previous figures of Clarke *et al.*¹ indicate for the population of Liverpool a relative incidence of ulcer of 1.54 in O's compared to 1 in the other groups. This figure may be applied to the sibship data. Thus, considering sibships containing equal numbers of O's and non-O's, the chance of the propositus being O is put at 0.6063 and of being non-O 0.3937, instead of the 0.5 and 0.5 of the null hypothesis, and similarly for other compositions of segregating sibships. The expected number of O propositi is 65.989. The difference from the observed 59 is 6.989, which is 1.39 times its standard error and so non-significant. In fact, the sibship data do not contradict at the 5% level of significance any figure for relative incidence in O's which does not exceed 1.71. This figure is much higher than 1.38, which is the average for all centres reported up to the present, and considerably higher than 1.57, which is the highest figure at any single centre. The additional information provided by sibships containing more than one ulcer patient gives the same result. It is not possible, therefore, to draw any conclusion.

The second point did not occur to me till after the paper appeared. This is the effect of sex when the sibships contain both men and women. Duodenal ulceration is nearly six times commoner in men than in women. If, therefore, we consider a sibship of two, a man and a woman, one of whom is O and the other not O, then which the propositus with the ulcer will be is overwhelmingly affected by sex and only to a much slighter extent by blood group, even if O's show within sibships the same higher incidence as in the population generally. In the great majority of such sibships it is the man who will have the ulcer, whether he be O or not O. If such sibships are included in the analysis the information they contribute, even if it is unbiased, is largely irrelevant, and the variance is artificially increased.

The correctness of this argument is confirmed by an examination of the data on sibships and secretion. Clarke *et al.* showed 89 sibships segregating for secretion. The observed number of propositi who were non-secretors was 52, the expected number on the hypothesis of equal incidence within sibships being 42.464, the difference being 2.13 times its standard error. Let us now consider only those sibships in which the sibs are all of the same sex as the propositus. Thirty of the 89 sibships are entirely unchanged, as all members were of the same sex. A further 23 can also be used, as the omission of one or more sibs of opposite sex to the propositus still leaves a segregating sibship. In the 53 sibships the observed number of propositi who are non-secretors is 38. The expected number is 24.900. The difference is 13.100 $\pm$ 3.518, or 3.72 times its standard error. Thus the omission of the (largely) irrelevant sibships, and the irrelevant members of some others, has reduced a probability of 1 in 30 to 1 in 5,000, and greatly strengthens the conclusion that the association between ulcer and non-secretion holds within sibships. Turning to the other 36 sibships, those of mixed sex, the expected number of propositi who are non-secretors is 14 against an expectation of 17.583 $\pm$ 2.881, a result entirely incompatible with that given by the sibships all of one sex.

As a further illustration, if we had any doubt that the greater incidence of duodenal ulcer in men held within sibships of brothers and sisters also, exactly the same treatment could be applied as for blood group or secretion. In the 36 sibships of mixed sex the propositus is a man in 30. On the hypothesis that within sibships the risk for the sexes is equal the expected number is 18.083; the difference is 11.917 $\pm$ 2.848, 4.18 times its standard error. If we substitute expectations which we know to be approximately correct for the general population—namely, 0.85 and 0.15 for men and women respectively—the expected number of propositi who are men is 30.086, very close to the number observed.

Applying the same treatment to the sibships segregating for O and non-O, the 112 sibships mentioned above are reduced to 60, the propositus being of group O in 35 instances. The expected number on the null hypothesis of equal incidence is 31.000, and on the hypothesis of a relative incidence of duodenal ulcer in group O of 1.54 is 37.000. The differences of 4.000 and 2.000 are respectively 1.08 and 0.54 times their standard errors. The question of relative incidence within sibships, with its important bearing on whether the association is directly causal or not, is still left open and must await the collection of further data.

It might be asked why we should standardize one factor affecting incidence and ignore others that may also be influential—for example, age. The answer is that with duodenal ulcer the effect of sex is so large that we must take it into account if we are to avoid the risk of being seriously misled. It could easily have happened that the hypothesis of increased incidence in group O within sibships might have been wrongly rejected. Standardization for age might effect some improvement, but in comparison this is likely to be very small. Actually, on the Liverpool data, using all the 293 sibships, the mean age of the propositi is only 0.6 years greater than that of their sibs.

I would suggest, therefore, that in applying to duodenal ulcer the valuable method devised by Dr. C. A. B. Smith, as described by Dr. Clarke and his colleagues, the safe and simple plan is to consider only sibs of the same sex as the propositus. Some information might be recovered from the other segregating sibships, but approximate estimates of sex incidence would have to be introduced, and it seems doubtful whether the trouble would be worth while. It would seem especially undesirable to complicate the analysis by including sibs of opposite sex when there were already sibs of the same sex as the propositus, and so information was being efficiently contributed without them.—I am, etc.,

London, W.C.1.

J. A. FRASER ROBERTS.

REFERENCE

¹ Clarke, C. A., Cowan, W. K., Edwards, J. W., Howel-Evans, A. W., McConnell, R. B., Woodrow, J. C., and Sheppard, P. M., *British Medical Journal*, 1955, 2, 643.

SIR.—In a recent paper (*Journal*, September 29, 1956, p. 725) we showed that, in duodenal ulcer sibships where the unaffected sibs acted as controls, there was no significant association between blood group O and ulcer. Reasons were given for thinking that stratification of the population was an unlikely explanation of this, and a suggestion was put forward that the findings might be due to a maternal factor—that is, a group O woman is more likely than a woman of

other groups to bear children liable to ulcer regardless of the children's own blood group. The other principal finding was that non-secretion of blood group antigens appeared to predispose to ulcer. This was found to hold both within the sibships and in the general population, where a random sample acted as a control (χ^2 using this control has now reached 23.2 $P < 0.001$).

The data have now been extended from 293 to 330 sibships, and some early families where eel serum was used in testing secretor status (and in which, therefore, the results were doubtful) have been excluded. The further analysis of the sibship data seems again to support the view that predisposition to ulcer is dependent not only on the blood group and secretor character of the affected individual but also on the type of sibship to which he belongs. Thus, the families can be divided into four classes: (1) Those in which the sibs are all of the same blood group, but in which there is segregation for secretion. Here there is a significant association between non-secretion and ulcer (Table I). (2) Those in

TABLE I.—Analysis of the Chance of Propositus Being Non-secretor in the Sibships Segregating for Secretion. The Sibships Have Been Considered Separately According to Their Composition With Respect to Group O

Sibs	No. of Sibships	Non-sec. Propositus		d $\pm$ s	P	*P for Comparison of Two Differences
		Observed	Expected			
All group O	23	15	11.43	+3.57 $\pm$ 2.34	0.12	0.91
All not group O	32	19	13.60	+5.40 $\pm$ 2.68	0.05	
Total not segregating for group O	55	34	25.03	+8.97 $\pm$ 3.56	0.02	
Segregating for group O	24	8	11.92	-3.92 $\pm$ 2.38	0.09	0.01

TABLE II.—Analysis of the Chance of Propositus Being Group O in Sibships Segregating for Group O. The Sibships Have Been Considered Separately According to Their Composition With Respect to Secretion

Sibs	No. of Sibships	Non-sec. Propositus		d $\pm$ s	P	*P for Comparison of Two Differences
		Observed	Expected			
All non-sec.	17	6	8.99	-2.99 $\pm$ 2.01	0.13	0.11
All sec.	51	27	24.97	+2.03 $\pm$ 3.48	0.55	
Total not segregating for secretion	68	33	33.95	-0.95 $\pm$ 4.02	0.81	
Segregating for secretion	24	17	11.58	+5.42 $\pm$ 2.35	0.03	0.04

In the tables d is the difference (observed—expected); s the standard error of d; P the significance probability for $\frac{d}{s}$ for a normal distribution; *P is calculated by the method used in Clarke *et al.* (1956).

The comparison of two differences (between expected and observed) per sibship together with the standard error was calculated as follows: let d_1 be the difference between the expected and observed for one set of families, s_1 the standard error, and n_1 the number of sibships, with the corresponding figures for the other set being d_2 , s_2 , and n_2 . Then the difference per sibship will be $(\frac{d_1}{n_1} - \frac{d_2}{n_2})$ and the standard error is $\sqrt{\frac{s_1^2}{n_1^2} + \frac{s_2^2}{n_2^2}}$.

which the sibs segregate both for blood group and secretor status. Here the association which might have been expected from the general population studies is, in fact, found—namely, that blood group O predisposes to ulcer (Table II). (3) Those in which there is segregation for blood group but not for secretor status. In these families there is no detectable effect of the blood group in producing ulcer (Table II). (4) Those in which there is no segregation either for blood group or secretor character. In this class, the most common in the population, the data cannot be analysed by the method we employ (a method necessary to eliminate racial stratification). However, it must be borne in mind that in this type of family there might well be a detectable association between blood group O and duodenal ulcer if a suitable control could be found, but the data are not yet adequate to decide this matter.

If the apparent associations we have discovered are real (and on this more data are clearly required), it is likely that the genetic constitution of the parents not only determines whether or not their offspring segregate but also influences the probability of one or more of them developing an ulcer. The maternal genotype is more likely to be of importance in this respect because of the possibility of an antigen-antibody reaction taking place between mother and foetus (see our data¹ suggesting that immunological reactions may be important in the production of ulcer).

Another possible, but less likely, explanation of the variation within families is that sibs with different blood groups and secretor status might also have different behaviour patterns. This could result in ulcerogenic stresses within a family.

The main conclusion of this further analysis is that both the ABO and secretor loci are playing some part in determining a predisposition to duodenal ulceration and that their effects in this respect are not independent of one another.

We are very grateful to Dr. C. A. B. Smith for his useful comments and invaluable help with the statistical analysis.—We are, etc.,

Macroglobulinaemia

SIR.—The article on macroglobulinaemia by Drs. Ian R. Mackay and L. I. Taft and Mr. E. F. Wood (*Journal*, March 9, p. 561) has added still three more cases to a literature which is becoming extensive on this interesting subject. They illustrated the symptoms of haemorrhages and weakness secondary to the associated anaemia, though there was no record of any visual symptoms or signs of venous dilatation and haemorrhages in the ocular fundus such as those described by Drs. D. G. Ferriman and A. B. Anderson (*Journal*, August 18, 1956, p. 402), and which were the presenting symptoms in a similar case with which I was recently concerned (shown at the R.S.M. clinical meeting on February 8).

One of the interesting aspects of this disease is the comparatively benign course, for in the cases originally described by Waldenström¹ one had been followed up for seven years and the other for two years without very much change in their general condition, while in the cases reported in this article the first two had symptoms dating back five years, and, in our particular case, three years.

Though the proposition made by the authors regarding mutation as a case for the altered metabolism of the lymphocytoid cells which appear to be the origin of the abnormal globulin is a very interesting one, their suggestion that this occurs "in a malignant lymphoma which is usually, if not always, a lymphocytic lymphosarcoma," would appear to be based on the pathological interpretation of a microscopic appearance that is as yet incompletely described and which does not fit the clinical picture.—I am, etc.,

London, S.E.18.

Gestation and Sex

SIR.—On the possible association between time of intercourse in the menstrual cycle and sex of child your leading article (*Journal*, February 23, p. 451) is, rightly, worded cautiously. Nevertheless this possibility is not excluded by the evidence to which Dr. H. Binysh refers in his letter (*Journal*, March 16, p. 645). It seems quite impossible to predict the effect on time of conception of restriction of intercourse to a period from the 12th day to the end of the cycle (as in some Jewish families). In women with cycles of 28 days or longer it might increase the frequency of conception from pre-ovulatory matings (by increasing the fre-

quency of intercourse); in women with short cycles it would tend to restrict conception to matings in the post-ovulatory phase. In any case the effect on the sex ratio would have to be very much greater than any hitherto observed in man before it could be established on the offspring of 57 families. There is in fact some evidence that the proportion of male children is raised among Jews.¹ Finally, even if it were true that time of mating had a sharp influence on sex of child, it would not be possible without some very large assumptions to predict the effect on the sex ratio of either (1) restricting intercourse to a considerable part of the cycle, or (2) increasing the frequency of intercourse throughout the cycle. My own guess, and it is little more, is that the effect would not be great.—I am, etc.,

Leukaemia and Natural Background Radiation

SIR,—It is now well established that ionizing radiations can cause leukaemia in man. The detailed survey carried out recently by the U.K. Medical Research Council¹ of the incidence of leukaemia among patients treated for ankylosing spondylitis with x-rays, as well as the earlier investigations by the U.S. Atomic Bomb Casualty Commission² of the survivors of Hiroshima and Nagasaki during the period 1947–55, have definitely shown that the incidence rate of leukaemia increases with the strength of the radiation dose received. Although the exact relationship between the two is not definitely established, it may not be unreasonable to assume—and there is some recent evidence in support³—that the probability of incidence of leukaemia is directly proportional to the strength of the exposure (at least for low and moderate doses).

In the analysis carried out by the U.K. Medical Research Council, the x-ray dose was estimated in two different ways—first, by calculating the total amount of energy absorbed by the whole body, and, secondly, by calculating the maximum dose of radiation received (at a point in the spinal marrow). The whole-body dose is more relevant in the present discussion.

In the table given below, the figures in the last column are calculated from the corresponding data in columns 1 and 2, which are reproduced from the U.K. Medical Research Council's report. Thus, for instance, the whole-body integral dose of 7.5–14.9 megagram-roentgens (average 11.2) would correspond to a whole-body dose of about 160 roentgens for the "standard man" (mass 70 kilograms). The leukaemia incidence rate for this dose is 4.4 cases per 10,000 men per year (if we exclude the natural rate of 0.3 cases per 10,000 per year). Thus the incidence rate per roentgen per year per million persons comes out to be 2.8.

Whole-body Integral Dose in Megagram-roentgens	Crude Incidence per 10,000 Men per Year	Incidence per Million per Year per Roentgen
0	0.3*	>0.4
<7.5	0.7	2.8
7.5–14.9	4.7	1.8
15.0–22.4	5.1	2.6
22.5–37.4	11.3	3.5
37.5–52.4	22.6	8.0
>52.5	60.2	

* The rate has been estimated from the national vital statistics for all forms of leukaemia excluding lymphatic leukaemia.

It may be seen that the incidence rate of leukaemia is roughly 3 per million per year per roentgen.

An analysis of the Japanese data leads to a figure of roughly 1 per million per year per roentgen. This represents a lower limit to the incidence rate, since the gamma-ray doses have been estimated for a person in the open. Apart from the uncertainty in estimating the dose in this case, the actual radiation dose received by the survivors must have been much less, by a factor of 2 to 3, due

to shielding. Thus the incidence rate is again seen to be very roughly of the order of 3 per million per year per roentgen.

Let us assume that the natural incidence of leukaemia is due entirely to the action of the background radiation (to which everyone is exposed). The average natural death rate due to leukaemia is of the order of 15 per million per year. (In England and Wales the annual death rate from leukaemia was 11 per million in 1920, and 49 per million in 1954; the reason for this increase is not yet clear. The Japanese death rate is about 16 per million per year.) A person receives a whole-body dose of 0.1 to 0.15 roentgen per year from natural background radiation—that is, from the naturally and normally present radioactivity in his own body and the radioactivity and cosmic rays in the environment. This is equal to a dose of 3 to 5 roentgens up to adult life (say, 30 years).

On the assumption that the natural incidence of leukaemia is due entirely to background radiation, the figure of 3 leukaemia cases per million per year per roentgen and a natural radiation dose of 5 roentgens up to adult life would lead to a natural adult incidence rate of 15 per million per year. The close agreement between the incidence rate as calculated above and the observed rate may, no doubt, be partly accidental, but it points to the high plausibility of the assumption that the natural incidence of leukaemia could be due entirely to the background radiation.

Our thanks are due to Professor D. S. Kothari and Dr. M. L. N. Sastri for stimulating discussions.—We are, etc.,

A.C.T.H. in Multiple Sclerosis

SIR,—Three years ago I tried A.C.T.H. on a few selected early cases of disseminated sclerosis (multiple sclerosis) because of my belief that it is a "stress" disease.¹ Patients treated have been maintained on long-acting A.C.T.H. or gel 10–15 units intramuscularly twice or three times a week. This is the calibre of dose I find adequate to keep sarcoidosis patients free of symptoms, and does not usually lead to side-effects. A "no added salt" regimen is advised, together with 1–2 g. of potassium chloride daily. The number of cases is small owing to limited supplies, but the results have been sufficiently encouraging to be worth recording. Unlike most other reported trials of steroids in disseminated sclerosis, treatment has not been started without the prospect of maintaining it, though an exception has been made occasionally. In some cases the results have been really dramatic, and severe disability in bladder control, walking, and co-ordination, though present for some weeks or months, have almost disappeared in a matter of hours. A search of literature shows that Reis, Sahlgren, and Jönsson² first used A.C.T.H. for this disease in 1949. In 1953³ their series totalled 51 patients and 69 courses of treatment; in 68% of the treatments improvement was considerable, and in 48% almost total disappearance of the symptoms of the last attack occurred. The best results were achieved when treatment was given early in an attack, and in young subjects. The number of previous attacks did not seem to have any effect on the response to treatment. T. Fog⁴ recorded improvement in 13 out of 14 patients treated with short courses of A.C.T.H. Glaser and his colleagues⁵ reported an improvement in a third of 33 cases, but said that the improvement was transient, and that regression occurred after stopping treatment. Miller and Gibbons's⁶ experience was that A.C.T.H. in adequate dosage over five days in seven patients had no specific effect on the acute manifestations of disseminated sclerosis, and recently Thygesen and

M. Fog⁷ have produced evidence that cortisone and A.C.T.H. had no effect on the course of the disease in 36 patients over 10 months using relatively heavy dosage.

In two of my ten cases no improvement was obtained and the treatment was stopped. In the rest, partial or complete remissions occurred, and no severe relapses have taken place over a period of one to three years. One patient went on holiday, and ran out of A.C.T.H. and relapsed in a week, but quickly recovered on starting again. In all cases superficial psychotherapy has also been used, and endeavour has been made to give the patients insight into their habit of emotional suppression, and to help them ventilate their problems. At the same time I have tried, where possible, to modify unhappy environments by explanatory interviews with those relatives closely involved, and who are so often unwittingly contributing to the stress situation (it should be noted that Jonez⁸ claims good results from supportive psychotherapy alone). With a disease whose natural course is so variable it is difficult to assess results of treatment, and one does not want to precipitate a rush on A.C.T.H. by doctors anxious to help hopelessly crippled patients. I suggest, however, that it is worth a trial in early cases, or in old cases who have had a relapse, however severe, if the duration of the relapse can still be measured in months. As to whether maintenance therapy with a relatively small dose will protect against severe relapses remains to be seen; if an initial remission has been achieved it seems a logical sequel with parallels in other diseases where steroids are effective.—I am, etc.,

Ipswich.

Hospital Confinement

SIR,—Miss Aileen M. Dickins and her obstetric colleagues (*Journal*, March 16, p. 645) have reminded us of the danger of home deliveries for those women whose pregnancies deviate, even slightly, from the normal. It has been truly said that a labour can only be considered normal in retrospect. Until there are more maternity beds in this country there will have to be rigid selection of mothers who can be allowed home delivery. To the list of indications for hospital delivery, I would add *all* primigravidae. The first pregnancy and delivery is as hazardous to the mother and baby as to the woman who has had five or more children.—I am, etc.,

London, W.C.1.

W. C. W. NIXON.

SIR,—There is much to be said for the plea for hospital confinement put forward by your Windsor correspondents (*Journal*, March 16, p. 645), but there is another relevant point of view.

To reduce the very high and still mounting costs of our hospital services, why not encourage many more home confinements of normal multiparae, with the family doctor in charge and with an adequate nursing service? By all means have some standard, such as a D.R.C.O.G., before admitting the younger practitioners to the obstetric panel, but surely the older general practitioners of experience are still capable obstetricians. Confinements in the home need not impose too great a strain on the doctor's time if good antenatal work is done and an experienced and reliable midwife nurse is in attendance.

In pre-N.H.S. days many practitioners owed their establishment in a good practice, and the best type of doctor-patient relationship, to having successfully attended the mothers in their confinements at home. This relationship should be fostered as much as possible, and even now it is fast disappearing in State medicine. In my own area we

have a small maternity hospital where the general practitioners attend their own cases, under supervision of the area consultant obstetrician, and this works reasonably well.—I am, etc.,

Old Kilpatrick,
Dunbartonshire.

WILLIAM GIBSON.

Suxamethonium and Post-operative Muscle Pains

SIR,—I was interested to read the observations of Drs. D. D. B. Morris and C. H. Dunn (*Journal*, February 16, p. 383) on post-operative muscle pains following suxamethonium administration. These pains were, in fact, first described by Dr. T. T. Currie (*Journal*, May 9, 1953, p. 1032) and directly attributed to suxamethonium by Dr. C. Sanger (*Journal*, May 23, 1953, p. 1162).

We have followed up a small series of 50 cases, 25 of which received suxamethonium chloride in doses of 50–150 mg., preceded by 2–3 mg. of decamethonium iodide (C.10), in the hopes of modifying the effects of suxamethonium by the initial depolarizing action of C.10; the other 25 received similar doses of suxamethonium only. All were dental or otolaryngological cases in which no post-operative sedation was needed. They received thiopentone, nitrous oxide and oxygen, and, in some cases, pethidine, in addition to the relaxants used. In the 25 controls 40% (10) developed typical suxamethonium after-pains, 4 of these being severe and generalized. Of those receiving an initial dose of C.10, 24% (6) developed after-pains, and only 1 of these was at all severe. These results did not seem to us to be good enough to merit the routine use of C.10 to reduce muscle pains, but they are comparable with the results obtained using small doses of tubocurarine before the suxamethonium. The necessity of using relaxants of opposing actions is avoided, and C.10 being a shorter-acting drug than tubocurarine, minor degrees of residual paralysis are less likely.

Our findings confirmed that the after-pains bore no definite relation to the initial muscle fasciculations. Eleven of the 15 in the control series who had no after-pains had definite fasciculations, 4 of them markedly so. Of those who developed after-pains, 2 out of the 10 had no observable fasciculations at all.—I am, etc.,

London, S.W.1.

FREDA PRINCE-WHITE.

Noradrenaline in Shock Due to Visceral Perforation

SIR,—In answer to Dr. J. V. I. Young's queries (*Journal*, February 23, p. 463) regarding my article (*Journal*, February 2, p. 261): respirations were at times controlled although not continuously so; the Magill "rebreathing" attachment (Mapleson type A) was used and the gas flows were 8 litres/min. I agree that the Magill attachment is not ideal for use in techniques involving continuously controlled respiration. That some retention of carbon dioxide might, at times, have occurred in the cases described is certainly a possibility.—I am, etc.,

ShIPLEY, Yorks.

D. D. DAVIES.

The Hurt Brain

SIR,—Dr. H. B. Kidd (*Journal*, March 16, p. 645) has misunderstood Dr. E. E. Prebble (*Journal*, February 16, p. 399), who was not criticizing the use of penicillin as such in the treatment of neurosyphilis, but the complacent assumption that a single course of 10 injections or 10 million units automatically guarantees a cure. The proof of the pudding is in the eating, and unless the apparent relief of symptoms, gain in weight, fall in E.S.R., and general improvement in health are supported by improvement in the C.S.F., as shown by repeated examinations, the long-term results may prove disappointing.

It is usually true, as Dr. Kidd's experience shows, that the young acute cases with high C.S.F. cell counts do very well with even moderate amounts ("10 injections") of penicillin, but the long-standing cases require much more prolonged treatment to effect a cure, and when penicillin does not achieve the desired results the clinician should be prepared to fall back upon the old and tried remedies of the pre-

penicillin era. Of these the most outstanding in the treatment of neurosyphilis is not fever therapy but tryparsamide, though scarcely less "dangerous" than malaria. The remarks quoted from J. Purdon Martin¹ that if penicillin fails nothing else will work, and that arsenicals and bismuth are of no value, are contrary to the clinical experience of most older venereologists. In my own experience I have seen cases of neurosyphilis with active C.S.F. formulae fail to respond to repeated, massive, but intermittent courses of penicillin, often persisted in for several years, and yet resolve to the patient administration of tryparsamide.

In the use of penicillin as the treatment of choice, it is very important that it be given at least once daily to maintain a high and continuous tissue fluid level; the temptation to use the longer-acting penicillins at intervals less frequent than once daily has led to very indifferent results in my hands. Given once or twice daily as the sodium or procaine salt in three courses of 10 injections each, with adjuvant treatment in the intervals, penicillin will produce a normal C.S.F. within four months in favourable cases. If it does not, the decision to employ tryparsamide should not be further delayed. No other arsenical (and certainly no trivalent arsenical) should be considered. In view of the dangers of tryparsamide therapy (principally of precipitating an incipient optic atrophy) it should be undertaken in collaboration with a friendly and courageous ophthalmologist.

On the general question of danger, all drugs are potentially dangerous in unskilled hands, and sudden death after penicillin is not unknown. The much more toxic arsenicals require experienced hands, one of the few *raison d'être* for the continued existence of the venereologist; fever therapy carries the greatest risk, and yet in skilled and experienced hands with careful selection of cases very few patients die, as those familiar with the operation of the hypertherm at Newcastle will testify.

Finally, on "authorities," it is inconceivable that Dr. Kidd is not familiar with the authority on his own doorstep in Wakefield, but if this unhappily be so I will gladly supply him with the name privately.—I am, etc.,

Hull.

C. P. HEYWOOD.

REFERENCE

- ¹ Martin, J. P., *Practitioner*, 1956, 176, 142.

SIR,—The letters from Dr. E. E. Prebble (*Journal*, February 16, p. 399) and Dr. Humphry B. Kidd (*Journal*, March 16, p. 645) raise two questions: (1) Is one course of penicillin sufficient to cure neurosyphilis? (2) Is penicillin alone the ideal treatment? As Dr. Prebble suggests, I am sure most, if not all, venereologists would answer the first question with an uncompromising negative. The second question is more difficult, and nearly everyone who treats neurosyphilis has a different view. Personally, I cannot forget the brilliant cures often achieved with tryparsamide before penicillin was available, and feel that this valuable drug should still play a part in treatment.

Neurosyphilis, however, is a chronic disease and we have had penicillin for little more than a decade. Now is not the time for dogmatic statements on treatment. At least another 10 years of careful experiment and assessment of results is needed before an authoritative decision on therapy can be reached.—I am, etc.,

Birmingham, 4.

GERALD H. KNIGHT.

Distinctive Tubes

SIR,—The rapid progress of medical sciences is unavoidably associated with occasional retrograde advances. Correct labelling of the army of new medicamenta for easy identification is as essential as ever. Labels which become detached are a menace. Dr. Frank R. Neubert's suggestion (*Journal*, March 9, p. 588) that oculenta should be dispensed in distinctively coloured tubes is excellent and overdue. This simple method to aid identification was, of course, common practice when differently coloured drop-bottles were used for guttae. But why not be a bit more progressively modern and tint the ointments themselves? Then from the

spreading of the ointment on to the skin around the victim's eye we would at a glance also be able to diagnose the medicamenta to which a new patient has been subjected elsewhere. I cannot, however, allow an old friend of proved merit to be slighted: ung. hyd. ox. flav. is excellent, properly exhibited.—I am, etc.,

Guernsey.

J. E. MARTIN.

Sickling and Malaria

SIR,—Since Allison¹ proposed that the high frequencies of the sickle-cell gene in Africa were to be explained by a relative immunity of the sickle-cell trait carrier to falciparum malaria, much evidence has been brought out both for and against this hypothesis. Although it is generally agreed that such an immunity exists, in many areas it does not seem to be effective enough to account for the high frequencies of the gene. For example, in South-western Nigeria, where the sickle-cell gene attains a frequency of 0.13 (about 26% of the sickle-cell trait), Walters and Bruce-Chwatt² have not been able to find any evidence for this immunity. For the sickle-cell gene to attain a frequency of 0.13 a great deal of differential selection between sicklers and non-sicklers must be occurring. Thus it seems that other factors may well be involved in addition to this immunity of the sickler to falciparum malaria. I should like to propose another mechanism by which falciparum malaria could account for the high frequencies of the sickle-cell gene.

It is a well-known fact that the advanced stages of development of *Plasmodium falciparum* are not seen in the peripheral blood. As the parasite grows, the erythrocyte which contains it adheres to the walls of the blood vessels, usually in the internal organs. Miller, Neel, and Livingstone³ have suggested that under these conditions the cell would be giving up oxygen to both the tissues and the parasite; thus the erythrocytes of a sickle-cell trait carrier with falciparum malaria would have a tendency to sickle in all the organs of the body except the lung, and be more easily phagocytized with consequent interruption of the life cycle. Since Raper⁴ has shown that sicklers do not suffer from cerebral malaria, it seems that, in the brain at least, the parasite cannot multiply as well in sicklers as in non-sicklers. This could then be the basis of the sickler's relative immunity to falciparum malaria. If this were true, the placenta would be another organ in which *P. falciparum* would fail to develop in sicklers.

There have been three studies done on falciparum infections of the placenta, those by Blacklock and Gordon,⁵ Garnham,⁶ and, more recently, Bruce-Chwatt.⁷ Generally these studies indicate that falciparum infections of the placenta are associated with higher abortion, stillbirth, and neonatal death rates. Bruce-Chwatt has also shown that an infected placenta is associated with prematurity and a lower mean birth weight. If falciparum infections of the placenta could not develop to the same extent in sickling mothers, these individuals should have a proportionately higher number of liveborn infants and their offspring a higher survival rate. From a genetic standpoint the important value is the extent to which the sickling mothers contribute to the next generation. I have calculated that in order to maintain 26% of the sickle-cell trait the female sickler would have to contribute to the next generation at a rate that was 1.44 times greater than that of the normal female. This is rather high; however, it should be remembered that only one-half of the sickling mother's offspring will be sicklers, and also that the sickling mothers only produce about one-half of the sickling babies. In addition, the calculation was made on the assumption that this greater contribution to the next generation of sickling females accounted for all of the high frequency of the sickle-cell gene. It seems more probable that the high frequencies are accounted for by a combination of this higher rate and the relative immunity of the sickler to falciparum malaria, and probably other factors.

Data on this problem are rather scarce. Edington⁸ has shown that sickling mothers have a greater fertility rate, and a slightly lower stillbirth rate, and also that their babies have a higher mean birth weight and a higher survival rate.

His figures for the mean birth weight of babies of sickling mothers (3,010 g.) and non-sickling mothers (2,880 g.) are almost identical with Bruce-Chwatt's figures of mean birth weight of babies born of mothers with a non-infected placenta (3,048 g.) and an infected placenta (2,903 g.). Combining Edington's figures for the fertility rate and the offspring survival rate, we find that non-sickling mothers contribute 2.00 offspring to the next generation, while sickling mothers contribute 2.69. The ratio is then 1.34. In the Southern Gold Coast, where this study was done, there is 20% of the sickle-cell trait. To maintain this frequency the ratio only needs to be 1.29. It should be remembered, however, that the offspring survival rate also includes the effects of the relative immunity of the sicklers to falciparum malaria. Although most of the differences quoted here are not statistically significant, the evidence seems to be generally favourable to this hypothesis.

While I was at the Liberian Institute of Tropical Medicine Dr. R. S. Bray and myself attempted to obtain malaria smears from the placentae of sickling mothers. Due to the fact that the sickling rate is only about 7% in this part of Liberia, and also that the majority of the babies are born in the "bush," we were unsuccessful. Since it seems that this mechanism could in some places be as important as the relative immunity of sicklers in maintaining the high frequencies of the sickle-cell gene, I would like to urge that colleagues in areas of high sickling frequencies investigate this aspect of the problem.—I am, etc.,

Ann Arbor, Michigan, U.S.A.

How Many Hospital Beds?

SIR,—May I be allowed to make a very brief reference to your reporter's excellent summary (*Journal*, March 9, p. 579) referring to papers read to the medical section of the Royal Statistical Society at Westminster Hospital on February 26?

While it is true that I referred to the high rising costs of capital building and agreed that there was some measure of agreement on a figure of 6 to 7 acute beds per 1,000 of population, I sought to demonstrate by the use of certain formulae and case-load studies that, even with the information at present available, it should be possible to plan on a basis of as low as 5, or just under 5, beds per 1,000 of population, including maternity departments. Present-day costs being what they are, it is rather important that we should arrive at certain methods of more accurate forecasting. I left out of my reckoning all mental hospital beds, tuberculosis beds, geriatric beds, and certain highly specialized beds only found in the medical teaching centres. It is true that certain of the criteria relating particularly to maternity-bed requirements require re-examination in the light of modern trends, but this factor is not of such material value as to affect to a great extent the basis of calculation so far as our present knowledge goes.

The discussion which followed these papers by Mr. Newell and myself was very stimulating, and it was very encouraging to find that the subject was one of such topical interest.—I am, etc.,

Belfast.

A. T. ELDER.

SIR,—Your report (*Journal*, March 9, p. 579) of the meeting of the medical section of the Royal Statistical Society, in which it was stated that the provision of "bisexual wards" was urged, prompts me to write a few words on this matter. Without reference to outside authorities on the subject we have developed what I understand must be intended by the expression "bisexual wards," and have found it most helpful in the degree of flexibility it offers,

thus in one way, at least, helping to solve the problem of emergency beds in an efficient and non-wasteful manner.

In the General Hospital, West Hartlepool, we have two surgical wards, each consisting of two main wards and a number of side wards which lie geographically between the two main wards and which are used for either sex. One surgical ward has a 12-bedded men's ward, a 7-bedded women's ward, and 6 single-bedded side wards. The other surgical ward has a 14-bedded men's ward, a 12-bedded women's ward, and 6 single-bedded side wards. In this way we can, if necessary, have a minimum of 26 men's beds with a maximum of 31 women's beds, or a maximum of 38 men's beds with a minimum of 19 women's beds. In practice, of course, there are usually only a few beds one way or the other.—I am, etc.,

West Hartlepool.

HUGO GRANT.

Police Evidence Preferred

SIR,—I cannot agree with Dr. Charles L. Worthington (*Journal*, March 16, p. 643) that a policeman is better qualified than a doctor to judge ability to drive a car. The requirements for safe driving are good visual and motor co-ordination together with adequate emotional control. To assess these is the doctor's regular task by techniques with which we are all familiar.

In cases of intoxication disease must be excluded. Agreed. A good clinical examination does this, and establishes unfitness too. A parallel is seen when a doctor certifies that a patient is unfit for his work. The man's employer or workmate cannot be expected to detect a feigned illness, or prevent an ill but willing patient from continuing his efforts; but the doctor's broader knowledge allows him to do these things. And in the case of the driver of a car the doctor is better equipped than ever, for he also is a driver and understands the job.

The alcohol concentration is sometimes unfair because of variations in individual tolerance, and this spoils it from being the complete answer. As doctors we can judge the degree of incoordination, and whether it is due to disease; and as drivers we can assess fitness to drive. But it is not a job for the inexperienced.—I am, etc.,

Paignton.

J. F. BURDON.

Medical Advice in the Lay Press

SIR,—I was most interested to read Dr. M. B. Matthews's letter (*Journal*, March 16, p. 647). Since I have been in practice I have been asked by patients, from time to time and albeit rather apologetically, for some expensive tonic or to "see an ear specialist" (when a simple syringing out of wax was all that was required), or "what about some vitamin tablets, doctor?" etc. On closer questioning they have admitted that these ideas originated from a medical article in the lay press. I have discussed this with a journalist and was told that the press will print what the public wants: and there is, I am sure, little doubt that these articles are widely read. A local chemist told me that he can tell what tonic a well-known Sunday newspaper has advised to its readers by the sale of this commodity in his shop on the Monday. As long as the community is so ill-natured, the press will continue to print these articles. I think that the safeguard is that patients will usually ask their own doctor about it and are quite prepared to accept his advice on the matter.—I am, etc.,

Dalkeith, Midlothian.

H. M. S. NOBLE.

Needle in Rectum

SIR,—One hears about needles disappearing in strange places and emerging from the human body in unexpected places. I think the following case is rather a unique one.

A woman, aged 38 years, brought to the surgery a black needle with cotton threaded in it. She told me that she suffered from constipation and piles. While at work she went to the toilet, and while there felt as if her back was locked and was in great pain. The bowels did not move. The sister at the works looked at the anal region, saying

there was nothing except a piece of cotton, and tried to pull it. The patient screamed, and, thinking the pain was due to piles, the matter rested there. When she got home she thought she would ease the pain by sponging the piles with hot water. Passing her finger into the rectum, she felt the needle lying across and pulled it out. The patient could not explain how long the needle and cotton were there and how they got into the rectum. The only explanation I can think of is that she might have sat on it and it was carried into the rectum by suction.—I am, etc.,
Liverpool, 18.

H. PRATAP.

Bolus Obstruction

SIR.—Further to Dr. John T. Corbett's letter on this subject (*Journal*, March 2, p. 524), it may be of interest to record a very similar case.

In mid-ocean, in October last, a ship's assistant cook, aged 34, reported sick with the classical signs of small-bowel obstruction. Examination revealed a well-healed midline upper abdominal incision which was said to have been "for indigestion in 1953—and I've only half a stomach now"—from which it was concluded that he had undergone a partial gastrectomy. At laparotomy a bolus was discovered firmly impacted in the lower jejunum. This was delivered by enterotomy, and at first baffled investigation, but when dissected at leisure was found to consist of five segments of an orange in one piece. The patient made an uninterrupted recovery but has still to live down this gastronomic reputation amongst his shipmates.—I am, etc.,
London, S.W.1.

LEONARD GOODMAN.

Pavlov's Works

SIR.—In a letter on Pavlov's works (*Journal*, December 22, 1956, p. 1482), Dr. W. Ritchie Russell reviews the choice between modern pseudo-psychology which neglects discipline and that gross materialist conception which posits man as no more than a machine made from cerebro-centric reflex arcs.

Fortunately we need not restrict our choice within such a field. We can go to the ancient stream of common-sense philosophy, which was founded when Aristotle solved the dilemma of Heraclitus and Parmenides by his discovery that corporeal things are constituted from matter and form, which, in man, are body and soul. Man is born with a temperament, rooted in matter ("behaviour patterns" for modern "psychologists"). But repeated acts of the will, a spiritual power, form not only facilitated reflexes but also habits, which are rooted in spirit. These habits are good or bad, virtues or vices. They are imprinted upon the temperament, and so character is formed. Hence, the importance of discipline.

Dr. Russell does well to draw our attention to the attempt of the Russians to found a philosophy on physiology. It is more absurd than the attempt to found a cathedral upon a solitary brick. But the consequences are much more serious. The essential distinction between man and brute is denied; and it becomes quite logical that man should behave like a brute when he is strong and be treated like a brute when he is weak. Let us hope that this be not a "basis for national education." Atheistic materialism is a dangerous playfellow.—I am, etc.,
Sydney, Australia.

VICTOR J. KINSELLA.

Herpes Zoster and Chicken-pox

SIR.—I was interested to read Dr. George Holloway's letter (*Journal*, March 9, p. 583), in which he refers to a case of chicken-pox following herpes in the same household. I had a similar experience last year. The father developed moderately severe herpes ophthalmica on September 19. This subsided, but he was not completely recovered until October 8. On October 4 his son, aged 7 years, developed chicken-pox. The child, suffering from bronchitis, had been confined to the house for the previous three weeks, and, so far as can be ascertained, the father had not been in

contact with chicken-pox. It will be noted that the time intervals between the onset of herpes in the one patient and chicken-pox in the other—18 days in the case recorded by Dr. Holloway, and 15 in this one—approximate nearly to one another. It is invariably the custom to warn parents whose children have chicken-pox of the danger of developing herpes, especially herpes ophthalmica, unless precautionary measures are taken, but hitherto I have not considered it necessary to give any similar warning in cases of herpes.

I am indebted to Dr. J. Durie, in whose practice this case occurred, for his permission to refer to it.—I am, etc.,
Middlesbrough.

H. CRESSWELL PIERCE.

Termination of Pregnancy

SIR.—Dr. James Arkle (*Journal*, March 9, p. 558) represents the ancient Hebrews as allowing therapeutic abortion. Even granted that there were "therapeutic abortionists" during the desert exodus, then they must have been peculiarly incompetent ones, for at the end of their 40 years' pilgrimage, while there were only two men of the original company left, there were still 601,730 Israelite males of 20 years and over. His deductions, whether from the Hebrew text or the Septuagint, appear liberal, to say the least. One might as well discuss the ethics and moral implications of a miscarriage resulting from a present-day car accident.

Not content with this, Dr. Arkle further misrepresents the Christian "laws" on abortion. While referring to various statements by various Christians, it is noteworthy that he does not give a single New Testament reference. Dr. Arkle fails to acknowledge, if not understand, the non-legalistic attitude of true Christianity. The Christian's attitude to this question is not conditioned by one difficult, and maybe irrelevant, Old Testament verse, but rather in the entire context of Biblical teaching. It is not a matter of the "1st Section of the Corpus Juris Canonici (Cap. 9)," but is rather what would have been the attitude of Christ in any given set of circumstances.—I am, etc.,
Cardiff.

D. E. B. POWELL.

Abdominal Hernia Appliance Fitters

SIR.—We would be grateful for the opportunity of bringing to the notice of the medical profession through your *Journal* the scheme for the training and certification of abdominal hernia appliance fitters.

This scheme, sponsored by the Institute of British Surgical Technicians, has been developed for the training of abdominal hernia appliance technicians and subsequent qualification by examination. The chairman of the board of examiners is a surgeon, and the object of the scheme is that the medical profession will be able to have their patients correctly fitted with abdominal hernia appliances and thereby avoid the discomfort and inconvenience often caused by ill-fitting appliances.

A number of courses of training have already been held and others will be arranged at suitable centres throughout the United Kingdom as the scheme increases in scope. There are at present 230 certificated abdominal hernia appliance fitters, the names of whom can readily be supplied to any doctor who is interested. By this means practical assistance will be given to the scheme.—We are, etc.,
HENRY SOUTTAR,
President.

H. GUY DREW,
Chairman.

Institute of British Surgical Technicians.

London, E.C.1.

POINTS FROM LETTERS**Laboratory Requests**

Dr. P. LAZARUS-BARLOW (Hastings) writes: I wonder whether the following two requests recently received in the laboratory here can be beaten. Both were written by medical men of some years' standing: (1) "Mrs. A. Feels sleepy after meals. ? Anaemic. Blood count please." (2) "Mr. B. 33 years. Gets browned off and feels tired in the evenings. Blood count please." What has modern medicine come to?

Obituary

F. W. PRICE, M.D., F.R.C.P.

Dr. F. W. Price, consulting physician to the Royal Northern Hospital and the National Hospital for Diseases of the Heart, died in London on March 19, two days after his 84th birthday. The famous textbook which bears his name ran into eight editions during the thirty years of his editorship.

Frederick William Price was born on March 17, 1873, the son of William Price, of Weston Rhyn, Shropshire. From Ruabon Grammar School he went on to become

a medical student at Edinburgh University, where he graduated M.B., C.M., with honours in medicine, in 1898. After holding the appointment of resident physician at the Edinburgh Royal Infirmary he came down to London as assistant resident medical officer at the Brompton Hospital. Other appointments he held at hospitals in or near London included those of pathologist and registrar at the

City of London Hospital for Diseases of the Chest, physician and honorary pathologist to the Mount Vernon Hospital for Consumption, medical registrar at Westminster Hospital, and physician to out-patients at the Hampstead General and North-west London Hospital. He took the M.R.C.P. of London in 1903 and proceeded to the M.D. in 1908. During these years he established himself in London as a sound physician and built up a large private practice. He was always specially interested in cardiology, an interest which was stimulated by his association with Sir James Mackenzie and Professor A. R. Cushny in pharmacological research. Price himself also carried out original work on the effect of digitalis and other drugs on blood pressure.

In 1912 he was invited to Canada to attend the meeting of the Toronto Academy of Medicine, at which he gave the opening address, and when the British Medical Association held its Annual Meeting at Brighton in 1913 he read a paper on the action of digitalis on the blood pressure in man. Shortly afterwards he was elected to the staff of the National Hospital for Diseases of the Heart as an assistant physician, and in due course he became senior physician and ultimately consulting physician at that hospital and at the Royal Northern. For some years Price examined in medicine for the University of St. Andrews. He was himself a good teacher at the bedside, having a highly developed skill in eliciting the physical signs of cardiac abnormality. In 1915 he was elected a Fellow of the Royal Society of Edinburgh and in 1936 a Fellow of the Royal College of Physicians of London; and in 1947 the honorary degree of M.D. was conferred on him by the Queen's University, Belfast.

Price was the editor of *A Textbook of the Practice of Medicine* from its first edition, published in 1922, to its eighth edition, which appeared in 1951. There were 26 contributors to the work, which set a new fashion, for up to the time of its first appearance most English text-

books had been written by one author. The stress on treatment was found particularly useful by those already in practice. Price himself wrote most of the section on diseases of the heart. To quote from the *Journal's* review of the first edition: "It . . . gives, in a most concise form, a vast amount of valuable information, and the experience of many of the most able London physicians." Price wrote one book himself on diseases of the heart, and he contributed chapters, mainly on cardiological and respiratory disorders, to several textbooks, including Latham and English's *A System of Treatment*.

In 1943 he married Miss Hilda G. Brown, of Bath, and she survives him. A memorial service will be held at All Souls Church, Langham Place, London, on Monday, April 1, at 12.30 p.m.

T. F. C. writes: Frederick Price, known as "Freddie" by many, died last week after a long illness at his home in London. He was an octogenarian leading a life of semi-invalid retirement for many years. When the time came for him to retire from the honorary staff of the National Heart Hospital he drifted away from colleagues and associates. One night during the "blitz" his home in Harley Street was destroyed, and he was found walking in the street in his pyjamas hugging his first love, the manuscript of a new edition of the famous *Textbook of the Practice of Medicine*. He seemed lost and found it difficult to adapt himself to new surroundings.

He married and was happy in his domestic life. He combined a deeply religious nonconformist outlook with a well-defined astuteness. When presiding at a hospital meeting he seemed to be more occupied with tactics than strategy. Shyness was largely responsible for some of his mannerisms and some of his bodily complaints. He did not seem to have many outside interests, and would be content to walk in the evening to his club and read the *Irish Times*. His complaint was always the heavy duties imposed on him as editor of his *opus magnum*, and his life seemed to be centred round the recurring editions; perhaps there was an element of escapism in this concentration through the years. At any rate, the *Textbook* made him a household name in the profession, graduates and undergraduates. It was this *Textbook*, by various authors, and not *Diseases of the Heart* which made his reputation and place in the medical world.

A graduate of Edinburgh University, he made the journey to London and soon came under the influence of Mackenzie, who later had a consulting-room in his house. On Mackenzie's retirement Price occupied the room and his practice increased. He did not harvest new knowledge, but few do. His contribution is a textbook, in many editions, which has been and continues to be generally accepted as a credit to British medicine, and will serve as a worthy memorial to a physician and cardiologist sure of remembrance by friends and others who have benefited by his many years of active life.

T. GRAINGER STEWART, M.D., F.R.C.P.

Dr. T. Grainger Stewart, consulting physician to the National Hospital, Queen Square, London, and consulting neurologist to the West London Hospital, died at Farnborough, near Wantage, Berkshire, on March 18. He was 83.

Thomas Grainger Stewart was born on December 2, 1871, the son of Sir Thomas Grainger Stewart, professor of medicine in the University of Edinburgh from 1876 to 1900. Educated at Edinburgh Academy and the University of Edinburgh, he graduated M.B., Ch.B. in 1900, and was elected a Member of the Royal College of Physicians of Edinburgh in 1902 and of the Royal College of Physicians of London in 1904. He proceeded to the M.D. in 1912, receiving a gold medal for his thesis. After graduation he held the appointment of resident

physician at Edinburgh Royal Infirmary, and then, in 1902 after a period of study abroad, began what was to be a lifelong connexion with the National Hospital in Queen Square. In that year he was appointed junior house-physician to the hospital and thereafter occupied successively the posts of senior house-physician, resident medical officer, medical registrar, assistant pathologist, assistant physician, physician, and, finally, consulting physician. From 1906 to 1909 he was also assistant physician to the Metropolitan Hospital. In the latter year he became assistant physician to the West London Hospital, where he subsequently became neurologist and, in later years, consulting neurologist. Among other appointments he held were those of physician to the Central London Ophthalmic Hospital, honorary neurologist to St. Vincent's Cripples' Home, Pinner, and consulting neurologist to St. James' Hospital, Balham. After the first world war he was consulting neurologist to the Ministry of Pensions. He was elected F.R.C.P. in 1913.

Dr. Grainger Stewart married Lady Frances Playfair, widow of Sir Patrick Playfair, in 1922, and she survives him.

J. P. M. writes: Grainger Stewart was in many ways a typical Scot—reserved, slow of speech, very cautious, very sound in judgment. As a young man he must have been very attractive with his reddish colouring and winning smile. He was appointed to the honorary staff of the National Hospital, Queen Square, at the age of 31. He had already written in association with Gordon Holmes a paper on the symptomatology of cerebellar tumours which was to become a classic, and also (again in association with Holmes) a paper on the connexions of the inferior olive with the cerebellum in man. After his appointment to the honorary staff he wrote in conjunction with Dr. Aldren Turner a textbook of nervous diseases which was published in 1910. Before the first world war he was building up a practice in London, and at hospital showed promise as a teacher. During the war he served as a specialist with the Army at home, and subsequently began an association as consultant with the Ministry of Pensions hospitals, first at Hammersmith and afterwards at Roehampton, which he was to maintain to the end of his days.

In middle life, in the early 1920's, he had a prolonged period of serious illness and was probably never the same man afterwards. He was slower, he had lost some of his keenness, some of his enthusiasm for neurology, some of his *joie de vivre*, and his illness had done great harm to his practice. Thereafter, apart from an occasional lecture, given as a duty, he did no teaching. However, in 1927, he published, in association with Dr. Greenfield and Dr. Blandy, one of the early papers on Schilder's disease (encephalitis peri-axialis), including a case of a variety until then undescribed. A tendency to withdraw from medical society was increased by his oncoming deafness. His physical health eventually recovered fully, and during most of the inter-war years he used to spend the autumn deerstalking in his beloved Scotland—a sport which required physical fitness. In the days when junior physicians had not so many beds under their care as they have now, this gave his junior the welcome charge of his wards for at least two months every year, and some pecuniary reward from looking after his private practice.

With the coming of the second world war Grainger Stewart's activities were necessarily reduced. He spent a good deal of time in London and continued to attend his hospitals—at Queen Square, the West London, Roehampton, and the Eye Hospital in Judd Street—until he reached retiring age in 1942. In committee he always spoke with wisdom and dispassionately, but he lacked vigour and was often short of words—shortcomings of which he was very conscious. For many years he was a valued member of the

board of management of the National Hospital, in the days before the National Health Service.

Brought up in a cultured and academic Edinburgh family, with its strong presbyterian background, Grainger Stewart remained in many ways typical of the society in which he grew up. His standards of conduct were of the highest; he was a loyal and trusted friend; shy and sympathetic, he treated his patients, rich and poor, alike. In the pre-war days, when the hospital was run on more intimate lines than is possible now, he knew not only the residents and nursing staff but every porter and clerk and carpenter and engineer, and was regarded by them all with an instinctive respect and a peculiar affection such as was not accorded to any other member of the honorary staff.

ISAAC JONES, M.D., F.R.C.P.

Dr. Isaac Jones, physician and chief medical officer to the Metropolitan Police and formerly medical tutor at St. Thomas's Hospital, died at St. Thomas's Hospital on March 24, aged 74.

Isaac Jones was born in Australia in 1882 and was a medical student at Melbourne, where he graduated M.B., B.S. in 1909, proceeding to the M.D. with honours three years later. After working as house-surgeon, house-physician, and medical registrar at the Royal Melbourne Hospital, he developed his interest in pathology by taking the post of clinical pathologist to the Royal Melbourne Hospital and the Women's Hospital. For a time he was also resident tutor in medicine, pathology, and physiology at Trinity College, Melbourne. During the first world war he served in the R.A.M.C. with the rank of major and was the author of a special report to the War Office on the control of malaria and dysentery among troops. After demobilization he decided to practise in London and took the M.R.C.P. in 1919. It was at this time that he began his long connexion with St. Thomas's Hospital, where he was appointed deputy director of the clinical medical unit, under Professor Hugh MacLean. In association with his chief and with Dr. Geoffrey Fildes, Isaac Jones published an authoritative paper entitled "Treatment of Gastric and Duodenal Ulcers by Intensive Alkaline Method."

When the staff of the medical unit at St. Thomas's was enlarged in 1928 Isaac Jones became medical tutor, and it was in this post that he continued to serve the medical school at St. Thomas's, retiring after the second world war. He always enjoyed the company of young people and he taught the fundamentals of clinical medicine clearly and entertainingly. Students recognized him for the kindly and genial man he was and held him in special affection for being something of a character. From the time when he ceased to be deputy-director of the medical unit at St. Thomas's in 1928, he served as chief medical officer and consultant physician to the Metropolitan Police, Scotland Yard. In 1947 he gave a memorable lecture to the Medical and Physical Society at St. Thomas's on Scotland Yard and the Metropolitan Police Force. He was always proud to be associated with the Metropolitan Police, and they in their turn were devoted to him.

For many years—from 1937 to his death—Isaac Jones represented the New South Wales and Queensland Branches on the Central Council of the B.M.A., and he also served on a number of the Association's committees, including the Dominions and Overseas Committees. Both inside and outside the profession he had many friends, who will wish to extend their sympathy to his widow and two sons.

G. F. STRONG, M.D., D.Sc., LL.D., F.R.C.P. F.R.C.P.(C.), F.R.A.C.P., F.A.C.P.

Dr. G. F. Strong, clinical professor of medicine at the University of British Columbia, Vancouver, died suddenly in Montreal on February 26 at the age of 60. His many friends in the British Medical Association will recall him as the outgoing President of the Canadian Medical Association at the time of the conjoint Annual Meeting in Toronto in June, 1955.

Born in St. Paul, Minnesota, in 1897, George Frederick Strong—better known to his friends as Fritz Strong—was educated at the University of Minnesota, taking the B.Sc. in 1918 and proceeding to the M.D. in 1921. A year of his graduate training was spent at the Vancouver General Hospital, and this contact with Canada appears to have impelled him to reverse the usual migratory trend, and Canada gained one of its most distinguished medical figures. Appointed to the staff of the Vancouver General Hospital as physician in 1926, Dr. Strong became the leading cardiologist of the west and the prime mover in all good works, locally, nationally, and internationally. The roster of his appointments and offices is long. This able man, whose forceful personality impressed itself on all his contacts, was no office-seeker, but he rose naturally to positions of responsibility and authority. President of the Vancouver Medical Association (1929–30), president of the British Columbia Medical Association (1936–7), president of the Canadian Medical Association (1954–5), president of the American College of Physicians (1955–6), president of the North Pacific Society of Internal Medicine, charter member and first president of the Family Welfare Bureau of Greater Vancouver, president of the Canadian Heart Association, president of the National Heart Foundation of Canada, president of the Greater Vancouver Health League, vice-president of the Western Society for Rehabilitation, director of the Canadian Cancer Society, chairman of the Medical Board of the British Columbia Research Institute—these represent a selection of his many interests. Last year, in the capacity of immediate past-president of the American College of Physicians, he visited Australia and New Zealand to attend the congress at Wellington of the Royal Australasian College of Physicians, before which he read the Arthur E. Mills Memorial Oration, choosing for his subject "The Changing Aspects of Medicine." During the visit he became an honorary Fellow of the College. At the memorable joint Annual Meeting of the British and Canadian Medical Associations in Toronto in 1955, Dr. Strong received the degree of honorary LL.D. of the University of Toronto. In the same year he was elected F.R.C.P.(London).

Dr. Strong took a leading part in the establishment of the Faculty of Medicine at the University of British Columbia. His work and worth were recognized at the founding of the school in 1951 in his appointment as clinical professor of medicine, and it is likely that his contribution to medical education gave him the greatest

satisfaction. He was proceeding to his presidential duties with the National Heart Foundation of Canada when stricken with his fatal illness. Fritz Strong's personal qualities, his energy and drive, his forthright and articulate manner of speaking, will be sadly missed in many organizations, not the least in the Canadian Medical Association, where he contributed so much.

H. E. SIGERIST, M.D., F.R.C.P., LL.D., D.Litt.

Widespread sorrow will be felt by the many friends and admirers of the distinguished historian of medicine, Dr. Henry Sigerist, when they learn of his death, at the age of 65 years, at his home, so pleasantly named Casa Serena, in Pura, Ticino, Switzerland, on March 17.

Born in Paris of Swiss parents, Henry Sigerist was educated at Zurich, and even in early boyhood he was attracted to the study of languages. Before the age of 15 he was familiar with Latin and Greek, and also Arabic, and soon he devoted much attention to Oriental languages, especially to Sanskrit and Chinese. From philology he turned to science and then to medicine, graduating M.D. at Zurich in 1917. Had he specialized in any branch of medicine he would have achieved notable success, but, as he told his audience in the Heath Clark Lectures ("Landmarks in the History of Hygiene"), delivered at the University of London in 1952, "I steadily refused to specialize. My interests were very broad, and I drifted into a field where I could combine all my interests, medical, philological, historical, and sociological. This I did against the advice of my teachers, who tried to impress upon me that the history of medicine was not a career, but a hobby for retired practitioners."

Sigerist commenced his unusual career by assisting Professor Karl Sudhoff, professor of history of medicine in the University of Leipzig, and he succeeded Sudhoff in this chair in 1925. Resigning in 1932, he went to the United States, and at Baltimore he followed Professor W. H. Welch, who had been the first occupant of the chair of medical history at Johns Hopkins University and director of the Institute of the History of Medicine. At that time the librarian of the Institute was Dr. Fielding H. Garrison. Sigerist carried out the duties of his office with characteristic energy and zeal. He founded the *Bulletin of the History of Medicine* in 1933 and by his lectures and writings did much to stimulate interest in an aspect of medicine which has been more fully adopted as a basis of medical education and practice in America than in Britain.

In 1947 Sigerist resigned from his chair at Baltimore and returned to Switzerland in order to devote all his time and energy to the writing of a *History of Medicine*, in eight volumes, which he had planned for many years. He felt that time was passing all too quickly and that if the task was to be completed it must be made a whole-time job. Unfortunately his health was not equal to the self-imposed discipline of this great work, and he was handicapped by a serious illness. Nevertheless he made a wonderful recovery, and it was hoped that he would complete the work as editor, if not as sole author. Unfortunately that hope was not realized. Nevertheless

the name of Henry Sigerist will long be honoured, not only in the annals of medical history but in the whole realm of medicine. Many who never met him will mourn his loss, having been helped and stimulated by his writings, while others who had the great privilege of his friendship will feel the loss more keenly, but will cherish and recall happy memories of his genial presence and his infectious enthusiasm.—D.G.

We are indebted to Dr. E. ASHWORTH UNDERWOOD for the following appreciation:

The death of Henry Sigerist will be a loss to scholarship in general and an irreparable loss to the history of medicine. Although he retired officially 10 years ago from his chair at Baltimore, he had really been working intensively in the writing of a history of medicine on very generous and unusual lines, and only the first volume of this work has so far been published.

Sigerist possessed all the qualities which make a scholar, and he made opportunities to train himself in widely different subjects. After graduating in medicine at Zurich he spent two years as a medical officer in the Swiss Army, where he obtained some clinical and public health experience. At the end of the first world war he decided to make the history of medicine his career, and he therefore spent three years studying that subject under Karl Sudhoff at Leipzig.

At the age of 30 Sigerist was appointed lecturer in the history of medicine at Zurich, and in 1924 he was given the title of professor. In 1923 he published an important work on the existing manuscripts of early mediaeval antidotaries, and also a facsimile edition of the Surgery of Hieronymus Brunschwig. In the next two years he edited a series of editions of early medical texts, and, in collaboration with Professor Charles Singer, a volume of essays in honour of Sudhoff. In 1925 Sudhoff retired and Sigerist followed him in the chair of the history of medicine at Leipzig. During the seven years of his tenure of that chair he edited two journals and wrote many scholarly articles, especially on mediaeval medicine. On the advice of William H. Welch, the founder of the Institute of the History of Medicine at Johns Hopkins University, that university invited Sigerist to be a visiting professor in 1931. He was then asked to succeed Welch as professor, a post which he held from 1932 until his retirement in 1947. On his appointment he began to display his deep interest in medicine in its broader aspect, and especially in the socialization of medical practice and the economics of medicine, for which he became widely known in the United States. He also travelled much abroad, and in 1935 and 1936 he spent the summers in the Soviet Union. These interests found expression in his books *Man and Medicine* (1931), *American Medicine* (1934), and *Socialized Medicine in the Soviet Union* (1937). In 1944 he advised the Government of Saskatchewan on the health services of that Province, and in the same year he was one of a small group of experts who toured India officially to advise regarding the future development of the health services throughout India. The German edition of his work *Great Doctors* was published in 1932.

During his period at Baltimore Sigerist was also intensely active in studying and teaching the history of medicine. Under his leadership various courses were inaugurated, and emphasis was placed on the thorough nature of the preliminary training required. Under him the study became a discipline. He also founded the *Bulletin of the History of Medicine*, which he edited until 1947: this important journal gave him a forum for his own researches and those of his colleagues. Among his best-known books of this period are *Medicine and Human Welfare* (1941), *Civilization and Disease* (1944), and *The University at the Crossroads* (1946), in which he collected some of his important articles on university education and similar subjects.

For many years Sigerist had been determined to write a very large history of medicine, which would place the subject in its relation to general history and to the other forces

and influences which had affected the destiny of mankind. He had been prevented from starting this work by his many activities, and especially by the additional offices which had fallen to him during the war. In the summer of 1947, therefore, he retired from his chair and went to live at Pura in the Italian-speaking part of Switzerland. Yale University appointed him a research associate in the history of medicine, with professorial status. With his splendid library and the assistance afforded him by European institutes he was at first able to make good progress, and the first volume of this very important work was published in 1951. Unforeseen difficulties in connexion with certain sections of the second volume have so far prevented its publication, but my information is that it is now complete. Possibly a third volume may appear as he had planned it; but it seems unlikely that any further volumes will appear actually from his pen. To the best of my knowledge none of the four volumes of his projected work on *The Sociology of Medicine* was ever begun.

Among his many honours were the D.Sc. of the University of London and the Fellowship of the Royal College of Physicians. Lack of space prevents me from giving here personal recollections of a revered friend, whose hospitality will be remembered by many.

ESTHER L. CARLING, M.D.

Dr. Esther Carling died at Ipswich on March 18, aged 86. She was one of the first to develop the open-air treatment of tuberculosis in England, being the founder of the Peppard Sanatorium in Oxfordshire in 1898.

Esther Lillie Carling (née Colebrook) was the daughter of William Colebrook, who was at one time mayor of Reading. She was a medical student at the London School of Medicine for Women, taking the L.S.A. in 1896 and the M.D. of Brussels in the same year. After working in Edinburgh for a time as resident medical officer at the Hospital and Dispensary for Women and Children she returned south to set up in practice not far from Reading at the village of Peppard. Even before this she had been inspired by reports of the open-air treatment of consumption on the Continent, and had made a study tour of Germany and Switzerland to see it in operation. A local doctor knew of her interest, and in 1898 asked her to undertake the treatment of one of his patients. So she obtained accommodation for the patient in a farmhouse in an Oxfordshire village on a spur of the Chiltern Hills, and thus the story of a well-known sanatorium began.

Others soon heard of her work, and unsolicited donations reached the young doctor and enabled her to extend her plans. Kingwood Farm was purchased at Peppard in 1902 and Maitland Sanatorium developed, being named in memory of a patient whose sisters contributed substantially to the project. Several enthusiasts with similar ideas were contemporaries of Dr. Carling, and there was later some friendly rivalry between her and Dr. Jane Walker about which was first in the field with certain features of sanatorium care.

In 1904 she married a family connexion, Henry Carling, an engineer. Together they expanded the sanatorium, providing in one part beds for private patients,

while in other wards patients of small means were received at a charge of 30s. weekly. Children came to the sanatorium from many parts of England.

Under the National Health Insurance Act treatment of tuberculosis became a public responsibility, and, encouraged by John Burns, the president of the Local Government Board, the county councils of Berkshire and Buckinghamshire acquired the sanatorium in 1914. Esther and Henry Carling continued as chief medical officer and superintendent of the Berks and Bucks Joint Sanatorium until 1938, and saw the hospital grow until it could take 180 patients.

From the purchase price paid by the county councils for the sanatorium, the original donations were withdrawn to form a fund named the Maitland Trust. Part of the fund was used to establish and maintain a convalescent home at Barton-on-Sea, where ex-patients who had returned to work could go for a rest. Many years later the home was sold by the trustees and an alternative "Maitland House" acquired at Frinton for female patients. Dr. Carling remained an active trustee of the fund until her death.

A pioneer of vocational therapy and of the employment of ex-patients on the staff of hospitals, Dr. Carling made her mark on sanatorium practice of her time. She published a paper in this *Journal* about the treatment of tuberculosis by artificial pneumothorax as early as 1913, and in the same year she wrote a paper about the management of open-air schools. She was also the author of a book about the Peppard Sanatorium during the forty years she was in charge of it.

A lover of flowers, Dr. Carling was a keen botanist, tramping the Chiltern Hills and the Berkshire Downs in search of the pasque flower and other treasures. A vivid, radiant, petite person (our photograph shows her at the age of 34), she was a frequent correspondent on subjects such as clean milk and nurses' welfare. Her output of personal correspondence was prodigious, and until her last days the letters conveyed to a wide circle of ex-patients and other friends her mental clarity and charm. During the last years increasing deafness and failing health caused her to tilt with spirit at the disadvantages of longevity. She was for some years a justice of the peace, in her youth a suffragette, and later a staunch supporter of Women's Institutes.

She came of a family with strong medical connexions, for she had as first cousins Sir Ernest Rock Carling and Dr. Leonard Colebrook. She was predeceased by her husband and by a son who was a doctor. A daughter and one son survive her.—E. H. S.

Dr. J. F. NICHOLL, a senior cancer clinic associate at Allan Blair Memorial Clinic (Saskatchewan Cancer Commission), Regina, Canada, died after an accident on February 25. He was 39 years of age. John Frederick Nicholl was born at Belfast on November 4, 1917, and was educated at the Methodist College there and at Queen's University, graduating M.B., B.Ch. in 1942. After graduation he held an appointment at the Smithdown Road Hospital and then, for a few months, a part-time post with the Essex county health department. He later studied therapeutic and diagnostic radiology at University College Hospital, London, completing his examinations at the University of London for the Diploma in Medical Radiology in 1946. He then served as senior assistant radiotherapist at St. Thomas's Hospital from 1946 to 1950, after which he went to Canada, where he was chief of radiotherapy and associate in diagnostic radiology at Victoria General Hospital, Halifax, Nova Scotia, from

1950 to 1954. He joined the Allan Blair Memorial Clinic in October, 1954, serving as radiotherapist, but devoting most of his time to the expansion of the radio-isotope laboratory and the development of newer techniques in this field. He was a member of the Canadian Association of Radiologists. He also served on the provincial executive of the Canadian Cancer Society. As an enthusiastic member of the Regina Natural History Society he was well known in ornithological circles. He is survived by his widow, one daughter, and three sons.

Medical Notes in Parliament

SOCIAL SERVICES UNDER CENSURE

The critical motion on the social services which the Opposition have been saving up for some weeks was debated on March 19. It originated in the shilling-an-item prescription charge, and got new impetus from the increased charge for school meals and welfare milk. Dr. EDITH SUMMER-SKILL (Warrington, Lab.), who moved it, declared that in recent Government measures there was an unmistakable trend which, if continued, would seriously weaken the social services. The motion declared that these recent measures placed an undue and increasing burden on those least able to bear it. The only valid test of a social policy, in Dr. Summerskill's view, was how the poorest were faring. Taking first the physical condition of children, she quoted from Dr. Arthur Massey's *Modern Trends in Public Health*—"Between 1935 and 1946 the death rate of children aged 1 to 5 years has been halved; that of deaths in childbirth has been reduced to one-third"; and, while recognizing the part that certain drugs had played, "nevertheless improved nutrition has in the opinion of most played an important role." It took many years for this to be achieved. That was why the Government's policy of reducing or removing the subsidies was such a retrograde step.

Inadequate Milk Consumption

The Inland Revenue revealed that there were two million children in families whose income per head was less than £2 a week, and in one million of them it was less than 30s. The National Food Survey reported that these children had much less than a fair share of the important body-building foods. To withhold cheap food and meals was deliberately to stunt these children's bodies. Milk consumption, which under a Labour Government continued to increase, was now decreasing. An investigation by the Milk Marketing Board had shown that the consumption of milk was inadequate in large families in the lower-income groups.

She demanded from the Minister of Health an unequivocal statement about maternity accommodation in hospitals, and that he should make clear that he approved of maternity accommodation being provided, on health and social grounds. She criticized the refusal to introduce a chiropody service, and the absence of an integrated domiciliary service which could deal at home with thousands of old people now contributing to the overcrowding in hospitals.

It was early yet to say what was happening as a result of the prescription charges imposed on December 1, but it looked as though the warnings then given were justified. The Minister's remarkable statement that he was willing to let chemists examine doctors' certificates, and in the event of being able to prescribe something cheaper be at liberty to do so, would cause harm to the chemist-doctor relationship. The new policy had meant a fall in the number of prescriptions but an increase in costs. It was difficult to understand why the Minister had given the concession to diabetics of obtaining their various items for 1s. but was not prepared to extend it to cancer cases, colostomies, and epileptics. Nothing had been done about the racket in proprietary drugs.

Remarkable Incident

Finally she touched on the grave dispute that had arisen between the Minister of Health and the doctors. The Prime Minister had apparently taken charge, but his attitude, far from improving the situation, had aggravated it. When the Prime Minister saw them in the previous week the doctors came away having been given no further information, and they decided forthwith to prepare a plan for withdrawal from the Service. This was a most remarkable incident, because politically the doctors were 90% Conservative. The Government could not have handled them more clumsily if they had been an implacable Communist bloc. There was no question of the B.M.A. wanting to withdraw the doctors. The Medical Practitioners' Union did not want to withdraw the doctors. The *British Medical Journal* said on March 9: "If politicians say that such an action [withdrawal] is an attempt to wreck the Health Service, who is the wrecker? The Government. The medical profession does not wish to wreck the Health Service." She invited Mr. Butler to take the opportunity of the absence of the Prime Minister to act as mediator in the dispute.

Government Reply

Mr. DENNIS VOSPER, Minister of Health, answered some of these criticisms, but on the doctors' dispute he refused to comment, saying that that would not be in the interests of the doctors or their patients. He was sorry Dr. Summerskill found the intervention of the Prime Minister not helpful. He had intervened because he felt it advisable to set up a Royal Commission to investigate the matter. It was estimated that during the past five years no fewer than 2,000 additional general practitioners had come into the Service. That was a very necessary development.

On the general charge he claimed that over five years of Conservative administration there had been little variation in the proportion of the gross national product expended on the social services. During that period more efficient use had been made of the expenditure. There had been a continuing drop in mortality rates, and a very welcome drop in deaths from children's infectious diseases. On the health of schoolchildren, the report of the Chief Medical Officer of the Ministry for 1954-5 stated: "Only 1.46% were considered to be in poor physical condition in 1955, compared with 2.55% as recently as 1952."

All these improvements had taken place while the Government had been pursuing a policy that recognized that the amount that could be spent on the social services was not unlimited, to eliminate waste and inefficiency, and to ensure that extensions were in the right direction. In hospital building the amount allocated in 1951-2 was £9.5m., in 1956-7 it was £13m., and next year would be £18m. The amount allocated at present for 1958-9 was £20m. (Some Labour ex-Ministers interjected that the £13m. was about equivalent to the £9m. in 1951.) He gave the assurance Dr. Summerskill had asked for about maternity hospitals: there had been no change in policy under the Conservative Government. He also agreed with her that the introduction of a chiropody service would be a welcome improvement, but "when it becomes possible."

On the finance of the Health Service, he repeated the statement of the Chancellor of the Exchequer that the estimated total cost for 1957-8 would be £690m., compared with £450m. in 1949-50. Much of this was due to increases in pay and prices, but there had been an increase in real terms of about 15%. The Health Service Act assumed that the percentage of cost borne by the Exchequer would be 72.4. This year it was 80.2. The Government's intention was to double the Health Service contribution and reduce the Exchequer percentage to 74.1.

Prescribing Levels

Whatever the deterrent effects of charges might be, the number of dental courses and sight tests were increasing to record levels, and prescriptions for 1956-7 were estimated

at 234 millions—the highest ever reached. Last December, compared with December, 1955, there was a fall of 25% in prescriptions, but in January, compared with the previous January, the fall was only 14%. He thought it wrong to suggest that vast savings in the pharmaceutical services could be found in proprietary medicines. Discussions had been proceeding for a vast amount of time with the manufacturers. If the Opposition had postponed their motion for a week or two he might have been able to answer the question more positively. Lastly, on welfare milk and school meals, the Minister would not accept the argument that no change should be made in price or that half-price was unreasonable.

Mr. SOMERVILLE HASTINGS (Barking, Lab.) looked forward to more attention being given to the prevention of illness, and suggested also that "wise spending" could mean savings in the hospital service. He looked upon the slight decline in milk consumption every year since 1951 as a disaster, and regretted the increased charge for welfare milk. Prescription charges were undesirable for many reasons; anything, real or imaginary, that prevented a patient getting advice as soon as possible was wrong, and the increased charge might also operate to divert more people into hospital than would otherwise go there.

Dr. DONALD JOHNSON (Carlisle, Con.) urged the need for a domiciliary psychiatric service.

Dr. J. DICKSON MABON (Greenock, Lab.) was concerned about the lack of social indices which hampered the assessment of values in the services. M.P.s had to find examples in their own constituencies, and in this process he had discovered that in Greenock changes in the price of milk had resulted in substantial changes in the amount of milk consumed in the poorer areas, and the increased charge for school meals had meant that the larger and poorer families had reverted to the dreadful practice of going to school with a sandwich for lunch. But the prescription charge was the most lamentable change in the social services. He had seen in chemists' shops prescription forms (E.C.10) with items obliterated because the customer had asked, "Which is the most important medicine on this?" and the chemist had given advice. If the Minister wished to find economies on the pharmaceutical side of the Service he should look at the American proprietaries. There was a conspiracy by the pharmaceutical firms to get more and more proprietary drugs used in prescriptions. The Medical Research Council should test each new drug and determine its pharmacological value.

Remuneration Claim

Mr. M. LIPTON (Brixton, Lab.) asked the Prime Minister on March 19 what negotiating machinery he was using to settle the interim adjustment of pay for general practitioners. Mr. MACMILLAN replied that it had not yet been decided what should be done by way of an interim adjustment for general practitioners, but, as he had said a week previously, he would make a further statement in due course.

Dr. D. JOHNSON asked the Prime Minister on March 21 from what bodies the Royal Commission would take evidence. Mr. R. A. BUTLER, who replied, said that was a matter for the Commission.

Claims for Damages for Negligence

Mr. D. WEITZMAN (Stoke Newington and Hackney North, Lab.) asked the Minister whether he was aware that claims for damages for negligence against a hospital board, which might well succeed upon their merits, were sometimes met by a defence under the Limitation Act; and upon which principle instructions were given to raise or not to raise this defence. Mr. VOSPER stated: I see no reason to deprive hospital authorities of the protection made available by Parliament to all, and they are normally expected to raise this defence wherever it applies.

Hospital Service Costs

Mr. H. BOARDMAN (Leigh, Lab.) wanted to know the annual cost of the hospital service under the Health Service

from its inception, and the percentage cost of professional and nursing services and administration. Mr. VOSPER gave him the following information on March 21:

Year	On Revenue A/c.	On Capital A/c.	Cost of Professional and Nursing Services as a Percentage of Column 2 (See Note 1)	Estimated Cost of Administration as a Percentage of Total Expenditure (See Note 2)
1948-9 (part year)	£m. 122.7	£m. 5.3	% 40.8*	% 4.4
1949-50	189.3	8.7	46.2*	4.3
1950-1	207.4	8.8	46.5	4.5
1951-2	224.8	9.7	44.8	4.8
1952-3	244.7	9.1	44.3	4.8
1953-4	257.4	8.8	44.0	4.8
1954-5	268.7	11.3	45.1	4.7
1955-6	293.1	11.5	44.6	4.7

* Partly estimated.

Note (1). The cost of professional and nursing services has been taken to be the remuneration of medical, nursing, professional, and technical staff and the cost of drugs, dressings, and medical and surgical appliances and equipment. Part of the general overhead expenses also relates to medical care, but this cannot be separately estimated.

Note (2). The figures for administration are based on the estimated administration expenditure of hospital authorities, including administration expenditure incurred at hospitals, but excluding operational expenses such as the salaries of medical records clerks.

Merit Awards to Consultants

The MINISTER OF HEALTH informed Mr. J. PEYTON (Yeovil, Con.) on March 25 that merit awards were made for professional distinction, and on the basis that 4% of consultants received awards at the rate of £2,500 a year, 10% awards at the rate of £1,500 a year, and 20% awards at the rate of £500 a year. The recommendations were made by the Advisory Committee on Distinction Awards. In view of the basis of the committee's recommendations regional hospital boards were not consulted upon them. Mr. PEYTON thought there was considerable need for wider knowledge about how the committee made its awards. There was considerable uncertainty among consultants and the medical profession. Mr. VOSPER said he knew that some concern had been expressed about this before. The whole basis was that the awards were made on a professional basis.

M.O.H.s and Hospitals

Mr. R. RUSSELL (Wembley, South, Con.) asked if the Minister had yet reached a decision on the recommendation of the Committee of Inquiry into the Cost of the Health Service that the medical officer of health, or one of his staff, should be given an honorary appointment on the medical staff of a hospital; that he should be a member of the medical staff committee; and that he should take charge of outbreaks of infection. Mr. VOSPER stated that after consulting the bodies chiefly interested he had decided not to adopt this recommendation. Hospital authorities had already been advised of the desirability of medical officers of health being members of group hospital medical committees, and of medical officers of health of sanitary districts being members of control of infection committees at hospitals. In his view arrangements of this kind contributed more satisfactorily to the link between the different parts of the Health Service which the Committee had in mind than the formal arrangements proposed.

Country Doctors' Petrol

Sir JOCELYN LUCAS (Portsmouth, South, Con.) wanted to know by how much the increase in tax and price, respectively, of petrol had increased the weekly costs of the average country doctor, more particularly those in hilly counties; and whether they would be reimbursed for the estimated extra cost involved. Mr. VOSPER said that data were not yet available to enable such estimates to be made. When the information came to hand any increase in total practice expenses of general practitioners, including expendi-

ture on petrol, would be met by an equivalent increase in the amount of money paid by the Exchequer into the Central Pool from which their remuneration was provided.

Senior Factories Inspector.—The present Senior Medical Inspector of Factories will be succeeded on September 1 by Dr. Sibyl Horner, a Deputy Senior Medical Inspector.

Homicide Act.—The Homicide Bill, which passed through its stages in the House of Lords without any alteration—as it had done in the Commons—received the Royal Assent by commission on March 21.

Medico-Legal**TRIAL OF DR. J. BODKIN ADAMS**

The trial of Dr. John Bodkin Adams, of Eastbourne, continued before Mr. Justice Devlin at the Old Bailey. Dr. Adams is charged with the murder of a patient, 81-year-old Mrs. Edith Alice Morrell, who died on November 13, 1950. He pleads not guilty.

Sir Reginald Manningham-Buller, Q.C., is appearing for the prosecution with Mr. Melford Stevenson, Q.C., and Mr. Malcolm Morris. Mr. Geoffrey Lawrence, Q.C., is appearing for Dr. Adams with Mr. Edward Clarke and Mr. John Heritage. The Medical Defence Union is acting for Dr. Adams.

The first three witnesses for the prosecution were pharmaceutical chemists who gave evidence on the prescriptions said to have been written for Mrs. Morrell by Dr. Adams. They were followed by the nurses who looked after Mrs. Morrell, the first being Miss Helen Rose Stronach, of Eastbourne.

Nurse Stronach said that Mrs. Morrell was of a neurotic disposition and also very weak indeed. She said that Dr. Adams gave Mrs. Morrell injections with a 1-c.c. syringe when he visited her late in the evenings, though she personally did not see the injections given. Nor did she know what was injected.

Record Books

Cross-examined by Mr. Lawrence, she said that she and other nurses had written down in a book every injection that they gave to Mrs. Morrell and the book would contain everything of significance in the patient's illness—injections, medicines, and the doctor's visits. Mr. Lawrence then produced three exercise books, which proved to be the note-books in which these details were recorded. He asked Nurse Stronach about entries in them. Miss Stronach agreed that her entries showed that Mrs. Morrell was having brandy and "sedormid" and not morphine or any injection from the doctor. She had never recorded the visit of the doctor in the evening when she was on duty.

Mr. Lawrence suggested that Nurse Stronach's memory played her a trick when she said she had never injected anything but morphine. The witness answered: "Yes. It was a long time ago to remember these things." Mr. Lawrence then continued: "Miss Stronach, let us face this. It is another complete trick of your memory to say that on the last day you left Mrs. Morrell was either semi-conscious or rambling—now you see what you wrote at the time—isn't it?" "I have nothing to say." "You have nothing to say?" "No." Mr. Lawrence: "Having refreshed your memory from records made by you and your colleagues at the time, it was obviously quite inaccurate to say that Mrs. Morrell was semiconscious and rambling on the day you left, was it not?" "Well, I have always believed she was so far as my memory was concerned." "Maybe. But having looked at these notes written down six years ago with no memory at all, it is quite clear it was wrong to say she was semiconscious and rambling, or was it not?" "Apparently so."

Sister Annie Helen Mason-Ellis, of Battle, Sussex, was then called. Asked by the Attorney-General whether she first went to nurse Mrs. Morrell she was having injections of any kind, Sister Mason-Ellis said she could not remember. The Attorney-General said there was an entry in one of the books, for July 27, 1950, that Mrs. Morrell had been given an injection in the evening of morphine and heroin. Sister Mason-Ellis said this had been given on the instructions of Dr. Adams. When Dr. Adams visited Mrs. Morrell, she said, the nurses were asked to leave the room. She could not remember ever seeing Dr. Adams give an injection to Mrs. Morrell—"It is too long ago."

Cross-examined by Mr. Lawrence, Sister Mason-Ellis said that right from the start in August, 1949, Mrs. Morrell had been under routine sedation. That had been maintained for months and months and months without alteration. Mrs. Morrell was receiving a standard dose at night of $\frac{1}{4}$ gr. (22 mg.) of heroin and $\frac{1}{4}$ gr. (16 mg.) of morphine. She had some sedative tablets shortly before she had the injection.

On the third day of the trial the judge issued a stern warning to one of the nurses about discussing the trial with the other nurses.

Turning to the afternoon of November 12, 1950, the day before Mrs. Morrell died, Mr. Lawrence asked Sister Mason-Ellis what was the first word she had written in her report for that afternoon. The witness replied that it was "Awake," and she had also written "but quiet." The nurse agreed that the report showed Mrs. Morrell was not in coma.

Cremation Certificate

Evidence about the cremation certificate showed that in answer to the question: "Have you, so far as you are aware, any pecuniary interest in the death of the deceased?" Dr. Adams answered: "Not so far as I am aware." A confirmatory medical certificate signed by a Dr. Fox said he was satisfied that the cause of death was cerebral thrombosis. Mr. Lawrence pointed out that Dr. Adams had put on the cremation certificate the addresses of the three nurses who were attending Mrs. Morrell, so that anyone could ask them any questions about Mrs. Morrell's case if they had wanted to. Dr. H. J. Walker, medical referee at the Downs Crematorium, Brighton, agreed that he would not have authorized the cremation unless he had had the confirmatory certificate from Dr. Fox in addition to the certificate supplied by Dr. Adams.

Nurse Caroline Sylvia Randall, of Eastbourne, then gave evidence. In reply to the Attorney-General she said that Mrs. Morrell was not suffering severe pain. There was stiffness because she was unable to use her limbs at times. On November 7, said Nurse Randall, Mrs. Morrell was getting bigger quantities of heroin, morphine, and "omnophon." Her reports for the next few days recorded the administration of increased quantities of drugs. On the night of November 12-13, the night of Mrs. Morrell's death, the patient was weak, semiconscious, and shaken by spasms. Nurse Randall said that Dr. Adams gave Mrs. Morrell an injection of paraldehyde, 5 c.c. He then refilled the syringe and gave it to Nurse Randall, saying that if the patient was restless Nurse Randall was to give it to her. After the injection Mrs. Morrell was quiet for about an hour, said Nurse Randall, and then the spasms became worse. She thought it was too soon to give the patient another injection, so she tried to get in touch with Dr. Adams by telephone, but he was out. In the end, she gave the patient the other injection. The Attorney-General: "What was the effect?" Mrs. Randall: "She became quiet, and when she became quiet I called Sister Bartlett because I could see that she was passing out."

Mr. Lawrence asked Nurse Randall about a period in September, 1950, when Dr. Adams was away and his partner, Dr. R. V. Harris, was treating Mrs. Morrell. Mr. Lawrence said: "Look at what happened to the injection at night which has been steady in the past for months and months." He read from the record: "Hypo injection morphia gr. $\frac{1}{4}$ and $\frac{1}{4}$. Heroin gr. $\frac{1}{4}$ and $\frac{1}{4}$ given 8.50 p.m. May have

omnophon gr. $\frac{1}{4}$ s.a.s. (if necessary)." Mr. Lawrence: "We have not seen any reference to omnophon before, but it appears here with Dr. Harris, and it is quite plain, isn't it, that on that night the usual injection of morphia and heroin was stepped up in the case of both types of drug?" Nurse Randall: "Yes." Mr. Lawrence said that Dr. Harris had to deal with a state of restlessness in the patient, and he said: "Do you observe that he deals with it by increasing the morphia and increasing the heroin?" Nurse Randall: "Yes." "And introducing omnophon in the night?" "Yes." Nurse Randall agreed that Dr. Harris had continued to use all the same drugs that Dr. Adams had been using, and that when confronted with a spell of restlessness at night he increased the drugs and introduced omnophon.

Nurse's Memory

Questioned about Mrs. Morrell's condition on the last three or four nights, Nurse Randall told the judge that she was not in a coma but was in a sleep like a coma. Mr. Lawrence then referred to the last page of Nurse Randall's notes and said that at 10.30 p.m. she had recorded an injection of 5 c.c. of paraldehyde by Dr. Adams. Nurse Randall agreed. She also agreed that there was no record of any subsequent injection. Mr. Lawrence: "It just is not conceivable, is it, that you would have left out of the record that injection if in fact it was ever given?" "I did give it." "You can't have it both ways. If it is a matter of any importance it would have gone into the book?" "Yes." After further questioning about the paraldehyde, Mr. Lawrence said: "Your memory is not trustworthy, is it?" Nurse Randall: "It appears not to be." Mr. Lawrence: "But the book is quite clear, isn't it?" "Yes."

After further evidence Mr. Justice Devlin intervened to ask the Attorney-General: "Are you going to invite the jury to say that these last two or one—whatever it was—injections in 5 c.c. were given or caused to be given by Dr. Adams with the intention of causing the death of Mrs. Morrell?" The Attorney-General replied: "I do submit that they were given deliberately by Dr. Adams and that they accelerated the death of the patient. But I won't elaborate, my lord. I adhere to that, and my medical evidence will indicate why."

Nurse Brenda Doreen Hughes, of Brixham, Devon (whose surname was Bartlett in 1950), was asked by Mr. Stevenson for the Crown whether she observed any sign of severe pain in the patient. She replied she did not. In the last few days of her life the patient was semiconscious, said Nurse Hughes, and she had twitching spasms. On the last night she remembered that the doctor gave Mrs. Morrell paraldehyde. He then came to the dining-room and prepared an injection which he gave to Sister Randall, but Nurse Hughes could not remember what the injection was. Mr. Lawrence drew attention to an entry in the record book for October 9, "Query stroke." Nurse Hughes agreed that from that time onward Mrs. Morrell was going downhill.

On the sixth day of the trial (March 25) Mr. Lawrence continued the cross-examination of Nurse Hughes. He said that up to 5.30 p.m., November 12, the last day of Mrs. Morrell's life, neither she (Nurse Hughes) nor Nurse Mason-Ellis had recorded anything like a coma. "Indeed you have recorded 'awake,' 'restless,' and 'talkative'?" Nurse Hughes: "Yes."

Evidence given by Mr. T. H. E. Price, formerly chauffeur to Mrs. Morrell, showed that after three years' service he had received £1,000 by her will.

Police evidence was given on the arrest of Dr. Adams, and then Mr. Hubert Sogno, solicitor, gave evidence on Mrs. Morrell's wills. This showed that when Mrs. Morrell died Dr. Adams was not a beneficiary under her final will. Dr. Adams got the oak chest and the Rolls-Royce by favour of Mrs. Morrell's son, the residuary legatee, "because it was his mother's last wish." The will also stipulated, as had always been her wish, that her body should be cremated.

Vital Statistics

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases (deaths for influenza) of certain diseases notified weekly in England and Wales (great towns for influenza). Highest and lowest figures reported in each week during the years 1948-56 (influenza 1952-6) are shown thus -----, the figures for 1957 thus ————. Except for the curves showing notifications in 1957, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

The only large variations in the notifications of infectious diseases in England and Wales during the week ending March 9 were rises of 1,777 for measles, from 23,060 to 24,837, and 91 for acute pneumonia, from 664 to 755, and a fall of 77 for dysentery, from 1,291 to 1,214.

The largest increases in the incidence of measles were 448 in Yorkshire West Riding, from 1,688 to 2,136, 349 in London, from 1,876 to 2,225, 326 in Warwickshire, from 700 to 1,026, 205 in Essex, from 1,707 to 1,912, 150 in Surrey, from 1,250 to 1,400, 149 in Southampton County, from 188 to 337, 113 in Middlesex, from 1,233 to 1,346, and 112 in Cheshire, from 800 to 912, the largest decreases were 133 in Lancashire, from 4,084 to 3,951, and 109 in Cumberland, from 570 to 461. The notifications of scarlet fever numbered 837, being 4 more than in the preceding week, and there were no large changes in the local returns. 2,995 cases of whooping-cough were notified, 5 fewer than in the preceding week; the largest variations were decreases of 63 in Lancashire, from 284 to 221, and 45 in Glamorganshire, from 139 to 94, and a rise of 44 in Cumberland, from 42 to 86. 6 cases of diphtheria were notified, being 1 fewer than in the preceding week.

33 cases of acute poliomyelitis were notified, and these were 5 more for paralytic and 2 fewer for non-paralytic cases than in the preceding week. The largest returns were Hertfordshire 6 (Barnet U.D. 6) and Gloucestershire 4 (Bristol C.B. 4).

The largest centres of dysentery were Yorkshire West Riding 235 (York C.B. 49, Sheffield C.B. 37, Leeds C.B. 28, Bradford C.B. 24, Rotherham C.B. 19, Batley M.B. 12, Worsborough U.D. 12), Lancashire 197 (Blackburn C.B. 43, Ashton under Lyne M.B. 31, Urmston U.D. 28, Stretford M.B. 15, Liverpool C.B. 11, Accrington M.B. 11, Blackpool C.B. 10), London 89 (Fulham 17, Wandsworth 14, Hackney 12), Surrey 76 (Surbiton M.B. 33, Esher U.D. 22), Bedfordshire 74 (Luton M.B. 56, Luton R.D. 11), Durham 63 (Blaydon U.D. 21, Gateshead C.B. 10), Northumberland 59 (Blyth M.B. 34, Newcastle upon Tyne C.B. 18), Middlesex 49 (Hayes and Harlington U.D. 24), Kent 47 (Deal M.B. 35), Warwickshire 45 (Coventry C.B. 24, Birmingham C.B. 17), Hertfordshire 44 (Welwyn Garden City U.D. 28, St. Albans R.D. 13), Nottinghamshire 33 (Nottingham C.B. 15), Cheshire 30 (Nantwich R.D. 10), Essex 22, and Carmarthenshire 20.

Week Ending March 16

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 935, whooping-cough 3,180, diphtheria 3, measles 24,825, acute pneumonia 770, acute poliomyelitis 38, dysentery 1,416, paratyphoid fever 4, and typhoid fever 4.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending March 9 (No. 10) and corresponding week 1956.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES in Countries and London	1957					1956

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenzal pneumonia.
§ Includes puerperal pyrexia.

Medical News

Faculty of Anaesthetists.—A "lively and happy gathering," in the words of the Minister of Health, filled the Great Hall of the Royal College of Surgeons for the ninth anniversary dinner of the Faculty of Anaesthetists on March 20. After the Dean of the Faculty, Dr. FRANKIS T. EVANS, had proposed the Loyal Toasts, Mr. DENNIS VOSPER, the Minister of Health, made the main speech of the evening. Remarking that it was not a very propitious time for the Minister of Health and his wife to fall into the company of doctors, Mr. Vosper said that he was not quite so inhuman as editorials in the *B.M.J.* might make his audience think. He regarded his job as a very personal and human one: he believed in the National Health Service, and he and his wife had been N.H.S. patients since 1948. Taken more slowly and easily, the scheme might not have been introduced in the same form as they had it to-day, but it was difficult to take a step back after taking a step forwards. Mr. Vosper paid tribute to the progress made by the anaesthetists in a relatively short time, especially in educational matters: it was good to have attracted so many overseas students to this country. In reply Dr. FRANKIS EVANS said that the research department under the direction of Dr. Ronald Woolmer was assured of a comfortable childhood through the munificence of certain fairy godfathers. The Faculty's next requirement was the endowment of a chair of anaesthesia at the College. Dr. Frankis Evans concluded by paying tribute to Sir James Learmonth's Clover Lecture. The health of the guests was proposed by the Vice-dean of the Faculty, Dr. JOHN GILLIES, and this was acknowledged by Sir EDWIN HERBERT, President of the Law Society. As the skipper of a yacht, he asked the research department to find a sea-sickness cure that did not put the crew into coma.

Bermuda Conference.—The statement issued on March 24 after the talks between President EISENHOWER and Mr. MACMILLAN in Bermuda contains an annexe on nuclear explosions. In the absence of an effective agreement for comprehensive disarmament, states this annexe, "continued nuclear testing is required, certainly for the present." With regard to the dangers from such tests, the annexe continues: "We recognize, however, that there is sincere concern that continued testing may increase world radiation to levels which might be harmful. Studies by independent organizations confirm our belief that this will not happen so long as testing is continued with due restraint." The annexe ends with a declaration, on behalf of both governments, that they will conduct nuclear tests only in such a manner "as will keep world radiation from rising to more than a small fraction of the levels that might be hazardous."

Medicine in Colonial Territories.—Appointments in Her Majesty's Overseas Civil Service and Colonial Research 1955-56, two recent Colonial Office publications, combine to give an informative picture of openings in the colonial territories. Each has a medical section. The first publication is concerned with conditions of service. The Overseas Civil Service does not recruit locally, and differs from its predecessor the former Colonial Service in that the British Government recognizes a special obligation towards its members should the territories in which they work attain self-government. The Government's assurances on this point are set out in detail in the introduction to the handbook. The various branches of the service, the method of selecting candidates, and the financial and other conditions of service are then described. In medicine there are openings for clinicians (including specialists), teachers, administrators, and research workers. The main co-ordinating agency for the last group is the Colonial Medical Research Committee whose chairman is Sir HAROLD HIMSWORTH, F.R.S., secretary of the Medical Research Council in London. An account of this committee's work and the research it is

sponsoring form an important chapter in the annual publication *Colonial Research*. At the end of the year reviewed in the latest volume the Colonial Medical Research Committee was supervising 39 research schemes. Of particular interest is the intensification of work on leprosy and trachoma, the latter in conjunction with the Order of St. John of Jerusalem. Both publications mentioned in this paragraph are issued by Her Majesty's Stationery Office.

British Association of Physical Medicine.—Messrs. Baillière, Tindall and Cox have taken over publication of *Annals of Physical Medicine*, the association's official journal. The journal has been restyled and appears in an enlarged format. Pride of place in the first number in the

new style is given to a picture and description of the association's presidential badge. The badge, which we illustrate by permission of the Goldsmiths Company, is a new one and was used for the first time last October. It bears on its reverse the following dedication: "In memory of the late Lord Horder, first President of the British Association of Physical Medicine, 1943-55. Subscribed by members of the Association." The designer was Mr. A. G. STYLES, and the makers Messrs. Garrard and Co. Being regarded as

a worthy example of contemporary art, the badge was exempted from purchase tax. The symbolism is explained by Dr. P. BAUWENS in his account in *Annals of Physical Medicine*. "The four elements of the ancient philosopher are represented and inconspicuously provide background ornamental motifs. The oval surround bears a wavy design to symbolize water, and a floral decoration the growth from earth, while flames of fire form a foundation for the initials B.A.P.M. which surmount the frame. The fourth element, air, is implied in the deep-blue enamel background to the central theme brought out in relief. This portrays a cripple being raised and supported by two other figures, the one on the dexter side symbolizing medicine, and that on the other side wearing a floral garland to indicate natural resources. The suggestion is the combination of medical knowledge and nature in a common aim for the good of man. In this context the blue of the background may be regarded as standing for truth and light."

Apartheid in Medical Education.—At a meeting this month the South African Medical and Dental Council discussed the position of the Durban Medical School (see *Journal*, March 23, p. 699), and adopted the following resolution:

"That the South African Medical and Dental Council is *inter alia* concerned with the entire pattern of medical education and particularly as far as the acceptance of minimum standards is concerned. It has been brought to the notice of the Council that a new method of control of education is envisaged for the Durban Medical School and that there is a possibility that this may lead to a new pattern which may not be acceptable to the Council for purposes of training of medical practitioners. As a statutory body the Council has grave responsibilities in regard to medical education and feels it incumbent on itself to express the sincere

hope that, in order to obviate unforeseen difficulties which may arise at some future date when the standards are to be considered and the facilities, school, and examinations inspected, the Council respectfully suggest to the Minister of Education and Health to take the necessary steps, prior to enacting the legislation now before Parliament, to have the implications as it affects the responsibilities of the S.A. Medical and Dental Council further investigated and reported upon."

In addition, the Medical and Dental Council appointed a deputation to meet the Minister of Education, Mr. J. H. VILJOEN. The deputation consists of Professor S. F. OOSTHUIZEN, president of the Council, Professor H. W. SNYMAN, dean of the Faculty of Medicine at Pretoria University, Professor VAN ZYL, dean of the Faculty of Medicine at Stellenbosch University, and Professor I. GORDON, dean of the Faculty of Medicine at Natal University—the Durban School.

Glasgow.—At the end of the second week of Glasgow's mass miniature radiography campaign 293,263 persons had had their chests x-rayed. This is claimed as a world record. Last week-end, as a prelude to the campaign's third week, milk distributors delivered one and a half million milk bottles bearing on their caps the words "X-Ray Now." In addition, a "talking aeroplane" has been reminding citizens to go to the radiography centres.

Carlsberg-Wellcome Travelling Research Fellowships.—The Carlsberg Foundation of Copenhagen and the Wellcome Trustees have established two travelling fellowships for Danish and British research workers in fields of science related to human and veterinary medicine. Each year one fellowship will be awarded to a candidate from the United Kingdom for a year's work in Denmark, and one to a Danish candidate for a year's work in Britain. The stipend will range from £800 to £1,200 per annum for whole-time research, and travelling and some incidental expenses will also be provided. The first appointments will be for the academic year beginning this September, and the last date for applications is April 30. Further information may be obtained from the scientific secretary, The Wellcome Trust, 52, Queen Anne Street, London, W.1.

National Institute for Nuclear Research.—The Institute's governing board held its first meeting this month, and discussed its terms of reference. It also appointed a physics committee to investigate proposals and designs for the construction of a large accelerator in Britain. The main object of the new Institute, as stated in Parliament on February 14 by the Financial Secretary to the Treasury, will be "to provide, for common use by universities and others, facilities and equipment which are beyond the scope of individual universities and institutions carrying out research in the nuclear field." The governing board consists of Lord BRIDGES, as chairman, and representatives of universities, the University Grants Committee, the Royal Society, the Atomic Energy Authority, and the Department of Scientific and Industrial Research.

R.C.O.G.—Two Sims-Black travelling professors were appointed at the council meeting on March 23. Mr. J. B. BLAKLEY, director of the obstetrical department at Guy's Hospital, London, is to visit New Zealand and Australia; Professor T. N. A. JEFFCOATE, of Liverpool University, is to visit Canada and the Caribbean area. They will be going next year.

Harveian Tercentenary.—The programme has been revised (see advertisement p. 43) so that speakers at the American Medical Association's annual meeting can take part in it by transatlantic telephone. The session on "Results of Cardiac Surgery" is now to be held on Wednesday afternoon, June 5. Colour television demonstrations will be transmitted from St. Bartholomew's Hospital to the meetings at the Royal College of Surgeons every day except Monday, June 3, between noon and 1 p.m.

Chairman of St. Mary's.—The Minister of Health has appointed Mr. EDGAR E. LAWLEY as chairman of the board of governors of St. Mary's Hospital, Paddington. He

succeeds Mr. ANTHONY DE ROTHSCHILD. Mr. LAWLEY joined the board in 1944; he became deputy chairman in 1948.

Courses for Hospital Administrators.—Leeds University is to run a pilot scheme of study courses for hospital administrators. The university council has accepted a two-year grant, at £8,500 a year, from the Nuffield Provincial Hospitals Trust for this purpose. The department of adult education and extramural studies will be responsible for the courses, which will be "on staff college lines." The courses will be open to senior members of the staffs of hospitals and regional boards.

National Spastics Society.—Dr. C. P. STEVENS has been appointed director of the National Spastics Society. Since the war he has been deputy S.A.M.O. to the South-west Metropolitan Regional Hospital Board and general secretary of the John Lewis partnership.

Dr. Ronald Woolmer, director of the department of anaesthetics in the Royal College of Surgeons, left on March 8 for a three months' tour of medical research centres and departments of anaesthetics in the United States and Canada.

Dr. Brian Stanford, chairman of the medical section of the Royal Photographic Society, has been visiting Holland at the invitation of the Royal Netherlands Scientific Film Association. He lectured in Utrecht, Groningen, Leyden, and The Hague.

COMING EVENTS

Histological Techniques.—Open demonstration by the Association of Medical Microtommists, April 5 from 7 p.m. in the biology laboratory, Guy's Hospital Medical School.

Haemophilia Society.—Annual general meeting, April 7 at 3 p.m., main lecture room, Hospital for Sick Children, Great Ormond Street, London, W.C.1. All interested invited to attend.

Naval Medical Compassionate Fund.—Meeting of subscribers on April 12 at 2.30 p.m., at the Medical Department of the Navy, Queen Anne's Mansions, St. James's Park, London, S.W.1, to elect six directors.

Mental After-Care Association.—Seventy-seventh annual meeting, April 16 at 3 p.m., at the Caxton Hall, London, S.W.1.

Radiological Protection.—Short course at the Atomic Energy Research Establishment, Harwell, April 29 to May 3. Details from the Isotope School, Atomic Energy Research Establishment, Harwell, near Didcot, Berks.

Fourth International Congress of Nutrition.—In Paris, July 26 to August 1, under the auspices of the International Union of Nutritional Sciences. Enrolment early in April to Professor E. TERROINE, Centre National de Coordination des Études et Recherches sur la Nutrition et l'Alimentation, 71, Boulevard Péreire, Paris, 17.

St. John Ambulance Brigade.—Surgeons' Conference at the Cairn Hydro Hotel, Harrogate, May 3 to 5. Details from conference secretary, 8, Grosvenor Crescent, London, S.W.1.

World Health Organization.—Eighth Study Course on the World Health Organization, Geneva, May 6-15. Details from World Federation of United Nations Associations, 1, avenue de la Paix, Geneva, Switzerland.

Second International Congress of Photobiology.—Turin, June 2-8. Details from the secretary-general, Istituto di Fisica dell'Università di Torino, Via Pietro Giuria 1, Corso Massimo d'Azeglio 46, Turin, Italy.

Association of Clinical Pathologists.—Fifty-eighth general meeting at Torquay, April 11-13. Further information from Dr. J. N. CUMINGS, National Hospital for Nervous Diseases, Queen Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, April 1

AUXILIARY ROYAL ARMY MEDICAL CORPS FUNDS (1939).—At 11, Chandos Street, W., 5 p.m., annual general meeting.
MARLBOROUGH DAY HOSPITAL.—8.15 p.m., Dr. F. K. Taylor: Mental Epidemics and Similar Social Phenomena.
● UNITED HOSPITALS CATHOLIC SOCIETY.—At 13, Devonshire Place, W., 6.15 p.m., Dr. C. L. C. Burns: Psychiatry and Psychotherapy.

Tuesday, April 2

GUY'S HOSPITAL MEDICAL SCHOOL: DEPARTMENT OF CHILD HEALTH.—At Physiology Theatre, 5 p.m., Dr. Alexander Nadas (Harvard): Complete Atriculo-Ventricular Block in Children.
ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., Lumleian Lecture by Dr. L. C. Hill: Systemic Lupus Erythematosus.
WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Dr. G. A. D. Gordon: demonstration of neuroradiology.

Wednesday, April 3

FOUNTAIN HOSPITAL.—3.30 p.m., annual general meeting. (Tour of hospital, 2.30 p.m.)
INSTITUTE OF LARYNGOLOGY AND OTOLGY.—5.30 p.m., Dr. H. A. Sissons: Bone Structure and Bone Pathology.
MIDLAND MEDICAL SOCIETY.—At 154, Great Charles Street, Birmingham, 8.15 p.m., Valedictory Address by Professor A. P. Thomson: Medical Education.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Moynihan Lecture by Professor R. M. Jones (Canada): Tumours of the Parotid Gland.
ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—3.30 p.m., Dr. H. D. Pavie: Study of Certain Aspects of the Relations of Hearing to Noise Exposure (illustrated).
ROYAL SOCIETY OF HEALTH.—2.30 p.m., Dr. W. R. S. Doll: Lung Cancer and Smoking.

Thursday, April 4

FACULTY OF HOMOEOPATHY.—8 p.m., discussion: Treatment of Migraine.
ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., Lumleian Lecture by Dr. L. C. Hill: Systemic Lupus Erythematosus.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.30 p.m., Otolaryngology Lecture by Dr. R. D. Hoare: Angiography in Throat, Nose, and Ear Surgery.
ROYAL PHOTOGRAPHIC SOCIETY (MEDICAL GROUP).—7 p.m., Mr. D. J. Bruce: B.A.: How do Films Teach?
ST. JOHN'S HOSPITAL DERMATOLOGICAL SOCIETY.—4.30 p.m., demonstration and discussion of clinical cases. Dr. H. J. Whiteley: Histologically Invasive yet Self-healing Tumours of Rabbit Skin.
SHEFFIELD UNIVERSITY.—At University Building, Sheffield Royal Infirmary, 5.15 p.m., Dr. B. B. Brodie (Bethesda, U.S.A.): 5-Hydroxytryptamine, Reserpine and the Central Nervous System.

Friday, April 5

INSTITUTE OF NEUROLOGY.—5.30 p.m., Dr. E. J. M. Campbell: Respiratory Muscles and the Control of Breathing.
NORTHAMPTON MEDICAL SOCIETY.—8.30 p.m., Dr. R. Wigglesworth: Changing Field in Paediatric Practice.
WHIPPS CROSS HOSPITAL MEDICAL SOCIETY.—8.30 p.m., Professor R. Rotblat, D.Sc.: Application of Nuclear Physics to Medicine.

Saturday, April 6

MIDLAND THORACIC SOCIETY.—3 p.m., visit to Prestwood Sanatorium, Stourbridge, for clinical meeting and annual general meeting.
Dr. R. D. T. Cape: Corticotrophin in the Management of Pulmonary Tuberculosis; Dr. J. Aspin: Steroid-treated Pleural Effusion; Dr. A. MacDonald: Occupational Risks in Local Industry.
● SOUTH-EAST METROPOLITAN REGIONAL TUBERCULOSIS SOCIETY.—At Brook General Hospital, Shooters Hill Road, S.E., 10.30 for 11 a.m., Miss L. I. H. Torrance: Female Genital Tuberculosis; Mr. B. B. Milstein: Practical Aspects of Hypothermia.

Sunday, April 7

PADDINGTON GENERAL HOSPITAL.—11 a.m., clinical meeting for general practitioners.
UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL.—10.15 a.m., clinical demonstration for general practitioners. Dr. W. N. Goldsmith and Dr. P. J. Hare: Common Affections of the Hand.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Crawford.—On March 21, 1957, at Hillingdon Hospital, Middlesex, to Jeanne, wife of Ian B. Crawford, M.B., B.S., a sister for Belinda and Steven.
Griffiths.—On January 14, 1957, at the Imperial Nursing Home, Cheltenham, Glos, to Elizabeth, wife of Dr. Eric Griffiths, a brother for Lynn Jones.—On February 18, 1957, at 4, Southwood Avenue, Highgate, London, N., to Drs. Alan and Erica Jones, a son—Crispin Howard.
Mac Donagh.—On March 16, 1957, at Cleethorpes Maternity Hospital, to Fay (formerly Cull), M.B., and Fintan Mac Donagh, M.R.C.S., a second daughter.

DEATHS

Armstrong.—On March 15, 1957, at Oakleigh, Stourport-on-Severn, Worcs. Gilbert Roy Angus Armstrong, M.B., Ch.B.
Austen.—On March 10, 1957, at Westcliff-on-Sea, Essex, Alfred Walter Austen, M.R.C.S., L.R.C.P., formerly of Putney, London, S.W., and Cambridge Gardens, London, W., aged 86.
Badeley.—On March 10, 1957, in London, Nancy Marion Badeley, M.R.C.S., L.R.C.P., of 1, Gunterstone Road, London, W., formerly of Loudoun Road, London, N.W.
Barkley.—On March 11, 1957, at The Knoll House, Weybridge, Surrey, Thomas Yuille Barkley, O.B.E., M.B., M.R.C.P.Ed.
Campbell.—On March 13, 1957, at Corbett House, Droitwich, Worcs. Malcolm Campbell, M.B., F.R.C.S.Ed., aged 84.
Devereux.—On March 9, 1957, at Trent Meadows, Puddletown, Dorchester, Robert Meade Daly Devereux, M.B., B.Ch.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Drugs for Tension and Anxiety

Q.—What drugs are most helpful in the management of patients suffering from nervous tension and anxiety states? How should they be given, and what are the dangers?

A.—The newer drugs used in the management of tension states include chlorpromazine, benactyzine, and meprobamate. It is very doubtful whether any of these except the first is more effective than ordinary amylobarbitone, and certainly they are more dangerous. Chlorpromazine may sometimes be used in severe tension states as a synergist to amylobarbitone, and the dosage employed would be of the order of 50 mg. three times a day. Complications include pyrexia in about 10% and jaundice in some 4%, and fatal agranulocytosis.² The toxic effects of meprobamate have been noted recently in this Journal.³

It is therefore seldom necessary to use drugs other than amylobarbitone for the treatment of simple anxiety states, and the failure of this drug is usually due to inadequate doses. During the daytime 1½ gr. (0.1 g.) three times a day will usually be required, and perhaps twice this dose in some cases. A hypnotic may be required in addition. The dose of amylobarbitone required to effect suicide is very large, which is why it is so widely used in routine practice. Also it does not readily produce confusion when alcohol is taken, unlike, for example, quinalbarbitone sodium.

Routine Cord Toilet

Q.—What routine toilet for the umbilical cord is now recommended? I see that one authority has recently suggested the routine use of penicillin cream for this purpose (*British Medical Journal*, September 22, 1956, p. 711), but surely this carries a grave risk of creating penicillin-resistant strains of bacteria?

A.—This question raises two separate problems. The routine use of prophylactic penicillin (or any other antibiotic) in a maternity hospital is certainly open to the serious objection that it will result in a progressive and ultimately serious increase in the proportion of resistant strains amongst the staphylococci which are exposed to it. The same objection applies in the home, although the results will be less immediately apparent. The fact that the correspondence to which the questioner refers is concerned with the occurrence of infection of the neonatal umbilicus and the puerperal genital tract with haemolytic streptococci (which are virtually devoid of this capacity to develop penicillin-resistant strains) does not detract from the importance of this objection. Staphylococci are still the commonest cause of serious infections amongst the newborn, and they will be exposed to the antibiotic, even when they are not the target at which it is aimed. These objections apply with even greater force when the local application of an antibiotic is in question: for it is the distinctive and life-saving property of antibiotics that they can be introduced into the patient's blood stream and tissues, there to destroy or inhibit the growth of sensitive bacteria which have extended their attack beyond the harmless stage of a purely superficial lesion. Where an antiseptic will do, as in any purely superficial lesion, its use is preferable.

Finger-pulp Infections

Q.—Is it sound practice to treat a finger-pulp infection by incision under local analgesia with a ring block of, say, 1% lignocaine without adrenaline?

A.—When a finger-pulp infection requires incision to let out pus it is certainly reasonable to do it under local analgesia induced by ring block at the base of the finger. It is the method of choice in some clinics, and is, of course, convenient if no assistant is available to give an anaesthetic. Lignocaine 1% without adrenaline is a suitable analgesic. Adrenaline is barred for digital-nerve block because its use has been followed by gangrene. It is also superfluous if the finger is made ischaemic with a tourniquet of rubber tubing round its base before the analgesic is injected. The analgesic is injected distal to the tourniquet through a single puncture on the back of the finger. The needle is directed first to one side and then to the other, and about 1 ml. of solution injected on each side. Analgesia distal to the block will be complete in about five minutes. The tourniquet is not removed until the operation is completed. Its removal is followed by reactive hyperaemia and brisk bleeding. It is worth while waiting for this to subside before applying the dressing, which will otherwise become soaked with blood and difficult to remove at the next visit.

Crush Fractures During E.C.T.

Q.—It is often stated that crush vertebral fractures, sustained in the course of electroconvulsive therapy, require no special treatment and never result in physical disability. Crush fractures from other causes, especially if left untreated, are often most disabling. What is the explanation of this difference?

A.—It is quite true that these vertebral fractures produce only a transient disability and often no symptoms at all. Thus Polatin and Linn¹ followed up a series over a period of 10 years and found no orthopaedic or neurological sequelae of any note. Indeed, convulsive therapy had been in use for some years before it was realized that these fractures were taking place at all. Before the introduction of muscle relaxants it was customary to continue treatment if the depression required it, and further damage to the injured vertebra was rare.

Fractures nearly always occur between the fourth and eighth dorsal vertebrae, and the body is injured as a result of longitudinal compression. Injury to the pedicles or the

transverse or spinous processes is practically unknown. The fracture is thus a rather specific one, and it is probably by this fact that the anomaly pointed out by the inquirer is to be explained.

Raspberry Leaf Tea

Q.—There is a widespread belief that raspberry leaf tea is beneficial during pregnancy. Has this subject been investigated scientifically, and, if so, with what results?

A.—In 1941 the late Sir Beckwith Whitehouse¹ reported a clinical trial of raspberry leaf extracts, and Burn and Withell² described some of the pharmacological properties of such extracts—while at the present time Mr. J. A. Stallworthy at Oxford is interested in the application of these extracts to obstetrics. Beckett *et al.*³ have studied the active constituents of raspberry leaves. They found that aqueous extracts contained a smooth-muscle stimulant, an anticholinesterase, and a "spasmolytic." The conflicting results of the action of raspberry leaf extracts are due to the presence of antagonistic substances, and these authors maintain that the degree of purification of the extracts will result in a preponderance of either a stimulant or a relaxing effect.

For centuries raspberry leaf tea has been prescribed as a herbal medicine during pregnancy and labour. Among rural communities in the North of England the wise women still prescribe a daily infusion during menstruation to relieve dysmenorrhoea. They also prescribe this tea throughout pregnancy and labour. The older midwives who practise in rural areas claim that such treatment reduces the duration and pain of labour. At present there is no statistical proof to support this, but the subject merits further investigation.

Restrictions for Colour-blind Children

Q.—What restrictions are necessary in bringing up colour-blind children? For instance, is there any reason to advise against games with a fast-moving ball such as cricket or squash?

A.—None, as a rule, except that it is obviously no use preparing the child for a job in which normal colour vision is required—e.g., in the Royal Navy or Royal Air Force (except certain branches), as a railway locomotive driver, in certain industries dealing with coloured materials, etc.

Very few people are completely colour blind. The usual abnormality is "defective colour vision," in which confusion arises if the colour stimulus is small or if the differences between various colours are slight. A person suffering from the rare condition of complete colour blindness, to whom the entire world presents a drab grey appearance, has obvious handicaps, but this is very rare indeed.

Differential Diagnosis of Macrocytic Anaemias

Q.—What place have examination of the bone marrow and the therapeutic response to cyanocobalamin in the differential diagnosis of pernicious anaemia from other macrocytic anaemias?

A.—The diagnosis of pernicious anaemia in Britain is usually a simple one, if the clinical and haematological findings and the results of a test meal are typical. Examination of the bone marrow is not necessary in a classical case, but is valuable if there is doubt. In untreated pernicious anaemia a typical megaloblastic picture is present, and this excludes at once a number of macrocytic anaemias where there is a macronormoblastic marrow such as may be found in some cases of acquired haemolytic anaemia and liver disease.

The response to cyanocobalamin (vitamin B₁₂) will be prompt, regular, and complete in pernicious anaemia, unless

there are complicating factors such as hypothyroidism or infection. If the clinical and haematological findings are not typical the possibility of one of the steatorrhoeas should be considered, and these do not usually respond completely to cyanocobalamin. The megaloblastic anaemias of the tropics and of pregnancy are easily excluded on clinical grounds.

NOTES AND COMMENTS

Treatment of Otosclerosis.—Air Vice-Marshal E. D. D. DICKSON, F.R.C.S.Ed., National Institute for the Deaf, 105, Gower Street, London, W.C.1, writes: We appreciate the reference to the National Institute for the Deaf in your reply on the treatment of otosclerosis ("Any Questions?" February 23, p. 473). The Institute has published a booklet (N.I.D. Booklet 493) on *Otosclerosis and the Fenestration Operation*, which is designed for the benefit of the lay public. We shall be glad to supply copies for any readers of the *Journal* or their patients. May I also draw particular attention to the N.I.D. Booklet 481, which sets out a list of companies and their agents whose names are included in the Approved List of the National Institute for the Deaf? These companies and agents have undertaken to observe certain rules of procedure in their dealings with intending purchasers.

The valve-amplifier type of hearing-aid which you mention in your answer is now largely superseded by the transistor type. Although these newer instruments are not necessarily better than the earlier kinds, it will interest patients to know that only a low-tension battery is needed for them; this has a very long life in these instruments and substantially reduces battery-running costs. Use of transistors means that hearing-aids can be further reduced in size and possibly more conveniently worn. The National Institute for the Deaf will at all times be glad to supply any information on this and allied subjects either to doctors or to their patients.

Painless Local Analgesia.—Dr. M. G. GOOD (London, N.W.11) writes: With reference to the query regarding a method of anaesthetizing the skin without injection ("Any Questions?" March 2, p. 536), I should like to recommend a paint recently described. An alcoholic 2% solution of procaine-base may be used for this purpose. Technique: the skin to be anaesthetized is painted first with a 0.1% solution of NaHCO₃, followed by the application of the alcoholic solution; the rapid evaporation of the alcohol favours the penetration of the anaesthetic into the intact skin. After some minutes the skin is less sensitive to pinching, etc.^{1,2}

CANCER—A BIOLOGICAL APPROACH

I. THE PROCESSES OF CONTROL

BY

Sir MACFARLANE BURNET, M.D., F.R.S.

Walter and Eliza Hall Institute of Medical Research, Melbourne, Australia

FORMULA

Prednisone (Delta-1-Cortisone)	0.5 mgm.
Acetylsalicylic acid	300 mgm.
Aluminium hydroxide	160 mgm.
Magnesium trisilicate	30 mgm.

PRESENTATION:

Bottle of 50 buffered tablets at 12/- each
+ Purchase Tax 3/7½d.

DOSAGE:

Two to four tablets,
twice to four times daily.

coactyl

BUFFERED TABLETS

*The anti-inflammatory
medication for
everyday practice.*

Available under N.H.S. prescription (Form E.C.10).

The understanding and control of cancer is the most urgent problem of medicine to-day. The volume of research on the subject, particularly in America, is vast and heavily biased in two "practical" directions. There is a strong tendency to concentrate on investigations that may provide leads (a) to the elaboration of tests for the early diagnosis of cancer, and (b) to its cure by non-surgical means. This has led perhaps to an undue interest in the biochemical aspects and especially the enzymic activities of tumour cells. Clearly if a chemotherapeutic substance is to be found it will be something which can differentially inhibit some processes by which tumour cells differ from normal cells. Such a bias is both inevitable and desirable, but it should have no influence on any attempts to gain a clear picture of the process in terms of general biological concepts.

Scientists may be divided into three groups. There are those, like myself, who believe that at every stage in scientific development it is necessary to provide the best available generalizations as a guide to effective work, both in the application of knowledge to human needs and in the planning of future research. At the other extreme are those who feel that the only valuable scientific activity is to concentrate on some significant facet of knowledge until the facts are incontrovertible and are expressible in some general statement, preferably mathematical in form, that is acceptable to all competent workers. Then we have available a defined unit of knowledge which can be used *reliably* when the time comes to apply the knowledge in any field where it is required. The great majority of scientists take an intermediate position, usually finding their immediate interest in the detailed study of a chosen field, but interested in learning of the emergence of general pictures in the various wider fields.

The present approach to a discussion of the general problems of cancer springs directly from an interest in the nature of antibody production and the ideas of macromolecular pattern developed in a recent essay (Burnet, 1956). It is necessarily based not on personal work in the field or on a comprehensive knowledge of the original literature, but on recent general treatises and compilations, reference to the original papers being made only when these provide essential contributions to the discussion.

Requirements for any General Theory of Cancer

It will be universally admitted that the essence of the group of phenomena we know as cancer or neoplastic

growth is *growth* of cells free from the normal control exercised by the organism as a whole. Experience of tissue culture suggests that most or all mammalian cells have a capacity for growth when provided with appropriate nutrients. The real problem of cancer is then to understand the processes of control by which normal cells from the fertilized ovum to the end of life are maintained in morphological and functional condition appropriate to the needs of the organism at the time. Perhaps it should be stressed how much more complex and difficult to understand are the processes by which a finger retains its character than what is happening in a carcinoma of the lung. Cancer is a negative condition—a manifestation of the breakdown in one or more aspects of the positive control that welds the cells of the body into a single functioning unit—the organism as a whole.

The failure in cancer is due not to any weakness of the organism but to a change in the character of the cells rendering them in one way or another insusceptible to the normal control.

This statement is self-evident when we consider the phenomena of metastasis and experimental transplantation. When cells from a gastric carcinoma produce metastases in the liver there is nothing to suggest any weakness in the control of liver cells. The secondary nodules are clearly due to cells from the primary tumour. This is even more clearly seen in the case of experimental transplants to animals homozygous with the original host of the tumour. The same two sets of phenomena indicate also that the change in the cells is something handed on from one generation of cells to the next. In the broad sense of the term the change is a genetic one. It is immaterial at the moment whether investigation will in any given case eventually give a more precise label to the genetic change, whether it represents a true somatic mutation, transfer of plasmagones, incorporation of a virus into a "provirus" state, or some new concept yet to be formulated.

Any hypothesis of a general basis for neoplastic growth must be related directly to this function of control—any other type of associated change can only be regarded as secondary. It is therefore from our point of view impossible to accept Warburg's hypothesis that a change from aerobic to anaerobic glycolysis is the essential feature of cancer cells. If cancer is, as indicated above, essentially a negative biological phenomenon like starvation, scurvy, agammaglobulinaemia, or phenyl-pyruvic oligophrenia, the only legitimate way

to discuss its relation to general biology is to use the phenomena of cancer as seen clinically and experimentally to throw light on the nature of normal controls in the organism. Basically this is the theme of the present essay.

Process of Control

It is in line with popular present-day thought to apply concepts from mechanical or electronic control and communication systems to biological phenomena. This has been specially evident in discussions of neural mechanisms, but the general principles would be equally applicable to any other type of biological control. Since there is no evidence of more than very minor influences of nervous action in the control of morphology, this will not be discussed. Forestalling subsequent discussion slightly, we may say that there is very much to suggest that control is a function of the movement of complex molecules carrying patterns equivalent to coded instructions from one part of the organism to another. Further, there is no substantial alternative to such a view; "fields of morphogenesis" may be a necessary provisional concept, but there is no serious suggestion that a physical field in any normal sense is concerned.

Any type of control of a collection of living cells subject to trauma and to variable demands on their function will have to incorporate a number of "components." (1) There will be needed a built-in "plan of action." The whole mechanism must function to favour survival of the individual, and we shall probably be correct in regarding the general plan of action in any developed organism as being to maintain or regain the *status quo*. (2) Information must be provided in some form about the state of the cells in question, particularly as it is relevant to the need of more or less cells or of greater or less functional activity. This is the "feed-back" needed by all mechanisms for any type of homeostatic control. (3) A central control mechanism is needed which will respond to this information by the despatch of appropriate "messengers" to the cells under control. (4) In the cells there must be a reception mechanism to accept instructions so delivered and to induce the appropriate cellular reactions.

This is obviously a generalized statement made to cover such an example as the interaction of pituitary and thyroid, which will be discussed later. Probably all biological control mechanisms need these four components, but one can conceive situations where they may be difficult to recognize. One has in mind the work of Weiss and others on the capacity of cells in appropriate conditions of tissue culture to come together into patterns significantly similar to the structures found in corresponding normal tissues. Here we seem likely to be concerned with something that can be looked on as an interchange of information and instructions between surfaces coming into contact. The third form of control to be discussed, which is referred to rather loosely as "immunological," will probably be found to fit rather clearly into the framework outlined above.

The general hypothesis of control by the interaction of complementary macromolecular patterns has been outlined in what was primarily a discussion of antibody production (Burnet, 1956). This is directly derivative from Ehrlich's hypotheses of lock-and-key action in immunology and chemotherapy. Most of the discussion in *Enzyme, Antigen and Virus* was concerned with protein pattern and the ways in which complementary patterns, not necessarily in the same medium, could arise. It was concluded that for the functioning of such systems there must be means of which (a) patterns can be replicated; (b) patterns can be used as blueprints from which complementary patterns can be fabricated; (c) information encoded in pattern, say on protein or DNA, can be expressed in another medium—for example, RNA or polysaccharide; (d) specific union of pattern and complementary pattern can initiate an appropriate reaction—for example, enzymic breakdown of substrate, liberation of histamine, initiation of oestrus, and the like.

The mammalian body contains a wide variety of differentiated cells which differ greatly in the way they are produced, in their potentialities of multiplication, and in their average life as cellular individuals. At the one extreme we have the erythrocytes and a wide variety of what appear to be highly expendable mesenchymal cells, including lymphocytes, histiocytes, granular leucocytes, and fibroblasts. These are produced in permanent and temporary centres of proliferation, spleen, bone marrow, lymph nodes, and a variety of submucosal collections throughout the body. After a life measurable in days or weeks, these expendable cells are got rid of largely by phagocytosis and intracellular digestion, while another large proportion is shed into the intestinal lumen or liberated on some other mucous membrane.

Next we have the epithelial surfaces of tissues exposed to external or internal environments—skin, and alimentary and respiratory mucous membranes. Here attrition, trauma, and infection are everyday occurrences, and there is a steady replacement of older cells by the reproduction of basal cells or their equivalent. Worn out or damaged cells are shed into the environment. These cells in a sense are always growing, and it is significant that the incidence of cancer in the corresponding situations is high. Carcinoma of the skin, larynx and bronchi, stomach, large intestine, and rectum are all common.

Rather closely related are the organs whose lining is modified sharply in relation to sexual periodicities of menstruation, pregnancy, and lactation. In ovary, uterus, and breast there are hormonally determined changes of cellular proliferation and regression. In the uterus excess cells are shed to the exterior. In the breast the process by which the lactating organ regresses to the quiescent stage probably involves a quiet autolysis of superfluous cells and absorption of their substance into the general pool of amino-acids, nucleotides, and other building blocks.

The endocrine organs have a special part to play in the control of bodily function, and provide equally important examples of the way in which cellular proliferation and function is controlled. In such an organ as the thyroid the amount of specifically functioning cells depends in part at least on the concentration of thyrotropic hormone reaching it from the pituitary. With regression the number of cells diminishes, presumably again by autolysis without the intervention of phagocytic processes. It is likely that similar situations hold for the other endocrine organs.

Most of the major tissues of the body seem to belong to the next class in which the average cell life is long, perhaps indefinitely long, but in which, when demand arises, proliferative and reparative processes take place readily and efficiently. Compensatory hypertrophy of remaining portions of tissue is regular after removal of any considerable proportion, such as one member of a paired organ. Liver, kidney, heart, lungs, and skeletal muscle belong here.

Finally we have the permanent cells of the nervous system which once maturity is reached are not expendable.

This provides a basis for the general consideration of the processes concerned in the development and evolution of cancer. For any given type of cell we have two questions—what are the ways in which control may be lost, and, if one or more such controls are lost, is there any way by which they can be reinstated? Since every cell of the mammalian body is derived from the fertilized ovum, it is reasonable to believe that to some extent all cells are subject to all methods of control, just as all cells have certain common metabolic functions. In practice, however, we find that the effective controls vary greatly from one cell type to another, and it will be convenient to divide them into three major types which can be discussed separately: (1) Hormonal control of cell growth and functional activity of certain organs. (2) Local control (a) by mechanical pressures, tensions, etc., and (b) by mutual interaction of cell surfaces. (3) "Immunological" control associated with the "self-markers" of the body.

Hormonal Control of Growth

It is a striking fact that the most effective chemotherapy of any type of cancer has been the use of oestrogens in prostatic carcinoma. This underlines the significance of hormonal control of growth.

The special quality of hormonal control can perhaps best be seen in the effect on the epidermis of the tadpole of premature exposure to thyroid hormone (Lindeman, 1929). This results in metamorphosis, and as part of the process we find cytolysis and atrophy of epidermal cells on the caudal side of a well-defined line, and proliferative changes on the cranial side. Changing hormone concentrations can in this fashion trigger biologically appropriate changes of different types in various target organs or tissues.

In higher vertebrates the effects are seen largely in endocrine tissues, but there is much to suggest that to some extent all cells are potentially subject to hormonal control. A point that may be of special importance is that control takes the form either of proliferation (and increased functional activity) or cytolysis and atrophy in which the cell substance is quietly broken down and its components are added to the general metabolic pool of the body. They are not "mopped up" by the scavenging cells in the way that most expendable mesenchymal cells are, and they appear to have little or no individual immunological specificity. There is some direct experimental work to support this view. Woodruff and Woodruff (1950), for instance, carried out extensive experiments on the transfer of thyroid tissue from one guinea-pig to the anterior chamber of the eye of another. He found that the tissue became established in the new host if there was a need for it—that is, if the host had been thyroidectomized. The evidence was highly suggestive that in the process by which the foreign tissue became established the stroma of the donor was destroyed and replaced by that of the host, only the specific thyroid cells being genetically still those of the donor.

The general basis of endocrine control has already been briefly discussed, and it has been pointed out how the pituitary control of thyroid function provides one of the most clearly manifested feed-back mechanisms in biological control.

There are a relatively large number of instances where controls of this general type can be distorted by accidental or experimental circumstances to produce hyperplastic or neoplastic growth. Thiouracil and other goitrogenic substances which decrease thyroxine output will induce the formation of thyroid tumours as a result of stimulation by thyrotropic hormone. These tumours are transplantable to other rats (presumably not genetically homozygous) provided the recipients have been rendered thyroxine-deficient either by thyroidectomy or by administration of antithyroid substances (Bielschowsky *et al.*, 1949). A relatively slight change in the situation can give a different picture, involving neoplastic change in the pituitary. Large doses of radio-iodine ^{131}I given to mice will destroy the ability of the thyroid to produce thyroxine, and there is therefore a continuing call for thyrotropic hormone, and the pituitary cells responsible for its production give rise to tumours (Gorbman, 1949). These tumours can be transplanted to mice treated with ^{131}I but not to normal mice. On transfer their autonomy increases and they can eventually be transplanted to untreated mice. Even in this autonomous state, however, they continue to secrete thyrotropic hormone.

Oestrogens will induce testicular tumours in mice by a basically similar mechanism, and, as might be expected, when such tumours are transplanted they will grow to tumours only in recipient mice treated with stilboestrol or other oestrogens.

A different type of experimental artifice to induce endocrine overactivity is to transplant a rat's ovary into the substance of the spleen, the other ovary being removed. A high proportion of such transplanted ovarian tissues give rise to granulosa cell tumours (Biskind and Biskind, 1944). This is

interpreted as resulting from the destruction of oestrogens produced by the ovary during their passage through the liver (in the portal circulation). There is thus a continuous stimulus to pituitary liberation of gonadotrophic hormone without the normal feed-back control. The same type of result is found in mice.

Local Controls

It is quite certain that the actual controls playing on all morphologically significant cells are more numerous and subtle than anything that could be suggested at the present time. All that can be attempted is to outline the simplest mechanisms that might account for some of the more easily recognized features of the phenomena of local repair, regeneration, and growth.

In the first instance there is the response to pressures and tensions which mould skin and skeletal tissues into the form needed by simple mechanical considerations. Even a fairly rapidly growing benign tumour of the subcutaneous tissues allows the skin to keep pace in covering it. There are hosts of similar mechanical controls which play their part in reshaping a functional limb after severe trauma or reconstructive surgery. The detail of the processes by which pressures and tensions lead to modification of growth and shape of cells is outside the field of this discussion, but it will have to be elucidated in full if a complete account of the mechanisms of control is to be provided. Indications of more direct influences associated with the cells themselves can be obtained from a variety of sources. A striking example is to be seen in the classical experiment in which an emulsion of disaggregated sponge cells of two species will come together into aggregates, each composed only of the one species.

Recent work, particularly from Weiss's laboratory, has shown that chick embryo cells, dissociated into single units by treatment with trypsin, can under appropriate conditions of tissue culture give rise to a tissue-like association (Moscona, 1953, 1956). An analysis of the process indicates that the first step is for the cells to become grouped according to kind, aggregating into clusters by a variety of processes which seem to include random encounter, directional migration, and surface interactions. The next process is one of organization within the aggregates and their interaction with clusters of cells of other types to develop the tissue-like appearance.

Essentially similar results are described by Leighton (1951, 1954), who used a type of three-dimensional tissue culture in cellulose sponge for embryonic and tumour cells. In this situation cells developed histological patterns very similar to those of tumours growing in the body. From both types of experiment it is clear that a significant proportion of the control of cellular relations is intrinsic to the cells themselves.

If attention is directed particularly on the mutual interaction of contiguous cells, the simplest working hypothesis is that when two adjacent cells are in their appropriate position in the organism the *status quo* is maintained by an interchange of information—in the form of patterned macromolecules—across the interface. Where a surface is free this particular control must be replaced by something of appropriately different character. If cells are removed by trauma or operatively, the gap will be filled by the proliferation of those adjacent to the gap. If this is a simple reaction, we could deduce from it that, in addition to the disappearance of the adjacent cell, either a failure of that cell to provide information of its existence or an inability of the cell itself to "recognize" the information might lead to the same result—that is, proliferation until in one way or another the remaining controls brought it to a halt.

It would seem that the first requirement for malignant growth is a loss of the control mediated by physiological contact with adjacent cells. The locally invasive character of a cancer, the feature which makes its histological diagnosis possible, is in itself the clearest indication of this. Proliferative reactions in general must eventually be seen against

the background of normal controls, a specially important type being the proliferative response to certain virus infections. This is the basis for the great amount of work and speculation that is associated with the virus theory of cancer, and it is best discussed in relation to that theme.

The various mechanisms which are concerned in embryonic morphogenesis must undoubtedly be relevant, but it would be hopeless for anyone not personally familiar with the field to attempt to draw general principles from their complexities.

One field, however, may be mentioned because it indicates very clearly the concept of control by mutual interactions of cells with which we are primarily concerned. In all vertebrates it appears that cells concerned with pigmentation are derived from a special group of ectodermal cells, the neural crest. At appropriate periods in embryonic life these cells pass to the various sites where melanoblasts will eventually be functionally active.

This migration provides extensive opportunities for experimental study of the process. Weiss and Andres (1952), for instance, injected embryonic cells, including melanoblasts, intravenously in chick embryos of a non-pigmented strain. They found that donor melanoblasts proliferated and produced melanin granules of the sort corresponding to their genotype only in locations in the host where they would normally have produced pigment in a bird of the donor strain.

By appropriate experimental action the normal supply of melanoblasts can be prevented from reaching an area of chick embryo skin. If this skin is now transplanted to replace an area of skin on a normal embryo it is rapidly and freely invaded by adjacent melanoblasts. This does not occur if the graft is of normal skin (Rawles, 1944).

There can be little doubt that migration of the primary melanoblasts is directed by processes involving mutual cell contact and that the sites of their functional proliferation are also determined in this fashion. The extent of their multiplication is also clearly related to processes involving the cell community and not by any self-limitation in their capacity to multiply.

All that need be attempted here is to apply some of the ideas drawn by Weiss from such studies to some aspects of tissue interactions at the immunological level that seem likely to be specially relevant to neoplastic phenomena. In a recent discussion (Burnet, 1956), I have tried to make use of Weiss's concept of complementary interaction between cell surfaces to broaden the idea of immunological "self-markers."

The Immunological Approach

The essence of the self-marker hypothesis (Burnet and Fenner, 1949) is that at a late stage in embryonic life the scavenging cell system of the body (reticulo-endothelial cells, etc.) is conditioned to recognize as self-components certain potentially antigenic constituents of the expendable cells of the body. A variety of foreign potential antigens which by accident or experimental manipulation may be present at the relevant time will also be recognized as self. They will then become part of that class of substances which are incapable of acting as antigens in the conditioned animal.

The observational and experimental basis for this concept is now extensive. The clearest evidence is in regard to tolerance of cells which are antigenically distinct but derived from another individual of the same species. Here complete tolerance can readily be demonstrated from twin studies in cattle, sheep, chickens, and one human case. In all these instances red-cell chimeras have been shown to persist indefinitely. In addition, Anderson *et al.* (1951) showed that non-identical bovine twins (with a common placental circulation during foetal life) were receptive to mutual interchange of skin grafts. Billingham *et al.* (1956) showed experimentally that inoculation of cells from a homozygous strain of mice B into late fetuses of strain A

resulted in tolerance of the grown mice for skin transplants from a B mouse. This tolerance was specific, being confined to skin grafts from strain B.

In all these examples we have the probability that the tolerant condition is associated with the continuing survival of the genetically heterologous cells in the body. Just as accelerated homograft immunity is produced only by experience of living cells, it may also be claimed that immunological tolerance of this type is dependent on the persisting foreign cells which are capable of "mopping up" any antibody that may be produced.

A variety of evidence, however, is strongly against this view. The most cogent experimental result is also due to Medawar's group. If a tolerant white mouse of strain A carrying a healthy black patch of skin of strain B is left untreated, the patch of foreign skin will remain healthy for an indefinite time. If, however, lymph-node cells from a normal A mouse are inoculated into the tolerant mouse they are accepted and can function normally. Within three to four weeks an immune response results in the breakdown and rejection of the black graft. This observation has two very important implications.

In the first place it shows that something has happened to condition the scavenging cells of the tolerant host which does not apply to similar cells reaching the body of the grown mouse. There can be no question of antibody against B cells being produced and absorbed or diverted by persisting B cells from the modifying prenatal injection.

In the second place it is clear that B cells in the tolerant mouse are liberating something which can stimulate unconditioned cells to produce a specific and destructive immune response. Everything suggests that what is liberated is the same antigen as is responsible for homograft immunity. Since purely epithelial skin grafts can provoke homograft immunity there is reasonable certainty that both the conditioning cells and the tolerated graft are contributing amounts of the antigen. In the tolerant animal this antigen is accepted as self—there is no immune response—but if normal lymph node tissue is made available the standard immune response occurs. Medawar *et al.* have found that a labile non-cellular antigen can be extracted from nuclei which will provoke homograft immunity. It seems highly probable that the same antigen, provisionally characterized as a DNA-protein complex, is the one concerned in provoking immunological tolerance.

From the point of view of cellular control in its relation to cancer the important aspect of these results is the indication that cells of many types are constantly liberating "self-markers" into the lymph and blood circulations. A hint of the way in which these markers may act is contained in the finding by Ebert (1954) that, when an animal is grafted with a tissue from a donor treated with an appropriate radio-isotope, labelled molecules "larger than amino-acids" pass selectively to the corresponding organ of the host. At the present time we have no more than hints that these specific agents have a control function, but those hints are insistent, and Green (1954) has built an interesting immunological theory of cancer by elaborating them. This will be discussed in a later section.

II. THE SIGNIFICANCE OF SOMATIC MUTATION

There is every reason to believe that mutation is at least as frequent in somatic cells as in the germ cells. Somatic mutation has been studied particularly in plants, where the phenomena of continuous growth make its effects more readily demonstrated than in the higher animals. In insects body colour mosaics due to somatic mutation at early stages of differentiation are not infrequent. In mammals most of the evidence for somatic mutation comes from studies in tumour pathology.

The essential difference between a mutation occurring in a germ cell and a similar process in a somatic cell depends simply on the extent and distribution of the cells descendant

from that in which the mutation occurred. A germ-cell mutation can potentially influence all the body cells of all those individuals who receive the modified allele in question. A somatic mutation can influence only those body cells which directly descend from the mutant cell. A mutation of any sort in a nerve cell can have no influence on any other cells but itself; a mutation in a cell giving rise to highly expendable descendants may have wider influence. Any mutation is, according to current opinion, an individual event occurring at a limited region of the genetic mechanism of a single cell. The potential effect of the mutation may be almost anything, although the chance of one type of specific damage will be more or less frequent than that of another.

From the practical point of view, however, we have to remember that every tissue is made up of many thousands or millions of cells. A modification of one cell or of any small proportion of the order characteristic of mutation—that is, $1:10^5$ per cell life—will have no detectable effect on the function of the tissue unless one condition is fulfilled. This is that the mutation results in a differential survival advantage for descendants of the mutant cell as compared with the descendants of normal cells. In other words, somatic mutation in higher animals is of no significance whatever unless it results in the loss or change of some quality which frees it in part from the normal control on its capacity to reproduce. Only mutations along the road toward cancer will be of any significance—they will also be almost the only ones detectable even in principle.

From a wide variety of sources it becomes evident that the change from a normal cell to a cancer cell is rarely if ever a single step. This is perhaps equivalent to saying that every normal cell in the body is played on by multiple controls, and that more than one of these controls must be abrogated to allow unrestrained or excessive growth.

There is first the clinical evidence of pre-cancerous changes in organs like breast, prostate, or skin. Benign hyperkeratoses are very common in the human skin. It is usual, too, to find that recurrences are more malignant than the tumour removed and that tumours held temporarily in check by hormonal treatment or irradiation always eventually break away from control. Later we shall mention the interesting relationship between age and incidence of cancer in various organs which points strongly in this direction.

At the experimental level the work of Berenblum and Shubik (1949) on the process of carcinogenesis in mice is relevant. They found that a brief treatment of the skin with a standard carcinogenic hydrocarbon would produce no tumours. If, however, the areas were subsequently treated for a prolonged period with croton oil, itself non-carcinogenic, tumours arose in numbers approximately proportional to the concentration of the carcinogen used. One essential step was induced by the carcinogen, but the so-called co-carcinogenic action of the croton oil was necessary to allow any manifest expression—that is, to induce or provide conditions for the appearance of some further change or changes.

Once a cancer has reached the stage of being transplantable to other individual hosts, the essential changes have taken place and any subsequent changes are, strictly speaking, irrelevant to the problem of the genesis of cancer. Nevertheless many changes do take place in the course of transplantation experiments, and it is logical to believe that, with due reservation, these changes are likely to be of the same general quality as those associated with the change from normal cells to cells recognizable as cancerous.

Perhaps the outstanding recent feature of work on transplantation has been the recognition that all populations of cancer cells are heterogeneous and subject to the processes of mutation and selective survival. There are two main lines of evidence. The first is in regard to the process by which a tumour strain can extend its virulence to other hosts. The second is concerned with the changes observed in response to agents being tested for therapeutic potentialities.

Koprowski's experiments may be mentioned as typical of a number of situations where selective survival of a fraction of a tumour cell population occurs. He tested mice of one strain (ICR) which had been inoculated *in utero* with blood from another strain (C3H) for their susceptibility to an ascites tumour grown in C3H and to which ICR were normally resistant. Tolerance was found to be present, but after a few passages in tolerant hosts the prior manipulation became unnecessary. The ascites tumour strain now grew in all mouse strains tested as well as in ICR and C3H. It appears that tolerance was only partial but allowed sufficient proliferation to let a process of selective survival come into play by which a substrain that had lost further antigenic markers came into dominance.

Almost identical types of result are obtainable by experiments in which tumours are enabled to grow in foreign hosts by making use of some other artifice to weaken the normal immunological resistance. Stewart (1954) used inoculation of newborn mice to adapt a strain of leukaemia to foreign hosts. Earlier Krebs (1943) had adapted a lymphosarcoma by inoculating mice whose resistance had been diminished by x-radiation. In each instance once the strain had been persuaded to grow in the immunologically weakened host it became capable of transplantation to the normal grown animal of the previously resistant genotype.

Hauschka (1953) has elaborated this point of view from his studies of ascites tumours. These often show in association with an extension in range of host a change in the distribution of chromosome numbers in the cells from diploid to heteroploid. He showed that a small fraction of heteroploid cells in a tumour could be concentrated by propagation in a partially incompatible host. In his view loss of transplantation specificity is a result of immunological selection of cell types with least antigenicity amongst the available chromosomal variants. The possibility that the selection is rather for cell types which are unduly resistant to the destructive action of immunological processes must also be considered.

When transplantable tumours are exposed to therapeutic concentrations of radiations or antimetabolites it is the rule to find the eventual appearance of resistant tumour strains. Law (1952), working with mouse leukaemias, found that the tumour cell behaved in a fashion amazingly similar to what is observed in regard to drug fastness in bacteria. It could be shown in classical fashion that resistance was not induced by the agent but that its appearance was due to the selective survival of small numbers of mutants present in the pre-existent population.

A similar situation obtains when pituitary tumours are induced by radiothyroidectomy. Furth (1954) transplanted 13 such tumours, finding that primary passage was possible only in thyroidectomized recipients. On continued transfer, however, most of them became autonomous and capable of growth in normal mice. Here again we have the selection of an appropriate mutant by the conditions in which the population is compelled to grow.

From many directions, therefore, we find support for the working hypothesis that the development of malignancy is the result of a biological process in which successive mutations occur in cells capable of continued proliferation, by which a certain advantage is gained. If cell A mutates to A¹, and A¹ has a slight advantage over A, there will be a gradual conversion of at least some regions from a population of A to one of A¹. If mutation A² is much more likely to occur in A¹ than in A and A² more likely in A² than in the others, then we develop a situation that may be very relevant to the behaviour of spontaneous cancer in men and mice.

There is some reason for guessing that on the average about six controls would need to be abrogated before a cell with the full characteristics of malignancy would emerge. The process is shown in the accompanying Diagram, which represents an epithelial layer derived from constantly proliferating basal cells. While these are normal there is no reason to postulate any deviation from the rule that each

basal cell produces only the pillar of cells reaching from it to the surface, where desquamation occurs. A mutation A^1 may, however, result in a progressively wider column of cells with the character of mutant A^1 developing. When these cells become sufficiently numerous, the possibility of a second mutation becomes steadily greater and eventually new columns of cells lacking two controls will appear. The process will continue indefinitely until perhaps when the sixth type of mutation occurs we have the initiation of a focus of frank cancer. As Armitage and Doll (1954) have pointed out, this is the type of process which would give rise to the very constant and significant mathematical relationship that governs the age incidence of death from cancer in human beings.

Diagram to illustrate the possible way in which successive mutation to more actively growing cell types could change the constitution of an epithelial cell layer derived from constantly proliferating basal cells (see text).

The frequency of cancer in general and of cancer of most important sites increases rapidly with age, and it is convenient to use a logarithmic scale to show the change in a compact and convenient form. With the usual time scale such a graph shows a gentle concavity downwards. If, however, the age scale is arranged logarithmically so that the intervals 10–20, 20–40, 40–80 have equal value, then the curves fall on straight lines. Exceptions have been discussed by Metcalfe (1955), notably cancer of the prostate, which shows a much steeper slope, and cancer of the ovary, which flattens after the age of 50. Where the incidence of a type of cancer has increased rapidly in the last 50 years, as is the case with bronchial carcinoma, a more complex relation holds. With these exceptions the curves are very uniform in slope and very close approximations to straight lines in America, Britain, and Australia.

The first explanation offered by Fisher and Holloman (1951) was based on the hypothesis that only one mutational step was necessary but that cancer did not develop unless a number of mutated cells found themselves in juxtaposition. If one mutational change occurs in random fashion throughout life and overt malignancy develops only when seven potentially cancerous cells are contiguous, then the observed age incidence would be expected. The interpretation offered by Armitage and Doll (1954), however, appears to be more in line with the clinical and experimental character of malignant change. They suggested that the observed log-log relationship would obtain if for the development of cancer a sequence of six to seven changes in the initiating cell are required. If a cancer cell is the end-result of a series of six or seven successive mutations, then, provided that the probability of the occurrence of each mutation remains constant throughout life and that each mutation is a relatively rare event, the age incidence of cancer would be as observed.

To express the situation in non-mathematical terms we can say that with increasing age more and more patches of cells in expendable tissues are the offspring of cells which have undergone more than one mutation in the line of progression to cancer. Perhaps a very clear indication of this is to look at the skin on the back of the hand of an elderly man and note its mosaic of colour and texture. Cowdry (1955) has treated these changes of skin epidermis with age in some detail, and though he does not specifically state that

he regards the changes as mutational in origin, this is virtually implicit in his summary of the main changes, which include: increased thickness of epidermis in some areas, lessened thickness in others, diminution in hairs, sweat and sebaceous glands, patchy areas of hypo- and hyper-mineralization, occasional marked hypertrophy of single hairs. There are probably invisible mosaics of similar character in many other parts of the ageing body.

There is an interesting clinical implication of the somatic mutation theory of neoplastic change, particularly in the form envisaged by Armitage and Doll. It is a cardinal point of the theory that only if a mutation results in the loss of some structure or function by which general control over growth is exercised will the descendants of the mutated cell become sufficiently numerous to produce clinically or chemically detectable effects. The commonest effects will, of course, be those resulting directly from malignant growth of the cell descendants concerned. There should, however, be occasional opportunities for mutations not themselves leading to or toward malignancy to become manifest because they have occurred in a cell line which has also become malignant.

Macroglobulinaemia (see Mackay, 1956) is a relatively rare condition found in elderly patients in which the blood contains an abnormal globulin of very high molecular weight. It is always associated with a gross replacement of the bone marrow by lymphocyte-like cells which are clearly neoplastic and which in a small proportion of cases give a blood picture hardly distinguishable from chronic lymphatic leukaemia. Whenever the abnormal proteins from different cases of macroglobulinaemia have been compared they have shown sharp individual antigenic differences (Habich, 1953; Kanzow, 1954). Immunologically, and therefore genetically, the appearance of a capacity to produce macroglobulins in excess cannot be directly related to the changes resulting in gross proliferation of the pathological lymphocytes. The only reasonable interpretation is that in each case an independent mutation has occurred in the cell line from which the neoplastic cells have sprung. No other explanation seems capable of covering the facts, notably the rarity of the condition, its age incidence, and the heterogeneous character of the abnormal protein.

Possibility of Directed Mutation

Mutation, whether occurring spontaneously or under the influence of mutagenic radiation, is regarded as a random occurrence, striking any given cell at random (a zero order reaction) and producing mutations of varied type, although for our present purposes only those associated with selective growth are observable. There is now, however, a fairly long list of chemical agents which can be called mutagenic on the basis of experiments on one or other form of organism, *Drosophila* and *Bact. coli* being the favourite test objects. These include a number of carcinogens, mustard gas and nitrogen mustard being the best documented. It is a necessary weakness of experimental work on mutagens that in general only rather gross mutations are recognizable, and, as might be expected, most of the known mutagens are toxic to cells at the stage of division and show a capacity to produce visible abnormalities in the chromosomes. More subtle changes may well be missed by current methods.

The observations and deductions of Bird and Fahmy (1952), who studied changes produced in the salivary chromosomes of *Drosophila*, suggest that carcinogens, like the diepoxybutane they used, may act to produce minor degrees of chromosome damage. They found a high proportion of minor deficiencies in the band pattern of the chromosomes of treated larvae; these varied from defects in staining properties to complete absence of a band. They suggested that the findings were best interpreted as due to chemical damage of the molecular pattern of a gene which prevents its normal replication.

As in every other natural situation, the effect of a mutation is observable only under a limited range of conditions.

If we have a somatic mutagen acting on a mammalian body cell a mutant character can be recognized only under one of two conditions: (1) it may itself provide an opportunity for the cell concerned to produce more descendants than its unmutated congeners; or (2) it is associated either randomly or necessarily with another mutational change allowing selective overgrowth of descendants. Examples of the second class may be found in the variety of rare pathological conditions in which antigenically atypical proteins appear in the serum in association with a variety of neoplastic changes, including myeloma and lymphatic leukaemia.

The problem of the aetiology of cancer or of the mechanism of experimental carcinogenesis may represent essentially a choice between three alternatives. In each it is accepted that the malignant cancer cell is genetically different from the normal cell from which it is derived.

1. Is "mutation" produced by direct damage to chromosomal material altering the genetic code in random fashion? Those mutations which "release" a control against excessive growth will prosper, others will have unobservable results.

2. Are mutations always occurring and the effect of the carcinogen merely to provide, by its combined stimulation of destruction and regeneration, large numbers of cells in which mutations can occur and a specially suitable environment for any cell with a mutation appropriate for differential overgrowth in the special local environment provided by the carcinogen?

3. Does the carcinogen, acting on some key cellular component x , render x non-functional by combining with it, and, by one or other causal mechanism, induce the cell or its descendants to undergo a genetic change by which the component x is no longer produced? One can imagine that a persistent demand for x , owing to its inactivation as soon as it is produced, might in some way lead to damage of the gene controlling the specific pattern of x .

Unfortunately it appears to be extremely difficult to find an experimental choice between the three alternatives, the main difficulty being that by the nature of the material we are precluded from being able to assess what other types of mutations are occurring. The type of experiment which might be expected to throw some light on the matter is that used by Berenblum and Shubik (1949) to demonstrate the co-carcinogenic action of croton oil on mice. Here only a single application of a carcinogenic hydrocarbon is needed to allow the eventual development under prolonged croton oil treatment of foci of neoplasia in numbers approximately proportional to the concentration used of the primary carcinogen. Here it becomes almost impossible to assume that the initiating carcinogen did no more than make use of spontaneously occurring mutations. Somehow or other the primary agent rendered a cell and/or its descendants susceptible to the co-carcinogenic action of the croton oil.

Of the suggestions that have been made to account for the action of carcinogens in producing what is at least an equivalent of somatic mutation, one of the most interesting is Green's (1954) immunological theory of cancer. This makes some use of the self-marker concept of antibody production and immunological tolerance described earlier. Prior to Green's work, immunological ideas were called in, in cancer research, only in discussions of the phenomena of transplantable tumours. It was well known that on first appearance a spontaneous tumour will be transplantable only to mice homozygous with that in which it appeared. After it has been thoroughly adapted to transplantation within the pure strain, it will often be found possible, by one artifice or another, to obtain growth in another strain of mice. Eventually it may be possible to obtain a tumour which is transplantable to and grows freely in any strain of mice.

It is the orthodox opinion, which is backed by a variety of immunological evidence, that the basic reason for failure to grow in a heterologous strain is the immune response of the new host to the foreign marker antigens in the graft.

If these marker antigens are lost the tumour develops a progressively wider range of transplantability. As this change is also associated in general with an increase in the other aspects which measure intensity of malignancy, it is a natural extrapolation to think whether loss of markers is not the primary determinant of malignancy.

Green developed his approach from the finding that certain non-carcinogenic hydrocarbons could render mice non-receptive to transfer of tumours which they would otherwise accept. He believed that a carcinogenic hydrocarbon acted by combining with one of the characteristic antigens of the cell type involved and so producing a new antigenic pattern and provoking an immune response against the modified cells. If a somatic mutation occurred by which a cell lost the marker with which the carcinogen could unite, this would give the cell an advantage, since it would not now be damaged by the immune response. If in addition the loss of the marker represented the loss of one of the points necessary for the organism's control the cell would be on the road to the development of malignancy. On this view the wide variation in the nature of carcinogenic molecules, and the equally wide disparity in the species and tissues susceptible to their action, depends essentially on the accident of specific capacity to combine with the pattern characteristic of a marker molecule.

Observations which may be highly relevant to this hypothesis concern the production of hepatomas in rats by administration of butter yellow and similar azo dyes. Here it has been shown that the dye, or derivatives thereof, is bound firmly to a liver protein which is found in the soluble fraction of homogenates and migrates slowly in electrophoresis. A single type of protein seems to be responsible for holding about 80% of the bound dye. When hepatomas develop they contain no protein-bound dye, and their content of the group of liver proteins concerned is much lower than in normal liver tissue. Dyes of this type have a variety of damaging effects on the liver, and small areas of regenerating cells arise, from some of which hepatomas eventually develop.

The suggestion that a specific protein is lost in the process is strongly supported by the immunological work of Weiler (1956). He showed that hepatoma cells contained very little or no specific liver antigen, and, by using Coons's fluorescent antibody technique, detected a series of changes in livers of rats fed the dye. In the earlier stages islets of cells developed which fluoresced less brightly than the normal liver cells surrounding them when stained with a specific anti-rat-liver serum. We thus have evidence of a series of changes involving the progressive loss of protein capable of binding dye products and, concomitantly, a series of changes in immunological character. As Green points out, these findings recall the fact that carcinogenic hydrocarbons are also bound early to proteins in epithelial cells of treated skin, but the fluorescence which evidences this binding is not seen in developed cancer cells.

It seems unlikely that we are dealing here only with the selection of random mutations. Even with associated damage and destruction with much regeneration of cells the speed of mutation would need to be greatly accelerated to account for the results. The possible interpretations are:

1. Spontaneous undirected mutation in cells rendered highly susceptible to mutation by the agent used.

2. Heightened selection against cells carrying the component with which the carcinogenic agent reacts. The only likely suggestion is Green's, that the action of the carcinogen creates a new (and foreign) antigen which provokes an antibody response. This will thus provide a specific selective agent acting against cells capable of binding the carcinogen. When such a mutation occurs it will have a high probability of giving descendants which will replace or overgrow the normal form.

3. By a mechanism perhaps related to what must be assumed to occur in the process of differentiation during development, specific mutations by loss occur when a functioning entity in the cell is unable to exercise that function. These result in the inhibition or disappearance of the genetic mechanism concerned with that function.

Broadly speaking, the choice is between interpretations 2 and 3, although it must be recognized that these are by no means mutually exclusive. Since 2 is concerned with a specific selective process and 3 with a hypothetical type of induced mutation, the two could well be combined.

Alternative 2, the immunological theory of cancer, has the great advantage of being susceptible to experimental attack along the lines discussed by Green (1954). I have not been able to find any account of experiments in which the action of standard carcinogens was tested in mice treated with x rays and cortisone to eliminate or greatly diminish the antibody response. A strong anticarcinogenic effect under these circumstances might speak strongly for the correctness of Green's hypothesis.

Alternative 3 is virtually what has been suggested by Haddow and others largely on the basis of the work by the Millers, Weiler, etc., on the production of hepatomas in the rat. It is wholly speculative at the present time, the difficulty of establishing it being the familiar biological one of differentiating between spontaneous mutations with selective survival and a direct environmental effect. Past experience should make us lean toward a Darwinian rather than a Lamarckian interpretation, but, on the other hand, we cannot ignore the possible analogies from the process of differentiation.

Differentiation can be legitimately regarded as a process by which the potentialities of a cell are progressively reduced with its taking on of a specialized function. Tissue culture studies indicate that to a considerable extent the differentiated cell is so in virtue of its inheritance. Even in the absence of normal body controls, its descendants differ from the descendants of other types of specialized cells. If this is so the differentiation must also involve the genetic mechanism. Various aspects of this must be "closed down" either by some form of inhibition or by actual irreversible loss of the genetic unit in question. This closing down cannot be of the nature of a random mutation; it is causally determined in the process of development. The sequence of cause and effect is unknown, but speculation would follow the lines adopted by Pollock (1953) in his interesting discussion of the way enzymes may be developed in the process of biochemical ontogeny. An enzyme is built when a substrate for it appears: a gene will be inhibited, destroyed, or lost when its final product ceases to be of functional significance. To convert that teleological statement into mechanism is a task for the future. At the very least it seems to demand that there is a "feed-back" of information from the cytoplasm to every functionally active component of the genetic mechanism. Most cytologists nowadays would probably be willing to allow this.

There may therefore be some justification for going beyond random somatic mutation to account for the high intensity of carcinogenic action of certain chemical agents.

[Parts III and IV, with a list of references, will appear in our next issue.]

The Casualties Union has published a booklet describing its history and work. In 1942 Mr. E. C. CLAXTON, then commandant of the Surrey County Civil Defence Rescue School at Leatherhead, founded the Casualties Union to provide skilled "casualties" for use in Civil Defence training schemes. So that they could play their part with realism these "casualties" were given a medical briefing and a theatrical make-up. The scheme proved so successful that by 1944 the School was turned over wholly to training members of the Allied Armies. When in 1945 Civil Defence was stood down the Casualties Union decided to continue its work, and still provides skilled "casualties" for use in rescue training of all types, first-aid lectures, and rescue competitions. The Union, with a membership of about 1,500, is run on voluntary subscription, and has extended overseas. Inquiries about the Union will be welcomed at its headquarters at 316, Vauxhall Bridge Road, London, S.W.1.

CLINICAL AND SOCIAL PROBLEMS OF PEPTIC ULCER*

BY

F. AVERY JONES, M.D., F.R.C.P.

Physician, Central Middlesex Hospital

Diagnosis

Establishment of the diagnosis of peptic ulceration can be difficult. The clinical picture may be atypical and there are fallacies about the various investigations.

Clinical Picture

Typically there is epigastric pain associated with food, eased by alkalis and coming on in attacks, but there are many variations. The pain may occur high up in the chest over the sternum, or lower down around the umbilicus or even in the iliac fossae. Sometimes the pain is predominantly in the loin under the costal margin, spreading into the back, simulating a renal pain, especially on the right side. It may be felt only in the back and thought to be muscular in origin—"dyspeptic backache." Apart from the position being unusual, the pain may range from a minimal discomfort to one of considerable severity. It is not uncommon for ulcer pain to come on unrelated to meals, particularly towards the end of the day; relief with alkalis, although the rule, may be lost, particularly with chronic perforation of the ulcer from the stomach or duodenum into the surrounding viscera. Sometimes no pain at all is felt and the ulcer reveals itself by bleeding or perforating. Heartburn, anorexia, periodic nausea, bouts of vomiting, waterbrash, all without pain, may be the only symptoms.

These unusual clinical pictures cause serious difficulties, particularly with patients in whom the radiologist has difficulty in demonstrating an ulcer. This occurs especially in ulcers in the roof of the pyloric antrum and with post-bulbar duodenal ulcer; in such cases a series of negative reports may be recorded before the presence of the ulcer is finally proved, perhaps by clinical complications, gastroscopy, or laparotomy. These patients tend to be diagnosed as having an abdominal neurosis, chronic pancreatitis, or lumbago. They may well develop a secondary neurosis from the uncertainty of their lives and from the failure of their doctors to establish a physical diagnosis. In practice these patients have a consistent story, clear-cut and unembellished by the flights of fancy so common with the true neurotic. The ulcer subject may have pain "like knives sticking in me," which is true, but he will not say he is being "burned alive with wind."

Why do some patients have atypical symptoms? The ulcer with a thick slough may itself be insensitive to pain while pylorospasm is producing oesophageal reflux and heartburn. Enterospasm may occur and the patient may complain of flatulence, trying to bring up wind unsuccessfully, as it may be locked in the splenic flexure of the colon. The ulcer may penetrate surrounding structures, giving rise to parietal pain in the back. A stomal ulcer after partial gastrectomy may become adherent to the diaphragm and chest wall, causing severe

*The second of two Lumleian Lectures delivered to the Royal College of Physicians of London on April 10 and 12, 1956. The first lecture was printed in last week's issue (p. 719).

intractable pain which is possibly diagnosed as intercostal neuritis. Similar pain may be felt in the back, with posterior perforation, and may be diagnosed as rheumatism. Even without parietal extension, pain reference may be bizarre. As the foregut is embryonically a midline organ, the pain reference may be to either side, and left-sided pain may be felt with a duodenal ulcer even when a gastric lesion has been fully excluded. Individuals vary greatly in their threshold to pain—some are very insensitive to parietal pain, others extremely sensitive—and this can be measured with an algometer (Keele, 1954). Lack of pain from viscera may correlate with pain insensitivity as measured in this way, but this is inconsistent and more work is needed on this point.

With any recurrent pain from below the nipples to the iliac crest, in the loin or in the back, one cannot exclude an ulcer because the pain is unrelated to meals or unaffected by alkalis or vomiting, and further investigation is needed. Physical examination, too, may be misleading. Usually there is epigastric tenderness, but this can be entirely absent in the presence of an active ulcer. Further investigation may involve examination of stools for occult blood, barium meal, gastroscopy, and gastric secretory tests.

Investigations

Barium-meal Studies.—With present-day radiology there are still practical difficulties in the demonstration of peptic ulcer, and there is need for the clinician to be more aware of the practical problems of radiology of the alimentary tract. Too often still the radiological report is regarded as final proof. The interpretation of various shadows, deformities, or lack of deformities, must be interpreted in relation to the clinical picture. Some radiologists readily interpret minor mucosal irregularities in terms of peptic ulcer, and others are not so misled. The interests of the patient are best served by maintaining a personal contact between radiologist and clinician who jointly discuss the films.

Considering the physical limitations of the method of investigation with its reliance on shadows and outlines, results are surprisingly accurate in expert hands. Nevertheless, both false-positive and false-negative reports can be made, but these diminish in direct proportion to the contact between clinician and radiologist, and their mutual experience of gastroscopy.

Gastroscopy.—With first-class radiological assistance, the scope for gastroscopy is limited, but it is of help in those cases where there is a discrepancy between the clinical and the radiological picture. Occasionally a chronic gastric ulcer missed by the radiologist may be discovered, and this occurs particularly with ulcers well away from the lesser curve or in the antrum. Sometimes rugal folds may simulate a gastric ulcer on x-ray examination, and the diagnosis can be disproved by gastroscopy. The diagnosis of a gastric diverticulum may be firmly established by direct inspection. The finding of gross mammillation and rugosity of the mucosa may lead to further radiography of the duodenal bulb for duodenal ulceration, or pH studies. Gastroscopy is especially useful in assisting in the diagnosis of bizarre x-ray pictures, when the question of malignancy arises. With present-day technique and adequate premedication, the procedure is extraordinarily well tolerated, and the risk of oesophageal trauma or other hazards is very small. The examination may be done under general anaesthesia if the patient is especially sensitive. Gastroscopy also has a place in defining the cause of bleeding after haematemesis and melaena, particularly in demonstrating acute gastric ulcers which heal quickly.

Gastric Secretory Tests.—Normally gastric secretory tests play a very limited part in the diagnosis of peptic ulcer. Their contribution has been very much overrated in the past, as their fallacies have not been sufficiently appreciated.

As commonly done by the nursing staff, fractional test meals are an almost worthless investigation and do not justify the discomfort to the patient or the time spent by the laboratory staff. If any value is to be given to a report it is essential to know where the tube was in the stomach. In at least one in five tests the tube will curl up in the fundus, where the level of acidity is often substantially lower than in the body of the stomach. This fallacy can be avoided by using a radio-opaque tube and screening the patient at onset to make certain the end of the tube is to the left of the spine and not coiled in the stomach. No test has yet been devised which conclusively separates duodenal ulcer patients from those without ulcers, but duodenal ulcer tends to be associated with hypersecretion, and its demonstration may contribute to the diagnosis in some cases. Alternatively, the finding of achlorhydria would be against the diagnosis. The stimulus of food may be better than histamine. Watkinson and James (1951) found that, by taking the pH of gastric juice aspirated at hourly intervals over the 24 hours, they could demonstrate the presence of acid often for hours in "achlorhydric" patients with gastric ulcer; during this time patients were eating their usual diet.

Stool Examination for Occult Blood.—Examination of the stools for occult blood provides the clinician with an important screening test in the investigation of dyspepsia, a positive reaction needing further investigation and a negative test being reviewed in the light of the patient's history. It is important to realize that negative tests may occur sometimes in the presence of active peptic ulcers. The Gregersen slide technique with benzidine is a simple and reliable test, and, provided the patient is not eating liver or dishes containing animal blood, no dietary restriction is needed.

Special Diagnostic Problems

There are certain recurring problems in diagnosis, and these particularly concern post-bulbar duodenal ulcer, giant gastric or duodenal ulcers, and the distinction between simple and malignant gastric ulcers.

Post-bulbar Duodenal Ulcer

These cases tend to be especially difficult to diagnose, as the duodenal bulb may fill well and distract attention from an ulcer crater which is difficult to see without careful study. Even at laparotomy the ulcer may be missed unless the duodenum is opened. Certain clinical features are to be noted. Pain tends to be in the back, occurs particularly towards the end of the day and at night, and is difficult to relieve. Bleeding is quite common, and episodes of intermittent obstruction with sudden pain and vomiting may occur.

A man aged 52 gave a three-year history of intermittent retrosternal pain going through to the back "like knives." It would occur at any time of the day and night, but particularly at night, sometimes awaking him. He would often vomit, but without relief. The pain would be severe for 20-30 minutes and then ease spontaneously. Alkalis gave little relief, but "liver salts" seemed to help. Two previous x-ray examinations had been reported as normal and a diagnosis of pancreatitis was suspected. Stools were negative for occult blood. When x-rayed again at Central Middlesex Hospital no ulcer was found: the duodenal cap was large and filled well. The examination was repeated and the diagnosis of post-bulbar ulcer was clearly established and confirmed at operation.

A man aged 38 had had a melaena four years previously and later developed severe attacks of vomiting and back pain which lasted several days, recurring six to seven times a year, with complete freedom between them. He had three negative x-ray examinations at different hospitals and was diagnosed as neurotic on two occasions, and as having intestinal obstruction on the third occasion. An emergency laparotomy was performed, but nothing abnormal was found. When he attended Central Middlesex Hospital, a barium-meal examination showed a duodenal ulcer in the second part of the duodenum, so he was admitted for partial gastrectomy. At operation no ulcer was apparent from the external appearances, but a crater was felt in the second part of the duodenum on the posterior wall.

The experience of this group of cases emphasizes the need to look for a post-bulbar duodenal ulcer when there are recurrent persistent symptoms of upper abdominal or back pain, and to be cautious in accepting a negative x-ray report.

Giant Gastric and Duodenal Ulcers

Large simple gastric and duodenal ulcers are not rare; with large gastric ulcers having a diameter of more than 3 cm. radiologically, the probability is much in favour of a simple rather than a malignant lesion. In the admirable series recorded by Jennings and Richardson (1954) only 1 out of 17 proved to be neoplastic. The clinical picture with large ulcers is invariably atypical, and the patient may be thought to have carcinoma of the stomach or of the pancreas. There may be a considerable degree of cachexia, and a depressive state may add to the difficulties of diagnosis. Atypical pain may lead to an initial diagnosis of renal colic, fibrositis, or angina until it is realized that the alimentary tract may be at fault and a barium-meal examination is arranged. A large gastric ulcer with a short history may heal completely and a medical trial is worth while, but the prognosis is poor if there are other associated illnesses.

Large duodenal ulcers also cause diagnostic difficulties, as the size of the ulcer may superficially simulate a normal duodenal cap until close study demonstrates the loss of mucosal pattern and its consistency of size and shape in different films. Oedema around such large duodenal ulcers may cause distortion of the antrum and lead to an initial diagnosis of carcinoma of the stomach.

Distinction Between Simple and Malignant Ulcers

A vital problem in the management of gastric ulcer is the distinction between simple and malignant ulcers. It has been stated frequently, particularly in the United States, that 10% of gastric ulcers are malignant and therefore all must be treated surgically. This bald statement of incidence is probably correct, but makes no allowance for the full use of radiology and gastroscopy in arriving at a diagnosis of a simple or a malignant ulcer. The gastric ulcer which projects clearly from the lesser curve, between the angulus and the cardia, is virtually never malignant. A follow-up study (Avery Jones, 1955a) showed that the chance of missing a malignant ulcer was under 1%.

A small point, but one of considerable interest, is the infrequency of aortic calcification in carcinoma of the stomach as compared with simple gastric ulcer. This was first reported by Elkeles (1949) and confirmed by our observations, although with lesser differences between the two conditions. It is not yet clear whether calcification is less common with carcinoma of the stomach or more common with gastric ulcer.

The distinction between simple and malignant ulcer at laparotomy can be difficult, and errors both ways are not uncommon. It would seem that x-ray films and gastroscopy are much more accurate aids to a correct diagnosis in the early case than inspection and palpation at laparotomy. The mistaking of malignant ulcers for simple ones at the time of acute perforation is referred to below. A wrong diagnosis of malignant ulcer may be made at laparotomy in the presence of a large simple ulcer associated with much inflammatory reaction and lymphatic glandular enlargement. A number of such cases have been seen where the surgeon was so confident of the diagnosis that no biopsy was taken, yet the follow-up has established the diagnosis of a simple ulcer.

There has been much controversy in the past about the risk of malignant degeneration of simple gastric ulcers. The experience at Central Middlesex Hospital would suggest that secondary malignant degeneration is extremely rare in a simple ulcer. With malignant ulcers the lesion has usually been malignant from the onset, but has undergone secondary peptic digestion. Alternatively, a carcinoma may have arisen independently, but adjacent to a simple ulcer. There

is evidence that patients who have had undoubted simple gastric ulcers are, in fact, more liable to develop gastric cancer subsequently.

Treatment

Does dietetic treatment influence the natural history of gastric and duodenal ulcer? The evidence is regrettably slender that real benefit is derived from the traditional dietary regime, and overtreatment can undoubtedly be positively harmful. There is, fortunately, a strong natural tendency to recovery, for which the patient tends to give the credit to his treatment. Martin and Lewis (1949) reviewed a series of 365 patients with gastric or duodenal ulcers 10 years after in-patient treatment and concluded: "It is undeniable that medical treatment relieves the discomfort of most relapses; but from our present evidence we cannot believe that it is any protection against further trouble if this is destined by the ulcer. . . . Those cases which were active persevered with their regimen and also suffered complications, while those who were inactive abandoned treatment and had no trouble." Rae and Allison (1953) reached a similar conclusion from a follow-up group of 63 men with proved peptic ulcer, kept on a careful dietetic regime for 12 months and then reviewed after five years.

Doll, Friedlander, and Pygott (1956) compared an almost normal (fried-free) diet with the standard ulcer regime in patients followed up for a year. In their series there were 64 in-patients with gastric ulcers, 80 out-patients with gastric ulcers, and 50 out-patients with duodenal ulcers. The out-patients were either advised to continue for a year on the standard ulcer diet with which they had previously been treated or were advised to revert to a wholly normal diet. At the end of the year the proportion who had remained free from pain and in whom the ulcer was radiologically healed was practically the same in both groups.

Do other measures besides ordinary dietetic care facilitate the healing of ulcers? In studying the effect of alkalis and milk drip, careful measurements concerning the rate of healing of gastric ulcer have been made with the addition of alkalis to a milk drip in sufficient quantity for the acidity of the gastric contents to be kept above pH 4 throughout the 24 hours. This trial (Doll, Price, Pygott, and Sanderson, 1955) demonstrated, however, that the milk drip produced a greater gain in weight—7 lb. (3.2 kg.) compared with 3 lb. 8 oz. (1.6 kg.)—and the impression was obtained that pain was relieved more rapidly with milk drip than without it, and that therefore it is a useful adjunct to the standard treatment in patients whose pain persists after rest in bed. Similar in-patient therapeutic trials have been made with phenobarbitone, ascorbic acid, and bed rest (Doll and Pygott, 1952), and with "robaden" and cabbage juice (Doll and Pygott, 1954). Two factors only have so far been demonstrated as having a beneficial influence—admission to hospital, which implies bed rest, and stopping smoking.

Our trials on out-patients with duodenal ulcer have not, unfortunately, produced any conclusive evidence of benefit from this treatment. Friedlander (1954) studied five groups of 25 duodenal ulcer subjects on "ribena" syrup, a control syrup, oral hexamethonium, olive oil, and oral methantheline, and followed them up clinically and radiologically for 15 months. Methantheline may have been of use in some cases in the initial relief of pain, but if there was any such effect it did not persist beyond the first nine months. There was otherwise no difference in the symptoms, rate of healing, or frequency of recurrence between the groups great enough to suggest a beneficial effect from any of the treatments. Even if there is no good statistical evidence for the beneficial effect of diet on the healing of ulcers, it cannot be abandoned in the acute stage when the patient is undoubtedly more comfortable on a light diet. Whether the patient is ambulatory or in bed initially, small two-hourly feeds are undoubtedly better tolerated than ordinary-sized meals, and enable him to become symptom-free more quickly. Very soon a reasonably generous basic diet may be given which

will enable the patient to maintain or gain weight. Patients who put on weight usually do well. If a milk drip has been started, it may be continued with the diet for a time in order to increase the calorie intake.

Bed rest is a most valuable measure. It probably means that the position of a gastric ulcer is altered in relation to the gastric juice and perhaps the jet of fluid from the pylorus may no longer impinge on a duodenal ulcer. It must be admitted in individual cases that it may be better for the patient to carry on at work rather than impose the added financial hardship of loss of work. Simple measures should be tried at first, designed to reduce fatigue, to increase regularity of meals, and to reduce or, preferably, stop smoking. If there is troublesome pain, bed rest is, however, necessary.

The next essential is to tackle the anxiety factor, which may seriously aggravate the disease process and retard healing. It is important to establish a good rapport with the patient, and this requires time, privacy, and patience, and on the whole is more easily achieved with a patient having bed rest. Once the patient feels he has a sympathetic independent person who is anxious to help in the capacity of a friend and not as a judge, he may be prepared to unburden the difficulties which too often have caused pent-up emotional stress because there has been no one in whom he could confide. The relief of such emotional tension is in itself of great therapeutic value; so often the patient has got his difficulties out of perspective and they have become much more important than they really are. This is where the independent observer can give valuable help. This approach is equally important with any other chronic illness, such as pulmonary tuberculosis and skin disease.

If there is pain, alkalis should be prescribed between each feed, using first an insoluble alkali, but if this is insufficient a mixture containing sodium bicarbonate may be used temporarily. There is no need to continue frequent alkalis after the symptoms have subsided, and the dose should then be reduced and finally stopped. Initial sedation is often very helpful.

During the past few years there has been a great spate of anticholinergic drugs. Belladonna has had a time-honoured role, and these new preparations have sought to emulate its action but with fewer undesirable side-effects. In general, the therapeutic contribution of these new drugs has not been impressive.

Over-treatment

Can over-treatment of peptic ulcer be harmful? Clinical practice provides many examples of the undesirable effect of overdosage of dietary regimes. A proportion of patients are obsessional in their strict adherence to a medical regime, and three examples are given.

A medical student with a duodenal ulcer was being treated on a very elaborate regime. The failure of the nursing staff to adhere completely to the instructions induced a state of nervous apprehension and annoyance, and his pain persisted. When transferred to another ward the elaborate regime was stopped and he quickly became free from pain.

A hospital doctor with a duodenal ulcer had his meal-times spoilt because his diet was not contrived as perfectly as he would have wished. His symptoms ceased when his diet was stopped and he joined his colleagues in eating the ordinary hospital food.

An out-patient came to the hospital asking for a partial gastrectomy. Inquiry revealed that he had not, in fact, had any pain for five years, but he was now engaged and wished to take his girl friend to a restaurant and have ordinary meals.

It is perhaps the same obsessional nature, coupled with too blind a faith in advisers, which leads to the more serious complications of alkalosis or the milk-alkali syndrome. The risk of excess of soluble alkalis, particularly in the presence of vomiting from pyloric stenosis, is very well known. It is, however, less well recognized that excess of calcium from taking too much milk and alkali over long periods can cause a calcinosis and with it an impairment of renal function (Burnett *et al.*, 1949).

Milk-alkali Syndrome

The first manifestation of the syndrome is usually general malaise with weakness and lethargy. Mental disturbance such as impairment of memory and confusion are common, and psychosis and coma have been reported. All cases so far reported have followed prolonged medical treatment for presumed or proved peptic ulcers, and a not uncommon presentation is that of nausea and vomiting occurring in the absence of pyloric obstruction. Polyuria may be a feature, and generalized severe pruritus has been a major complaint in many cases. An antipathy to milk may develop. Hypercalcaemia is consistently found, usually but not always with an alkalosis, but Burnett *et al.* pointed out that hypophosphataemia is noticeably absent and increased urinary excretion of calcium does not occur. The serum alkaline phosphatase is normal, but a raised blood urea and albuminuria are always present. Metastatic calcification may occur and nephrocalcinosis and nephrolithiasis are common findings. In advanced cases with irreversible renal damage death may occur from uraemia.

It would appear that the syndrome is precipitated by the absorption of base from the ingested milk and alkalis in excess of renal excretion with accumulation of calcium and possible magnesium in the body. Whether this can occur in the presence of previously normal renal function is still undecided. Wilkinson and Jordan (1934) suggested that antecedent renal damage is present in most cases, but Kirsner and Palmer (1942) disagree. It is known that a metabolic alkalosis can lead to renal damage, but not all the reported cases have shown an alkalosis when examined. Hypercalcaemia itself may lead to impairment of renal function, but it is a feature of the 30 cases so far reported that at no stage has an excessive renal excretion of calcium been noted. The importance of the condition lies in the fact that it is iatrogenic and reversible, the latter feature being unfortunately all too rare in chronic renal disease. A reappraisal of patients with peptic ulceration and so-called "chronic nephritis" may perhaps reveal more cases of the milk-alkali syndrome.

Surgical Treatment

Surgical treatment of uncomplicated peptic ulcer will not be discussed in detail. In approximately half the patients with gastric ulcer and a third with duodenal ulcer persistence of symptoms and failure of the ulcer to heal earn the patient surgical treatment. The results, although generally good, do not allow complaisance and must encourage all further medical avenues of research. There is no reason for believing that a simple medical treatment will not one day be found.

Complications

Pyloric Stenosis

Pyloric stenosis is an inaccurate terminology, as so often the obstruction is in the duodenum. Some degree of narrowing is a common occurrence from healing of juxta-pyloric and duodenal ulcers. The presence of narrowing is not necessarily reflected by clinical symptoms of obstruction or radiological evidence of delayed emptying. There can be appreciable narrowing of the pylorus demonstrated at operation in patients in whom no clinical or radiological evidence of retention has been noted. The anatomical lesion may be fully compensated by muscular hypertrophy of the stomach. The development of clinical symptoms of pyloric obstruction is often due to an exacerbation of the ulcer with increased narrowing from oedema and spasm in the presence of an already narrowed lumen.

Failure of this compensation, either from chronic narrowing or from acute or chronic obstruction, leads to evidence of gastric stasis from gastric aspiration or by delayed emptying of the stomach. An evening aspiration of more than 300 ml. or an early morning volume of over 100 ml. suggests obstruction, and so does barium in the stomach six hours after a barium meal. It is necessary to distinguish between gastric stasis and pyloric obstruction.

Gastric stasis may occur apart from pyloric obstruction and be due to hypotonia from potassium depletion, or it may occur in association with migraine. The unexpected finding of a large slow-emptying stomach may sometimes be explained by an attack of migraine coinciding with the barium meal examination.

Pyloric obstruction is most commonly due to peptic ulceration or neoplasm, but acute small marginal erosions may be sufficient to cause distressing symptoms with pain and vomiting (Kinsella, 1951). Other causes include achalasia of the pylorus, hypertrophic pyloric stenosis in adults, a congenital duodenal diaphragm, a polyp of the stomach intermittently prolapsing through the pylorus, a cholecystoduodeno-colic ligament obstructing the first part of the duodenum, the delayed effect of corrosive poisoning, or ferrous sulphate poisoning, which has also caused pyloric stenosis in children.

Pyloric obstruction can be produced by adhesions to an inflamed gall-bladder, without duodenal ulceration being present. Although the symptomatology of pyloric stenosis is usually typical, the presenting clinical picture is sometimes unusual. A number of cases have been sent to hospital as haemorrhages because of the dirty vomitus. Diarrhoea is an occasional initial symptom with pyloric obstruction.

The important recent progress in the management of pyloric stenosis is related to a better understanding of the disturbances in electrolytes. It is well known that in pyloric stenosis there is a deficiency of serum chloride ions with an excess of bicarbonate. In the past this has been attributed to loss of hydrochloric acid by vomiting or gastric aspiration, and the dangers of alkali therapy have been stressed. More recently attention has been focused on potassium depletion as a cause of alkalaemia.

Black and Jepson (1954) have shown by retrospective balance studies that there may be a deficiency of up to 800 mEq of potassium in patients with pyloric stenosis. How this arises is not entirely clear. Some potassium is lost in the gastric juice, but the concentration is much lower than that of sodium and chloride, and vomiting by itself would hardly account for such severe potassium depletion. Deficient dietary intake and renal inability to conserve potassium under the metabolic conditions obtaining in pyloric stenosis are presumably additional important factors.

When potassium is lost from the cells it is replaced by sodium and hydrogen ion, giving an intracellular acidosis. If there is an adequate supply of sodium this process can be continued until one-fifth of the intracellular potassium has been lost without serious disturbance of function. This fraction has been called the muscle labile potassium. In potassium depletion the kidneys excrete a more acid urine than seems appropriate to the serum electrolyte levels, so that in pyloric stenosis with alkalaemia a "paradoxically" acid urine may be found. The paradox is explained by the intracellular acidosis, and overall there may be a greater deficiency of basic rather than acidic ions.

The response of patients with pyloric stenosis and alkalaemia to intravenous sodium therapy is explained in part by the ability of sodium to replace potassium in the cells. The potassium becomes available to the kidneys for excretion as alkali and the alkalaemia is decreased. In the untreated case there is rarely an excess of sodium available to replace the muscle labile potassium. In this way potassium deficiency can impair the renal ability to excrete alkali without gross depletion of the body reserves. Severe potassium depletion of the muscles can occur following prolonged sodium therapy.

Sodium deficiency may be gross in pyloric stenosis; in one of the cases reported by Black and Jepson it amounted to 1,600 mEq. Serum levels and clinical dehydration are probably reliable guides to saline therapy. Potassium depletion is more difficult to assess, and normal serum levels are the rule in the untreated case. It is probably safe to assume there is potassium deficiency whenever there is a raised serum bicarbonate level. In mild cases potassium

by mouth will usually correct the electrolyte deficiency. In more severe cases intravenous normal saline should be given with potassium as soon as it is clear that there is adequate renal function.

Acute Perforated Peptic Ulcer

The mortality from this complication has fallen very considerably since before the second world war. The changing mortality is seen in Table VI. With the introduc-

TABLE VI.—Acute Perforated Peptic Ulcer, 1939-55

Years of Admission	Operated		Not Operated		Total	
	No.	Deaths	No.	Deaths	No.	Deaths
1938-40	106	29 (27.4%)	1	1	107	30 (28.0%)
1941-3	115	20 (17.4%)	8	7	123	27 (22.0%)
1944-6	135	12 (8.9%)	16	16	151	28 (18.5%)
1947-9	168	4 (2.4%)	14	12	182	16 (8.8%)
1950-2	218	9 (4.1%)	12	10	230	19 (8.3%)
1953-5	168	13 (7.7%)	15	13	183	26 (14.2%)
	910	87	66	59	976	146

tion of antibiotics and relaxant anaesthesia the mortality in operative cases fell to 4% in 1952, but this level has not been maintained since and there is still a toll of delayed deaths in the third or later weeks from haemorrhage or sepsis. Forty per cent. of deaths occurred in patients not operated upon. A third of these patients were, in fact, not diagnosed in life, the figures being:

Undiagnosed in life	..	..	24
Too ill for operation	..	..	36
Refused operation	..	..	1
Elective conservative treatment	..	..	5

Those undiagnosed in life presented a variety of clinical pictures—heart failure from cor pulmonale; pneumonia with pleuritic pain; unusual tachycardia after admission for severe haemorrhage. In none had there been any real clinical evidence of an acute perforation such as a sudden episode of pain or collapse, but there was usually a degree of toxæmia out of proportion to the presumptive diagnosis. The therapeutic dividends in this group are small, but it is important to remember this possibility when dealing with a patient whose degree of toxæmia is out of proportion with the presumed illness. No rigidity or tenderness may be present, and an x-ray examination is essential to establish the diagnosis.

Those too ill for operation are patients with peripheral circulatory failure who fail to respond to resuscitation. These are mainly patients with long-delayed admission to hospital. Early diagnosis is unfortunately sometimes prevented by the amazing fortitude of patients.

Operation has been the treatment of choice and medical management used only for patients whose perforations had obviously sealed off or whose general condition for some other reason precluded operation. Following an earlier analysis (Avery Jones and Doll, 1953) emergency partial gastrectomy has been performed particularly when there has been a history of ulcer symptoms for more than two years, and especially for perforated gastric ulcers, as this analysis had revealed that 10% of the assumed simple gastric ulcers at laparotomy were in fact neoplastic. The results since 1949 are shown in Table VII.

TABLE VII

	No.	Deaths	Mortality
Suture	365	18	4.9%
Emergency partial gastrectomy	87	4	4.6%

Hermion Taylor and Warren (1956) have made the practical observation that perforated acute ulcers—that is, those without a history of previous pain—may be treated safely without operation, and report on 47 patients who have recovered without complications. They confirm the value of emergency partial gastrectomy for perforated chronic ulcers.

Haematemesis and Melaena

In my Goulstonian Lectures (Avery Jones, 1947) a survey of 649 admissions for haematemesis and/or melaena was made, and this series has now grown to 2,011 (Table VIII). The frequency of acute ulcers causing haematemesis reported previously has been further confirmed. Of 559

patients in the acute-lesion group—that is, those with negative x-ray films—305 have been gastroscopied and 111 acute gastric ulcers demonstrated. In addition some further acute ulcers were discovered at necropsy or from the presence of minimal radiological evidence without previous dyspepsia.

Within this acute lesion group there are other causes of bleeding, such as acute gastritis, drug reactions, and traumatic ulceration from vomiting. Traumatic tearing of the oesophago-cardia junction, the Mallory-Weiss syndrome, is an important recent advance in our knowledge of the cause of haematemesis. It is well known that violent vomiting can cause a rupture of the lower oesophagus, but it is less widely known that the same trauma may cause lesser degrees of longitudinal laceration causing haematemesis (Decker, Zamcheck, and Mallory, 1953).

In the earlier series the patients were mainly treated medically to evaluate the mortality with the help of the then recently introduced drip blood transfusions and the more liberal feeding regime introduced by Meulengracht and developed in this country by Witts. It was, however, clear from the experience with these earlier series that a proportion of patients died whom surgical intervention might have been expected to help. A change in policy was considered necessary and from 1946 operation has been performed, especially on patients with known chronic ulcer whose age was over 40 and who had brisk recurrent bleeding after admission. In addition, patients with a proved or presumed acute ulcer have been operated on if there has been recurrent bleeding on two or three occasions, particularly if there was shock. There was a bias towards operation for cases with persistent pain after admission and for those whose bleeding was obviously rapid and causing marked circulatory collapse. Other factors, such as a shortage of blood of a particular group, might also have favoured surgical treatment.

In considering the problem of surgery for haematemesis and melaena, one is not concerned with the mortality of surgical intervention, for figures for surgical mortality can be very misleading. Some of the patients operated on were obviously appalling risks whose only chance of survival might have come from surgical arrest of bleeding. The proper criterion for success or failure of a surgical policy is whether the overall mortality of all admissions is influenced and also how the patients fare subsequently.

Table IX shows that changing from a medical to a surgical policy has not been accompanied by a decrease in mortality

—if anything, the overall mortality has increased. The extent of emergency surgical intervention is shown in Table X.

The series is not a homogeneous one. The scales have been weighed against the later years as the proportion of patients over 60 has increased (Table XI). There has not, however, been any significant change in the proportion of chronic ulcers. Table IX does not allow for differences in age distribution, but when this is calculated there is still clearly very little change in mortality (Table XII). The differences are not significant, but the mortality has in fact decreased in the last period.

In Tables XIII and XIV the admissions during 1941-6 have been compared with those during 1951-4. In the former period extremely few were operated on; in the later period there was a firm surgical policy towards those with recurrent bleeding after admission, particularly those over 40 years and with probable chronic ulcers. Allowing for the effect of age, it will be seen that there is a definite, although numerically small, reduction in the mortality under

TABLE IX.—Cases Admitted for Bleeding, 1941-54; Proved or Probable Cases of Peptic Ulcer

60, but over 60 the mortality was correspondingly increased. These results may be interpreted in two ways. It may be said that since the introduction of surgery in a proportion of the more severe cases with continued or recurrent bleeding the overall mortality has not changed significantly, and the same proportion of patients leave hospital as when a policy of energetic transfusion and other medical measures only were used. On the other hand, it may be said that certain groups have significantly benefited from a surgical policy, especially patients under 60 with recurrent bleeding and those patients with a chronic gastric ulcer. It may also be argued that there has, in fact, been some benefit to the group as a whole, as the later years have a higher age distribution and therefore should carry a higher mortality; and, again, the mortality from partial gastrectomy is already included in the overall figure. It must also be remembered that this analysis has covered only proved or probable cases of peptic ulcer and there are other possible causes, although rare ones, for severe gastro-intestinal haemorrhage which may require surgical intervention, as, for example, simple tumours of the stomach or intestine, diverticulitis, vascular lesions, etc.

The unchanged mortality cannot be accepted at once as proving that the surgical policy should be reversed and that one should return to general medical measures in nearly every case. Certain sub-groups of patients have a better prognosis with surgical rather than medical care. The situation has also to be reviewed with reference to the follow-up. There is a responsibility not only for ensuring that the maximum number of patients leave hospital alive, but also that the maximum possible number remain alive and well after a period of years. A follow-up analysis has demonstrated very poor late results in those treated medically as compared with those who had had emergency partial gastrectomy (Avery Jones, 1956). The situation has also to be assessed in relation to the state of the blood bank. During the second world war there were ample supplies of blood available in civilian hospitals, held in reserve against air-raid casualties, but to-day pressure is constantly brought to bear by the pathologists to reduce demands on blood. This naturally encourages a bias towards surgery. There are still some physicians who prefer not to seek surgical assistance, but the balance of evidence is in favour of selective emergency surgery.

Our present policy is to continue a surgical bias knowing that the arrest of bleeding by partial gastrectomy in those patients with severe continued or recurrent bleeding can be undertaken without causing an increase in the overall mortality and that it offers a better outlook for the patient in the future. Our practice is as follows.

In patients with a known history of chronic gastric ulcer there is a strong bias towards a partial gastrectomy at some stage during the admission. In a few patients it may be decided to operate within the first twelve hours even if there is no further bleeding, and this applies particularly to poor-risk patients who might have difficulty in withstanding the strain of a further sharp bleed. If brisk bleeding occurs, or if there is obvious continued bleeding after admission,

then an emergency partial gastrectomy is performed within a few hours and after further blood transfusions have been given. In the remaining cases, careful consideration will be given to the need for an elective operation before leaving the hospital. The general inclination is towards more surgery in this group and at any early phase of admission.

With a known history of duodenal ulcer, the tendency is towards less emergency surgery and more elective operations, but operating immediately if there is severe continued bleeding or severe recurrent bleeding with shock. The same policy holds for those who have had previous operations for duodenal ulcer.

Patients with a history suggestive of chronic peptic ulcer but in whom the site of the crater is uncertain are gastroscopied the same evening or the following morning. Aspirations of gastric juice may be made for pH estimations.

Patients with a short history only—less than two weeks' discomfort—or in whom there has been no previous dyspepsia, are gastroscopied, usually on the next regular gastroscopy session or after a recurrent haemorrhage. If there is bleeding and if shock recurs twice in patients thought to have an acute lesion, the stomach is opened and an attempt made to determine the bleeding-point by digital palpation. The usual procedure then is a partial gastrectomy in men and possibly a submucosal resection of the ulcer in women. If no cause for the bleeding is found, a partial gastrectomy is performed and a further search made of the fundus before the final anastomosis is made.

In patients with evidence of pyloric stenosis an elective operation is planned, if possible after one to two weeks, when the electrolytic balance has been restored.

Patients who have an acute perforation after admission for haemorrhage, or those with simultaneous bleeding and perforation, have an immediate laparotomy, when, if possible, a partial gastrectomy is performed.

Patients admitted with an acute perforated ulcer treated by simple suture who then bleed again after admission have a laparotomy with a view to an emergency partial gastrectomy.

Conclusions

The increase in duodenal ulcer noted previously has continued, although the incidence of gastric ulcer seems to be stationary. Gastric and duodenal ulcers behave differently when analysed statistically in relation to many factors such as blood groups, age, incidence, social class, occupation, and heredity, and it seems probable that they represent independent disease processes.

The cause of gastric and duodenal ulcer remains unknown. Acute erosions and ulcers are common occurrences, and it seems likely that anti-healing factors exist which promote chronicity.

The diagnosis of peptic ulcer, although often simple, may at times prove difficult, and there are important fallacies in relation to radiological and other methods of diagnosis.

The evidence that dietetic treatment influences the healing of gastric and duodenal ulcer is unconvincing. Bed rest and cessation of smoking seem to be beneficial. There are dangers inherent in overtreatment, medical and dietetic.

Better appreciation of the role of potassium depletion has greatly improved the management of pyloric stenosis.

There is still scope for reducing the mortality from acute perforation. A proportion of cases have atypical clinical pictures and may escape detection. There is a role for immediate partial gastrectomy in patients with chronic ulceration, causing perforation.

The introduction of emergency partial gastrectomy for bleeding ulcer has not lowered the overall mortality, but nevertheless there are good reasons for undertaking it in selected cases.

I thank Dr. D. Teare for his necropsy observations, and my colleagues, Dr. R. Doll, Dr. F. Pygott, Dr. T. D. Kellock, Dr. M. P. Spence, and Dr. J. Balint, for their assistance in the preparation of these lectures. I am especially indebted to Miss B. White, who has undertaken the statistical analysis of my material, and to Miss Downie and Mrs. Smith for their secretarial assistance.

Three leprosy clinics have been opened in Sokoto Province, Northern Nigeria, by Dr. C. M. Ross, Senior Specialist in Leprosy for the Northern Region. Discharge certificates were recently presented to 23 people in the province who had been examined and found free from leprosy. These are the first discharges in the province, and are an indication of the amount of control which is now being gained over the disease. The Minister of Health for the region has recently announced plans for the building of a leprosy training school at Kaduna to continue the fight against the disease.

RESULTS OF SURGERY IN TREATMENT OF CANCER OF THE LARGE INTESTINE

BY

F. G. SMIDDY, F.R.C.S.

Surgical Tutor, Leeds General Infirmary

AND

J. C. GOLIGHER, Ch.M., F.R.C.S.

Professor of Surgery, University of Leeds; Surgeon, Leeds General Infirmary

In recent years the attitude of surgeons towards cancer of the large bowel has become increasingly more aggressive. Formerly a large proportion of the patients suffering from this disease were regarded as inoperable, and if, as was often the case, the growth lay in the rectum or distal colon they were treated by colostomy alone. Experience has shown, however, that a simple colostomy of this kind seldom afforded any real palliation, and all too often its only effect was to add the inconveniences of an artificial anus to the patient's existing discomforts. Though it overcame any obstructive element it did little to allay the other distressing features of an inoperable growth—the incessant spurious diarrhoea with discharge of slime and blood, the occasional profuse and alarming haemorrhages, the severe sacral or sciatic pain, and the development of fistulae into other organs or externally. This is not surprising, for these symptoms all spring directly from the continued presence of the growth in the bowel and can only be obviated by its removal. It is therefore clearly desirable, where possible in treating cancer of the large bowel, to excise the primary growth for palliative purposes alone quite apart from any question of cure.

Fortunately, despite their well-known predilection to become fixed to adjacent organs or to the pelvic or abdominal walls, carcinomata of the rectum or colon can generally be excised by a really determined operation, comprising, if necessary, resection of implicated adjoining viscera or parietes. Pathological examination of the operating specimens thus secured shows that the binding adhesions often contain no actual growth but are purely inflammatory in character, so that the prognosis is frequently much better than was anticipated at the time of operation, and an excision which was undertaken essentially for palliation sometimes turns out to be curative. Even if the growth should eventually reassert itself the patient may often enjoy two or three years of comfortable and useful life before this occurs. There is thus everything to be said for excision if at all possible, and indeed with almost no other form of malignant disease does really extensive surgery pay such handsome dividends as it does with cancer of the large bowel.

In his pursuit of this more ruthless policy the surgeon is, of course, much assisted by the greatly enhanced safety of surgery since the end of the second world war, due to better blood-transfusion facilities, improved anaesthesia, a clearer understanding of the problem of fluid and electrolyte balance, and the advent of antibiotics for systemic and intestinal use. As a consequence there must now be few patients, even amongst the elderly frail individuals who represent such a large proportion of the sufferers from cancer of the large

bowel, who cannot be made justifiable risks for an excision operation. Thus Allen (1950), of Boston, has recorded a resectability rate of 95%, and an immediate operative mortality of only 2.7% in a series of 195 cases of carcinoma of the colon and rectum treated at the Massachusetts General Hospital; and Naunton Morgan (1955) in this country has reported a resectability rate of 94% and an immediate mortality of only 4.3% in a series of 477 cases of rectal cancer treated at St. Mark's, St. Bartholomew's, and other hospitals.

It is to be presumed that similar trends have characterized the care of cancer of the rectum and colon in the hands of the average general surgeon throughout the country, but we have been unable to discover any extensive published data to support this supposition. It seemed to us that it would be interesting to determine whether the management of cancer of the large bowel has undergone any significant improvement during the past 20 years in a large teaching hospital where the patients suffering from this disease are shared among several general surgical "firms." We have recently attempted to secure such information from the Leeds General Infirmary, where this state of affairs has obtained. For this purpose we have analysed and compared, with special reference to the treatment and mortality, the clinical notes of two groups of cases of carcinoma of the rectum and colon. The first group represented all the patients admitted to the Infirmary with these diseases during the years 1938-43 inclusive, and comprised 485 cases; the second one included all the patients similarly admitted during the years 1947-55 inclusive and totalled 1,159 cases. We believe that the survey of these patients is instructive in another way, for the Leeds General Infirmary, unlike some other teaching hospitals, still functions as the main regional hospital of its area. Its clinical material therefore gives a fairly accurate picture of the relative frequency and common modes of appearance of various diseases. For that reason the opportunity has been taken to elicit from this fairly large combined series of 1,644 cases of cancer of the large bowel certain facts regarding the incidence and manner of presentation of this condition.

Site Incidence of Growths in the Large Bowel

The distribution of the carcinomata in the rectum and colon in the two series and collectively is shown in Table I. It will be seen that there is no essential difference in the incidence in the two periods under review. The frequency

TABLE I.—Distribution of Carcinomata in Various Parts of Large Intestine

Site	Percentage of Growths in Each Site		
	1938-43 Series (485 Cases Analysed)	1947-55 Series (1,159 Cases Analysed)	Combined Series (1,644 Cases Analysed)
Rectum ..	61.5	55.7	57.4
Sigmoid colon ..	21	21.4	21.3
Descending ..	2.9	2.7	2.7
Splenic flexure ..	2.7	3.2	3.0
Transverse colon ..	4.6	4.7	4.7
Hepatic flexure ..	1.0	2.1	1.8
Ascending colon ..	1.6	3.5	2.9
Caecum ..	4.7	6.7	6.1

of growths in different parts of the colon is also very similar to that reported by previous writers, such as Fraser (1938) and Judd (1924), but, unlike the cases referred to by them, the present series includes carcinomata of the rectum and thus reveals the site incidence of malignant disease in the entire large intestine. It will be seen that 57.4% of the growths in the combined series of 1,644 cases lay in the

rectum, and that of the 42.6% of growths in the colon proper exactly half occurred in the sigmoid region. This indicates the enormously increased liability to malignant disease in the distal part of the large bowel, and is important from the diagnostic point of view, for it means that 78.7%, or approximately four-fifths, of the sufferers from bowel cancer have their lesions in a situation which can in most cases be reached directly by the finger or the sigmoidoscope.

The remaining 21.3% of carcinomata in the colon were distributed over the other parts of the large intestine in the following order of frequency: caecum, transverse colon, splenic flexure, ascending and descending colon, and hepatic flexure. But even in the caecum the incidence amounted to only 6.1%.

Sex Incidence

The distribution of the carcinomata at different sites in the two sexes in the combined series is shown in Table II. It will be seen that altogether 907 of the patients were men and

TABLE II.—Relative Numbers of Growths in the Two Sexes at Different Parts of Bowel in Combined Series of 1,644 Cases

Site	No. of Patients with Growths in Each Site	
	Males	Females
Rectum ..	559	385
Sigmoid colon ..	176	174
Descending ..	18	27
Splenic flexure ..	25	25
Transverse colon ..	37	40
Hepatic flexure ..	20	9
Ascending colon ..	24	24
Caecum ..	48	53
All sites ..	907	737

737 women, but that this slight male preponderance is explained entirely by the higher incidence of cancer of the rectum in men than in women—the proportion in this site being 559 men to 385 women. Elsewhere the incidence in the two series was approximately equal.

Mode of Presentation

Broadly speaking, there were three ways in which these 1,644 patients presented at hospital with malignant disease of the large intestine.

As Non-acute Cases at the Out-patient Clinics.—The great majority of the patients were referred to the out-patient clinics or consulting-rooms with an obvious carcinoma of the rectum or colon or with suggestive symptoms requiring further investigation, and were admitted to hospital in due course as non-urgent cases with a view to radical or palliative treatment.

As Emergency Cases with Acute Intestinal Obstruction.—A much smaller proportion of the cases were admitted as emergencies with symptoms of acute intestinal obstruction. Roughly two-thirds of these had had, for some weeks or months prior to the onset of these acute symptoms, other complaints referable to their growth, but their significance had not been appreciated by the patient or his doctor. It was therefore essentially on account of the acute obstruction that the patient was admitted to hospital, and the relief of obstruction was the prime essential in treatment.

As Emergency Cases with General or Localized Peritonitis Due to Perforation of Colon.—A still smaller percentage of the patients were admitted urgently with a local or general peritonitis due to perforation of the colon either through a stercoral ulcer some distance proximal to an obstructing growth, and often in the caecum, or, much more commonly, at the site of the carcinoma itself.

The proportion of patients in these three categories was roughly the same during the two periods under review. Of the combined series of 1,644 cases, 1,239 (75.2%) were admitted as non-urgent cases, 290 (18%) as emergencies with acute intestinal obstruction, and 115 (6.8%) as emergencies with perforation and peritonitis.

Results of Treatment

Our ultimate aim in this survey was to determine the proportion of patients in the two series who were given the benefit of a radical operation and the number who survived this operation. But first of all it is instructive to review the initial management of the cases admitted with acute obstruction or perforation of the bowel and see if, with our better knowledge of fluid and electrolyte balance and the use of antibiotics, there has been any improvement in the results of treatment of these emergencies in recent years.

Cases With Acute Obstruction

Nine of the patients with acute obstruction were virtually moribund on admission and never rallied sufficiently for an operation of any kind to be performed before they died. In 15 other cases the only treatment employed for the obstruction was enemata, which were successful in 14. The remaining patients were subjected to operation, which usually took the form of a decompression or a short circuit, leaving the neoplasm *in situ*, but in a few instances involved a resection of the growth by an intraperitoneal technique with sutured anastomosis, or a Paul-Mikulicz type of operation. The various measures employed in these obstructed cases in the two series and the resulting immediate mortality are listed in Table III.

TABLE III.—Immediate Treatment of Acutely Obstructed Carcinoma of Large Intestine

Forms of Treatment Employed	1938-43		1947-55	
	No. of Cases Treated	No. of Hospital Deaths	No. of Cases Treated	No. of Hospital Deaths
Expectant ..	5	5	4	4
Enemata alone ..	1	0	14	1
Caecostomy ..	24	12	54	24
Ileo-transverse colostomy ..	14	8	68	11
Primary resection: Right hemicolectomy with anastomosis ..	0	0	31	3
Other forms of colectomy { With anastomosis By Paul-Mikulicz method ..	1	0	16	1
Miscellaneous operations ..	0	0	7	2
	10	3	24	6
	4	4	13	2
All forms of treatment	59	32 (54%)	231	54 (23.4%)

It will be seen that the immediate mortality of acutely obstructed carcinomata has declined from 54% during 1938-43 to 23.4% during 1947-55. Some of this improvement may be attributable to the relatively less frequent use, during the latter period, of caecostomy, which appears from this analysis to be a particularly hazardous operation, often followed by fatal sepsis. Another factor which may have been of importance was the better control of fluid and electrolyte balance and the availability of antibiotics during the second period. Incidentally, it is interesting to note that the number of deaths following primary resection—that is, right hemicolectomy, colectomy at other sites with intraperitoneal anastomosis, or Paul-Mikulicz resections—in 58 of these obstructed cases was not as great as might have been feared—being only 12 (20.6%), the majority occurring after operations of the Paul-Mikulicz type.

Cases With Perforation and Peritonitis

Many of these patients were desperately ill on admission and rapidly died; included in this group were most of the 20 patients with a diastatic perforation, usually of the caecum, proximal to an obstructing carcinoma of the left colon. A certain number of the others were treated by laparotomy, suture of the perforation, and the establishment of a proximal colostomy or caecostomy. In a few cases the perforation was exteriorized as a colostomy, or a resection of the perforated growth was performed. The frequency with which these various methods of treatment were used and the immediate results are indicated in

TABLE IV.—Immediate Treatment of Carcinomata of Large Bowel Complicated by Perforation and Peritonitis

	1938-43		1947-55	
	No. of Cases Submitted to it	No. of Hospital Deaths	No. of Cases Submitted to it	No. of Hospital Deaths
Expectant ..	11	11	23	23
Drainage only ..	1	1	1	1
Suture of perforation together with colostomy or caecostomy ..	25	19	32	25
Primary resection (right hemicolectomy or Paul's resection) ..	6	2	16	3
All forms of treatment	43	33 (76.7%)	72	52 (72%)

Table IV. The mortality remained approximately the same in the two groups, being 76.7% during the first and 72% during the second. It will be seen that the best results were obtained by primary resection of the perforation and growth where their relative proximity made this possible.

Cases Proceeding to Radical Excision

Altogether 765 (48.4%) of the 1,644 cases were eventually submitted to radical operation, but there was a considerable difference in the resectability rate during the two periods under review. Thus radical excision was carried out in only 127 (26.2%) of the 485 patients seen during the years 1938-43, but 638 (55%) of the 1,159 patients treated during 1947-55 proceeded to excision of the primary tumour.

Influence of Mode of Presentation of Disease on Ultimate Resectability.—Most of the patients proceeding to resection during both periods under review were derived from the group of cases presenting non-acutely. The proportion of patients eventually achieving resection in the groups with acute obstruction or perforation was much less, partly owing to the smaller size of these groups and partly on account of the rather lower resectability of growths which have been complicated in these ways. Thus of the 1,239 patients presenting non-urgently at the out-patient clinics, 631 (50%) were submitted to resection. By contrast, only 124 (43%) of the 290 cases with acute obstruction and 22 (19%) of the 115 with perforation and peritonitis eventually proceeded to resection.

Influence of Site of Growth on Operability Rate.—If the resectability rate is related to the site of the growth in the two periods under review, as in Table V, the interesting fact

TABLE V.—Influence of Site of Growth on Resectability Rate of Carcinoma of Large Intestine

Site of Growth	1938-43			1947-55		
	No. of Cases Seen with Growths in this Site	No. Deemed Resectable	Resectability Rate	No. of Cases Seen with Growths in this Site	No. Deemed Resectable	Resectability Rate
Rectum ..	298	47	15.7%	646	363	56.2%
Sigmoid ..	102	35	34.3%	248	118	47.5%
Descending colon ..	14	8	57.1%	31	26	83.9%
Splenic flexure ..	13	4	30.8%	37	19	51.4%
Transverse colon ..	22	11	50.0%	55	33	60.0%
Hepatic flexure ..	5	3	60.0%	24	14	58.3%
Ascending colon ..	8	7	87.5%	40	20	50.0%
Caecum ..	23	12	52.2%	78	45	57.7%
All sites	485	127	26.2%	1,159	638	55.0%

emerges that the rise in resectability in the second period is due almost entirely to the more radical management of carcinomata in the rectum and sigmoid colon. In the first period few of these lesions were removed, but during the second an increasing proportion have been subjected to excision each year. For growths elsewhere in the colon, and

especially those on the right side, there has been little change in the resectability rate, which actually has been fairly high throughout.

Influence of Rise in Resectability Rate on Mortality of Radical Operations.—This increase in the proportion of patients proceeding to radical operation in the post-war period would be a very hollow achievement if it were accomplished at the expense of a considerable rise in the operative mortality. In fact, the number of operative deaths following radical operation in the 1938-43 period was 24 out of a total of 127 radical operations, which gives an operative mortality of 18.8%, whilst the number of immediate deaths in the 638 patients proceeding to resection in the 1947-55 period was 71, giving an operative mortality rate of 11.1%. The mortality rate has thus actually fallen despite the increased operability in this latter period, the effect being that a much greater proportion of patients have left the hospital with a chance of cure during 1947-55 than during the 1938-43 period (see Table VI).

TABLE VI.—Proportion of Patients Leaving Hospital Alive After Radical Operation for Carcinoma of Large Bowel

	1938-43	1949-55
No. of patients seen	485	1,159
No. of patients treated by radical operation	127 (26.2%)	638 (55%)
No. of patients leaving hospital alive after radical operation (includes some palliative excisions)	110 (23%)	589 (51%)

Choice of Radical Operation.—The various types of radical operation employed in both these series of cases are listed in Table VII. As would be expected from the increasing resectability of rectal and sigmoid cancer in the latter years revealed in Table V, many more rectal excisions have been performed during the 1947-53 period than in the previous period. In addition, it will be noted that the perineal or sacral type of operation, which was previously in vogue for excision of the rectum, has given way largely to the combined abdomino-perineal excision.

TABLE VII.—Types of Radical Operation Used in Treatment of Carcinoma of Large Intestine

Type of Operation Performed	1938-43		1947-55	
	No. of Times Used	No. of Hospital Deaths	No. of Times Used	No. of Hospital Deaths
Right hemicolectomy with anastomosis	20	4	79	4
Resection of transverse or left colon with anastomosis	24	6	142	12
Resection of transverse or left colon by Paul-Mikulicz method	33	6	62	11
Anterior resection of rectum with anastomosis	0	0	12	1
Abdomino-perineal excision of rectum	4	2	338	40
Perineal excision of rectum	46	4	5	0

Number of Patients Ultimately Cured by Radical Excision.—As nearly half the combined series of 1,644 cases surveyed in this paper were treated in the last five years, and as no reliable follow-up system was in operation during the earlier years, it is clearly impossible to provide any reliable information regarding the percentage of five-year survivors amongst the patients discharged after radical operation. However, Dukes (1944) has estimated that approximately 50% of the survivors from combined excision of the rectum are alive and well five years later, and Rankin and Graham (1950) claim that, of the survivors of radical operations for carcinoma of the colon, between 50 and 60%—depending on the precise site of the growth—live free of recurrence for at least five years. It would be tempting to suppose, therefore, that some 50% of the patients in this series who left hospital after a radical operation will survive for five years or more. It has to be remembered, however, that

included among these resection cases are a number of patients who underwent purely palliative resections in the presence of hepatic metastases or other evidences of irremovable growth. No question of cure arises in these cases, and their inclusion will obviously lower the five-year survivals. It would be too much to hope, therefore, that an overall cure rate of 50% will be achieved, but we reckon that the results should not fall far short of this figure.

Summary and Conclusions

The treatment and operative mortality of carcinoma of the large intestine are compared in two consecutive series of cases admitted to the General Infirmary at Leeds during 1938-43 and 1947-55 respectively.

In the former group of 485 cases the growth was found to be resectable in 26.2%, with an operative mortality of 18.8%. By comparison in the latter group of 1,159 cases resection was performed in 55%, with an operative mortality of 11.1%.

Approximately four-fifths of the growths in both series lay in the rectum or sigmoid, and the improvement in the resectability rate in the second series was due almost entirely to the more radical management of carcinomata in these situations during the latter period. The resectability of carcinoma of other parts of the large intestine remained much the same in the two periods under review.

The reduction in the immediate mortality following radical resection during the second period is attributed mainly to better control of fluid and electrolyte balance and to the use of antibiotics. The improvement in the results of emergency operations for the cases complicated by acute intestinal obstruction may have been due in large measure to these factors also, but was probably referable in part to changes in the choice of operation—namely, to the greater use of transverse colostomy instead of caecostomy for obstructed growths of the left colon. The high mortality of perforation of the colon with resulting peritonitis has remained virtually unchanged, making this still a most lethal complication of cancer of the large intestine.

We are indebted to our surgical colleagues at the Leeds General Infirmary for kind permission to include their patients in this survey, and to Professor E. Grebenik for much helpful criticism from the statistical point of view.

Science for Everyman is an annotated book list due to be published by the National Book League early next year. Its production has been made possible by a generous donation from Unilever Ltd. The list, which will comprise some 1,500 titles, is intended for the non-specialist scientist. It will cover many branches of science, including mathematics, physics, chemistry, astronomy and meteorology, geology, oceanology, biology and biochemistry, genetics and evolution, zoology, ornithology, botany and agriculture, technology, and the history of science. The lack of a non-specialist bibliography, and the need for it, became apparent during the preparation of an exhibition of books for last year's meeting of the British Association. The National Book League hopes its list will prove a useful basis on which to build a non-specialist scientific library.

HOMOSEXUALITY: AN ANALYSIS OF 100 MALE CASES SEEN IN PRIVATE PRACTICE

BY

DESMOND CURRAN, M.B., F.R.C.P., D.P.M.
Consultant Psychiatrist

AND

DENIS PARR, M.D., D.P.M.
Research Fellow

Department of Psychiatry, St. George's Hospital, London

Amongst the reasons why facts about homosexuality are so hard to come by are: (1) the problem of definition. What are the criteria for homosexuality? Should the emphasis be on preference or performance? How widely should the net be cast? Thus, according to the psycho-analysts, a homosexual component (sometimes conscious but often not) exists in everybody; and if this is correct homosexuality in this sense is universal. (2) The natural reluctance of individuals to admit to a component or preference which is socially condemned or to acts that are illegal and liable to heavy penalty.

But we can probably all agree (a) with the general definition—namely, that homosexual means "having a sexual propensity for members of one's own sex" (O.E.D.); (b) that this propensity varies quantitatively in different individuals and can also vary quantitatively in the same individual during different epochs in life; and (c) that, as in other fields of experience and behaviour, introspection being neither exhaustive nor infallible, the individual may quite genuinely not be fully aware of either the existence or the strength of his motivations or propensities; and of course he can lie about them.

We can probably also agree that "having a sexual propensity for members of one's own sex" can affect behaviour, both in psychosexual and in other spheres, in a variety of ways. Explanations of individual behaviour in these terms range, however, from those based on the recognition of sexual acts consciously motivated by homosexual propensities to others that (to many) are in the nature of queer speculations, unproved and improbable (for example, that all aesthetic appreciation has roots in homosexuality). Between these extremes lies a whole series of more or less legitimate deductions and inferences.

Selection of Cases.—We have tried to short-circuit these difficulties by confining our study to cases in which homosexuality was recorded on the diagnostic summary cards kept by one of us as being either the presenting problem or a major part of the diagnostic formulation. All of these patients were consciously aware of their homosexual propensities and/or had indulged in homosexual acts with others. Cases of inferential or "latent" homosexuality were not included, nor were the cases whose homosexual preference or performance seemed to be an incidental finding of secondary significance from the psychiatric point of view.

Incidence.—From a series of 5,000 cases seen in private practice, the incidence of homosexuality, as outlined above, worked out as 5% of males over the age of 16 and 0.3% (a total of 7 cases) of females over 16.

Of the original 128 male cases, 100 were chosen for further study on the arbitrary basis of adequacy of documentation.

General Findings

The reasons for reference of the 100 cases were:

Criminal charge or executive consequences thereof	30
Worry over homosexual propensities (for example, "Can I change?") as the presenting complaint	25
Various psychiatric problems (for example, depression, excessive drinking) rather than direct worry over homosexuality as the presenting complaint	22
Pressure from friends or relatives	12
Marital difficulties, including impotence	5
Homosexual jealousy or deprivation reactions	2
Executive problems	2
Fear of scandal arising from homosexual acts	2

Age.—The ages of the group ranged from 16 to 69, the mean being 28.2 and the median 33 years. Table I shows the age distribution. In successively higher age groups, the proportion who came because of a criminal charge rose steadily.

TABLE I

Age:	16-25	26-35	36-45	46-55	56-65	66-	Total
Charged	2	11	9	5	1	2	30
Not charged	20	23	18	8	1	0	70
Totals	22	34	27	13	2	2	100

Education and Occupational Status.—The educational and occupational status of the group as a whole was high: 51 had been to public schools, 19 to grammar schools, 13 to secondary schools, and only 10 to elementary schools. Satisfactory information about the education of the remaining 7 is lacking. Of the 100, 41 had been to universities. As regards occupations, using the Registrar-General's coding, the distribution was as follows: (I) professional, 34; (II) intermediate, 24; (III) skilled, 21; (IV) semi-skilled, 1; (V) unskilled, 1; students, 8; not classified, 11; total 100. The most highly represented occupations were: civil servants, 7; doctors, 6; clergymen, 6; school teachers, 6; and 7 worked in jobs connected with stage or radio. There was one window-dresser and one dress designer.

Associated Psychiatric Disorders

Abnormalities of Personality.—It is always difficult to assess or classify these. The best we could do was to group them as follows: sociopathic, 12; inadequate or neurotic, 18; average, 38; good, 26; not classified, 6.

Previous Breakdowns.—In 23 there was a history of nervous trouble in the past which had either received medical treatment or was judged retrospectively as severe enough to have merited this. In addition, 8 had in the past received treatment specifically for homosexuality.

Psychiatric Diagnoses.—The following diagnoses were made at the time of consultation: anxiety state, 6; alcoholism (including 1 paranoid), 4; reactive depression, 2; hysterical reaction, 2; obsessional or phobic, 3; endogenous depression, 2; psychopathic mood-swing, 2; mixed neurotic problem, 2; suspected dementia, 1; post-meningitic personality changes, 1; mental deficiency, 1; total 26.

In all, 43 had either an associated psychiatric syndrome (often minimal) or a neurotic, inadequate, or "sociopathic" personality, or a combination of both. Of the remaining 57, 6 gave a history of psychiatric trouble in the past. Thus in spite of the probability that any group of homosexuals referred to a psychiatrist might be expected to be heavily weighted in the direction of psychiatric abnormality, no fewer than 51% were considered to be free from gross personality disorder, neurosis, or psychosis during their adult lives. Only one was certifiably defective and none certifiably insane. They included a number of important and talented individuals of high integrity, successful, efficient, and respected members of the community. Only two had been on any criminal charge other than homosexuality. Very few showed the traditional "pansy" picture of homo-

sexuals; indeed, only 21 were noted to have at all obvious homosexual personality traits, only one of these being a paedophile.

Psychosexual Experience

Continence.—All but 11 of the 100 cases admitted to one or more homosexual acts with others since adolescence.

Frequency of Acts.—Sufficient information was available in 60 cases who admitted to activity with others to say that, at a very conservative estimate, these 60 persons committed between them 600 and 700 (criminal) acts a year. We have no doubt that the true figure would be much higher. This opinion is based on special inquiry directed to those cases we were able to follow up personally and fortified by data given by other patients, not included in this series. In an ordinary psychiatric assessment, as opposed to a research project, it is often not relevant to inquire into the sexual practices of patients in full detail, whether as regards frequency or type.

Types of Act.—Between practising adults, mutual masturbation was almost universal. Including follow-up information, buggery was noted in 29% and fellatio (and concerning oral-genital activities no special inquiry was usually made at all) was noted in 11%.

For the reasons just given, we are satisfied that the percentages given for buggery and fellatio greatly underestimate the true incidence of such practices. We have little doubt that, although individuals do differ in their preferences, most regularly practising homosexuals indulge at some time or another in all available types of homosexual acts, both actively and passively.

TABLE II.—Comparison of Continent Homosexuals, Known Buggers, and Practising Homosexuals not Noted as Practising Buggery

	Continent		Buggery		Practising, No Known Buggery	
	No.	%	No.	%	No.	%
Age 30 or under	6	54	12	41	24	40
Occupational class I or II	7	64	18	62	33	55
Public school	4	36	16	55	31	51
Charged	—	—	10	34	20	33
Charged more than once	—	—	5	17	11	18
Associated mental disorder or history	4	36	11	38	20	33
Sociopathic	0	0	4	14	8	13
Neurotic or inadequate personality	2	18	4	14	12	20
"Good" personality	3	27	7	24	16	26
"100% homosexual"	2	18	16	55	24	40
6 or more partners admitted	—	—	19	66	11	18
Acts with boys under 16	—	—	3	10	12	20
Totals	11	100	29	100	60	100

Comment.—In respect of the factors tabulated, there was no statistically significant difference between the continent and practising groups.

The Special Legal Position of Buggery.—The law singles out buggery from other homosexual crimes and prescribes a maximum penalty of life imprisonment; whereas for "indecent assault" and acts of gross indecency the maximum penalties are ten years and two years respectively.* Taking a number of criteria (Table II), the only differential point we could find between those known to practise buggery and those in whom buggery was not noted was the apparently higher level of promiscuity, 66% admitting to six partners or more as compared with 18%. (Difference highly significant, $P<0.01$.)

***Medico-legal Note.**—(1) Any act between males anywhere, whether in public or private, is at present a criminal offence if it involves "indecent assault"—that is, contact with or exposure of the private parts with the intent, either admitted or reasonably inferred, of obtaining sexual excitement. (2) "Indecent assault" means in effect (with few exceptions) homosexual behaviour with a partner under 16 years of age, and need not and usually does not contain any ingredient of violence. It very often consists only in gentle fondling.

Paedophilia

We found it possible to divide our series rather sharply into those who were sexually attracted by pre-pubertal boys (paedophiliacs) and those who were not. Seventeen admitted, or showed, paedophile impulses. Of these, twelve were not attracted by adults and only five were attracted at different times in their lives both by pre-pubertal boys and older males; the number of these five who admitted acts with young boys and adults was two. Further, one of these was mentally defective, and in the other impulsive fondling of a young nephew was a transient phase of doubtful significance.

In our series the age of the preferred love object was quite strikingly fixed; apart from the two dubious cases mentioned, there was no evidence in favour of the concept that adult-seeking homosexuals tend, sooner or later in their lives, to prefer young boys (the so-called "rake's progress").

Further analysis of the 17 paedophiliacs in our series showed that they differed from the "adult-seekers" in the following respects: (1) The paedophiliacs came more often because of a charge than for other reasons. (12 out of 17 as compared with 18 out of 83.) ($\chi^2=13.7$; $P<0.01$.) (2) A higher proportion of paedophiliacs were married (7 out of 17 as compared with 12 out of 83.) ($\chi^2=4.96$; $P<0.05$.) (3) They tended to be older than the remainder—for example, 9 out of 17 paedophiliacs were over 41 as compared with 19 out of the other 82 members of the series ($\chi^2=4.9$; $P<0.05$).

Another distinctive feature of paedophiliacs lies in their social isolation from other homosexuals, many (probably the majority) of whom regard the seduction of young boys as abnormal and immoral. Paedophiliacs are seldom members of homosexual coteries; they are obliged to be lone wolves in their sexual pursuits, of which they are often much ashamed. The capacity for self-deception which many paedophiliacs show is possibly a reflection of this shame. For example, in our series a married schoolmaster of 40 who had made a practice for years of inspecting and fondling boys' genitals in the dormitories at night, explained his actions as a means of making sure that the boys were not masturbating—that is, as benevolent supervision. A 69-year-old priest who had been assaulting boys twice weekly for at least a year said, "I must have known it was wrong, but somehow I never thought of it."

According to Kinsey (personal communication) paedophiliacs constitute only a small fraction, not more than 3%, of homosexuals as a whole. In our experience of psychiatric practice, the proportion is somewhat higher, and amongst those criminally charged it is very much higher, in fact misleadingly so.

The Homosexual-heterosexual Scale

Homosexuality is not an "all-or-none" condition. In this series every gradation was found between apparently exclusive, lifelong, "100%" homosexuality, without any conscious capacity for arousal by heterosexual stimuli, and predominant heterosexuality with only transient or minor homosexual inclinations. Kinsey *et al.* (1948) introduced a seven-point rating of homosexuality, with a maximum of 6 points for sexual arousal and activity with other males only, 0 for exclusive heterosexuality, 3 for arousals and acts equally with either sex, and intermediate scores accordingly. The

TABLE III

Original Classification	Approx. Kinsey Equivalent	Number
"100%" homosexual (or nearly so)	5-6	42
Bisexual, predominantly homosexual	4	29
Bisexual, not predominantly homosexual, or transitional homosexuality	1-3	16
Bisexuality not otherwise specified	2-5	3
Homosexual, not classified	—	10

original notes did not use this scale, but in the following classification the very approximate "Kinsey equivalents" are shown in Table III.

Diagnostic Criteria

The fact that the same act may have a totally different psychosexual significance for different individuals was illustrated by the cases of two young men who had both been fined for the same act of gross indecency (mutual masturbation). The doctor of the organization for which they both worked sent them for an opinion on prognosis. One was found to be exclusively homosexual and was judged to have no chance of changing in the direction of heterosexuality; the other was almost entirely heterosexual in his psychic responses, and the incident in his case was considered an isolated and insignificant one. Follow-up confirmed these opinions.

In forming an opinion on the place of a given individual on the homosexual-heterosexual continuum, account was taken of masturbation fantasies and erotic dream content. Friendly but disinterested relations with girls were taken to mean a poorer prognosis, in terms of possible changes in the direction of heterosexuality, than shyness and embarrassment in female company.

Heterosexual Activity

Many homosexuals indulge in intercourse with women out of academic curiosity or in an attempt at self-diagnosis or treatment. For assessment purpose the subjective aspect of heterosexual experience—whether it is enjoyed or desired or not—is more important than what physically takes place.

In our series 19 were at some time married and another 17 had physical heterosexual experience. One 60-year-old man was persuaded by his wife to seek advice for impotence. He had married 25 years previously in the hope of curing his homosexual tendencies, but found that he could achieve orgasm only with the help of homosexual fantasies. He continued to do so, and was physically successful for the first 23 years of his marriage, after which his potency failed. He had six children, but remained homosexual. Sexual intercourse was, in effect, masturbation per vaginam so far as his psychic responses were concerned.

Facultative Homosexuality

Facultative homosexuality is not an entity apart, and the term may be used in respect of almost any bisexual individual. In our series there was clear evidence of facilitation of homosexual acts by environmental factors in 10 cases. One man, for example, avoided the company of women on legal advice while his divorce was pending, and got involved in homosexual activities which led to a criminal charge. Another, also on a charge, had sought consolation in homosexual contacts when economic failures increased the isolation which he felt as a relative dullard in a clever family.

Treatment

Objects.—The objects of treatment can be arbitrarily divided under four main headings: (1) change in direction of the sex urge, (2) greater continence, (3) greater discretion, and (4) better adaptation to the sexual problem and to life in general.

Methods.—As always in psychiatry, treatment consists in a mixture of physical, psychological, social, and environmental measures in varying proportions according to the case.

Recommendations Made.—(a) In-patient care, generally for an associated psychiatric condition such as alcoholism, was advised in 11 cases. (b) Psychotherapy, in the broad sense of further psychiatric interviews of any number or type (including analysis), was recommended in 23 cases. A choice of hospital or private treatment was available. (c) In the remaining 66 cases treatment was limited to discussion at the initial interview, simple counsel, prescription of medi-

cines or environmental adjustments. Psychotherapy in these patients was either not advised or (for example, for geographical reasons) was impracticable.

Legal Reports.—Reports were written to solicitors in 22 cases, but evidence was given in only 9. The discrepancy may be partly due to the fact that reports often contained information and opinions which would have been highly damaging to the defence if revealed in court. For example, in two such reports, the opinion was expressed that prison would be the most appropriate treatment.

Follow-up

Method.—The extent of the follow-up was limited by the need for circumspection. In 95 cases letters were sent to the patient and/or one or more of the following: relatives, family doctors, psychiatrists, other doctors, solicitors, probation officers. Letters to patients generally contained an invitation to attend for personal interview. The response is shown in Table IV.

TABLE IV

Seen personally by one of us	15
Documentary information bearing on sex life	44
Documentary information not bearing on sex life	11
No reply, or useless reply	30

Changes in Orientation.—Of the 59 patients about whom sufficient information was available, 9 (or roughly 1 in 6) reported less intense homosexual feelings, or increased capacity for heterosexual arousal, 3 became more homosexual in preference than when first seen, and no change, even of a minor order, was found in the sexual orientations of the other 47. When a change was found it often amounted only to a slight alteration in the balance of masturbatory fantasies.

Changes in Performance.—Of the above-mentioned 59 patients, 11 showed improved discretion in or control of their persisting homosexual desires. 4 became more active, and another 9 were charged during the follow-up period with homosexual offences.

Changes in Adjustment.—Twenty-three were reported to show improved subjective adjustment or general well-being; this (rather than increasing unhappiness) was the main trend. Three died (one by suicide).

Those Seen Personally.—The 15 who came for interview were a self-selected minority, but they provided more reliable follow-up data than the remainder. Five reported a change towards heterosexuality, 2 were more homosexual in preference, 2 were more discreet, and 3 were more actively practising than before.

Comparison with Original Prognosis.—Of the 59 cases in whom follow-up information was available, the original opinion on the diagnosis and prognosis of the homosexual condition was sufficiently detailed in 52 for the comparison shown in Table V to be made between prediction and

TABLE V

Diagnosis and Prognosis	Total	Changes in Preference		
		Towards Heterosexuality	More Homosexual	No Change
"100%" homosexual—no change of change	24	1	—	23
Predominantly homosexual—little chance of change	14	2	0	12
Bisexual, reasonable chance of change	14	6	3	5

outcome. It will be seen that the original forecast was most often correct in cases of the "100%" type. Adding the first two groups, 3 out of 38 changed towards heterosexuality as compared with 6 out of 14 of the third group. The difference is highly significant ($P<0.01$).

Age and Prognosis.—Changes in preference in the direction of heterosexuality occurred more often in those aged

16 to 25 (6 out of 20) than in those aged 26 or over (3 out of 39). This difference was not, however, statistically significant. Thus, such changes were related more clearly to the degree of bisexuality as originally formulated than to age.

Effects of Psychotherapy.—Twenty-five patients who had psychotherapy of any kind during the follow-up period were compared with a matched group not so treated. The mean duration of follow-up was 4½ years. No difference between the two groups could be discerned as regards change in sexual orientation, discretion, or control. Rather more of the treated patients (12 out of 25 as compared with 8 out of 25) appeared to come to better terms with their problems at a subjective level, but increased overt activity was sometimes noted after treatment. None of these differences was statistically significant. (It is proposed to publish detailed findings separately.)

Some Special Problems

Education.—There were few differences in the histories of ex-public and grammar school boys respectively. Homosexual practices at school age were noted in 12 out of 51 of the former and in 7 out of 19 of the latter; these proportions are not significantly different from each other.

Seduction.—Seduction, or an attempt thereat, by an adult or much older youth was stated to have occurred before the age of 14 in 13 patients and between 14 and 18 years in four other patients. Seduction was reported in 9 out of 30 cases on a criminal charge, and 8 out of 70 who were not, the difference being just significant ($\chi^2=3.90$; $P<0.05$). Comparison of the incidence of a history of seduction in those with impulses directed towards pre-pubertal boys (5 out of 17) and the remainder (12 out of 83) revealed no statistically significant association.

Promiscuity.—Some patients were extremely promiscuous, and great risks were taken in making contacts in public lavatories despite the known observation kept on such places by plain-clothes police. Among reasons given for taking these risks were anatomical proximity and convenience, voyeuristic pleasure ("Penises to me are like tits to the reader of *Vie Parisienne*"), and fantasies of meeting prominent figures ("You never know—X.Y. (a well-known film star) might be standing next to you"). Uriferous odours have an aphrodisiac effect on some. It has been suggested that the illegality of homosexual acts enhances their appeal. We think that some homosexuals do gain vicarious added pleasure by eluding capture. On the other hand, we have found no patient whose enjoyment has been enhanced by detection and punishment—any more than thrill-seeking racing drivers enjoy a crash. It is our impression that homosexuals tend to be more persistently and consciously pre-occupied with sexual thoughts and images than other males.

Blackmail.—Only two patients had a history of being blackmailed in the past. Fear of blackmail was absent in the group as a whole. There was little knowledge of it even at second hand.

Marriage.—Nineteen were, or had been, married. In only eight was marital adjustment apparently satisfactory. A significantly higher proportion of the married (10 out of 19) than of the single men (20 out of 81) came because of a criminal charge ($\chi^2=5.1$; $P<0.05$). The charge concerned boys under 16 in 5 married and 8 single men. Of the 10 married men on a charge, the wives of three were pregnant at the time of the alleged offence.

Criminal Charges.—The criminal charges which brought 30 to the original consultation were: buggery, 2; indecent assault, 12; indecency or gross indecency, 11; importuning, 5. Only one man was charged with acts with adults in private. Adding past history and follow-up findings, in all 36 men were the subject of 54 homosexual charges.

The apparently higher rate of recidivism in those who had been charged before was not significant. Psychiatric findings were negative, in the sense previously used, in 19 out

TABLE VI

	Total	Charged During Follow-up Period
Charged when first seen, and/or previously	33	6
Not charged when first seen, nor previously	67	3
Totals	100	9

of 30 seen because of a criminal charge, and 32 out of 70 of the remainder. There was no significant difference in these proportions. A similar comparison taking into account also past and subsequent charges also failed to reveal any significant difference in the incidence of psychiatric abnormality in those who were charged once or more than once, as compared with the homosexuals who kept out of legal trouble. Two men in the series were at one time or another on other criminal charges (one false pretences, one living on immoral earnings).

Alcohol.—Four of the 100 patients were alcoholic, and another 10 drank excessively. Homosexual acts were allegedly facilitated by alcohol in 12 cases, including 2 of the aforementioned 14. Such facilitation occurred more often (5 out of 13) in those charged more than once than in those charged once only (3 out of 23), and least often (4 out of 64) in the remaining practising homosexuals who were not charged at all during the span of the investigation.

Associated Perversions.—Apart from the various available types of homosexual act the incidence of other known perversions in the series was four. Three men had sado-masochistic fantasies (one involving horses) and one a muscle fetish—that is, he derived erotic satisfaction from the contemplation, *per se*, of well-developed muscles.

Discussion

The literature on homosexuality shows a very wide divergence of opinion on what should be included. The present study was restricted to persons who we believe were homosexual or showed homosexual problems by any criterion. On the other hand, owing mainly to two factors, the group was a highly selected one, and to this extent cannot be regarded as representative of homosexuals as a whole.

The first of these factors was that all cases were referred for a psychiatric opinion, and would therefore be likely to contain a high proportion of the psychiatrically disturbed and criminally charged (these latter having come in the hope of establishing medical reasons for mitigating the rigours of the law).

The second was that all cases were referred for a psychiatric opinion in private, and hence contained a high proportion of the well-to-do. This was reflected in their high educational and social status, and in the relative adequacy with which they were able to verbalize their problems. (By contrast, dull and inarticulate persons are often unable to give more than the crudest account of their psychosexual reactions, and accurate assessment of propensities or the significance of activities is correspondingly difficult.)

The patients were all seen for specific practical reasons, either clinical—for example, "Can I change?"—or legal—for example, "Will he relapse?"—and the case notes were inevitably less complete than in a planned research project. Records differed in scope and emphasis from case to case, and negative findings were not routinely recorded unless considered relevant. Since all cases were seen initially by the same psychiatrist, the personal factor in history-taking was relatively constant. However, it must be remembered that the one psychiatrist may have been uniformly wrong, and—like a stitch dropped in knitting—the resulting omissions and bias may have become increasingly serious and the pattern evolved correspondingly distorted.

In general, the recorded differences between sub-groups in the series found to be significant on test are suggestive,

but not always easy to interpret. Such differences might, for example, arise from the nature of the original sample.

Although sufficient data were not always available for exact classification, we believe that with more information all of these cases could have been placed on a continuum between exclusive heterosexuality and complete homosexuality—that is, somewhere on the seven-point Kinsey scale. We have no doubt that this scale provides the best means of classifying homosexuals. It is unambiguous, descriptive, carries no moral connotation—for example, "invert" or "pervert"—and is not based on dubious theories of aetiology—for example, "congenital" or "acquired." It also carries useful prognostic implications.

Promiscuity is a striking feature of most practising homosexuals. We believe that diversity of acts is the rule, and that there is no medical value in attempting to differentiate those practising buggery from other homosexuals.

The distinction between paedophiliacs and adult seekers is, however, a valid and useful one. The overlap between these groups in our series was so small as not to disturb the hypothesis that the age of the preferred love object is, within limits, a characteristic and fixed attribute of an individual's psychosexual make-up.

Only half the patients showed significant psychiatric abnormality other than their sexual deviation, and such associated abnormalities were often slight. Moreover, many of these abnormalities were explicable as a reaction to the difficulties of being homosexual. Symptomatic homosexuality was rare. If homosexuality is a disease (as has often been suggested), it is in a vast number of cases monosymptomatic, non-progressive, and compatible with subjective well-being and objective efficiency. In our series, both practising and non-practising homosexuals were on the whole successful and valuable members of society, quite unlike the popular conception of such persons as vicious, criminal, effete, or depraved. Only one-fifth were at all obviously "pansy," and we found no reason to regard most of the patients as physically, intellectually, or emotionally immature (unless the basic criterion for "immaturity" is that of being homosexual—a circular argument).

The information recorded was insufficient to throw much useful light upon the controversial issue of psychosexual development; but, so far as they went, our data accorded with the widely expressed view (held by authorities as different as Freud and Kinsey) that the main pattern of psychosexual responses is established not later than puberty. Many of our patients were emphatic that they had felt "different" from others and had in fact been homosexual in their orientation so long as they could remember.

The follow-up gave evidence of a change in the direction of heterosexuality in 9 cases out of 59 (roughly 1 in 6) about whom sufficient information on the sex life was available; but such change sometimes amounted to no more than one or two points on the Kinsey scale. There was no evidence, from our series, that psychotherapy had any obvious effect in any way, on points that could be tested. The original prognosis was substantially correct in those of any age classifiable as Kinsey 5 or 6; changes of preference in either direction were less often successfully predicted in bisexual cases, but prognoses were more often right than wrong. We believe that claims for the cure of homosexuals should be treated with reserve unless the Kinsey rating before and after treatment is clearly stated and relevant evidence adduced. It seldom is.

In a search of the literature—concerning which West (1955) gives many references in his valuable monograph—we have been unable to find studies of a group of homosexuals comparable with our own. Most surveys have been concerned with special problems met with in prison—for example, Henry and Gross, 1938; Apfelberg *et al.*, 1944; Taylor, 1947—or mental hospital practice—for example, Gardner, 1931; Ruskin, 1941; Klein and Horwitz, 1949. The discrepancy in composition between our group and that of Taylor working at H.M. (Remand) Prison at Brixton is

a marked one, particularly in respect of the higher incidence of serious mental abnormality that he found (3% insane and 9% certifiably defective). Selected groups are seen by medicine and the law, and it is probable that the majority of practising homosexuals never reach either.

Summary

The incidence of homosexuality (as defined) was 5% in males over 16 seen in private psychiatric practice. 100 cases were studied retrospectively and so far as possible by follow-up.

In round figures, 9 out of 10 indulged in homosexual acts with others. Many were highly promiscuous and the majority quite active, the practising group committing at a conservative estimate an average of at least 10 (criminal) acts annually each.

There was no evidence that those who admitted to buggery differed from other practising homosexuals in social or economic success, stability or social worth, or that the continent group differed from practising homosexuals in these respects.

Only 49% of cases showed significant psychiatric abnormalities; these were usually minimal.

Paedophiliacs (meaning by this those who were attracted to pre-pubertal boys) were found to constitute a distinct group and only two committed acts with both adult men and pre-pubertal boys. There was no evidence of those preferring adults subsequently seeking boys (the "rake's progress").

In 59 cases where relevant information was obtained in the follow-up, a change towards heterosexual preference was noted in 9, while 3 became more homosexual, and 47 were unchanged. Only 1 of 24 cases originally regarded as "100% homosexual" reported a change in the direction of heterosexuality.

Twenty-five patients treated psychotherapeutically derived no apparent benefit in terms of changed sexual preference or behaviour as compared with 25 (matched) patients not so treated.

We are grateful to Dr. J. A. Fraser Roberts for statistical advice, and to Dr. Maurice Partridge and our other colleagues at St. George's Hospital for their helpful criticism.

A small booklet has been written by Dr. J. Gibson, describing the history and work of St. Lawrence's Hospital for mental defectives at Caterham. The hospital was founded in 1870. The booklet, which includes photographs, was set up and printed by patients in the hospital. Originally the hospital was known as Caterham Metropolitan Asylum, and both mental defectives and patients with mental diseases were accommodated. Gradually the buildings were expanded and improved, and they now house about 2,000 patients from the age of 5 upwards, with a nursing staff of 390. For many years the majority of the patients were low-grade mental defectives, but there are now some high-grade mental defectives there also, and so workshops have been built for them. The booklet was produced in the new printing workshop by some of the high-grade mental defectives working under supervision.

PARATHYROID DEFICIENCY
PRESENTING AS EPILEPSY

BY

R. G. WILLISON, B.M., M.R.C.P.Ed.

AND

C. W. M. WHITTY, D.M., M.R.C.P.

*From the Department of Neurology, Radcliffe Infirmary,
Oxford*

Parathyroid deficiency may occasionally present as epilepsy. When this occurs there is almost always evidence also of tetany, latent or overt, though this may be trivial compared with the fits. Moreover, the pattern of the fits may be unusual and suggest the possibility of a reduced serum calcium concentration. Thus the attack may begin or end with carpo-pedal spasm. Occasionally generalized convulsive movements may occur without loss of consciousness and be terrifying to the patient. Sometimes the movements are of a peculiar athetotic variety and resemble the mobile spasm seen in some cases of Kinnier Wilson's disease. This may be linked with the fact that in long-standing cases calcification in the basal ganglia may be demonstrated radiologically—a point of some diagnostic value.

The range and variety of convulsive attacks which may occur has been reviewed by Robinson, Carmichael, and Cumings (1954) in discussing three cases of idiopathic hypoparathyroidism. Such attacks include many varieties of motor epilepsy and some which appear clinically to be petit mal. These authors conclude that the cerebral cortex may participate directly in the increased excitability caused by low serum calcium and readily demonstrated in peripheral nerve.

Diagnostic difficulties may arise, since some patients show an association of papilloedema, fits, and tetany; but Grant (1953) pointed out that the fits and papilloedema may be abolished by the administration of "para-thor-mone," and might thus be the result of electrolyte imbalance and consequent cerebral hydration.

The following case is considered worth recording because in the presence of a focal brain lesion fits occurred only when serum calcium was lowered. The case also illustrates clearly the part played both by the cerebral lesion and by the electrolyte imbalance in determining the pattern of the epileptic attacks.

Case Report

A woman aged 52 had had a partial thyroidectomy for thyrotoxicosis in 1953. Symptoms subsided, but a year later dysphagia developed and progressed. In 1955 a post-cricoid biopsy was performed, and showed grade 3 thyroid carcinoma. On December 22, 1955, Mr. R. G. Macbeth performed a radical thyroidectomy and first-stage pharyngectomy. Extensive local spread was revealed at operation, and deep x-ray therapy was started.

On January 13, 1956, she had what was thought to be a fit, though the onset was not observed, and when first seen she was breathing stertorously, was cyanosed, and was frothing at the mouth. There was no personal or family history of fits, faints, or migraine. She was started on phenobarbitone, 1 gr. (65 mg.) three times a day. On January 14 she had another seizure, in which clonic movements, mainly of the left side, were observed. On the following morning she was found to be weak in the left arm, with some increase in tendon reflexes and an up-going toe on the left side. On January 17 full neurological

examination revealed a slight left spastic hemiparesis, with some reduction of passive movement sense and an extensor plantar response on the same side. There was no papilloedema.

At noon on January 18 she had another fit, which was observed at its onset. It began with carpo-pedal spasm in both hands. The spasm spread over the whole of the left side and consciousness was lost. Clonic movements then occurred, but only on the left side, although there were stertorous breathing, cyanosis, and frothing at the mouth. The movements lasted for about 10 minutes, and consciousness was regained in about 30 minutes. Because of the carpo-pedal spasm at the onset of the attack, and because some myotatic irritability was present, the serum calcium was estimated and found to be 6.2 mg. per 100 ml. Intravenous calcium gluconate was given, and calcium lactate, 10 gr. (0.65 g.) three times a day was combined with para-thor-mone, 25 units four times a day. Forty-eight hours later the serum calcium was 7.3 mg. per 100 ml. and 24 hours after this (January 21) it was 9.4 mg. per 100 ml. On January 24 her treatment was changed from para-thor-mone to dihydrotachysterol, 3 ml. daily by mouth. The phenobarbitone was continued. There were no fits during these six days.

On January 25 she had another left-sided fit, and on January 27 an attack which was witnessed in full. On this occasion the onset was with carpo-pedal spasm, and there was slight risus sardonicus before the spasm, and clonic movements spread to the whole of the left side. The serum calcium, estimated at the end of the attack, was 7.1 mg. per 100 ml. Dihydrotachysterol was increased to 4 ml. daily and extra milk was given in addition to calcium lactate. On January 29 serum calcium was 9.6 mg. per 100 ml. The left hemiparesis was now worse, and by February 4 a virtually complete left spastic hemiplegia, with gross sensory loss, was present. Cerebrospinal fluid was not examined, but skull x-ray films were normal. The electroencephalogram showed a localized slow-wave abnormality in the right parietal region.

It was thought that she probably had a metastasis in the right Rolandic area, but radioactive iodine showed no uptake in this region. On February 3 and 4 there was vomiting and regurgitation through the gastric tube, so that little, if any, of her dihydrotachysterol was retained. On February 6 she had two further focal motor fits in the left arm and leg. The serum calcium at this time was 6.1 mg. per 100 ml. As vomiting had subsided and she was now retaining her medicine, no change in treatment was made. Thereafter she had no further fits, but the hemiplegia and diminishing responsiveness called for a right parietal burr-hole biopsy, which established the presence of a tumour. During the next 10 days she deteriorated steadily, and she died in coma on February 16. Full necropsy was not obtained, but extensive infiltration of growth was seen at the site of operation in the neck, and the regional glands were involved. Histological examination of portions of the brain tumour was carried out, but its appearance was regarded as more that of a primary glioma than of a thyroid secondary, though clinically the latter was more likely.

Comment

This case showed clearly that a low serum calcium was an important factor in precipitating fits. When the serum calcium was maintained at normal or near-normal levels the fits did not occur; when it fell they reappeared. Moreover, the pattern of onset of the attacks, with carpo-pedal spasm, was also determined by the serum calcium level. The local lesion in the right hemisphere, however, appeared to dictate the further course of the fits, in which clonic movements were confined to the left side.

It provides an unusually clear demonstration of two precipitating factors, general and local, combining to produce symptomatic epilepsy. Electrolyte imbalance and local brain lesion can each of themselves produce an epileptic attack. Here a combination of the two seems to have been the necessary stimulus. Even when the cerebral tumour

was present and was probably actively expanding, fits occurred only when the serum calcium fell. It is of further interest that each of the two causal factors contributed recognizable features to the pattern of the attacks.

Summary

A case is described with a focal brain lesion and parathyroid deficiency in which fits of the focal pattern expected from the brain lesion occurred only when the serum calcium was lowered.

Our thanks are due to Mr. R. G. Macbeth and Dr. Frank Ellis for the opportunity of studying this case.

FAILURE OF PENICILLIN TO PREVENT
POST-OPERATIVE CHEST INFECTION

BY

EVAN GRIFFITHS, F.R.C.S.

Surgeon, Mid-Glamorgan Hospitals

Penicillin and other antibiotics have been widely used in recent years in an attempt to reduce the incidence of post-operative chest infection. There has, however, been considerable doubt about the efficiency of penicillin in reducing the incidence of these complications when given prophylactically, and many authors have pointed out that they still occur, despite advances in surgery and anaesthesia and the use of antibiotics.

Hasslinger (1956) reports a striking series of 443 patients who underwent partial gastrectomy. Of these, 153 were given prophylactic penicillin. The number of patients with post-operative febrile bronchitis was 23 in the penicillin group and only one in the group who were not given any prophylactic antibiotics. Again, McKittrick and Wheelock (1954) reported on a series of 60 patients submitted to gastrectomy; 36 were given prophylactic antibiotic coverage without any advantage being gained by its use.

This paper describes a clinical investigation undertaken in an attempt to assess the value of penicillin given prophylactically for the prevention of post-operative chest infections.

Methods

For 18 months patients undergoing operations in alternate months were given an injection containing procaine penicillin G, 300,000 units, crystalline penicillin G, 100,000 units, and dibenzylethylenediamine dipenicillin G, 200,000 units, at the same time as the pre-operative injection. Patients operated on in the intervening months received no prophylactic penicillin.

Emergencies were excluded from the series. Most of these emergencies required antibiotics for conditions other than chest infections. All cases requiring gut resection, or considered to need antibiotics by mouth for any reason other than chest complications, were also excluded, as were patients who were given antibiotics post-operatively for threatened or established peritonitis. All other patients were included in the investigation, a careful note being made of their history of bronchitis and their smoking habits.

Physiotherapy was standardized for both groups, being given as a routine before and after operation. Any chest infection which did develop was treated on its merits, antibiotics being prescribed when indicated.

The investigation was essentially a clinical one relying primarily on clinical and not x-ray assessment of the chest condition of the patients. All patients were examined

before operation and daily afterwards for three days. When a severe infection normally warranted a radiograph of the chest it was done, and all cases diagnosed clinically after operation as atelectasis or consolidation were verified by chest films. It was not thought necessary to rely on films to assess the pre-operative chest category in the absence of physical signs.

Estimation of what constitutes a post-operative chest infection is not easy. Following the procedure used by Ellis and Shooter (1952), patients were placed before and after operation into one of the following five categories: group 1, normal; group 2, with cough, but without sputum or physical signs; group 3, with cough and sputum, but without physical signs; group 4, with cough, sputum, and physical signs of infection; or group 5, with a definite pulmonary lesion such as consolidation or collapse.

Patients were regarded as having a post-operative chest infection if, after operation, there were respiratory signs and symptoms that were not present before operation. A change of one step between pre-operative and final post-operative chest grouping was considered to indicate a mild post-operative chest infection, whereas a patient whose post-operative chest category was two or more grades worse was assessed as having a severe post-operative infection.

Results

The particulars of patients included in this investigation are given in Table I, which shows that in respect to the items recorded the two groups were comparable.

TABLE I.—Particulars of Patients in the Investigation

	No. of Patients	No. with History of "Bronchitis"	No. of Smokers	No. of Females	Average Age
Penicillin series	219	21	90	104	42
No penicillin "	221	28	92	106	38

Briefly, the main operative procedures undergone by the patients in the two groups were: (1) hernia operations of all kinds; (2) gall-bladder and common-duct procedures; (3) interval appendicectomies; (4) laparotomies, excluding gut resections; (5) operations on the sympathetic nervous system; (6) thyroidectomies and other general surgical procedures on the head and neck; (7) general surgical procedures on the limbs, such as ligation of varicose veins; (8) minor operations on breast and chest wall; and (9) minor ano-rectal and bladder procedures.

The complete results are given in Table II, which shows the correlation between the pre-operative and post-operative grading. The numbers between the heavy lines are those of patients with a mild (one-stage) post-operative infection, the numbers printed in italics are those with a severe (two stages or more) post-operative infection. It will be seen that an appreciable number of patients in each group had a lower grading after the operation. The results shown in Table II are summarized in Table III. A study of this table shows that the penicillin group did in fact do very slightly better than the control group, but that the difference was exceedingly small, and a statistical test shows that it could have easily occurred by chance.

On further analysis these results were shown to hold good if the comparison was applied separately to smokers and

TABLE II

Pre-operative Grading	Penicillin Group						No-penicillin Group					
	Post-operative Grading						Post-operative Grading					
	1	2	3	4	5	Total	1	2	3	4	5	Total
1	133	12	14	5	5	169	142	18	17	9	2	188
2	8	6	1	3	—	18	5	6	2	—	—	15
3	3	1	7	—	—	11	2	1	8	3	—	14
4	2	—	2	15	2	21	0	—	1	3	—	4
5	—	—	—	—	—	—	—	—	—	—	—	—
Total	146	19	24	23	7	219	149	25	28	17	2	221

non-smokers. It cannot be concluded from these figures that penicillin reduces the risk of post-operative chest infections when given immediately before operation.

TABLE III

	Penicillin	No Penicillin
Severe post-operative chest complications	27	30
Mild post-operative chest	15	23
No change post-operatively	161	159
Post-operative improvement	16	9
Total	219	221

Summary

An attempt has been made to assess the value of penicillin given to prevent post-operative chest infection. Comparing two similar groups, one given penicillin before operation and one not, no evidence has been obtained that penicillin is useful for this purpose.

I am indebted to Dr. R. A. Shooter for advice during this investigation and the preparation of this paper, also to Mr. M. P. Curwen for statistical assistance. I also thank many of the resident surgical staff at the Bridgend General Hospital for their willing co-operation.

PRIMARY AMYLOIDOSIS PRESENTING WITH A CONFUSING CLINICAL PICTURE

BY

IAN N. LEE, M.B., B.S.

Late House-physician, the Middlesex Hospital

It is well known that primary amyloidosis closely resembles other diseases. It can affect most organs, giving rise to a clinical picture which is often indistinguishable from that produced by a more common disease. When several unrelated organs are affected multiple diagnoses are often made.

The heart by itself or in company with other organs is most commonly involved, such cases usually presenting with congestive heart failure (Eisen, 1946; Lindsay, 1946). The picture may simulate that of failure due to cardiac ischaemia or constrictive pericarditis (Mathews, 1954), but often no obvious cause of failure is found.

Liver disease, often suggestive of cirrhosis, is a frequent mode of presentation. Nephrosis is another common presenting syndrome (Mathews, 1954). The alimentary tract is also a frequent site of infiltration, and a diagnosis of carcinoma may be made in these cases (Koletsky and Stecher, 1939). A sprue-like picture also occurs sometimes (Steinhaus, 1902; Golden, 1945; Adlersberg and Schein, 1947; Schein, 1947; Finley and Adams, 1948). Carcinoma of the lung (Koletsky and Stecher, 1939; Dirkse, 1946) and even of the bladder have been simulated by this disease on occasion. Arthritis and osseous disease have also been reported (Mathews, 1954). Peripheral neuritis is frequently present (De Navasquez and Treble, 1938; Götze and Krücke, 1941; Finley and Adams, 1948), but is often mild and apt to be missed.

The present case is of interest, because it prompted three different diagnoses, besides peripheral neuritis, before the true nature of the disease was established.

Case Report

The patient, a man aged 50, had had no illnesses of note until 1955, apart from a duodenal ulcer for which a gastro-enterostomy had been performed in 1942. In August, 1955, he developed a sensation of food sticking in the epigastrium after meals, with regurgitation of food and anorexia. He was admitted to a hospital, where hepatomegaly was noted. A barium-meal examination revealed a rigid stomach, suggestive of carcinoma. Gastroscopy showed a rigid mucosa and absent pyloric peristalsis. A diagnosis of carcinoma of the stomach was made, but subsequent laparotomy failed to confirm this. Liver biopsy taken at the time was thought to show a pericellular fibrosis. He was sent to a convalescent home in January, 1956, where he developed swelling of his legs with pain and numbness in his left foot and an increase in the size of his abdomen. He attended the out-patient department of the Middlesex Hospital in March, 1956.

On examination he appeared to be wasted, with early clubbing of the fingers, dilated and pulsating neck veins, gross hepatic enlargement, considerable ascites, and oedema of both legs, scrotum, and anterior abdominal wall. The heart appeared to be of normal size, gallop rhythm was not heard, and there were no significant cardiac murmurs. A tentative diagnosis of constrictive pericarditis was made, and he was admitted on March 10.

Investigations.—The venous pressure was 160 mm. of blood, the circulation time (arm-tongue) 30 seconds. The electrocardiogram showed a low-voltage curve with T wave inversion over the left ventricle, suggestive of pericardial change. X-ray examination of the chest showed a slightly enlarged heart, with no pericardial calcification, which pulsed normally on screening. The urine contained a variable quantity of protein from day to day (1–14 g. per litre), but Bence Jones proteose was not present. The haemoglobin was 103% (Haldane) and the white-cell count was normal. The total plasma proteins were 4.5 g. per 100 ml. (albumin 2.1 g., globulin 2.4 g.). The serum bilirubin was 0.6 mg. per 100 ml.; serum alkaline phosphatase 6.2 K-A units per 100 ml.; and serum acid phosphatase 7.2 K-A units per 100 ml. The flocculation tests were all within normal limits. The bromsulphthalein excretion was grossly impaired. The blood urea level was 29 mg. per 100 ml., and the serum cholesterol 260 mg. per 100 ml.

After consideration of these results the diagnosis of constrictive pericarditis was changed to one of severe parenchymal liver disease associated with congestive heart failure of unknown aetiology.

On closer inquiry into the patient's social history, it was found that he had been a wine-waiter for 20 years, and that for some years before the onset of his symptoms his alcohol intake had been excessive and his diet inadequate. This, together with some of the biochemical findings, suggested a diagnosis of portal cirrhosis. The symptoms and signs in the left foot were thought to be those of peripheral neuritis.

The previous liver biopsy was then reviewed and the possibility of amyloid disease was suggested. The section, however, showed so much autolysis that histological diagnosis was uncertain. A Congo-red uptake test was positive, the one-hour sample containing only 30% of the dye in the four-minute sample, with only a trace in the urine. A further liver biopsy by needle confirmed the diagnosis of amyloid disease.

While investigations were being carried out the patient was treated on the usual lines for congestive heart failure, with digitalis and diuretics. This was only moderately successful. Cortisone therapy was contemplated, but the patient died on April 3, before this was begun.

Post-mortem Findings

At necropsy bilateral pleural effusions, gross ascites, and a small pericardial effusion were found. The heart was slightly enlarged and the myocardium was of a waxy consistency.

The coronary vessels were relatively free of atheroma. At the lung bases there was some bronchopneumonic consolidation, but no evidence of tuberculosis or bronchiectasis was found.

The liver was grossly enlarged, weighing 74 oz. (2,100 g.). It was firm and waxy. The cut surface was pink, due to staining with Congo red. The lining of the stomach was also of a very striking pink colour throughout, and so to a lesser extent was the lining of the small intestine. The large intestine did not show any staining with Congo red. The spleen was small but firm and waxy. The kidneys appeared normal macroscopically. None of these organs gave the typical colour with iodine. Thrombosis of the superior mesenteric and left common iliac arteries was also found.

Microscopically the myocardium, liver, spleen, stomach, and small intestine were found to contain a large quantity of amyloid, which did not stain typically with methyl violet. The kidneys were only mildly affected.

Discussion

Wilks (1856) was the first to differentiate primary amyloidosis ("simple lardaceous disease") from the more common secondary variety, originally described by Rokitsky (1842). It was not until 1929 that Lubarsch described the different histological characteristics of primary amyloid.

A search through the literature has revealed 145 previously reported cases. Only 29 of these were diagnosed correctly in life. The reason for the lack of correct diagnosis in the remainder of cases is not far to seek. Probably the most important factor is the close resemblance to more common diseases which primary amyloidosis often shows. The clinical picture thus produced is, however, only rarely absolutely typical, and often several unrelated syndromes are present. Analysis of the literature suggests that primary amyloidosis should be suspected in cases of congestive heart failure of unknown cause and in patients presenting with what appears to be a collection of unrelated conditions, especially if some peripheral nerve involvement is also present. Idiopathic macroglossia often occurs in this disease, and when present is an important physical sign.

It is in the laboratory investigations that the other main difficulty is met. Primary amyloid material has very much less constant staining reactions than the secondary variety (Lubarsch, 1929; Koletsky and Stecher, 1939). It frequently fails to show the staining reactions with Congo red, iodine, and methyl violet. Thus the *in vivo* Congo-red uptake test is negative in over 50% of cases, through failure on the part of the amyloid to take it up (Eisen, 1946; Mathews, 1954), though some authors believe that the liver needs to be affected for this test to be positive (Jackson and Slavin, 1954). If a biopsy of the organs concerned can be done this will usually confirm the diagnosis, but again the absence of typical staining reactions must be borne in mind.

A high serum alkaline phosphatase level is usual in this disease, and is a useful diagnostic aid if other causes for this finding can be excluded (Gutman, 1955). The albumin/globulin ratio is stated to be reversed even in cases with purely cardiac involvement (Jackson and Slavin, 1954).

The aetiology of this disease is very obscure and theories of causation vary greatly, including unrecognized plasmacytomas (Apitz, 1940), non-bacterial hypersensitivity states (Lindsay and Knorp, 1945), and a collagen type of aetiology (Ehrich, 1952).

On the basis of the last theory corticotrophin therapy has been advocated (Jackson and Slavin, 1954). Cortisone has been tried, but without apparent effect (Williams, 1955), and there is some experimental evidence to show that corticotrophin and cortisone in fact increase the production of amyloid in animals with suppurative affections (Peräsalo and Latvalahti, 1954). Thyroid extract seems to have some inhibiting property. Success has been reported in cases of secondary amyloidosis with desiccated liver (Grayzel and Jacobi, 1938), but no attempt to treat the primary disease by this method has so far been recorded.

The congestive heart failure in these cases, if present, is very resistant to digitalis and diuretic therapy.

Summary

The remarkable similarity of the symptoms of primary amyloidosis to those of other conditions is shown by the 145 cases cited from the literature, of which only 29 were diagnosed correctly in life, the remainder being ascribed to a variety of more common diseases. The patient whose case is described above was believed to be the victim of several different conditions before the correct diagnosis was established.

The main diagnostic difficulties are attributable to the extremely variable clinical picture, the close resemblance to other more common diseases, and the frequency of non-specific staining reactions.

I thank Dr. G. D. Hadley for permission to publish this case and for his help in preparing the article. I am indebted to Dr. W. Richardson, of the Bland-Sutton Institute of Pathology, for the post-mortem and histological reports.

EPIDEMIC OF MENINGOENCEPHALITIS AND BORNHOLM DISEASE

BY

H. G. LANGDALE-SMITH, M.B., Ch.B.

D. M. LANGDALE-SMITH, M.B., Ch.B.

AND

B. R. WILKINSON, M.B., B.S.

The occurrence of a localized epidemic of meningo-encephalitis and Bornholm disease during the latter part of the summer of 1956 has provided an exceptional opportunity for studying the conditions clinically, tracing the possible sources and spread of infection, and considering the problems of immunity. The study has been purely on clinical grounds; the bacteriological aspect is still being investigated.

The relationship between meningitis and Bornholm disease has been reported on previous occasions (Howard *et al.*, 1943; Finn *et al.*, 1949; Warin *et al.*, 1953), but, except for an outbreak in Sweden, meningeal involvement has been noted in less than 10% of patients in large epidemics. A Swedish group of investigators (Gabinus *et al.*, 1952) have described an outbreak of Bornholm disease with a high incidence of aseptic meningitis associated with Coxsackie virus group B type 3. They

advanced a hypothesis that the virus entering a highly susceptible population affects persons of all ages, with pleurodynia and myalgic symptoms as predominating features, especially amongst older children and adults; on the other hand, in a relatively immune population, where children are primarily affected, aseptic meningitis may be a prominent feature. Our own findings on clinical grounds tend to support this theory.

Present Epidemic

The epidemic occurred within a radius of about 1½ miles (2.4 km.) in the small hamlet of Stretton Grandison (population 550) and Eggleton (population 133), and was centred at the school. The early cases during August and September were of Bornholm disease. This epidemic merged at the end of September into an outbreak of meningoencephalitis, centred largely in Stretton Grandison school. At the end of October encephalitic cases became fewer and Bornholm cases again reappeared.

An interesting feature of the epidemic was that three groups of cases were observed: (1) typical Bornholm disease, (2) typical encephalitis, and (3) a small group of intermediate cases. The Bornholm cases appeared to be related to an epidemic of this disease occurring in the neighbouring Bromyard district.

These cases showed a sudden onset with excruciating abdominal and thoracic pain (Devil's grip), accompanied by great prostration. The thoracic pain was aggravated on respiration, and the patients often feared to move. The infection lasted from two to ten days, and the adults were prone to relapse. The incubation period was two to ten days, often five.

The encephalitic cases appeared to be similar to those occurring in other parts of the country—"Nottingham meningitis." These cases often had a prodromal period of several days of lassitude and anorexia, but perhaps more frequently the onset was sudden, with severe frontal headache, pyrexia, vomiting, neck stiffness, and photophobia. The headache in some cases was paroxysmal and devastating. In a few cases a rash was observed with an erythema of wide distribution or a local macular rash. Sore throat and sore mouth were present in a few cases in the prodromal or acute phase. Coryzal symptoms were also noted in a few instances. Clinically either neck stiffness or a positive Kernig's sign was found. C.S.F. findings in the cases subjected to lumbar puncture showed an increase in lymphocytes.

The intermediate cases occurred in houses where there was already one type of case. In these cases there was headache and vomiting but no photophobia or neck stiffness.

A "Pickles chart" shows that the incidence increased until the end of September and beginning of October, when a peak was reached (Fig. 1). This peak was due to the explosive outbreak at Stretton Grandison school.

Altogether 52 subjects were affected: 27 with meningoencephalitis and 17 with Bornholm disease; 8 were intermediate cases. Of the 52 cases 25 occurred at the school, where there were 47 children (see Table). Of these 25, 15 were meningoencephalitis, 3 intermediate, and 7 Bornholm disease.

FIG. 1—Incidence of cases (August–November, 1956).

Incidence at School

	Boys	Girls	Total	No. Affected
Juniors	8	11	19	8
Infants	18	10	28	17

The following possible sources of infection have been considered. (1) The neighbouring Bornholm epidemic (with a possible change of type, or mode of action of the virus producing the encephalitic features). (2) Introduction from the influx of "travellers" (hop- and fruit-pickers) which occurred in August. (3) From mice, fleas, lice—but they appear to have played no part. (4) From food and water at the school. The food seems to be beyond suspicion, but is handled by the wife of the latrine attendant. The water has been condemned for three years and is boiled before use. Recently two brothers, young active farm-workers in this area, contracted poliomyelitis simultaneously. From the history it seemed probable that they contracted the disease from contaminated food. Barber (1938) described an epidemic of poliomyelitis in a school where the source of the infection seemed to resemble that of food-poisoning. There does not, however, appear to be any direct evidence of food contamination in the present epidemic.

The spread of infection seems to have been by direct contact, by finger-mouth route. This is supported by the plan of the seating arrangements at the school. The school is a mixed one, with two classes only. The seating arrangement in the infants' class (where there was a larger proportion of cases) is not constant. In the junior class the children adopt a permanent seating arrangement, and all the cases occurred in one section of the room only (Fig. 2).

The children have their meals at the school desks.

Where children seemed to contact a massive infection, as in the school, a large proportion contracted the disease. In the homes the attack rate seemed to depend on susceptibility. It is remarkable that some adult males seemed to be particularly susceptible and developed very severe attacks. This may explain how sporadic cases appear. In one house all five members contracted the infection, but in another of 14 members only one contracted the disease.

In the school the vast majority of cases were of encephalitis, with only a few Bornholm and intermediate cases. Several home contacts of the encephalitic cases developed Bornholm disease. In one family the father and three children had typical encephalitis, and the mother had a very typical Bornholm disease. In another family the mother and one child had Bornholm disease, another had encephalitis, and the father had an intermediate condition.

It is interesting to note that in the neighbouring schools of Yarkhill and Ashperton no cases occurred, although the Stretton Grandison children travel on the same bus as the Ashperton children.

Two children who had a benign encephalitis in 1955 developed Bornholm disease during the epidemic. No children in the school have been vaccinated against poliomyelitis, and so the relationship of this to the development of immunity could not be studied.

The Research Laboratory at Colindale have so far isolated a cytopathogenic agent (not poliomyelitis) from the cerebrospinal fluid or faeces of 10 cases.

Summary

An attack of Bornholm disease and encephalitis is described clinically and an attempt made to link the two conditions on epidemiological grounds. A similar outbreak in Sweden is mentioned for comparison.

We are indebted to the following for help received in studying this epidemic and compiling the data: Dr. J. S. Cookson, Dr. W. Hogg, Dr. A. T. Roden, of the Ministry of Health, and Dr. D. R. Christie.

Medical Memorandum

Three Cases of Torsion of the Testis

Torsion of the testis is uncommon, and when it has a gradual onset it can easily be mistaken for acute epididymitis. Three new cases are recorded which emphasize the difficulties in early diagnosis described in full by Kennedy (1948) and Walton (1952).

CASE 1

A private soldier aged 19 woke with pain and swelling in the left testicle. Four and a half hours later he was referred for admission as a case of acute epididymitis. On examination he was afebrile and not in severe pain. The left side of the scrotum was swollen, red, oedematous, tender, and faintly ecchymosed round its neck. The skin was not adherent to the testis. Lifting the scrotum made no difference to the pain. Through a shallow hydrocele the epididymis could just be made out, lying anterior to the testis. The cord and opposite testis were normal. Examination per rectum and of the urine showed nothing abnormal.

Operation.—The testicle was delivered through a left inguinal incision. The hydrocele contained blood-stained serous fluid. The testis and epididymis were congested, with petechiae and subserous haemorrhages, and were rotated on a narrow pedicle through 180 degrees. After untwisting the testis the colour gradually returned. The surplus tunica vaginalis was resected, and after the testis was replaced the wound was closed without drainage.

Post-operative prophylactic streptomycin was given for 48 hours. Recovery was uneventful. Six weeks later the testis and epididymis were found to be normal in size, position, and consistence.

CASE 2

A lance-corporal aged 20 had intermittent sharp pain in the left loin whilst lifting heavy crates. Two days later the left testicle began to ache, and the next day it became swollen, and a diagnosis of acute epididymitis was made elsewhere. He was admitted on the following day. On admission he remembered three identical attacks in the last four years, during the first of which his appendix was removed. On examination he was afebrile. There was a red tender oedematous swelling of the left scrotum, the skin of which was not bruised or adherent to the testis. Elevation made the pain worse. The testis was indistinguishable from the epididymis; a tense hydrocele was present, and the cord was swollen and tender. Examination per rectum and of the urine showed nothing abnormal.

Operation.—Through a left inguinal incision an elongated tense purple hydrocele containing serofibrinous fluid was delivered. The testis and epididymis were attached at their upper pole by a rounded pedicle which had been twisted through almost one complete turn. The testis was pale, cyanosed, and black at its inferior pole, and the epididymis was congested and haemorrhagic. The vas deferens made a long loop in the parietal layer of the tunica vaginalis, which therefore could not be resected. When the colour was restored the testis was replaced in the scrotum and sutured to the dartos, and the skin closed without drain-

age. Prophylactic streptomycin was given for two days. Recovery was uneventful. One month later the testicle was normal in size and sensation.

CASE 3

A private soldier aged 21 was admitted complaining of lower abdominal pain and nausea for four days and swelling and pain in the right testicle for two days. Acute epididymitis had been diagnosed and sulphonamides had been given for two days before admission. On admission he was afebrile, and the only abnormal finding elsewhere was a scar, from tuberculous glands in the right side of his neck when he was 8. The left testis was normal. The right side of the scrotum was swollen, oedematous, red, and tender, and the testis and epididymis were indistinguishable in a tense hydrocele which adhered to the skin. Elevation made the pain worse. Examination per rectum and of the urine revealed nothing abnormal.

Operation.—Through a right inguinal incision a black hydrocele containing a haemorrhagic effusion was delivered. The testis had rotated anticlockwise through one and a half turns and was cyanosed and soft, while the epididymis resembled a clot of blood. Twenty minutes after untwisting the testis its colour had scarcely improved, but it was returned to the scrotum, and after dusting with penicillin-sulphathiazole powder the skin was closed without drainage.

Prophylactic streptomycin was given for five days afterwards, and recovery was uneventful. One month later, at a second operation through a small scrotal incision, the left testis was sutured to the areolar tissue of the scrotum. Eight weeks later both testicles were found to be normal in size, consistence, and sensation, and the patient was enjoying normal intercourse with his wife.

COMMENT

In adolescent boys "epididymitis" must be regarded as torsion of the testis or its appendix until proved otherwise (Dix, 1931). It is no less important to find good reason for a diagnosis of epididymitis in older patients, for many cases of torsion give a misleading history, lacking the story of trauma, abdominal pain, and vomiting of classical description (Kennedy, 1948). In early cases the local signs are ambiguous, swelling, redness, oedema, and hydrocele being common to both conditions, and unless seen very early the abnormal relations of the parts are obscured by swelling and pain. Dillon's sign (tethering of the skin in torsion) can occur in either condition, and elevation of the scrotum is of doubtful value, being painful whenever the scrotum is tender. Torsion is equally common on either side (Kennedy, 1948), and fever may occur with either condition.

The only reliable guide is the presence or absence of urinary infection, so a careful examination of the urethra, prostate, vesicles, and urine must be done in each case. If there is still any doubt then one should explore, rather than wait until gangrene of the testis makes itself plain. The different estimates of the survival time of the organ (Walton, 1952; Bailey, 1953) can only be a rough guide, because the tightness of the twist may vary from case to case. It is never safe to wait.

If operation is done in time the testis can be untwisted. A frankly gangrenous testicle is usually removed, but a doubtfully viable organ should, I feel, be restored, for it may recover against every expectation, as did Case 3.

If the underlying anomaly—abnormal mobility of the testis within the tunica vaginalis—is bilateral, the other testicle will be apt to twist. If one is already damaged, or absent, this risk should be explained to the patient and the remaining testicle made secure at a later operation, if he wishes.

J. P. BLANDY, B.M., B.Ch.

Reviews

FREUD CENTENARY ADDRESSES

Sigmund Freud—Four Centenary Addresses. By Ernest Jones, M.D. (Pp. 150. 18s.) New York: Basic Books Inc. London: Tavistock Publications Ltd. 1956.

When the centenary of Freud's birth was celebrated last year it was inevitable that Dr. Ernest Jones should be asked to give a number of commemorative addresses, and this book puts them on record. With his unique knowledge of the man and his work, and immersed as he has been in his great biography of Freud, it would have been easy for Dr. Jones to have restricted himself to aspects of Freud's personality or of psycho-analysis. The addresses, however, present reflections on topics which, though stimulated by the occasion, have a more general appeal. In the first, on "The Nature of Genius," the author reviews the literature and then adds a "modest contribution" on what he suggests is a characteristic feature of the genius as contrasted with the man of great talent—namely, the coexistence of a particular scepticism and a curious credulity. Intellectual gifts of a high order are often combined with scepticism; but it is a credulous streak that seems to assist in the birth of fundamentally new viewpoints, as is neatly illustrated in a comparison between Huxley and Darwin, though, as the author notes, there is a common tendency to ignore the manifestations of this credulity in the biographies of geniuses. (It was this first address, incidentally, which the author delivered so memorably in London, and not the second one as is stated in the book.) The second address deals with "Our Attitude Towards Greatness"; the third, on "Psychiatry Before and After Freud," gives a broad consideration which must be of interest to every psychiatrist. Following these three addresses is the shorter broadcast talk given last May; and finally there is reproduced most of the author's appreciation of Freud written at the time of his death. These addresses, as would be expected from Dr. Jones, are both substantial and well written, and, along with the beautiful production, make this a delightful book.

J. D. SUTHERLAND.

DEMONIACAL POSSESSION

Schizophrenia, 1677. A Psychiatric Study of an Illustrated Autobiographical Record of Demoniactal Possession. By Ida Macalpine, M.D., and Richard A. Hunter, M.D., M.R.C.P., D.P.M. (Pp. 197+ix; illustrated. £6 10s.) London: Willam Dawson and Sons Ltd. 1956.

In 1677 Christoph Haizmann, a Bavarian painter, began to suffer from convulsions and frightening visions, especially "when he had drunk a little too much wine." He confessed that eight years before, after the death of a relative ("ex morte parentis"), he had sold himself to the Devil, and feared now that the Devil would soon claim his due. He went to the Brothers of a Holy Order at Mariazell in Austria and begged them for help. After three days and nights of exorcism he saw the Devil at the altar. Tearing himself from the restraining hands of the priests, he rushed to the spot and returned with a piece of paper, rolled into a ball and torn into four pieces, on which was written his pact with the Devil in 1669. The painter's illness then improved, though a second exorcism was necessary the following year. Afterwards joining a religious order, he wrote the story of his encounters with the Devil and illustrated it with nine paintings.

In 1923 Freud analysed this case of "demoniacal possession," assuming that—as in Schreber's autobiographical account of his "paranoia" which Freud had analysed in 1911—a passive homosexual attachment to the father (or the Devil as a father-substitute) could be discerned here as well. In order to show that Freud had based his views on selected and partially misconceived evidence Dr. Macalpine and her son, Dr. Hunter, had previously published a translation of

Schreber's memoirs. In this volume they present photographic copies and translations of the original manuscript, as well as of the original paintings which recorded the painter's meetings with the Devil. We must be grateful to the authors for having made this material available. It is obvious that the data are so scanty that no kind of dynamic interpretation or diagnostic evaluation can be based on them. It is interesting to learn that Freud had assumed that "ex morte parentis" indicated the death of the father, in spite of its equivocal meaning; and that he had been unaware that, in mediaeval paintings, the Devil was frequently depicted as having conspicuous, or even multiple, breasts. The authors' further claim that concepts of libido and transference are less essential than concepts indicating the patient's disturbed experience of himself is hardly supported by their arguments, which fill the greater part of the book.

F. K. TAYLOR.

NEUROLOGICAL NURSING

Neurological Nursing: A Practical Guide. By John Marshall, M.D., M.R.C.P.Ed., M.R.C.P., D.P.M. (Pp. 166; illustrated. 18s. 6d.) Oxford: Blackwell Scientific Publications. 1956.

Not only does the nursing of neurological patients present a special problem because of the disorders of movement and of sensation to which they may be subject, but so many of the diseases that they have are of such slow progression that their care calls for special skills and attitudes. The investigation of the cause of disease in these patients includes such procedures as injection of air and opaque substances into the cerebrospinal pathways and the use of increasingly complex electronic methods of diagnosis. In all these procedures the active and intelligent co-operation of nurses is essential. In treatment, too, the nurse forms an integral part of the team, whether in prolonged reablement or in the techniques of neurological surgery. The viral diseases, of which poliomyelitis is the striking example, make special demands on the initiative and knowledge of nurses who constantly attend patients in a variety of forms of respirator—patients who may have a tracheotomy or an associated pulmonary disorder.

In the last ten years courses in this specialty of neurological nursing have been carried out in special centres, and this practical textbook will be most valuable both to those who conduct and to those who attend them. There is a good deal in it that the neurological physician takes for granted or has forgotten, but which can make so much difference to his peace of mind as well as to his patients' welfare. In thirteen short chapters Dr. Marshall covers most of the aspects of management of the patient with neurological disease, including his psychological well-being and his social care.

DENIS WILLIAMS.

VASCULAR DISEASES

Diagnosis and Treatment of Vascular Disorders (Angiology). Edited by Saul S. Samuels, A.M., M.D., F.A.C.A., F.A.C.C. (Pp. 621+ix; illustrated. £6 8s.) London: Baillière, Tindall and Cox, Ltd. 1956.

This book by seventeen contributors under the editorship of Dr. Saul S. Samuels deals with disorders of the peripheral vascular system, and on the whole succeeds in giving a clear and up-to-date account of those abnormalities. To British readers it is of interest that four of the contributors are from the Commonwealth (Boyd, Goetz, Ratcliffe, and Rose), and these four have written more than one-third of the book. The chapters by the editor on thromboangiitis obliterans, by Simeone on vascular injuries, and the four chapters by Goetz are all good. Unfortunately, the chapter on angiography is below the standard of the rest of the work. In the first place, too wide a field is covered. To try to include angiocardiology has meant the exclusion of many other techniques, including lymphangiography and the percutaneous techniques of arterial catheterization. And in the second place one gets the impression that this chapter was written several years ago. Perhaps these authors got

off the mark quickly and submitted their sections too long before the other contributors had written theirs. The authors of this chapter also have a different conception of the scope of the book from the editor; in addition to angiocardiology they discuss cerebral arteriography and portal venography, but nowhere else in the book is there a discussion of lesions of these vessels.

In the preface the editor states that he originated the term "angiology" to cover the specialty of vascular medicine and surgery. In my view this is a good term, but it is very difficult to decide upon its scope. Are the diseases of all the blood and lymph vessels in the body to be included? Theoretically yes, but in practice no. The intracranial vessels, for example, are part of neurosurgery, not angiology, although the cervical carotid arteries—not discussed in this book—are, I think, part of angiology. In this book the diseases of the aorta and the blood vessels to the limbs have been discussed, and this must be taken as the editor's conception of angiology—that is, diseases of the peripheral vascular system. As such it is good and should have a wide appeal, and it is recommended.

CHARLES ROB.

ANAESTHESIA IN HEART SURGERY

Anesthesia for Surgery of the Heart. By Kenneth K. Keown, M.D., F.A.C.A. (Pp. 109+xiv; illustrated. 27s. 6d.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1956.

The author is anaesthetist at the Hahnemann Hospital and the Bailey Thoracic Clinic, and therefore this book was received with keen interest. The preface states that no attempt is made in the book to include a detailed step-by-step description of techniques for anaesthetic management. The reviewer was disappointed to find only a very superficial account of the anaesthetic techniques used. The methods described differ in important details from those used in leading centres in Great Britain. The author reiterates the importance of postponing operation whenever hypotension follows induction of anaesthesia, and repeatedly emphasizes the beneficial effects of inhalation of pure oxygen during anaesthesia for cardiac operations.

The best parts of the book are those describing the pathology of the various cardiac diseases. In each case there is a succinct account of the mechanism of circulatory derangement. There are several notable omissions. Pericardectomy and operations for aortic aneurysm are not mentioned. A section on anaesthesia for diagnostic procedures should have been included, and a description of the management of cardiac arrest would be a valuable addition. It was disappointing to find that hypothermia and cardio-pulmonary by-pass receive only passing mention. The style is often cumbersome, so that the meaning is difficult to follow—for example, "Blood loss from haemorrhage is an excellent example of the needed teamwork for an outcome that will be successful for the patient" (p. 36). Unfortunately there is no index, so that the claim to be a "Ready reference for anesthesiologists" (publishers' note on dust cover) is not substantiated. In view of its small size the price of this book is rather high.

C. F. SCURR.

MEDICAL TREATMENT OF HEART DISEASE

Treatment of Heart Disease: A Clinical Physiologic Approach. By Harry Gross, M.D., F.A.C.P., and Abraham Jezer, M.D. (Pp. 549+x; illustrated. 91s.) Philadelphia and London: W. B. Saunders Company. 1956.

In recent years there have been so many books written on so many aspects of cardiovascular disease that the authors of this one start their preface by posing the question, Why another? Perhaps a critic is in a better position to answer this question than the authors: quite simply one might say because this is probably the best modern book on the medical treatment of heart disease written in the English language. It is remarkably informative, accurate, concise, comprehensive, up to date, and restrained; it is also nicely

written and well produced. The authors have not been able to resist wandering into the neighbouring and inviting fields of pathology, physiology, clinical features, and diagnosis, on the plea that rational treatment commands these excursions, and on the whole such breaks are refreshing. The first chapter, on the pathologic physiology of myocardial insufficiency, condones any subsequent philandering. Appended are a variety of useful diets the ingredients of which are comprehensible to British residents; and 12 pages of appetizing low-sodium recipes left one speculating whether it was Dr. Gross or Dr. Jezer who had the personal interest in these matters.

PAUL WOOD.

VIRUS DISEASES AND THE CARDIO-VASCULAR SYSTEM

Virus Diseases and the Cardiovascular System. A Survey. By Ernest Lyon, M.D. (Pp. 215+viii. \$5.75.) New York and London: Grune and Stratton. 1956.

The author has produced a comprehensive review of his own and other published work on virus diseases, with special reference to the cardiovascular system. The book is arranged in two parts. Part I deals with the general manifestation of virus diseases and with the present concepts of cardiovascular involvement, while the second part covers individual virus diseases in detail. Undue concentration upon the cardiovascular system has been avoided and the whole picture of each disease is presented. There is a useful and full bibliography at the end of each chapter. Unfortunately the style of the text makes it rather difficult to follow, while the inclusion of some illustrations would have added greatly to the value of the work. But the section on the present concepts of cardiovascular involvement in virus disease is worthy of special attention, and the book should be noted by all who are interested in the subject.

J. F. GOODWIN.

Justly renowned for his translations of Chinese literature, Mr. Arthur Waley again puts English readers in his debt by a delightful biography of an eighteenth-century poet, *Yuan Mei* (Allen and Unwin Ltd., 21s.). China, or least the China of its classical literature, was a country where friendship was exalted above the more turbulent passions that have fired many European writers, and contemplation of nature the source of life's deepest pleasures. The feeling in many of the poems that Waley presents here is well evoked in the phrase from one of them: "All my life moonlight and snow are the things I have loved best." That this is a poetic rather than a literal expression of Yuan's impulses is evident from the biographical details that Waley gives us, for the poet, like many another, was rather a libertine. Of special interest to medical men is the glimpses this book gives of the medicine practised in eighteenth-century China. It was by no means primitive, and, though evidently rather different from the medicine of eighteenth-century Europe, it seems to have been no more irrational.

In the John Matheson Shaw Lecture for 1955, delivered at the Royal College of Physicians of Edinburgh, Dr. C. A. H. Watts discusses neuroses in general practice and stresses the need for more accurate definition in surveys of psychiatric cases. He suggests a scheme of classification based on his own experience of these cases. He feels that the average doctor, with the spectre of the chronic hypochondriac in mind, tends as far as possible to avoid the treatment of psychiatric disorders. Dr. Watts also discusses various types of psychotherapy. The lecture has recently been published by the College, at 9, Queen Street, Edinburgh, price 3s. 6d.

The *Hospitals Year Book, 1957*, once again provides an up-to-date and authoritative guide to the hospitals in Great Britain and Northern Ireland, covering all aspects of administration and management. Particulars of blood-transfusion services, Government departments, statutory bodies, local authorities, etc., are included. The editor's annual review of hospital service developments deplores the fact that the Guillebaud Committee's recommendation for increased capital expenditure has not been accepted, pointing out that the need is particularly urgent in the mental hospital field. The *Year Book* is published by the Institute of Hospital Administrators, 75, Portland Place, London, W.1, price 52s. 6d.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY APRIL 6 1957

THE FIRST DECISION

Two important decisions were taken by the Council of the B.M.A. last week. It decided not to co-operate with the Royal Commission in present circumstances, thus accepting a recommendation from the G.M.S. Committee, a recommendation that will go also to the special Conference of Local Medical Committees and, from the Council, to the special Representative Meeting, both to take place in about three weeks from now. The interval will give time for reflection, and it is to be hoped that any who doubt the wisdom of the Council's decision will have their doubts dispelled during this interval. To take part in the work of the Royal Commission with its present terms of reference would be to acquiesce in the nullification of the two Spens Reports, to depart from the customary and proper method of negotiating terms and conditions of service with the Ministry of Health or through the Whitley machinery, and to agree that a Royal Commission is a suitable body to determine the remuneration of doctors working in a State medical service. And there is one point that must be made abundantly clear. Our negotiators have been authoritatively informed that the Royal Commission now set up is not a form of arbitration. Arbitration is excluded completely and absolutely. The Royal Commission, presided over by a business man and excluding doctors from its membership, is going to decide what doctors should be paid in the N.H.S. and how this payment should be kept under review. It is true that its recommendations may be rejected, or accepted in part or in whole, by the Government, and—it may be rash to assume—may be accepted or rejected by the profession. We say "rash," because Mr. Macmillan has already set a pattern of behaviour which bodes ill for doctors if they meekly accept it. Having said at one moment that an increase for junior hospital staff should be negotiated through a Whitley committee he then arbitrarily announces in the House of Commons what this increase is to be. This is dictation—the dictation of the employer to his employees. We know that in meetings of the profession registrars have sharply criticized this. But it is a sign of the ill-health of the N.H.S. that they have not—so far—made their protest public, for example, in letters to this *Journal*. They do not wish to prejudice their future in the

hospital service. In these circumstances they will be given the shelter of anonymity if they wish to protest.

We may be sure that the next step Mr. Macmillan will take will be to announce from the floor of the House of Commons that other doctors in the Health Service—excluding, as has been made clear, medical officers of health—will receive as from a certain date a certain percentage increase. Whatever the amount, the profession will find itself in a difficulty. For general practitioners such an addition will go into the Central Pool. For hospital staffs the various salaries paid will be automatically raised. But our colleagues in the public health service, who, if words mean anything, are included in the terms of reference, will get nothing. This is dictation. It is the power of the purse ruthlessly exercised by an all-powerful employer who is adopting autocratic methods that civilized people thought were outmoded. If the medical profession still preserves any sense of dignity, any sense of fair play, any concern for the welfare of future doctors, it will reject these methods with contumely. To co-operate with the Royal Commission under its present terms of reference would be to put expedient before principle. If the terms of reference were altered they would have to be examined afresh, but it is difficult to see how any terms of reference could alter the fact that a Royal Commission is not the proper body to negotiate terms and conditions of service of doctors in a State medical service. The Council of the B.M.A. has given the profession a firm and completely correct lead in refusing co-operation with the Royal Commission, and it is hoped that it will receive from all sections of the profession the unhesitating support this decision deserves.

THE SECOND DECISION

During the past several months dissatisfaction with the present National Health Service has mounted. From the appointed day in July, 1948, it has become progressively obvious that the machinery of the Service badly needs overhauling, and in the meanwhile doctors for the most part have become either rebellious or apathetic and cynical. These attitudes have been more or less concealed by the fact that in spite of all provocation doctors have gone on with their absorbing task of looking after sick people in what is called a Health Service. Their frustrations have been brought to a head, not caused by, the dispute over the present claim for fulfilment of the recommendations of the two Spens Committees. The Council of the B.M.A., which has long been aware of this state of affairs, has now decided to set up a Committee of Inquiry into the N.H.S. as a

whole. This is a courageous and wise move—courageous because the B.M.A. advised the profession in 1948 to enter the N.H.S., wise because the N.H.S. has in many respects fallen short of what even its severe critics thought might come out of it. Even if the Government gave the profession a 24% increase in pay to-morrow, the B.M.A.'s Committee of Inquiry would still go on. It will in effect complete the investigation begun in 1941–2 of the B.M.A. Planning Commission. This Commission, it may be recalled, produced a draft interim report. It produced no final report, but at the time allowed itself to be diverted from this by the publication in 1942 of the Beveridge Report which inaugurated the Welfare State in this country.

It is probably as well that the B.M.A. did not proceed to a final report in and immediately after 1942. The new committee of inquiry into the N.H.S. will now have the great advantage of direct experience of a system of medical care which has with ever-mounting cost been in existence for close on nine years. It will have the advantage of knowing the results of similar—but not identical—schemes in other countries, especially in the Commonwealth and in Europe. The membership of the committee will be widely based, and it will go beyond the Planning Commission set up in the early years of the last war by seeking the co-operation in its work of persons outside the medical profession: it will take the consumer of medical services into close consultation. The B.M.A. thus declares in advance that its intention is not just to recommend modifications to its advantage, not just to pursue selfish aims and objects. If the National Health Service is to evolve into something in which the profession can serve contentedly and from which the public can obtain the real benefits of modern medicine, much hard thought will be necessary. No one denies that there is much that is of value in the present N.H.S. What bedevils it is party politics: witness the stupid attempts of the past eighteen months to make some political capital out of the poliomyelitis vaccine. What we need is the minimum of interference with the individual practitioner of medicine, and the maximum responsibility for the individual hospital in the management of its own affairs. Medicine in its growing enforced subservience to the State machine is in real danger of becoming static, frozen in a series of servile attitudes. Medicine needs to be freed from much that is inhibiting in the present scene if it is once more to become free and dynamic in its responses to challenge. The N.H.S. needs to be subjected to what Mr. Dulles called an "agonizing reappraisal." The opportunity for this reappraisal has now been provided by the B.M.A. Council; and we may be confident it will be grasped eagerly.

VIRUS MENINGITIS AND ENCEPHALOMYELITIS

Infections which simulate poliomyelitis in one form or another have been recognized for a number of years. In Great Britain knowledge of them has grown particularly since the poliomyelitis epidemic of 1947. Usually they have come to be recognized as something distinct either because they fail to conform to the normal pattern of poliomyelitis, whether the major or minor illness, or because of unusual findings in the spinal fluid. G. H. Jennings¹ reported a series of cases of encephalomyelitis seen in North-west London in the summer of 1946 which in his opinion were caused by a neurotropic virus other than poliomyelitis. On the other hand the experience of the 1947 epidemic led others to believe that poliomyelitis was the most likely cause of a brain-stem encephalitis in this country.² The only definite evidence in support of this view was the identification of poliomyelitis infection in two fatal cases of encephalitis during 1947–8 which were reported in this *Journal*.^{3,4} This was ten years ago, when the investigation of virus infections was a complicated business. Fortunately a period of great development lay just ahead which was to have its effect on methods of laboratory diagnosis.

The first step came in 1948 from the small town of Cocksackie on the Hudson River, where G. Dalldorf and G. M. Sickles recovered from the faeces of two children acutely ill with paralytic poliomyelitis a new type of virus which produced disease in suckling mice.⁵ Cocksackie or C viruses were soon recovered from cases of aseptic meningitis, non-paralytic and paralytic poliomyelitis, and from apparently healthy individuals in many parts of the world.⁶ The following year came the important discovery that poliomyelitis virus would grow in tissue culture, and from being one of the most difficult viruses to handle it became one of the easiest. Current methods of virus isolation and antibody estimation provide highly reliable methods of diagnosis.⁷ As the technique of tissue culture developed, it soon became evident that a number of viruses isolated from the alimentary tract were not related antigenically to poliomyelitis, Cocksackie, or to any other known virus, and, being for the most part unrelated to human disease, they were termed "orphan viruses," a name which recently has been changed to the ECHO group of viruses (or enteric cytopathogenic human orphan viruses).^{8,9} Thus there exists a large mixed group of human enteric viruses—poliomyelitis, Cocksackie, ECHO, and probably other viruses as well. The task now is to make use of new techniques to define the exact relationship of these viruses to human disease.¹⁰

Circumstantial evidence has been accumulating in recent years pointing to Coxsackie group B viruses as an important cause of aseptic meningitis. From Rhodesia,¹¹ South Africa,¹² Canada,¹³ and many other parts of the world have come reports of this. In a recent review of 96 cases of aseptic meningitis at the Hospital for Sick Children in Toronto, A. J. Rhodes and A. J. Beale showed that 18 of these could be attributed to Coxsackie B, and in 5 of these cases virus was isolated from the spinal fluid.¹⁴ A close association exists between aseptic meningitis and Bornholm disease. Quite often in outbreaks of Bornholm disease cases are encountered of frank meningitis, particularly in young children, of pleurodynia and myalgia, and of combinations of the two. The view has been advanced in Sweden, and there is much to commend it, that the varied clinical pattern is a reflection of the individual host's reaction to infection with the same infectious agent. This view would serve to explain the character of the epidemic of meningo-encephalitis and Bornholm disease reported by Dr. H. G. Langdale-Smith and colleagues in this week's issue of the *Journal* (p. 805). Although the exact cause of these cases is not yet known, they may have been caused by a Coxsackie virus or, in view of recent observations, by one of the ECHO viruses; the same varied response may be expected in a number of virus infections. The position with Coxsackie A virus is less clear. It has been established as the aetiological agent in herpangina, but only recently has evidence appeared that it has a role in meningo-encephalitis. In a study of meningo-encephalitis in Johannesburg from 1951 to 1954 eleven strains of Coxsackie A (and 20 of Coxsackie B) were isolated from the faeces and in some cases from the spinal fluid as well.¹⁵ In the Toronto series three viruses isolated from the spinal fluid were classified as orphan or ECHO viruses.¹⁴ Other workers have made similar findings. A recent report from the Children's Hospital in Buffalo¹⁶ describes a series of 24 cases (17 children and 7 adults) in a village of 500 inhabitants characterized by an acute onset of fever, headache, and other symptoms suggestive of pre-

paralytic poliomyelitis. The incidence of family infections was high, but no cases of paralysis were encountered. Type ECHO-6 virus was isolated from the faeces of several cases and a specific increase in antibody was detected. The same type of virus was isolated from the spinal fluid of subsequent cases, and it appears that this virus strain was responsible for a number of similar infections in the United States in the summer and autumn of 1955.¹⁷

In Europe similar cases have been encountered. Two reports from Western Germany and one from Switzerland indicate that cases of aseptic meningitis were widespread in the latter half of 1956.¹⁸⁻²⁰ Both clinical and epidemiological features were similar to those observed in the U.S.A. and in Great Britain; in one or two instances meningitis with a rash was observed. Several strains of virus were recovered from the sputum and faeces with properties suggestive of an ECHO virus. In Great Britain outbreaks of aseptic meningitis, often associated with a rash, were reported from widely separated parts of the country in 1955 and 1956. Nottingham,²¹ Lancashire,²² Wensleydale, Sheffield,²³ and many other districts appear to have experienced outbreaks of this kind. Each outbreak had some peculiar feature, but in the main these cases were principally in young children and presented with a sudden onset of fever, headache, nausea, and vomiting. In many a biphasic type of illness was seen. Lymphadenopathy and a rubella-like rash, more often on the face and neck than elsewhere, were seen in some cases. Pleocytosis in the spinal fluid was common, with cell counts ranging from 50 to 2,000. Such high cell counts are not normally associated with poliomyelitis but are occasionally seen in aseptic meningitis caused by mumps or lymphocytic chorio-meningitis viruses. D. A. J. Tyrrell and B. Snell,²⁴ investigating an outbreak at Sheffield in which mouth lesions were also present, recovered several strains of virus in tissue culture of human kidney which subsequently produced lesions in suckling mice suggestive of a Coxsackie A virus. A similar outbreak was observed in East Suffolk in the last few months of 1955, most of the

patients being of primary school age.²⁴ From several of these cases G. P. B. Boissard and his colleagues at Colindale isolated a number of virus strains from faeces, throat washings, and spinal fluid in tissue culture of monkey kidney.²⁵ Tissue-culture fluids produced lesions in suckling-mice, and it seems that these viruses, now identified as type ECHO-9, are related to the Coxsackie-A group. Subsequent tests have shown that their strain is similar to those recovered in Sheffield and in other parts of the country, from a case in Toronto, and from an outbreak of mild meningitis in East London a few years ago.²⁶ Confirmation of the role of ECHO-9 virus in this type of aseptic meningitis comes from Sweden. Also confirmed is the interesting phenomenon, observed in Britain,²⁵ that this virus produces lesions in suckling mice of the Coxsackie-A type only after first being passed in tissue culture.²⁷ A different type of virus, possibly an ECHO, but with properties similar to the agent recovered by F. A. Neva and J. F. Enders from an unusual epidemic exanthem in Boston,²⁷⁻²⁸ was also isolated from a few cases of aseptic meningitis.

These outbreaks of aseptic meningitis have several points in common. Signs of infection of the brain parenchyma are uncommon. Pleocytosis in the spinal fluid is a marked feature and the number of cases with positive virological findings is significant. But in some outbreaks of encephalomyelitis the findings were the reverse, a problem discussed recently at the Section of Epidemiology of the Royal Society of Medicine.

Cases of encephalomyelitis at first thought to be poliomyelitis, until this diagnosis became no longer tenable, were first described in 1949 by Sigurdsson and others²⁹ from Iceland and have since been seen in Australia,³⁰ New York,³¹ Berlin,³² and Great Britain.³¹⁻³³ In the Iceland and Adelaide epidemics many hundreds of young people were affected, and in Britain three outbreaks³³⁻³⁵ have now been seen in hospitals, principally among the nursing-staff. The most recent in the hospitals of the Royal Free Hospital Teaching Group were the most extensive.³⁵⁻³⁶

In a review of the epidemiology of these outbreaks N. Crowley, M. Nelson, and S. Stovin³⁷ have shown that the first cases appeared at the Royal Free Hospital in Gray's Inn Road in July, 1955, and during the course of the next few weeks spread to the other hospitals in the group. Of the population at risk approximately 9% were affected, and it seemed clear that institutional life played an important part in the spread of the disease, in which nurses and resident staff were predominantly affected. Again each outbreak both in this country and abroad has had its own peculiar features, but several points in common emerge from the published reports. Prodromal symptoms were not prominent and were usually insidious

in onset. Low-grade fever and enlargement of the posterior cervical lymph nodes were often seen. Headache, tiredness, and muscle pain were notable features, the last persisting for many months. At a later stage in the cases at the Royal Free Hospital involvement of the reticulo-endothelial system was apparent, with many cases showing tender lymph nodes, liver, and spleen, together with various abnormalities in the lymphocytes in the peripheral blood. Neurological signs were variable, but the main points of difference from poliomyelitis were the signs of muscle weakness without paralysis which continued to develop for several weeks, normal or exaggerated reflexes, and sensory disturbances. Other neurological manifestations encountered were cerebral irritation with photophobia and neck rigidity and considerable emotional disturbance. Ocular and other cranial-nerve palsies and pyramidal signs were seen in many cases.³⁴⁻³⁶ In many instances convalescence has been protracted.³⁵⁻³⁶ In a follow-up of the Iceland cases the more severely affected patients still complained of nervousness, tiredness, and painful muscles six years after infection.³⁸

The pathology of this condition is not known, though the detailed observations on the Royal Free cases suggest that there is widespread systemic involvement.³⁶⁻³⁷ There can be little doubt that in many cases an organic lesion of the brain parenchyma exists. The valuable electromyographic studies, however, indicated that there was no evidence of lower motor neurone degeneration, the picture being one of a myelopathic lesion with the additional abnormality in motor-unit activity. Apart from the Iceland cases,²⁹ in which only a small number were examined and found to show a mild pleocytosis, the spinal fluid has been found to be normal and the virological investigations, many of which have been exhaustive, have been consistently negative.³³⁻³⁶ At present the viral aetiology attributed to this condition rests on the clinical and epidemiological data. The possibility of poliomyelitis, Coxsackie, or ECHO viruses as aetiological agents can be ruled out, but laboratory diagnosis of these infections presupposes that the virus can be recovered from the alimentary tract and, except for poliomyelitis, from the spinal fluid. It is probable that in these atypical cases, and also in encephalitis lethargica, inclusion-body, and related forms of encephalitis, the pathogenesis is different in that virus spreads in a different way and is mainly localized in the central nervous system. For this reason, and because so little is known of the underlying pathological process, all that can be done at present is to exclude known virus infections for which reliable diagnostic tests are available and to make use of improved virus techniques for studying acute and carefully selected cases.

PEPTIC ULCERATION AND ACID SECRETION

In his Lumleian Lectures, published in this and last week's *Journal*, Dr. F. Avery Jones undertook a very necessary task—the summing-up of recently acquired knowledge about the prevalence, pathology, and treatment of peptic ulcer. This disorder is so common that by the time men reach the age of 45 to 54 about 1 in 10 has had a peptic ulcer, and for about 1 in 40 there has been serious pain or troublesome complications.¹ At the Central Middlesex Hospital admissions of men and women for acute perforations of the duodenum roughly doubled between 1938 and 1955, and this trend is widespread. To judge from the incidence of acute perforations in Glasgow, it appears that the increase in the prevalence of peptic ulcer is largely the result of an increase in duodenal ulceration.²

Peptic ulcers tend to run in families, patients with gastric ulcer tending to have relatives with gastric ulcer, while patients with duodenal ulcer tend to have relatives with duodenal ulcer.³ Among patients with duodenal ulceration there is an unduly high proportion of them with blood group O. However, when the comparison was made between sibs, the patients with duodenal ulcer were found not to have an increased incidence of blood group O, which suggested that the possession of blood group O is not by itself the important factor.⁴ In last week's *Journal* (p. 758) Dr. J. A. Fraser Roberts⁵ and Dr. C. A. Clarke and his colleagues⁶ at Liverpool discuss these findings in the light of further research.

Peptic ulcer does not occur in patients with Addisonian anaemia, who do not secrete pepsin and acid.⁷ About 80% of patients with peptic ulcer are men, duodenal ulceration being up to six times commoner in men than in women. It is possible that among patients with duodenal ulceration there may be some men with less effective duodenal defences against acid and pepsin than are found in women. If this were so it might be expected that the lowest levels of secretion associated with duodenal ulcer in men would be lower than those found in women with duodenal ulcer. As this is not so,⁸ presumably duodenal resistance is not markedly unequal in men and women with ulceration. Again, it might be thought that the jet of gastric contents playing on the first part of the duodenum could be more vigorous in men than in women, a condition perhaps associated with more rapid gastric emptying in

men. However, studies of emptying with test meals of saline and of water have failed to show any difference between normal men and women.⁹ Curiously enough, it has been found that male patients with duodenal ulcer but no signs of pyloric stenosis empty test meals of saline, glucose solutions,¹⁰ and dilute solutions of acid¹¹ at the same rate as normal men. So far the notion that the increased incidence of duodenal ulcer in men is associated with increased vigour of emptying has not been substantiated.

There remains the possibility that the higher prevalence of duodenal ulceration in men may be associated with increased acidity and peptic activity of the gastric contents. Ewald test-meals (with tea and toast) have shown that men have a higher acidity in their gastric contents after puberty than do women,¹² and it is only after puberty that there is an increased incidence of peptic ulcer in men.¹³ This difference in the secretion of acid is still found when groups of normal men and women are carefully matched, the men secreting about one-and-a-half times as much acid and pepsin as do the women.⁹ If the greater acidity of the gastric contents in men was an important reason for the greater prevalence of ulcer in men, it might be expected that any condition associated with a fall in the acidity of the gastric contents in women would further increase the discrepancy between men and women by reducing the incidence of ulcer in women. It is known from the work of M. B. Strauss and W. B. Castle¹⁴ that gastric acidity falls in pregnancy, and D. H. Clark¹⁵ has reported that many women patients with peptic ulcer have remissions of their disease during pregnancy. Thus the lower acidity of the gastric contents in women as compared with men may at least partly account for the lower prevalence of peptic ulcer in women.

J. N. Hunt^{10, 11} found that under a variety of conditions a group of male patients with duodenal ulcers secreted about twice as much acid as did normal persons, although there were, as would be expected, some patients with duodenal ulceration with subnormal levels of secretion. The mechanism of this hypersecretion of acid has been studied. A. W. Kay,¹⁶ using four times the normal body-weight dose of histamine concurrently with antihistamine to reduce the side-effects, was able to obtain maximum secretion of acid in normal persons and in patients with duodenal ulcer. He found that the power of the parietal cells to secrete acid was about twice normal in patients with duodenal ulcer. This increased secretory power is probably the result of an increased number of parietal cells in the gastric mucosa of patients with duodenal ulcer.¹⁷ There is a further possibility that the hypersecretion found in patients with duodenal ulcer results from derangement of the duodenal mechanism which normally inhibits secretion in response to the acidity of the effluent gastric contents.¹⁸ A recent study shows that this hypothesis can only partly account for the hypersecretion in some patients with duodenal ulceration, for very marked hypersecretion can exist in the presence of an apparently normal inhibitory mechanism. From the facts available at present it would seem reasonable to suppose that in patients with duodenal ulcer the mechanism exciting gastric secretion is normal, but it acts on about twice as many cells as

are found in people without duodenal ulcers.¹⁹ Hence the secretory responses to all stimuli are about doubled. As Avery Jones mentions, there is already some evidence that hypersecretion is familial.

In patients with gastric ulcer the acidity of the gastric contents is often subnormal and cannot by itself be the cause of the ulcer. Avery Jones suggests that anti-healing factors, endogenous or exogenous, may play a part in the progression of an acute ulcer into a chronic one. As R. Doll and F. Pygott^{20, 21} have shown, the healing of ulcers is aided by in-patient treatment and by stopping smoking, and no doubt there are other factors yet to be discovered which help to promote healing. About 22% of the population do not secrete the mucopolysaccharides of ABO blood groups in their saliva, and these people are about 45% more likely to develop duodenal ulcer than are secretors of ABO.⁴ It has been suggested that these substances in some way protect the gastric mucosa.²²

It now seems unlikely that there is a single cause of gastric or duodenal ulcer. It is therefore all the more important that those working on this problem should collect information from as wide a field as possible. The Lumleian Lectures provide many pointers to promising lines of inquiry.

TOTAL SYNTHESIS OF A PENICILLIN

The synthesis of phenoxymethylpenicillin, or penicillin V (Fig. 1), has recently been accomplished by Professor J. C. Sheehan and Dr. K. R. Henery-Logan,¹ of the Massachusetts Institute of Technology. It completes the formal proof of the β -lactam-thiazolidine structure assigned to penicillin in the joint wartime Anglo-American penicillin programme.² In the early stages of this programme the hope was entertained that penicillin would prove capable of synthesis, but improvements in fermentation methods and the intrinsic difficulties of synthesis at the time brought attempts at synthesis to an end without their objective being attained. Though du Vigneaud and his associates³ obtained in minute amount a specimen of synthetic benzylpenicillin, the reaction which they employed did not give unequivocal confirmation of the structure. Sheehan, who was a member of the Merck group during the wartime work, has maintained an interest in the synthetic formation of penicillin and has meanwhile also contributed to the great advances that have taken place

in methods for the synthesis of peptides. It is in the application of one of these newer methods of peptide synthesis that success in the synthesis of penicillin has lain.

Early in the study of penicillin it was found that the penicillins are inactivated by alcohols and alkali and also by amines, such as benzylamine. Inactivation takes place by rupture of the β -lactam ring at the position indicated by the dotted line in Fig. 1 to give the corresponding penicilloic acid (Fig. 2) or a derivative. It is this same Achilles heel in the penicillin molecule that is the site of action of the enzyme penicillinase. Various penicilloic acids were prepared during the war, but the methods then available were too coarse to effect ring-closure between the α -carboxyl group and the imino group of the thiazolidine ring to generate the β -lactam ring of penicillin. The essential merit of Sheehan's latest work is that he has overcome this hitherto insurmountable difficulty by taking the penicilloic acid (Fig. 2) related to phenoxymethylpenicillin and shown that treatment with NN'-dicyclohexylcarbodiimide at 25° C. for 20 minutes in aqueous dioxan yields 10–12% phenoxymethylpenicillin (Fig. 1). Other improvements have been effected in the synthesis of the penicilloic acids, permitting a wide choice for the substituent R, and earlier stages of Sheehan's synthesis give yields of about 80%. The flexibility of the methods that have thus been developed can be gauged by the fact that quantities of 2–5 g. of each of ten new penicillins have been prepared by Sheehan's techniques in the Merck-Sharp and Dohme laboratories for biological study.³

It is too soon to say whether the new methods are likely to have much bearing on practical medicine, and they are unlikely to compete with established fermentation processes for the preparation of known biosynthetic penicillins. But by giving access to new penicillins that have not proved accessible by biosynthesis new light may be thrown on the mode of action of these antibiotics, and new drugs effective against organisms resistant to the present penicillins may appear. The biosynthetic penicillins, now numbering upwards of 30, all incorporate the D-penicillamine moiety (Fig. 3), and it is only with respect to the group R that any variation has so far proved possible biosynthetically. Even then only monosubstituted acetic acids are incorporated into the penicillin molecule as the group R.CO. In addition to carrying through the synthesis of phenoxymethylpenicillin from D-penicillamine, Sheehan and Henery-Logan have also carried out the synthesis from DL-penicillamine, and the resulting racemic phenoxymethylpenicillin was found to have approximately half the antibacterial activity of the penicillin derived from D-penicillamine. This indicates that the enantiomorphous penicillin derived from L-penicillamine must be practically devoid of antibacterial activity. The replacement of D-penicillamine in syntheses of the type used by du Vigneaud and his collaborators² by cysteine and thiothreonine gave mixtures of slight antibacterial activity, and no doubt further developments in that direction will be forthcoming with the aid of the new techniques. The possibility also remains that a form of penicillin insusceptible to hydrolysis by penicillinase may yet emerge.

Reports of Societies

COMMON CONGENITAL ABNORMALITIES AND THEIR MANAGEMENT

The management of the common congenital abnormalities was discussed by four speakers in the Section of General Practice at the Royal Society of Medicine on March 20.

Prevention is Better than Cure

Dr. LINDSEY BATTEN, opening, observed that a wealth of abnormalities could exist in the just-delivered, healthy-seeming babe. A saving clause must be inserted after "Look! You've got a fine boy," and a detailed, purposeful examination follow to find such defects as could be found at this stage. Management at home should include prevention, and to this end he proposed three aetiological classes—"bad seed," "injured embryo," and "pressure group." X-ray trauma was a controllable factor in classes 1 and 2, and the family doctor should stand guard over the ovaries, embryos, and fetuses of his patients against light-hearted radiology, especially in pregnancy. Rubella, innocuous in childhood, was deadly to the developing embryo; every girl-child should have it, and her doctor should do his utmost to make the fact known and to see that she got it. Young wives, if not immune or pregnant, should be warned and advised to acquire immunity by the only means yet known; if exposed and at risk of pregnancy, they should have gamma globulin and contraceptive advice. Actual rubella in early pregnancy called for declaration of the risks to the expectant parents and for a consultation at which termination of pregnancy must inevitably be discussed.

Could anything be done to prevent deformities ascribed to intrauterine compression? The foetus had been described as "moving freely in his bath of liquor amnii." What stopped him in these cases? Did the bath-walls exert too much inward or the bath-water too little outward pressure, or did the sluggish foetus become womb-bound? Prevention might be possible if the answers were known. When defects occurred the doctor must persuade parents not to impute blame, despair, or seek magic cures, but to obtain and act upon sound advice. His responsibility and opportunity were greatest in such impalpable, invisible defects as congenital deafness. Here doctor and mother could effect a diagnosis without apparatus or expert aid, and, since deafness was rarely complete, institute the vital auditory training—the mother, patiently and in faith, speaking words into her infant's ear in the few precious months when the foundations of speech are laid.

Orthopaedic Deformities

Mr. DENIS BROWNE discussed three groups of congenital abnormalities that were often missed, and treatment delayed, on account of failure to examine the parts adequately. With congenital deformities of the hip the results of treatment depended almost entirely on the age treatment was started, he said; the earlier the better. He had diagnosed congenital dislocation at the age of 16 hours, with a perfect result by the time the child was at the walking stage; unfortunately the average age at which patients were being referred for treatment was 2 years. The essential test for early diagnosis of congenital dislocation of the hip was the detection of a limitation of abduction. This required no elaborate techniques and took only a few seconds to carry out. Likewise dysplasia of the acetabulum with failure to develop a good cup could also be diagnosed in this fashion, and likewise early treatment was needed for perfect results. Treatment was simple, and was based on the principles of controlled movements, ensuring that useful and beneficial movement was left unrestricted and preventing useless and harmful movements. Proper scientific splintage was the answer.

No one missed cases of gross deformities of the feet, but two less obvious, though very important, deformities requiring early manipulation were unfortunately very easily missed. These were the varus and the valgus deformities of the metatarsus. Both could be diagnosed at once if one remembered them. Treatment by pressure with adhesive felt on an aluminium splint was eminently successful.

"Idiopathic" scoliosis, like the two metatarsal deformities, was the result of abnormal intrauterine conditions. Here, also, early diagnosis was essential if serious consequences were to be prevented. This condition could easily be spotted by noting that the child always tended to screw round in one direction in the first months of life. Abnormal creases on the concave side of the back confirmed the diagnosis. A splint was shown that reversed the curve of the back without immobilizing the baby. If not corrected before the walking stage, this scoliosis was progressive and most intractable.

Naevi and Ichthyosis

Dr. G. B. MITCHELL-HEGGS discussed some of the common congenital skin abnormalities. About a quarter of all the work of the skin department at a children's hospital was concerned with congenital defects, he said, the two commonest groups being the various types of naevus and ichthyosis.

Each of the three common vascular naevi—the strawberry naevus, the port-wine stain, and the spider naevus—presented a different problem. The strawberry naevus tended to undergo spontaneous resolution around the age of 5–7 years, and therefore it was prudent to wait till then before advising treatment. Some cases needed special treatment. Port-wine stains were very disappointing in their response to therapy on account of their widespread nature. Spider naevi were very easily cured by electrolysis or cautery.

Ichthyosis was an inherited congenital abnormality which rendered its victims liable to eczematous complications. However, a good deal could be done to prevent these ill effects. Bathing in water should be limited as much as possible, and bland oils or vanishing creams used for cleansing purposes in the winter. If water was used it should be "softened" as much as possible; rain water was ideal. Sedatives were valuable when irritation was present. Locally, coal-tar derivatives and the more recent hydrocortisone preparations were indicated to control inflammatory reactions and itching.

Planning of Plastic Surgery

Mr. D. N. MATTHEWS opened his contribution on the role of plastic surgery by stressing the great importance of appreciating and managing the psychological effects of a congenital deformity on the whole family. If parents were to cope satisfactorily with a disabled child, time should not be grudged in explaining to them the scope and plans of any treatment contemplated. Good rapport between consultant, parents, and the family doctor was vital. Besides the technical procedures proposed, the parents and family doctor should be told when was the best time for surgery and the likely length of stay in hospital.

Discussing individual congenital abnormalities, Mr. Matthews said that hare-lip was best treated surgically at around 3 months of age. An associated cleft palate should be left till the age of 15–18 months before being repaired, and any residual soft-tissue deformities till 3–4 years. Deformities of the nasal bones should be left till the age of 12–13 years. The indications for surgical treatment of naevi were haemorrhage, erosion of the skin, growth out of proportion to the growth of the child, or disfigurement. Moles usually required excision and skin graft. The final cosmetic result could not be judged for 18 months. "Bat ears" could be cured only by planned surgery involving some resection of the cartilage. Sticking the ears down to the scalp by adhesive plaster never corrected this abnormality. The best age for treatment was around 4 years. Congenital ptosis should be left until at least 2 years of age, as spontaneous improvement might

occur up till that time. Syndactyly, on the other hand, should not be left too long, otherwise there would be interference with the growing epiphysal ends of the phalanges.

In many instances the operations of circumcision and for tongue-tie were not needed, said Mr. Matthews. But at the same time there were cases in which these minor procedures were essential, and he summarized the indications. Whenever a congenital defect possibly needing surgery was discovered it was wise to refer the child to a consultant at once so that future treatment might be planned and the parents relieved of uncertainty.

ARTERIAL BLOOD PRESSURE

[FROM A SPECIAL CORRESPONDENT]

The co-operative inhabitants of the Vale of Glamorgan and the Rhondda Fach have again been the source of important new information, this time in a non-respiratory field. Dr. W. E. MIALI and Mr. P. D. OLDHAM, of the Medical Research Council's pneumoconiosis research unit, have been studying the arterial blood pressures of samples of the population of these two communities, and Mr. Oldham presented some preliminary results to the Medical Section of the Royal Statistical Society at a meeting held at the Westminster Hospital on March 26.

One purpose of the survey was to confirm the recent findings of Professor G. W. Pickering and his colleagues that blood pressure is a continuously variable attribute depending on age, there being no distinguishable dividing line between normal and abnormal values; and that it is, genetically speaking, a multifactorial attribute rather than one dependent on a single pair of genes. Professor Pickering's analysis was based on hospital out-patients, and to give his results complete generality it was obviously important to see whether or not they applied to a representative sample of the population at large. At the same time the opportunity was taken of studying the relation between blood pressure and occupation, social class, parity, and so on.

The sample consisted of about 600 people, aged 5–80 years, chosen at random from the already card-indexed population of the two valleys; to this were added more than 2,000 of their first-degree relatives, including most of those living within a radius of 25 miles (40 km.). Standard methods were used for measuring the arterial pressure, and the technique of age-correction developed by Professor Pickering and Dr. J. A. Fraser Roberts was also followed.

Surprising Effect of Parity

Apart from the clear confirmation of the earlier findings the most interesting results were those in which the systolic pressure was related to the number of children. Instead of the possibly expected increase of pressure with parity, it was found that the average pressure of the women in the series, after adjustment for age, was about 2.6 mm. Hg lower for each additional child in their family. But what was even more surprising was the fact that almost the identical pattern emerged if the analysis was applied to the men. Mr. Oldham found it hard to explain this discovery: it was presumably related to some environmental factor, possibly diet. The only occupational comparison which yielded anything of interest was that between light and heavy workers. Above the age of 50 the systolic pressure of the light workers was, on the average, about 8 mm. Hg higher than that of the heavy workers, a difference corresponding to about 7 years of age. There were good reasons for supposing that this was not the result of self-selection.

This study is only a beginning. Mr. Oldham concluded his paper by observing that its main value, from a medical point of view, would only become apparent when the sample had been followed up for a number of years. It should then do much to clarify the prognostic value of blood-pressure measurements.

Correspondence

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

Benactyzine

SIR,—Perhaps I may be permitted to give some further information on the points which Dr. E. H. Hare raises (*Journal*, March 9, p. 582) in discussing our paper on benactyzine (*Journal*, February 9, p. 306).

First, on the question of side-effects and other clues to the identity of the substance which a patient is receiving: The side-effects we noted were not "of such severity that the dosage had to be reduced"; they were in most cases, as we said, "very mild," and we often wondered whether they were not artifacts of our curiosity. We reduced the dose because they might not have been. Depression seemed to us to be a more reliable clue, but, as our paper reports, our impression was mistaken. Probably the clue that is most influential is a marked improvement in symptoms in the absence of any apparent environmental influence. It proved to be equally fallacious. A case may illustrate this point. A miner who had been caught in the haulage and dragged for a considerable distance underground developed a severe anxiety state after the accident, which had been present for 12 months when we saw him. During the test period his symptoms abated in a remarkable manner and his self-confidence returned. Within forty-eight hours of withdrawal of the "drug" he had a complete relapse, and his general practitioner telephoned urgently to ask for details of the drug to which he had previously responded so well. In the meantime we had broken the code and found that his tablets were inert.

The conflicting clues were one impediment to the discovery of the identity of the drug; the other was the "external examiner," who did not know whether or not side-effects had occurred during the test period. As we mentioned, his independent ratings had a correlation of 0.89 with those of the psychiatrist in charge of the case. In those cases whose improvement we thought had probably resulted from "very favourable changes in the patient's life situation," our conclusions were not based on the "bare criterion of 'changed' or 'unchanged,'" as perhaps we should have illustrated in our paper by a case such as the following: A woman of foreign birth, who came to this country as a war bride, developed a severe anxiety state when left alone to support and care for her children after her desertion by her husband, who went abroad. During the test period the husband unexpectedly returned and a reconciliation took place. Her symptoms disappeared. We had to decide what attitude to adopt toward such cases where a powerful influence had unexpectedly intervened compared with which the effect of a symptomatic aid, such as benactyzine, is probably small, and we were interested in assessing the effects of the drug rather than the effect of major changes in the life situation. In a series as small as ours we thought it best to eliminate such an effect rather than "assume" the effects to be eliminated.

We do not, in our paper, "dismiss" the self-controlled trial. For us its advantages were offset by "the disadvantage of providing no information on the course of the malady in comparable patients who do not receive the drug being investigated." We did not deprive ourselves of this advantage of the independent control, since, as our paper states, none of our controls received benactyzine until a fortnight after the test period was over. The considerable degree of improvement shown by controls during the test period is set out in our paper and appears to us to be an important finding.

Your correspondence columns are no place for a lengthy discussion of the literature on the relative merits of global judgments and rating scales, beginning with Galton's con-

clusion in 1879 that "general impressions are never to be trusted." Our paper explains why, rightly or wrongly, we did not employ global judgments. Regarding estimates of probability, we do not share the fairly common medical view that such an estimate is a kind of Wassermann test which suddenly becomes positive when $P=0.05$. There is a 92%–94% chance of the differences we found being the result of the drug. It is therefore at present not unreasonable (to rephrase our previous temperate statement) to attribute them to the drug without being too overconfident about it.

Regarding the comparability of the two groups in all the "factors likely to influence prognosis": unfortunately few, if any, of the factors are known. But the data Dr. Hare requests on the "severity of symptoms" are shown in table II of our paper, where the mean initial symptom scores for control and benactyzine groups are given as 31.6 and 31.4 respectively. The other data he requests, and much more besides, were omitted in the interests of brevity. There were seven men and five women in the control and seven men and seven women in the benactyzine group. The mean age of the groups was 38.3 years and 37.5 years, and the mean duration of symptoms (in months) was 22.0 and 23.7 respectively.

It is not possible to comment on Dr. Hare's finding that the probability of differences being due to chance can be altered by inverting the marking of the rating scale without having details of the procedures he employed, but such a manoeuvre would not affect the estimate of probability obtained by a t test.—I am, etc.,

Leeds, 2.

G. R. HARGREAVES.

Smoking and Lung Cancer

SIR,—The advocacy of non-smoking among school-children who have not begun to smoke is suggested as a precaution against cancer of the lung, and, if the abolition of smoking is desired, this is doubtless the most effectual method.

Islam maintains teetotalism among over 400,000,000 persons (no doubt there are a few offenders) who have not tasted alcohol; to convert such a population who had had access to it would be impossible. This gigantic achievement rests upon a very small basis of two passages in the Koran:

"They will ask thee concerning wine and games of chance. Say, in both is great sin, and advantage also, to men; but their sin is greater than their advantage" (Sura II). "O believers! Surely wine and games of chance, and statues, and the divining arrows, are an abomination of Satan's work! Avoid them, that ye may prosper" (Sura V. Translation by J. M. Rodwell).—I am, etc.,

London, E.C.1.

E. L. KENNAWAY.

Developmental Acro-hypertrophy of Foot

SIR,—Developmental acro-hypertrophy of a foot with horny enlargement of toenails is the best descriptive name for a condition which I once saw many years ago and have since then retained in my mind's eye.

An early-middle-aged male had enlargement of the right foot, especially in length and towards the toes, which showed a kind of gigantism of the toenails, notably that of the big toe. This long nail was of true polished horny appearance, slightly translucent, nothing like the dense, opaque, thickened hyperplastic toenails due to old infection. The case was shown at the Royal Society of Medicine at a clinical demonstration (? dermatological) arranged for French colleagues. No one present had apparently ever seen a similar case, and it was this feeling of being completely baffled that made the picture haunt my imagination. The meeting was, I think, never regularly reported. Now, however, I feel fairly confident that the case was allied to those which in 1918 I termed "haemangiectatic hypertrophy of limbs." It seems fairly certain that there are cases of this class which show no obvious telangiectatic or other enlargement of blood vessels. My name was associated with this condition by

Sir Archibald Gray, and later by some others. P. P. Reichenheim gave an elaborate description of the condition. By far the most complete account of the literature is given by Gerhard Koch in his study entitled: "Zur Klinik, Symptomatologie, Pathogenese und Erbpathologie des Klippel-Trenauney-Weber'schen Syndroms."—I am, etc.,

London, N.W.1.

Treatment of Acute Appendicitis

SIR,—In the correspondence about the treatment of acute appendicitis, Mr. R. J. McNeill Love (*Journal*, March 9, p. 585) mentions the teaching of his old chief, Mr. James Sherren, and I think this teaching should be remembered; a personal experience may be of interest.

I was surgeon to the British Legation in Kabul at the time I am recalling, and looking back over 20 years I realize that I had had several attacks of appendicitis but had attributed the trouble to "punkah colic"—that is, a chill from sitting or lying under a punkah in the hot weather in India. When I realized that I was in for the real thing I had to decide what to do; the nearest surgical aid was 200 miles away over a road which in those days took the better part of two days to negotiate, and in addition there would be the usual delays in getting a permit to enter Afghanistan. I did what Mr. McNeill Love mentions—that is, I took to my bed, had nothing but sips of water by mouth, and kept myself under morphine. In due course an abscess formed, but I took a completely detached view of this, thanks to the morphine, and after about a week or 10 days I felt I could drop the morphine and take some nourishment. After three months I went to Simla to have my appendix out, and went through a most uncomfortable and alarming experience. Only the remains of the appendix were found among adhesions which had not yet resolved, and after the operation I suffered from a partial ileus, retention of urine, and an attack of severe urticaria as the result of an injection of anti-gas-gangrene serum, which in those days was given as a prophylactic against peritonitis. I had to have a catheter passed twice and I have seldom experienced so much acute discomfort, to put it mildly, and I do hope that nowadays patients are given some treatment to mitigate the pain of this manoeuvre.

The conservative treatment of acute appendicitis must always be considered under certain circumstances, but I think the doctor in charge probably suffers the most anxiety; if only he could produce the same detachment in himself as in his patient by morphine he would be saved the week or 10 days of acute anxiety which he has to suffer before his patient has weathered the storm.—I am, etc.,

Melrose.

H. H. ELLIOT.

Tetanus Prevention

SIR,—The excellent article on this subject by Drs. H. J. Parish, L. J. M. Laurent, and N. H. Moynihan (*Journal*, March 16, p. 639) could be a timely beginning of the much-needed rationalization of our current national practice of tetanus prevention. Two things they very rightly stress which are not always accepted. First, that the object of a trial dose of antitoxin is to determine any predisposition to general reaction and not to detect any local reaction, the latter having no practical significance. Secondly, that, whenever antitoxin has been given, the patient should be asked to return in 6 to 8 weeks for active immunization with tetanus toxoid. On the other hand, they accept 1,500 international units as being the routine protective dose of antitoxin in a non-immune individual. This is now questioned by many, as was discussed by Dr. Leon S. Kind (*Journal*, March 2, p. 498) when an increase to 10,000 was suggested.

It is regretted that the decision concerning which injuries require tetanus prevention was not regarded as falling within the scope of the article, but the summary, given in footnote, of the criteria of the Birmingham Accident Hospital is most interesting. It is particularly of interest to read this in conjunction with the Registrar-General's Statistical Review for 1954, quoted briefly in the *Journal* (March 9, p. 594), which shows that a large proportion of fatal cases would not have qualified for tetanus protection under the Birmingham criteria. That of course may be the reason why they died of tetanus.

Each year in this country there are many millions of injuries which could produce a case of tetanus. In fact, less than a hundred cases do occur. Many are doubtless prevented by toxoid or antitoxin, but in the process the latter causes much pain and illness and some death. When a case of tetanus does occur the doctor who treated it and did not give antitoxin is open to a charge of negligence. As a result of this it is possible that more injections of antitoxin are given to protect the doctor than are given to protect the patient who has been individually judged to be suffering from a wound meriting the injection of antitoxin, in spite of its danger. In the casualty departments of many hospitals it is a rule that all patients with open wounds are given antitoxin as a "blind routine." This rule may be more for the protection of the staff than of the patients.

I should like to suggest that the Medical Research Council appoint a committee to the task of preparing notes on the prevention of tetanus in injured persons which would include a statement of the types of injuries which require such protection. If such notes were forthcoming from such an authoritative source, practitioners who adhered to them would give protective injections to those patients requiring them; would not be driven by medico-legal considerations to giving them, with all their concomitant risks, to those not requiring them; and would in fact be immune from a charge of negligence if and when tetanus occurred after a minor injury.—I am, etc.,

Cowley, Oxford.

W. A. REYNARD.

SIR,—The notes on prevention of tetanus by Drs. H. J. Parish, L. J. M. Laurent, and N. H. Moynihan (*Journal*, March 16, p. 639) serve a very useful purpose in drawing to light the confused state that exists at the present moment in the prophylaxis against tetanus that is practised in this country. For some months it has been the custom in the casualty department of the Ancoats Hospital to give to those whom we reasonably presume to be in the actively immune state, as defined in the article, a booster of tetanus toxoid. There are something like 8,000 inoculations against tetanus in the year in this department, and about 20% of these are booster doses of tetanus toxoid. This 20% are almost entirely those who have recently served in Her Majesty's Forces, together with some who have been actively immunized in the hospital. It has been the practice to actively immunize all those who suffered any reaction to antitetanus serum and who are reasonably intelligent and understand the distinction between active and passive immunization. They are given a card to state what has been done.

Regrettably, of those requiring tetanus injections many have escaped the routine tetanus toxoid injection given in the Forces by virtue of reserved occupations, and in those groups particularly such people as miners, employees in the engineering industry, and labourers are in real need of active immunization against tetanus. It would seem that it was high time, not only with tetanus toxoid but with all other types of active immunization against disease, the patient himself should possess a record of the injections he has received, and there should be created a universal card giving these details and which could be presented as the occasion arose. In order to achieve universal understanding of prophylaxis against tetanus it seems that there must be also overall agreement in the administration of these sera in the casualty departments throughout the country.—I am, etc.,

Manchester, 4.

DEREK BUNTING.

Rupture of Uterus Involving Bladder

SIR,—My copy of the *Journal* has just come and I was much interested in Dr. M. A. Majekodunmi's report (*Journal*, February 2, p. 270), which reminded me of a near similar case I had a few years ago. Now that I am more experienced in Nigeria and have adjusted myself to the fact that I am usually the last outpost after all the native doctors have done their best and worst, it is a routine for me to examine the bladder extra carefully in all cases of obstructed labours.

My case was a 25-year-old Ishan (Bini) woman brought to the Zuma Memorial Hospital, Irrua, on February 12, 1954, with a history of having been in labour for the past three days. Six hours previously the strong regular pains suddenly ceased and she felt comfortable enough for relatives to be able to carry her for the 12 miles' journey on a push bicycle. On examination she was a small woman, multipara 2—none alive due to difficult labours; pelvic measurements were 8 in., 9 in., and 6½ in. (20 cm., 23 cm., and 16 cm.). She was exhausted, and had a weak, thready pulse; the abdomen was distended with guarding and tenderness. There were no foetal heart sounds, no movements, and the head was wedged in the pelvis. Per vaginam, the os was fully dilated but the vertex was high up and fixed. Because of the previous history, the fixed head, and signs of peritoneal irritation, I suspected ruptured uterus. Later, in the theatre, I found the peritoneal cavity full of bloody fluid; because of the dark and purplish bladder, peritoneal reflection, and the oedema over the area, I smelt the fluid and found it smelling strongly of urine. Further examination revealed a uterus ruptured anteriorly in the lower segment with the baby born to the neck and the head nipping the bladder against the pubis; this portion of the bladder was oedematous and at its posterior aspect it was lacerated. Owing to the shocked condition of the patient both the uterus and bladder were dealt with by débridement and repair; the peritoneal cavity was cleaned out and the abdomen closed. The post-operative period was hectic, but she made it.—I am, etc.,

New York.

XTO G. OKOJIE.

Multiple Sclerosis

SIR,—It is always stimulating to read of a dynamic and positive approach to a difficult problem such as multiple sclerosis, and Dr. Douglas McAlpine's interesting contribution (*Journal*, March 2, p. 475) is such. Nevertheless, it was disappointing that in his remarks on treatment he makes no comment on the considerable value that can be gained from correctly applied physical treatment in selected cases. In mildly affected patients it is not necessary; in severely affected ones it is valueless, except to minimize the development of awkward contractures (and this can be dealt with by a relative); but it is in moderately affected patients that it can make a good deal of difference to function, and in some cases salvage the individual from invalidism. In such cases the time to start is in the convalescent stage, with both physiotherapy and occupational therapy as possible contributors.

Physiotherapy consists in training the patient in a system of progressive co-ordination exercises. Normally, attendance by the patient at the physiotherapy department need not be more than twice weekly, and within three months the immediate maximum improvement will have been achieved; after that only rare visits for follow-up should be required. The success or failure of this programme depends largely on the attitude of the physiotherapist and of the patient. Each visit must be regarded by both as a lesson with the all-important homework to follow daily. I usually give the patient the analogy of somebody who is learning to play the piano, visiting his teacher, but relying on repeated practice to improve the crudity of execution of the piece that he is learning. This principle applies to the rehabilitation of a number of other chronic neurological disorders—e.g., cerebral palsy, hemiplegia, partial paraplegia, etc. Occupational

therapy can also help to improve co-ordination, particularly in the upper extremities, and whenever there is need for assistance with the activities of daily living.

Finally, on the question of telling the patient. In those cases where an active rehabilitation programme is planned, if one is to obtain the intelligent co-operation that is necessary for success the patient has to be told a good deal about his illness, and, if he wants to know its name, he should be told. This may be a shock, but it allays doubt, and he can then be encouraged to face the future with courage and determination. After all, the average expectation of life in this disease is relatively long.—I am, etc.,

Durham.

ANDREW ZINOVIEFF.

Tonsils and Adenoids

SIR,—In the recent correspondence on tonsils and adenoids, the indications for removal of the latter appear to have been completely eclipsed by most complex statistics denigrating the removal of the former. As far as I am concerned, by merely substituting the operation of "A's" for "T's and A's" a sense of realistic proportion will finally be attained.—I am, etc.,

Denton, Lancs.

W. BRAND.

Safety Factor in Car Design

SIR,—Motor vehicle designers are concerned to minimize both the likelihood of accidents and their effects. Both are engineering problems, but towards the solution of the latter the medical profession can contribute extremely valuable help. Given sufficient information as to the causes of injuries, engineers should be able to get some considerable way towards eradicating them. To those concerned with this subject Mr. William Gissane's letter (*Journal*, February 16, p. 399) was of exceptional interest in view of the increasing popularity of miniature cars.

While agreeing with your correspondent that flimsy construction is to be deprecated, one must point out that it is not only to be found in midget vehicles. Further, Dr. Gissane's belief that four wheels are essential for safety is not in accordance with recent experience. It would be possible to name more than one make of three-wheeler that provides just as much protection for the occupants, in the event of a crash, as could be expected from a four-wheeled car of orthodox design—and substantially better protection than some foreign four-wheelers appear likely to afford.—I am, etc.,

Studley, Oxford.

FRANCIS JONES.

Speed Warning Device

SIR,—A speed warning device, such as that mentioned by your correspondent Dr. Allen Glenn (*Journal*, March 23, p. 705), was fitted as standard to some cars pre-war. I had one on a 1937 M.G., and it consisted of a green light on the dashboard which went out when 30 m.p.h. was exceeded. It was undoubtedly effective, but after the first five miles it was switched off and never used again, as by that time I had learned to judge the speed of the car, by ear and "feel," to within a mile an hour or so of the vital thirty. I am quite sure that the "solid core of well-disposed motorists" are all quite capable of the same judgment, and that they are in no need of such a device. Unfortunately, the type of driver in most need of such guidance is the one who is least likely to fit the device, or to heed one should it be fitted as standard. In any case, is not Dr. Glenn confusing safety with legality? There are stretches of road where 40 m.p.h. is safe, though illegal, whereas half that speed is deadly dangerous, though quite legal, in many other built-up areas.

Surely, Sir, money and ingenuity would be much better spent in educating all motorists up to the very high standards set by the police drivers, and in the building of proper roads.—I am, etc.,

Dunstable, Beds.

G. E. PINKERTON.

Police Evidence Preferred

SIR,—Dr. Charles L. Worthington's letter under this heading (*Journal*, March 16, p. 643) puts forward a case for more police evidence and less medical evidence, but, as many people have observed, police evidence in court is not treated with the respect that it deserves and a jury's reactions are very often hostile in an effort to be neutral or impartial. This is only with respect to cases under Section 15 of the Road Transport Act.

Police prefer to use medical evidence because the statement of fact can stand up to counsel's cross-examination and because the borderline case can be dealt with by a police surgeon in a more satisfactory manner. Now, with the advent of the urine alcohol test (which incidentally does not produce its result until some days after the charge is preferred), a stronger case can be made out and the borderline case can also be eliminated by the presence or absence of lateral nystagmus (again a function of the police surgeon). Finally, where the charge may be a serious one involving manslaughter it is only fair to make available every possible evidence including the blood alcohol in addition to the police evidence.—I am, etc.,

Watford, Herts.

CHARLES ROTMAN.

SIR,—A great deal of interest and, I am sure, some harmless amusement has been aroused by the unnerving experience recently of a doctor (*Journal*, March 16, p. 643) who was called by the police to examine a motorist suspected of being "drunk in charge," when, to prove his innocence and sobriety, the detained person started somersaulting "all over the place," as one of the Sunday papers has it.

However, "the shouting and the tumult dies, the sinners and the saints depart," and on cool reflection I wonder if there is not a perfectly simple explanation of this startling performance. In assessing, say, the handwriting of a person suspected of being under the influence, we must always bear in mind the level of literacy expected in that type of person. Surely this will apply also to, say, acrobatic attainment. If the gentleman concerned happened to be a professional dancer or acrobat, he would have been trained in this métier from the toddler stage up, and turning somersaults would come as easily to him as falling off a log would to me—it's just a question of doing what comes naturally. Driving a motor-car is a skill which might well have been acquired much later in life (if at all), and we do know that under the influence of alcohol the most recently acquired skill is the first to be lost, while older-established habits and skills are retained longer.

This case, and all the publicity it has received in the daily press as well as medical and motoring journals, does seem to suggest, as I have felt for a long time, that it would be advisable in all cases to inquire how long the person had been driving, for the shorter their experience the more likely would even a small amount of alcohol be to render them "incapable of having proper control." Had this inquiry been made, and possibly a similar one in this particular instance about his acrobatic prowess, some enlightening answers might have been obtained—and the doctor spared some embarrassment.—I am, etc.,

West Bromwich.

K. E. JOLLES.

Tablet Test for Proteinuria

SIR,—It is a pity that the excellent idea behind the various tablet tests for urinalysis should be discredited by over-enthusiasm. In common with many other G.P.s, I have always carried a 25% solution of salicylsulphonic acid in my bag—previously in a dropper bottle, more recently in a "polythene" squeeze bottle as used for hydrocortisone lotion. The tablet test for proteinuria described by Drs. D. N. Baron and Celia Oakley (*Journal*, March 16, p. 628) appears to offer no serious advantage whatever, and costs more.—I am, etc.,

London, W.11.

J. TUDOR-HART.

The Black Sheep

SIR,—Dr. John D. Kershaw's letter (*Journal*, March 16, p. 645) prompts me to point out that the time and place to educate potential food-handlers, and everyone else, in the importance of food hygiene is at school. Until we have reasonably sanitary conditions in our schools and in our homes—that is, until children can be taught to practise cleanliness during the most impressionable years of their lives—it is futile to hope that any sort of laws can make people clean in later life.—I am, etc.,

Truro.

V. E. WHITMAN.

Domiciliary General Practice

SIR,—It was with interest that I read Dr. R. N. Theakston's article on domiciliary general practice in prevention and treatment of illness (*Journal*, March 23, p. 696), but cannot agree with his practice of leaving perineal and vaginal tears for 24 hours before attempting any repair.

Perineal and vaginal tears are surely best repaired as soon as possible after delivery. In this way there is less time for the introduction of sepsis into the wound, and the patient is spared the nervous anxiety and apprehension which otherwise occur during the hours that elapse before the repair is carried out. After a mother has successfully weathered the experiences of labour she deserves the service of being tidied up completely, without having to anticipate the process of stitching in 24 hours' time. Carried out immediately after delivery, under local infiltration with 1% procaine, the repair is quickly performed, and the freshly damaged tissue is easily sutured.

Dr. Theakston may prefer to "suture the repair in comfort" some 24 hours later, but surely it is more kind, and certainly more scientific, to carry out the repair immediately, allowing the patient to recover sitting in physical and mental comfort.—I am, etc.,

Brompton-on-Swale, Yorkshire.

UGO N. PHILLIPS.

Underfeeding of Babies

SIR,—The second paragraph of Dr. Ian G. Wickes's letter under this title (*Journal*, March 23, p. 702) should be reprinted, framed, and a copy hung in a prominent position in every maternity and paediatric unit. The habit of ascribing the cause of excessive crying to overfeeding is even more widespread than Dr. Wickes suggests, and his remarks might possibly—I use the word advisedly—make some slight impression on the iron prejudices of many senior nurses. My own practice in these cases is to listen in silence to the report, write out on the back of the chart the words "You cannot overfeed a baby" in capitals, and hand it over without comment. I have little illusion about its reception, but regard it as the drop of water which may eventually dent the stone.

Perhaps it is all our own fault in leaving nearly all the care of new babies to nurses. Many practitioners, perhaps the majority, are untrained or uninterested in paediatrics. If so, they should say so and direct the parent elsewhere. The consultant paediatrician is much too senior to be bothered with trivia, and yet these are often the despair of the young mother. So she falls back on the maternity nurse or nanny, who, however expert at the job she was trained for, is given a responsibility beyond her qualifications. This dependence on nurses may go to extreme lengths, and indeed some have extensive paediatric practices, travelling from house to house, advising on every sort of infantile disorder.

Whether this is a desirable state of affairs may be disputed, but many mothers feel that they are entitled to medical rather than nursing advice on their multiple problems, and it is surely the duty of the profession to provide it. Probably the ideal method would be the provision of a great many more "baby doctors," as distinct from consultant paediatricians. It is unreasonable to expect the latter to be concerned with the minutiae of infant life, but it is equally so to leave these unregulated. The "baby

doctor"—a trained paediatrician willing to carry out a sort of general practice amongst infants—is an institution in several Continental countries and the U.S.A., and the few practising here are obviously only partly filling a widespread need.

The work done at infant welfare clinics is generally of a very high order, and covers the bulk of the infant population, but it cannot provide the almost daily supervision in the home which minor ailments often require, and which can only be effectively carried out by the sort of paediatrician I have described above.—I am, etc.,

London, W.1.

ALBERT DAVIS.

Subacute Bacterial Endocarditis

SIR,—In their important contribution Drs. F. G. Hobson and Dr. B. E. Juel-Jensen (*Journal*, December 29, 1956, p. 1501) ask if subacute bacterial endocarditis due to *Str. viridans* ever occurs in an edentulous patient. The following case history may provide an answer.

A water board engineer, aged 59, was admitted to hospital on February 4 this year. He had been edentulous since 1942, when a total extraction had been done "for tooth-ache." Five weeks before his present admission he had complained of pains in his head and back, and his doctor, finding a raised temperature, had ordered him to bed and had treated him for a few days with sulphonamides and later, again for a short period, with penicillin. The fever had initially responded to these treatments but had recurred when the drugs were withdrawn. There was no past history of rheumatism, and the patient denied any tendency to sore throat or to nasal catarrh.

On admission the patient, of moderate build, had evidently lost weight. He had a muddy pallor and was anaemic (Hb 45%). Temperature 101° F. (38.3° C.); pulse regular, 100. The apex beat was displaced towards the anterior axillary line. There was an apical systolic thrill, and a systolic murmur could be heard at the apex and also in the first interspace to the right of the sternum. The spleen was palpable. The urine contained pus cells and red blood cells. Leucocyte count, 6,700/c.mm.; neutrophils, 78%; lymphocytes, 19%; monocytes, 2%; eosinophils, 1%. Within 24 hours of admission three blood cultures were taken and each grew *Str. viridans*. Thereafter the patient was treated with penicillin, 1,000,000 units being given six-hourly. Within four days of treatment he was afebrile, and remained so throughout the six weeks during which he had penicillin, and at the time of writing there is no sign of relapse. On February 13 x-ray screening showed the large left ventricle and calcified valve shadows of aortic stenosis. My colleague, Mr. G. W. Vincent, has seen this patient and the x-rays of his jaws, and confirms that there are no dental remnants.—I am, etc.,

Wolverhampton.

J. V. S. ARLINGHAM DAVIES.

Hospital Confinement

SIR,—The grounds for hospital confinement should be: (1) social—to be investigated by the M.O.H.; (2) medical—to be investigated by the doctor responsible for the patient. Each case should be dealt with on its merits. A general practitioner (especially that now so many have the D.R.C.O.G.) should be in a position to decide if a hospital confinement is necessary at the first booking or if it becomes so later. This would obviate the "blind" categories used as a result of statistics and would lessen the number of normal deliveries blocking beds in hospital.—I am, etc.,

Plymouth.

O. LL. LANDER.

SIR,—Dr. Aileen M. Dickins and her colleagues (*Journal*, March 16, p. 645) ask for views on their remarks on hospital confinements. It is right that hospitals should persuade patients to stay at home. No hospital service could otherwise accommodate all those seeking admission for confinement. It is the duty of the general practitioners to select patients requiring admission, using the criteria that Dr. Dickins *et al.* suggest.

In this area we have found that no patient has been refused immediate admission to hospital either before or during labour, when we have requested it. Alternatively, the patient may be seen at the hospital by the consultant obstetrician, who is always ready to advise. It is very reassuring for a general practitioner to know that he has a first-class hospital obstetric service behind him, and that he can arrange immediate admission without any questions asked until the patient is safely delivered.—We are, etc.,

WILLIAM L. CALNAN,
VICTOR M. BORRELLI.

Chiseldon, Wilts.

Operations for Varicose Veins

SIR,—The leading article on the treatment of varicose veins (*Journal*, March 23, p. 692) makes no mention of their spontaneous cure following thrombophlebitis. A patient of mine was confined to bed for 18 days with acute bronchitis, treated in the first instance with chlortetracycline, and subsequently with "crystamycin" intramuscularly. One week after being allowed up, during which time he made a journey to the local chest clinic for chest x-ray (which was normal), he developed thrombophlebitis in the left internal saphenous vein, the site of extensive varices extending along its whole length from ankle to groin. He was treated with phenylbutazone by mouth, in addition to rest, lead lotion dressings, and crêpe bandaging. The condition subsided, and now, three weeks later, he has, in place of a varicose vein, a solid cord of clot, 18 in. (45.7 cm.) long, which represents a most satisfactory spontaneous cure.—I am, etc.,

London, N.W.10.

K. SANDERS.

Non-venereal Genital Diseases

SIR,—I was interested to read the review of the book on non-venereal genital diseases by Drs. Fritz T. Callomon and John F. Wilson (*Journal*, February 16, p. 388).

I must take it that it is the same Dr. Fritz Callomon whose *Die nichtvenereischen Genitalerkrankungen*² is in my library. The address of Dr. Callomon is given as Dessau-Anhalt, Germany. This will explain the "bias, perhaps determined by a nostalgic devotion to out-of-date German literature" and "the quaintly phrased" English, "almost as though it had been translated too literally from a foreign language," as the reviewer, Dr. Ambrose J. King, puts it.

In conclusion, may I add that the copy of only 189 pages is well bound, its illustrations, just as the paper and print, excellent? It is also perhaps interesting to note that the price of this book was 20 marks, which was of course 20s. *Tempora mutantur!*—I am, etc.,

East London, S. Africa.

NATHAN FINN.

Mild Endogenous Depression

SIR,—Continuing this welcome discussion on endogenous depression, I would like to add a few more comments. I am continually surprised at the prejudice and suspicion with which convulsive therapy is regarded by the vast majority of the medical profession. The only reason and excuse I am able to conjecture to account for this most tragic and lamentable attitude is the unfortunate outcome of cases inadequately treated by this method. In my experience the majority of depressives are made temporarily worse and many will obtain only transient remission from four or five E.C.T.s—the number specified by Dr. Robert Thompson (*Journal*, February 16, p. 401). Having made the diagnosis of depressive illness and embarked upon a course of E.C.T., I would suggest that it is generally advisable to give at least seven treatments and that the therapist must be prepared to give at least 12 treatments if necessary to obtain a full and lasting remission.

Although I fully agree with Dr. C. A. H. Watts (*Journal*, March 2, p. 521) that each case must be fully assessed before treatment, and that a case which from the history would appear likely to remit spontaneously should not be rushed into E.C.T., I do not share his view that E.C.T. is a traumatic operation. To me it would appear that in E.C.T. we have a therapeutic weapon of a stature ranking with that of the organic arsenicals, penicillin, and cortisone. We have also a physiological phenomenon of greater fundamental interest and potentiality than the discovery of cortisone itself. I have never observed clinically any traumatic effect from the use of E.C.T. with relaxants, but I would venture the opinion that, when the medical profession learns to recognize depressive illness, truly traumatic operations will be often avoided. Dental extractions, antrotomies, tonsillectomies, laparotomies, and even craniotomies are done every day in the mistaken belief that one particular organ is diseased when it is only dysfunctioning secondarily to a dysfunction of its autonomic nerve supply.

Finally, I would plead again for the use of E.C.T. in the home. Sensitive, depressed patients are far more readily and pleasantly treated in their own beds, when it is usually unnecessary for them or anyone but a close relative even to know the nature of the treatment being given.—I am, etc.,

Paignton.

R. J. T. WOODLAND.

Popular Delusion

SIR,—During the recent war it was quite common to find men in the Services who firmly believed that "something was put in the food to make them feel less sexual." It was usually thought that this substance was administered either in the tea or the potatoes. I thought that this curious idea had died out, but on questioning a young National Service man recently found that soldiers, at least, still believe in it. However, the theory has been diminished inasmuch as they think that this is done only during the period of training. After this presumably they may run wild.

This belief is strangely similar to the paranoid delusions which many psychotic patients develop, that poison is put in their food. It seems to me that in both cases it is used to explain diminished sexuality from other reasons. Possibly in the psychotics this may be due to a variety of factors, but, in the case of the National Service men, no doubt is caused by anxiety over a new and strange life. This explains the fact that after the initial training the "treatment" seems to stop. It would be interesting to know if others have met this or any similar popular delusions.—I am, etc.,

London, W.1.

CLIFFORD ALLEN.

Wire Brush Surgery

SIR,—May I comment on certain aspects of this method of treatment which is discussed by Dr. J. T. Ingram's very thoughtful review (*Journal*, March 23, p. 688) of the book by Dr. James W. Burks, Jr.,¹ on the subject?

The value of dermabrasion, by wire brushes or by other methods, is widely disputed. Thus Dr. George V. Webster,² in a lecture at Guy's, stated that the effect of dermabrasion depended on the length of the time of the follow-up; the longer the interval after operation, the worse the result. My own view, based on over three years' use of Kurtin's wire brushes and Eller's abrasive wheels, and a longer experience of abrasion by the cruder, now generally abandoned, method of sandpaper, is more optimistic.³ I believe the failures and adverse results which have been widely seen in the States and elsewhere have been largely due to indiscriminate use of the method.

In particular it should be remembered that this technique for the improvement of appearance is only one of a number of techniques which can be used for the same end. The best results can often only be obtained by a combination of abrasion with excision of some lesions, or more often by a general tension of the cheek (as is provided by the standard riedectomy techniques). The question of diagnosis

Obituary

F. C. O. VALENTINE, F.R.C.P.

Dr. F. C. O. Valentine, reader in chemotherapy and consultant bacteriologist to the London Hospital, died there on March 23 at the age of 59.

Frank Cyril Oliphant Valentine was born at Dundee on July 26, 1897, and was educated at Winchester. Before going as a scholar to Magdalene College, Cambridge, he served as an officer in the Royal Field Artillery during the first world war. He qualified M.R.C.S., L.R.C.P. from the London Hospital in 1923, and his early appointments there included house-physician to the medical unit under Professor Arthur Ellis. After this he was admitted to the London M.R.C.P. and became pathology assistant in the Bernhard Baron Institute, before spending six months as travelling fellow to the Rockefeller Institute, where he worked with T. M. Rivers on the growth requirements of *Haemophilus influenzae*.

He returned to the London Hospital to take up the appointment of assistant director of the clinical laboratories under Dr. P. N. Panton. For eleven years from 1926 he worked there in the various branches of clinical pathology. During this time he developed a special interest in haematology and in research on staphylococcal infection, on which, with Panton, he published observations and on the toxins of the organism, in particular the leucocidin. From 1937 to 1939 he was director of the inoculation department in succession to Dr. G. T. Western.

During the last war Valentine held the post of pathologist in the Emergency Medical Service at Claybury, and while there became attracted to problems of chemotherapy. His interest developed with the growth of the subject and was to be the main focus of his further research, clinical work, and teaching. He came back to the London Hospital in 1946 as director of the department of chemotherapy and soon afterwards was made reader in this subject as a member of the staff of the bacteriology department under Professor S. P. (now Sir Samuel) Bedson and with consultant duties in the hospital. As a result Valentine very effectively met the frequent need for practical advice on matters of treatment and the control of infection and was always careful to relate his laboratory findings to the problem of the individual patient. During these years he also played a considerable part in the teaching of medical, dental, and nursing students.

He was elected a Fellow of the Royal College of Physicians in 1952. With R. A. Shooter he wrote the third volume of *Recent Advances in Chemotherapy* (published in 1954): this book provided a short, very useful, and practical account of the subject. He devoted much time to research on antibiotics, and in this he was particularly concerned with the important and variable capacity of different organisms to survive periods of bacteriostasis. Up to the time of his last illness he was energetically studying chemotherapeutic drugs with special reference to their effects in combination.

During Frank Valentine's long association with the London Hospital and its medical school, to which he was deeply attached, he formed many lasting friendships among those who have worked and now work there. His gentle nature, quiet efficiency, and modest

of depth of ingrained dirt, or tattoo pigment, also affects the proper choice of technique. Depth can sometimes only be assessed accurately during the course of planing through the affected area of skin. It not infrequently happens that the whole depth of skin has to be removed. The operator then has to make a decision whether to use a surgical method of closure or to allow healing by marginal ingrowth with a risk of keloid or other formation of gross unsightly scarring. Clearly choice of method and end result will be influenced by training of the operator in use of local flaps and other plastic methods.

It is for these reasons that I would plead that the method be used only under full operating theatre conditions, not in the inadequate arrangements of consulting-rooms. It also seems reasonable to plead that whoever uses this method should be able to supplement it by other plastic techniques, such as riedectomy, when these are necessary for the best standard of result, or when complete abrasion of the lesion or pigment leaves a skin defect.

The use of "freon" and other freezing agents as the anaesthetic also raises important points for debate. Freezing⁴ causes intracellular dermal rupture; and Pomerat and Lewis⁵ have shown by tissue culture methods the added burden that this causes to normal healing. Nor do English patients take well to the freezing of large areas of the face; nor can it be considered really safe for use near the eyes. For these and other reasons I prefer local analgesia; a general anaesthetic is preferable for the most extensive cases.

There are also reasonable matters for debate about almost every aspect of the abrasive techniques at present used; about type of abrasive wheel, about rate of revolutions per minute of the wheel (the faster rates probably cause loading of the wheel more quickly, causing thermal friction to the tissues rather than abrasion), and about the type of post-operative dressing, as well as about the range and scope of method. My own view is that dermabrasion is capable of dramatically successful results in a minority of patients (such as with small superficial angiomas), and can give a very reasonable margin of improvement to many other patients (such as girls with acne scars, provided it is repeated two or three times); but it must also be remembered that it can be harmful and has some special complications of its own. This especially holds if it is not used with technical skill.

While minor areas can be successfully abraded under local analgesia on an out-patient basis, extensive facial operations can, I believe, only be safely done under general anaesthesia in an operating theatre with adequate post-operative nursing as an in-patient for two or three days. If these precautions are not observed, the method is likely to fall into the disrepute in England that prevails for it in many parts of America.—I am, etc.,

London, W.1

Test for Handedness

SIR,—The dominant-eye test for handedness described by Dr. M. Q. Birkbeck (*Journal*, March 23, p. 703) has been found to be less reliable than the following one.

The patient is given a small metal or cardboard ring of about 2 in. (5 cm.) diameter and asked to hold it with both hands. He then raises it quickly and sights a suitable target object with both eyes open. Each eye is then closed in turn, and the one which sees the target through the ring is the dominant eye. One advantage of this test is that it is not influenced by the handedness of the person, as has sometimes been found with the "pointing" test, although as far as I know the evidence for this is entirely empirical.—I am, etc.,

London, W.C.2.

D. A. SHEARD.

manner endeared him to many, by whom he will be keenly missed and long remembered with affection.—
C. F. B.

KATE FRASER, C.B.E., M.D., B.Sc., D.P.H.

Dr. Kate Fraser, a former commissioner of the General Board of Control for Scotland, died at Paisley on March 20 in her eightieth year, after a short illness.

Kate Fraser, whose father, Dr. Donald Fraser, was a distinguished physician in Paisley, went on from Paisley Grammar School to study medicine at Glasgow University and later in Vienna, Paris, and the U.S.A. After taking the B.Sc. (with special distinction in physiology) in 1900, she graduated M.B., Ch.B. in 1903. There-

after she worked for a time as a resident at the Crichton Royal and as a general practitioner, until she was appointed a school medical officer in Govan, where she introduced the use of intelligence tests in schools. In 1913 she published a paper on the use of Binet-Simon tests in determining the suitability of children for admission to special schools. In the same year she took the D.P.H. and proceeded to the M.D.

Dr. Fraser's association with the General Board of Control for Scotland lasted for 33 years; she was the first woman to be appointed a deputy commissioner and later a commissioner and member of the Board. For 21 years as a deputy commissioner she visited patients under guardianship throughout Scotland—in cities, in the country, and in the Highlands and Islands that she loved so well—maintaining a close co-operation with local doctors and local-authority officials. It was during these years that Dr. Fraser attained her unrivalled knowledge and understanding of the social implications of mental handicap and of the importance of the relationship between the handicapped and the community. As a commissioner she organized the ex-Service psychiatric after-care scheme for Scotland. Her determination was largely responsible for the mentally handicapped being included in the provisions of the Disabled Persons Employment Act.

Dr. Fraser was appointed C.B.E. in 1945. She was chairman of the Scottish division of the Royal Medico-psychological Association for three years and was made an honorary member of the Association in 1952.

A colleague writes: Dr. Fraser commanded the respect and affection of all who knew her and of all whose interests touched the field of mental health. Throughout her life, often as a pioneer, she devoted the zeal of the "Fighting Frasers," to whom she was proud to belong, to the service of the mentally ill and handicapped with insight, sympathy, and courage. In spite of her outstanding abilities and achievements she was always absolutely unassuming. Thinking of her, we recall her slight figure, her quick step, her clear and critical mind, her delightful sense of humour and enjoyment of so many things, her kindness and understanding, and her unflinching readiness to give help and encouragement from her own strength of character and ripe experience. She always retained her youthful spirit, and, to her, retirement in 1947 at the age of 69 did not mean rest; indeed, her work in various parts of the mental health

field came to absorb all her time and energy. She devoted herself particularly to the Scottish Association for Mental Health, of which she had been one of the founder members. In August of last year she attended the Conference of the World Federation for Mental Health in Berlin, and only eleven days before her death she was occupied, as chairman of executive, with arrangements for the conference of the Scottish Association for Mental Health to be held at the end of March—a conference which must now take place without her, but not without the continuing inspiration of her work and personality.

Kate Fraser has made a unique contribution to social psychiatry in Scotland; her name will be honoured and her influence will continue for many years to come.

W. S. RUSSELL THOMAS, M.B., B.Chir.

Dr. W. S. Russell Thomas, formerly Member of Parliament for Southampton, died at his home at Warlingham, Surrey, on March 21 at the age of 61.

William Stanley Russell Thomas was born at Talgarth, Breconshire, on February 5, 1896, and was educated at Brecon County School, Christ College, Brecon, Queen's College, Cambridge, and Guy's Hospital. During the first world war he served as a surgeon sub-lieutenant in the R.N.V.R. with the Northern Patrol. Returning to Guy's he qualified in 1919, graduating M.B., B.Chir. in the following year and being awarded the Treasurer's gold medal in clinical medicine. After holding resident appointments at Guy's Hospital and Sheffield Royal Hospital, he worked for a time as assistant medical officer at the West Riding Asylum, Wakefield. He was in general practice at Warlingham from 1922 to 1932 and afterwards in London. While in Surrey he was radiologist to the Caterham Cottage Hospital, and from 1926 to 1932 a member of the Caterham and Warlingham Urban District Council. During these years he read for the Bar and was called by Lincoln's Inn in 1930.

Dr. Russell Thomas stood for Parliament several times as a Liberal. He was unsuccessful at the General Elections in 1931 (Ilford), 1935 (Aberdeen and Kincardineshire Central), and 1936 (Ross and Cromarty). In 1940, standing as a Liberal-National, he was returned unopposed as the Member for Southampton in the vacancy caused by the elevation to the peerage of Sir John Reith. He failed to retain his seat at the 1945 General Election, and was defeated at the polls at Middlesbrough East in 1950 and Brecon and Radnor in 1955. From 1937 to 1945 he was deputy chairman of the London Liberal National Party. He was a member of the Select Committee on Public Petitions from 1942 to 1944, the Select Committee on National Expenditure in 1944, and the British-American Parliamentary Committee from 1942 to 1945. For some years also he was a member of the court of governors of Southampton University College.

Apart from his professional and political duties Dr. Russell Thomas took a keen and abiding interest in the welfare of animals. He became a member of the Royal Society for the Prevention of Cruelty to Animals and of its council in 1943, and was chairman of the society in 1951-2. Since 1944 he had been a vice-president of the National Federation of Property Owners. He married Miss Kathleen M. Bennett in 1922 and she survives him.

R. C. CLARKE, O.B.E., M.B., F.R.C.P.

Dr. R. C. Clarke died at his home at Bristol on March 23. He was 71 years of age. His death after a few days' illness came as a great shock to his wide circle of friends.

Richard Christopher Clarke was born on June 15, 1885, and came of an old Bristol family. From Clifton College he went on to study medicine at University College, Bristol, and at the Middlesex Hospital, qualifying in 1910. In the following year he graduated M.B., Ch.B. at Bristol. After holding several resident appointments at the Bristol Royal Infirmary he was elected assistant physician in 1913. As far back as 1904 he joined the Bristol Rifle Volunteers as a private, and from the first formation of the Territorials he was closely connected with the 4th Gloucesters. He went to France as their M.O. in 1915 and resumed this post after the war. From 1916 to 1919 he was with the 19th Casualty Clearing Station and was one of the first to recognize the new disease of trench fever. Mentioned in dispatches, he was appointed O.B.E. for his services and awarded the Territorial Decoration.

After being demobilized he took the M.R.C.P. in 1920 and returned to his hospital and private practice in Bristol, becoming lecturer in clinical medicine at the university. The diseases of children were his particular interest, and most of his medical writings were on paediatric subjects. Many past students at Bristol retain affectionate memories of "Dickie" Clarke. He was elected F.R.C.P. in 1934.

At the beginning of the second world war he went to the Royal Herbert Hospital, Woolwich, as lieutenant-colonel A.M.S., and in the following year, as full colonel, he formed the No. 2 General Hospital and took it to the Middle East. He was wounded in 1941 and relinquished his commission, under the age limit, in 1942. The loss of his elder son during the war struck him a grievous blow.

Since his retirement from the staff of the Royal Infirmary in 1947 he had devoted to other interests his abounding stores of energy and enthusiasm. Chief among these hobbies was the Clifton Zoo, which owes him an incalculable debt for its present status and ever-increasing popularity. Scarcely a day passed without his paying it a visit, and his fertile brain was constantly hatching new schemes for its development and modernization. He was a vivid personality and to the last his mind remained alert as that of a young man. He was a loyal friend, and his loss will be felt for many a long day. He leaves a widow, one son, and two daughters, one of whom is a doctor.—H. C.

We record with regret the tragic death of Dr. JOHN PULFER on March 26 at the age of 54. He was stabbed to death in his Hendon surgery while seeing a man who was believed to be a patient of his. Johannes Pulfer, who was a native of Hildburghausen in Thuringia, studied medicine at the Universities of Würzburg, Freiburg, Leipzig, and Berlin, graduating in medicine at Würzburg in 1925. The years between 1925 and 1933 he devoted to extensive studies in several fields of medicine, including radiology, bacteriology, and serology. He held several hospital appointments in Berlin, and was on the staff of the Urban Hospital there. During these years he published a number of papers in medical periodicals. In 1933 he became a victim of Nazi oppression and came to England at the end of May. This was the turning-point of his life; he loved Britain and its institutions and traditions to the last day of his life. He took a postgraduate course in Glasgow, obtaining the triple conjoint qualification early in 1935. Later that year he established himself in general practice at Colindale, where he was successful and happy in his work until his untimely and terrible end.

Dr. C. WIESNER writes: Medicine was John Pulfer's true vocation, inspiring him and keeping him deeply interested

during the whole of his professional career. He was a great reader. In spite of a very busy life he found time to keep abreast with the progress and advances of medicine, and he took a great delight in taking medical students to share his surgeries and rounds before their final exams. His keen sense of humour helped many of his patients and was appreciated by all his friends. He was 54 years of age when fate struck him down at work, at the end of a long day, plunging his family, his patients, and his friends alike into the depths of despair and grief, because they could not believe that a light which had shone so brightly could have been extinguished with such cruel suddenness for ever.

J. G. writes: The cruel and tragic death of John Pulfer has been a most grievous blow to many people, not least to his very many patients, to whom he was at all times a good friend and a physician of rare wisdom. It has become almost a commonplace to say that such a man represented general practice at its best, but in John's case this was literal truth. To him his patients always came first, and in the 16 years which have been enriched for me by his friendship I have never known him refuse help to anyone in distress. He brought to his patients not only considerable clinical skill but also a rich and happy personality. He bubbled over with the joy of living and was full of kindness, good humour, and toleration. Despite a very large practice and an immense amount of work, he found time to read of the latest developments in medicine as well as fairly widely in general literature. His enthusiastic praise for such books as *Cry the Beloved Country* by Alan Paton (he must have given dozens of copies of this to friends and relations) shows not only his instinctive recognition of fine literature but also his even more instinctive and fundamental sympathy with the world's unfortunates. Those who knew him and loved him will always be grateful for his friendship. His compassion, courage, and modesty will remain fresh in many hearts. Of no one can it more simply or unaffectedly be said that "in his tongue was the law of kindness."

Mr. C. B. F. Tivy, consulting surgeon to the Plymouth Royal Eye Hospital and consulting ophthalmic surgeon to the Prince of Wales's Hospital, Plymouth, died at his home near Brixham, Devon, on February 27, aged 76. He had patiently endured a long illness. Cecil Brian Forsayeth Tivy was born at Cork on May 3, 1880, and was educated at the old Queen's College there, graduating M.B., B.Ch. from the former Royal University of Ireland in 1903. Four years later he proceeded to the M.Ch. After graduation he held house appointments at the Staffordshire General Infirmary, Sunderland Royal Infirmary, and the Cork Eye, Ear, and Throat Hospital before going into general practice at Brixham in 1908. At the beginning of the first world war he served in the R.N.V.R., and after being invalided out of the Navy in 1915 he joined the R.A.M.C., serving in France, and later in Mesopotamia and Egypt. In 1918 he returned to Brixham, but he had always been interested in eye work, and early in 1919 became a clinical assistant at Moorfields. At the end of that year he joined the late Mr. J. R. Rolston in ophthalmic practice in Plymouth, and was appointed honorary surgeon to the Plymouth Royal Eye Hospital in 1925. He also became consulting ophthalmic surgeon to the Prince of Wales's Hospital and the City Hospital, Plymouth, and to the Royal Albert Hospital, Devonport. He was honorary secretary of the Plymouth Medical Society for some years, and a former president of the South-western Ophthalmological Society. He served as a vice-president of the Section of Ophthalmology when the B.M.A. held its Annual Meeting at Plymouth in 1938. During the second world war he was medical officer to the Yealmpton Home Guard. He retired from hospital work in 1946, but continued in practice until 1948. Mr. Tivy was a great lover of the countryside and country pursuits. He enjoyed shooting most of all, but was an enthusiastic follower of most kinds of sport and a keen golfer. He took a great interest in freemasonry and was a past master of his lodge. He will be sincerely mourned by his former patients not only

for his skill but for his invariable kindness and generosity. To many he became a personal friend. He leaves a widow and two daughters, to whom our sincere sympathy is extended.—P. R. G.

Dr. R. J. WEEDNER died unexpectedly on March 14 at his home at St. Brelade's, Jersey, where he and his wife had settled after he retired from practice at Tynemouth. Some weeks ago, after a visit to his native north country, he was taken ill on returning to London and spent a fortnight in hospital. He had been home about two weeks, apparently fully recovered. Robert Joseph Weedner was born at Newcastle upon Tyne on April 22, 1882, where his father was prominent in business and civic affairs, being an alderman and magistrate, and, in 1912, lord mayor. He received his education at St. Cuthbert's Grammar School in Newcastle, and afterwards at the Institut St. Joseph, La Louvière, in Belgium. At the latter college he and his twin brother Edward, who lives in Newcastle, introduced soccer. His medical education was undertaken at the College of Medicine in the University of Durham, and there he graduated M.B., B.S. in 1906. General practice claimed him, and in 1906 he settled in the borough of Tynemouth, where over the years his practice became a large and representative one. He was interested in surgery, and in 1911 was elected an honorary surgeon to the Tynemouth Victoria Jubilee Infirmary, where he proved himself to be a valuable member of the staff. At the time of his retirement he was chairman of the medical staff. Active in British Medical Association matters, he was chairman of the Tyneside Division from 1938 to 1943. During the first world war he served abroad and was present at the assault on Gallipoli. During the second world war he lost a son in action in Burma, and in 1955 a daughter died after a painful illness. There are two sons and a daughter surviving. Sport was a lifelong interest. As a medical student he played for his college at football, and after his playing days were over kept up a keen interest as a spectator. Tennis and golf he also enjoyed, and the country pursuits of fishing and shooting completed his wide sporting activities.

S. C. S. writes: I knew Dr. R. J. Weedner for over thirty years, both as a colleague in general practice and as a fellow member of the Tynemouth Infirmary staff, and I would like to pay tribute to one who was a worthy member of his profession. With his high integrity and loyalty, he was representative of the very best type of hard-working family doctor. His many friends and patients in the north will mourn his passing, while retaining happy memories, and would wish to extend to Mrs. Weedner and the family their sincere sympathy.

Mr. G. H. CAIGER writes from Durban, Natal: I see from the *Journal* of January 26 (p. 232) that my old friend, E. BARRINGTON BROOKE, has passed on. We first met at Caius, where he entered as a classical scholar during the first world war. After one term, junior medical students were advised to join H.M. Forces. Debarred on medical grounds, Brooke left to relieve a schoolmaster fit for service. Later, when the need for medical men was stressed, he decided to take up medicine, and so, on return from the war, those who survived joined him again. One of the most sociable of men, he was much prized as a friend. Brooke was a lifelong sufferer from asthma and would ask what flowers were in bloom before accepting an invitation for the week-end. We once shared a "long vac." term at the Old Vicarage at Grantchester, where the church clock still stood at 10 to 3 (as in Rupert Brooke's nostalgic war poem). Brooke was on the organizing committee for the International Gerontological Congress held in 1954. Owing no doubt to his modesty, I had not known of his Fellowship of the Royal College of Physicians until I saw his obituary. The memorial service held by his old hospital paid no undeserved tribute, I feel sure, to a classical scholar diverted by war into the realm of medicine, which he served and adorned so faithfully and with that incomparable human touch which was second nature to him.

Medical Notes in Parliament

EDINBURGH HOSPITAL CONTROVERSY

The controversy over the appointment of a consultant physician to a group of hospitals in Edinburgh was brought into the House of Commons on March 25 by one of the local M.P.s, Mr. J. H. HOY (Leith, Lab.). The two hospitals chiefly concerned are the Bruntsfield Hospital for Women and Children and the Elsie Inglis Maternity Hospital, the only two hospitals in Scotland, Mr. Hoy said, where women could be assured of seeing women consultants.

Both were memorial hospitals commemorating two pioneers, Dr. Sophia Jex Blake and Dr. Elsie Inglis, and were established by subscriptions to provide medical care for women by women doctors. The Bruntsfield Hospital started with 17 beds and now had 81, and the Elsie Inglis Hospital was the second largest maternity hospital in Edinburgh, and dealt with about 1,700 cases a year. The consultant physician was about to retire. By a coincidence the consultant physician at two other hospitals in the Southern Group, the Deaconess Church of Scotland Hospital and the Longmore Hospital, was leaving to take up an appointment elsewhere. The South-east Regional Hospital Board had decided to amalgamate the two posts. The decision had aroused a storm of protest. This had been supported by the Edinburgh Medical Committee, the Edinburgh Executive Council, the Medical Women's Federation, various other organizations and public figures, and the consultant and specialist committee of the South-eastern Region, whose reasons were that the volume of work was too great to be done efficiently by one consultant, and the need for at least one woman consultant physician in the region. In spite of this opposition the Secretary of State had upheld the decision of the regional hospital board and supported the paltry excuse that here was an opportunity to combine the two posts and pay a larger salary.

Mr. Hoy summed up his argument with a quotation from a letter by Dr. T. R. R. Todd and others, published in the *Supplement* of February 9 (p. 62), which referred to "a regional hospital board out of touch with medical and lay opinion—underestimating the valuable part played by the smaller hospitals"; and the opinion of Miss Margaret Kidd, Q.C., that "to appoint a man consultant to these hospitals must appear to every honest person an outrageous breach of trust."

Government Reply

Mr. J. NIXON BROWNE, Under Secretary, Scottish Office, did not give the promise of reconsideration for which Mr. Hoy asked. He summarized the Secretary of State's decision, published in the *Supplement* of March 16 (p. 116). It was the duty of the regional board, under the Health Service regulations, to plan the specialist services in its region. The Secretary of State could not intervene in the day-to-day exercise of functions which had been delegated to the board. The health department was frequently consulted by regional boards about their specialist services. The Secretary of State could advise and recommend, and ultimately direct. But to override the decision of a statutory body was a serious matter. The regional board was fully seized of the value of special hospitals for women, and it also knew there was a demand for the services of a woman consultant physician in Edinburgh. But the demand was limited. There were only 19 medical beds in Bruntsfield Hospital (compared with the 1,001 in Edinburgh); the other 62 were still staffed by a woman surgeon and a woman gynaecologist; and all the 68 beds at the Elsie Inglis Hospital were staffed by women. The appointment had not yet been made, and it might still be a woman.

The regional board and the board of management had assessed the services required as five half-days out of 11. The salary would be £1,100 to £1,600. The board concluded that the Bruntsfield and Elsie Inglis post alone would not attract a wide enough range of applicants of satisfactory

quality. They combined it with the Deaconess and Longmore Hospitals, in the same group. The salary for the combined post would be £2,100 to £3,100 on a whole-time basis, or about £1,800 to £2,600 on a maximum part-time basis. It was considered that a post of this broad scope and at this salary would attract, if open to either sex, a consultant of the highest calibre. There was no evidence that regional boards were prejudiced against women consultants. This regional board had asked him to emphasize that should a woman candidate prove herself worthy in open competition she would be appointed to the post with the board's fullest confidence. The Secretary of State's decision was the right one, and the only possible one.

Testing New Drugs

Mr. A. BLENKINSOP (Newcastle-upon-Tyne, East, Lab.) asked the Minister of Health on March 25 whether he would invite the Central Health Services Council to inquire into the advisability of establishing some system of laboratory and hospital testing of new drugs before their use in the Health Service. Mr. D. VOSPER said that a joint committee of the Central and Scottish Health Services Councils already advised on the therapeutic value of new proprietary drugs and preparations, and he thought in present circumstances that was as far as they could go. Mr. BLENKINSOP asked if the Minister did not feel that with the large number of new drugs coming on the market almost every week—some expensive, and some that were challenged medically—it was desirable that there should be some independent test of a more extensive kind than the committee could provide. Mr. VOSPER told him that that was a matter exercising his mind. There were certain proposals under consideration. But Mr. Blenkinsop's proposal had far greater implications than he realized.

The PRESIDENT OF THE BOARD OF TRADE informed Mr. H. WILSON (Huyton, Lab.) on March 28 that imports of drugs, medicines, and medicinal preparations, excluding antibiotics, from the United States were valued at £1.1m. in 1956. These goods were not separately specified in the trade returns for 1951, but imports in that year were estimated to have been of the same order as in 1956.

Tuberculosis Among Immigrants

Mr. T. IREMONGER (Ilford, North, Con.) asked what examination of immigrants into the United Kingdom was made to determine whether they were suffering from tuberculosis or other communicable diseases. Mr. J. K. VAUGHAN-MORGAN, Parliamentary Secretary, replied that any alien immigrant might be subjected to a general medical examination before he was permitted to land. Where tuberculosis was suspected in any person, British or alien, coming to this country the port medical officer notified the medical officer of health of the district to which the person was proceeding, so that he might be brought under observation. The port medical officer had power to examine any person if he had reason to think he was suffering from any other infectious disease, apart from venereal disease. Dr. EDITH SUMMERSKILL (Warrington, Lab.) asked why, if it was considered necessary to x-ray people in factories to diagnose this disease, it was not equally important to x-ray immigrants. Mr. VAUGHAN-MORGAN said it had been explained that to establish a sufficiently thorough health check would involve new restrictions out of all proportion to the danger involved.

Cloistering Emoluments

Mr. JOHN RANKIN (Glasgow, Govan, Lab.) asked the Secretary of State for Scotland on March 26 if he would inquire into the prevalence of the cloistering-emolument system of service in State hospitals in Scotland, and indicate what steps he proposed to take to bring about its termination. Mr. J. NIXON BROWNE, Under Secretary, Scottish Office, said that, if Mr. RANKIN was referring to the fact

that some doctors were required to live in hospital premises where it was necessary that doctors should always be available, the Secretary of State had no evidence of dissatisfaction with this practice. Mr. RANKIN asked if the Minister agreed with the principle that employers had the right to claim emoluments from cloistered staff who were cloistered for the purpose of carrying out their duties. Mr. BROWNE said that was a different question. No responsible group in the hospital service had objected to the present practice. He would look into any case that Mr. Rankin had in mind.

Notification of Burns and Scalds

Dr. DONALD JOHNSON (Carlisle, Con.) suggested that the Minister of Health should introduce legislation to make burns and scalds, causing accidents that needed hospital attention, notifiable by the appropriate authorities. Mr. VAUGHAN-MORGAN said he scarcely thought this would be justified. Dr. JOHNSON asked that at least there should be some arrangement for reliable statistics to be collected. Mr. VAUGHAN-MORGAN said that in some areas medical officers of health were notified, by arrangement with the hospitals. That was being encouraged, and he would welcome a wider extension of it.

Mineral Waters at Bath

Mr. I. PITMAN (Bath, Con.) asked the Minister of Health whether, in view of the anxieties of expectant mothers and others in Bath, he would institute an inquiry into the properties of the mineral waters there. Mr. VAUGHAN-MORGAN, the Parliamentary Secretary, stated that the maternal and infant mortality rates and the number of premature babies born in Bath had all been lower than the national average in most recent years; the stillbirth rate had recently been higher, but in the period since 1936 had more often been below than above the national average. The Minister therefore saw no cause for local anxiety. The content of the mineral waters was known and seemed to have no relation to the matter.

Medical Lists

In reply to a question by Sir KEITH JOSEPH (Leeds, North-east, Con.) on numbers of doctors on medical lists in England and Wales, Mr. VOSPER stated on April 1 that between July, 1952, and July, 1956, the number of doctors increased by 1,908, or 11%, and the number of patients per doctor diminished from 2,436 to 2,272. In 1952 there were 7,596 doctors practising in areas then classified as under-doctored with about 21½ million patients on their lists. By 1956 the areas classified as under-doctored had been so reduced that there were only 3,484 doctors practising in them with about 9½ million patients, a very substantial improvement.

Handicapped Persons' Welfare

Mr. J. K. VAUGHAN-MORGAN, Parliamentary Secretary, Ministry of Health, announced on April 1 that Mr. Edward Evans, M.P., was to be chairman of an advisory committee on the health and welfare of the handicapped. The other members would be (medical members in capitals):

Mr. N. D. Bosworth-Smith, Dr. T. M. CUTHBERT, Alderman Mrs. O. G. Deer, Miss S. T. Hart, Miss G. MacCaul, Alderman E. E. Mile, Sir Cecil Oakes, Alderman Miss May O'Connor, Professor Sir HARRY PLATT, P.R.C.S., Mr. R. G. Richards, Mr. Godfrey Robinson, Alderman R. G. Robinson, Lady Sempill, Professor A. B. SEMPLE, Mr. T. H. Smith, Miss B. H. F. Townsend, S.R.N., Alderman Lieutenant-Commander J. H. Turner, Dr. J. A. L. VAUGHAN-JONES, Mr. H. Willard.

N.H.S. Hospital Staffs.—The number of nurses employed in Health Service hospitals has increased from 125,752 full-time and 23,060 part-time in 1949 to 145,802 and 35,568 respectively in September, 1956. The administrative staff increased from 25,215 in 1949 to 29,664 in 1955.

Medico-Legal

TRIAL OF DR. J. BODKIN ADAMS
EXPERT EVIDENCE

[FROM OUR SPECIAL CORRESPONDENT]

The trial of Dr. John Bodkin Adams, of Eastbourne, continued before Mr. Justice Devlin at the Old Bailey. Dr. Adams is charged with the murder of a patient, 81-year-old Mrs. Edith Alice Morrell, who died on November 13, 1950. He pleads not guilty.

Sir Reginald Manningham-Buller, Q.C., is appearing for the prosecution with Mr. Melford Stevenson, Q.C., and Mr. Malcolm Morris. Mr. Geoffrey Lawrence, Q.C., is appearing for Dr. Adams with Mr. Edward Clarke and Mr. John Heritage. The Medical Defence Union is acting for Dr. Adams.

On the seventh day of the trial (March 27) after evidence had been taken from Superintendent Hannam, of Scotland Yard, and other police witnesses, Dr. Adams's partner, Dr. R. V. Harris, gave evidence. He said he saw Mrs. Morrell on June 12, 1949, and on several occasions in May, 1950. Dr. Adams, he said, usually instructed one to carry on with whatever treatment he had been giving to the patient, and to the best of Dr. Harris's memory he had complied with the instruction. He said he must have increased the morphine and heroin dose on September 12, 1950, because Mrs. Morrell was in an extremely irritable state over Dr. Adams being away. In cross-examination by Mr. Lawrence, Dr. Harris agreed that Dr. Adams was using the morphine and heroin in combination to effect the sedation which was necessary.

Next day Dr. Arthur Henry Douthwaite, of Harley Street, London, was called as the Crown's expert medical witness.

Dr. Douthwaite, described as senior physician to Guy's Hospital, consulting physician to the Royal Hospital and Home for Incurables, honorary consulting physician to the Horsham Hospital, and editor of Hale-White's *Materia Medica*, said he had been in general practice from 1924 until 1928 in Worthing. He described the three common causes of a stroke as (1) haemorrhage of the brain, (2) cerebral thrombosis, and (3) cerebral embolism. Severe cerebral haemorrhage almost always resulted in death within three or four days; cerebral thrombosis patients usually survived and their condition would improve spontaneously over several months. A patient could live for many years after such a complaint.

The Attorney-General then directed the witness's attention to the case of the deceased. He said:

"You have heard the evidence given in this case, and I think you have seen the nurses' reports?"—"Yes."

"What is your conclusion as to the cause of the stroke from which Mrs. Morrell suffered in 1948?"—"In all probability a cerebral thrombosis."

"We have also heard that one effect of the stroke was paralysis of the left side?"—"Yes."

"Is such a stroke followed by any other symptoms?"—"Well, yes, in so far as that naturally the patients, finding themselves unable to move, will naturally be depressed and irritable, lacrimose."

"I want you to indicate quite briefly what is the proper course of treatment for a patient who has suffered a stroke as a result of cerebral thrombosis?"—"Within a few days, as soon as one is able to obtain any co-operation from the patient, when the mind is clear, as it may well be within a few days, one should do one's best to mobilize the patient, encourage movement of the body and indeed encourage her to try to move the paralysed part. Massage, exercises, and so forth."

The witness was then referred to the prescription list, which showed that on July 21, 1948, 40 hypodermic tablets each of heroin and morphine sulphate had been prescribed, the total being 6 2/3 gr. (430 mg.) of each drug.

Attorney-General: "Is there, in your opinion, any justification for injecting morphia and heroin immediately after a

stroke caused by cerebral haemorrhage?"—"No, there is no justification."

"Is it right or wrong to do so?"—"It is wrong. In all circumstances it would be wrong to inject heroin and morphia."

"What about morphia alone?"—"Morphia alone should not be given to someone who has had a stroke unless there was an episode of acute mania; then that would be justified as a single injection."

The witness was then referred to the remainder of the list, which, he agreed, indicated that up to the end of 1949 morphine and heroin had been prescribed for the patient throughout the period.

"What would be the effect of administering morphia and heroin to an old lady who has suffered a stroke? What would be the effect on her rehabilitation?"—"It would greatly interfere with any progress of rehabilitation."

Severe Addiction

Dr. Douthwaite explained that the administrations referred to would inevitably produce severe addiction to both drugs; they would seriously interfere with the patient's prospects of resuming normal life, for they would take away all the co-operation necessary. It was not necessary or generally desirable to use sedation immediately upon a cerebral thrombosis, except that it was reasonable to give something to make sure of sleep at night, but certainly not morphia or heroin. It was not necessary to keep the patient as quiet as possible in the daytime; on the contrary, if the patient were kept very quiet the risk of another stroke was increased because clotting in any artery was more likely to occur when the blood circulated slowly through the patient being kept very quiet. Heroin and morphia would tend to slow the respiration, which might become deeper, and that would result in interference with ventilation of the lungs, possibly leading to collapse and pneumonia—putting it shortly, chest complications. Morphia was also powerfully constipating. Cerebral irritation for a few days after the stroke would result in irritability, but the condition would soon pass off. He would expect a patient of 81 to be suffering from some degree of cerebral arteriosclerosis, however, which was likely to result in irritability, but it would be quite wrong in that case to administer morphia and heroin, because addiction would be rapidly caused and because there were many other safer drugs which were much more effective. In 1950 bromide, barbitone, and lots of the barbiturates had been available. The administration of morphia and heroin together regularly over a short period of time would probably produce drowsiness and sleep to start with, but on recovery from that, on awakening, the patient would feel ill and irritable, possibly sick, and might vomit. The administration of the two, over a period, to a person of 81 who had not suffered a stroke would produce irritability; if irritability were already present due to arteriosclerosis regular injections of the two would worsen the condition.

The patient's normal reaction to the feeling of pleasure referred to was one of dependence on the doctor, who naturally obtained a complete ascendancy over the patient once addiction had occurred.

The Attorney-General: "What legitimate purpose can injections of morphia be daily administered for over a long period?"—"Only for a severe pain which cannot be quelled by drugs which are less dangerous. By 'prolonged periods' I have in mind, as I think you have, sir, several months."

The normal dosage of morphia was 1/4 gr., but the *British Pharmacopoeia* maximum was 1 gr. Nervous insomnia was a strong indication that morphia should not be used, for it would certainly establish addiction in such a case. The normal dose of 1/4 gr. would be given four-hourly in the case of severe pain; it would be given more frequently if the pain were intense, possibly every hour.

"Is morphia a dangerous drug?"—"In the legal sense?"

"Yes."

"Is it a dangerous drug also in the medical sense?"—"It is a dangerous drug in both senses."

"What about heroin?"—"Also in both senses."

"How do they compare?"—"Well, heroin is a stronger drug than morphia, is a more dangerous drug. Its action in many respects is similar to that of morphia, but it differs in some important respects."

"What is the effect of heroin on respiration?"—"It is powerfully depressant. That is the great danger."

"Powerfully depressant?"—"Depressant, yes, of what we call the respiratory centre in the brain."

"When you say 'powerfully depressant' can you give an idea of how it compares with morphia?"—"In that respect?"

"In that respect?"—"Oh, about four times, three or four times more powerful."

"As a depressant of respiration?"—"Yes."

The maximum dosage was 1/4 gr. according to the 1948 B.P. recommendation, said Dr. Douthwaite, seldom given more than once in six hours except in the face of terrible pain. Heroin relieved pain and calmed the patient in consequence. It exercised a slight sedative effect when given to a patient who was not in pain and was not accustomed to the drug, but the drowsy effect was mild and uncertain and disappeared with frequent repetition. Heroin would facilitate sleep by removing pain.

Twitching of Limbs

Twitching of the limbs could be induced by heroin; barbiturates would tend to depress or prevent that if adequately applied. Heroin stimulated the spinal cord much more constantly and violently than morphine, the visible effect being twitchings or convulsions. The natural tolerance of human beings to heroin and morphia varied, but would develop very quickly within a fortnight to three weeks with routine administration. The effect of the 1/4 gr. decreased and lasted for a shorter time once addiction was achieved. If the administration to an addicted patient were stopped the patient became terribly ill, wildly excited, getting pain in the limbs, sweating, sneezing, and possibly collapse—a whole host of what were known as withdrawal symptoms. These became maximal if morphia or heroin were withheld for about two days. Curing an addiction was a very unpleasant process for the patient. Maintaining routine injections of morphia and heroin at the same level for a long period would produce suffering; it would keep the patient in a state of almost constant craving for more drugs and thus ensure that she would be excitable, bad-tempered, impossible to live with.

"Omnopon," which contained 50% morphia, had a similar effect to the latter drug, said Dr. Douthwaite. Paraldehyde was a sedative, the distinguishing features of which were its revolting smell and taste; it also acted as a depressant on the respiratory centre and on the whole of the central nervous system.

The Attorney-General: "But could that properly be used in an endeavour to stop twitchings?"—"Yes."

"But what would be the effect if it was used to stop twitchings if it was superimposed on heavy administrations of heroin alone or heroin and morphia?"—"That would be likely to produce death." It was not of itself a dangerous drug, he said, it would deepen coma or heavy sleep if that existed.

"Is there any justification or legitimate ground, in your view, for administering morphia and heroin together?"—"No."

"What would be the object of giving a routine administration of morphia and heroin? What would be the medical object?"

"The medical object?"

"Can you think of one?"—"There is not one."

Mrs. Morrell, on June 20, 1949, was, in the witness's view, a fully addicted patient.

Keeping Patient Under

The witness was then taken through the remainder of the nurses' reports. After the luncheon adjournment the Attorney-General directed his questions to treatment extending up to the night of November 9-10, 1950:

"I would rather, Dr. Douthwaite, if you would say in your own language what these reports indicate, what the application of this heroin indicates was the basis of the instruction given on November 9 and 10 to give heroin 1 gr. s.o.s."—"It seems to me that the only reason why this was given was in order to keep her under. There was no indication that I can see for the therapeutic administration of heroin on those dates in those quantities."

"When you say 'keep her under' what exactly do you mean by that?"—"Well, to put it in simple language, to keep her thoroughly doped or drugged."

"Now I want you to express your considered opinion as to the effect on this lady of 81, this semi-paralysed lady of 81, of the dosages of heroin given in these last few days, that is to say, from November 8 onwards, allowing for the tolerance which had been acquired to routine injections? What, in your opinion, was the effect of the dosage of heroin given since November 8 as shown by the nurses' reports? Seeing the rise from 2 of morphia and 2 of heroin on the 8th, 2 of morphia and 1 1/2 of heroin on the 9th, and then on November 10 to 4 of heroin and 1 of morphia, then on the next day 3 1/2 and 5 respectively and on the 12th 2 and 3 1/2; looking at those dosages of heroin that she had leading up to the 12th, leading up to the time of her death on the 13th, making all allowances for acquired tolerance, what in your opinion was bound to be the effect of that dosage of heroin as administered to her as shown in the nurses' reports?"—"I believe that it would have produced jerking spasms or convulsions and ultimately death."

"Is there anything in the nurses' records or in the evidence that you have heard to justify this administration of heroin and morphia in November, and particularly on the 10th, 11th, and 12th?"—"No, there is nothing."

"Did you find any evidence of her suffering severe pain since her stroke?"—"No." A condition of severe pain following upon a stroke occurred very rarely, he said, and was known as a thalamic syndrome. There was no indication in the reports of any such complaint.

After referring the witness again to the prescriptions the Attorney-General said:

"I need not take you through the quantities, but you have examined, I think, the entries in particular from No. 81 onwards, have you not? You have seen those ones in November?"—"Yes, the ones in November."

"I think it follows, if those prescriptions in fact exceeded the amount shown in the nurses' reports and the difference was in fact administered to Mrs. Morrell in that period, what effect would that have had on her prospect of life?"—"They would have killed her." He said that the drugs administered on the last day would have been enough to kill the patient.

"We have also heard evidence that one phial of morphia and one phial of heroin or omnopon were left over after her death?"—"Yes."

"Deducting that from the amounts prescribed for her—deducting that—what would have been the effect of administering the balance of the prescriptions?"—"It would still have resulted in death."

"You heard Nurse Randall's evidence as to the symptoms of jerkiness and all that, did you not?"—"Yes, I did."

"Having regard to that dosage of heroin, were they to be expected or not?"—"Yes, they were."

"Is there in your view any other explanation for them?"—"No other explanation is possible in my view."

Cerebral thrombosis in November, 1950, could not have produced the picture created by the nurses' evidence in the last few days, he said. The initial treatment with heroin and morphia was not justified, either the morphia or the heroin, and certainly not the two together. The certain consequence of that treatment was addiction.

"Was there any justification, so far as you can see from the records and the evidence, of continuing such daily treatment from 1948 to November, 1950?"—"No, there was no justification."

"What conclusion do you draw from the dosage administered according to the nurses' reports in the last few days before her death as to the intention with which that dosage must have been prescribed and administered?"—"The only conclusion that I can come to was that the intention was to terminate her life." The injections of paraldehyde on top of the heroin would make the heroin more lethal.

"In the cremation form Dr. Adams, we know, has recorded as the immediate cause of death cerebral thrombosis. Are there any signs in the nurses' reports in your opinion which justify that conclusion?"—"No."

"Supposing there had been any signs of cerebral thrombosis in November, would there then have been any justification for administering those doses of heroin?"—"No, certainly not."

"Can you tell whether a person has died as a result of cerebral thrombosis as a result of an external examination?"—"No, you cannot."

"In your opinion, should heroin be given to old people?"—"No."

"Having considered all the evidence and these documents, can you think—I am sure you will say so if you think so—can

you think of any legitimate reason for the amounts prescribed from November 8 onwards of heroin and morphia?—"No."
"Dealing with the amounts prescribed, were the amounts prescribed on November 8, 9, 10, 11, and 12 sufficient to cause death?"—"Yes."

General Practitioner's Expected Knowledge

On the ninth day of the trial Dr. Douthwaite was recalled, and the Attorney-General continued his examination-in-chief.

Asked to describe the effect of heroin and morphine in conjunction with barbiturates ("allonal" and "sedormid") shown by the night reports to have been administered, the witness said that that would increase the depressant effect of one or the other. Looking back over the period, the degree of drugging, taking into account both the barbiturates and the heroin and morphia, was heavy.

Turning to the question of a general practitioner's expected knowledge of drugs, the Attorney-General said:

"To what extent would knowledge of those matters—that is to say, the nature of heroin and morphia, doses to be administered, the risks of addiction, and the consequences in regard to tolerance, etc., and convulsive spasms at the end—to what extent would those matters be within the knowledge of a general practitioner?"—"He would have the knowledge of all the main occasions, of all the main drugs that are taught to students and repeatedly referred to in the wards in training."

"Would the holder of a diploma in anaesthetics have more or less knowledge in relation to morphia and heroin than an ordinary general practitioner?"—"He would have more. They have to make a special study of drugs of this sort in order to achieve their specialty."

"When you say 'a special study of drugs of this sort' does that include morphia and heroin and the barbitones?"—"Yes, certainly."

Cross-examination of Witness

Mr. Geoffrey Lawrence then opened his cross-examination:

"Dr. Douthwaite, my client, Dr. Adams, in this case, as you know, is charged with the murder of Mrs. Morrell?"—"Yes."

"Before I embark on my cross-examination of what you have said, I want to be quite clear what your proposition to my lord and the jury is in relation to the charge of murder. Have I understood it correctly in this way: that as a doctor and a specialist yourself you are saying that he formed the intention, as you say, 'to terminate her life' on November 8, and carried that intention into effect over the next five days?"—"Yes."

"I think it follows from what you said to my lord yesterday that that murderous intent in your view was present in his mind from and including November 8 onwards to the end?"—"Yes."

"A specialist's profession is a responsible one, no doubt, but I hardly suppose that you have often expressed a graver or more fateful opinion on a matter of medicine than that, have you?"—"No."

"Before going into the witness-box and expressing that view upon oath in this court, have you satisfied yourself that you have had every piece of relevant evidence before you on which to judge?"—"Yes."

"You gave evidence in this case before the magistrates at Eastbourne, did you not?"—"I did."

"For the prosecution?"—"Yes."

"Supporting the charge of murder?"—"Yes."

"At that stage of the matter your knowledge of the medication, the treatment, of Mrs. Morrell began at the beginning of January, 1950, did it not?"—"Yes."

"When you gave evidence at that stage you were entirely in ignorance of what her treatment by Dr. Adams had been before January, 1950, were you not?"—"I was."

"And you gave that evidence at least partly upon the hypothesis that for the last three or four days of her life this lady had been in a continuous coma, did you not?"—"Yes."

"That has turned out on the facts now to be quite wrong?"—"Yes; not a continuous coma."

He agreed that the court had now a complete picture of the patient's treatment. His conclusions, he said, had been based on a medication that began in July, 1948. He had known about the stroke. He had said in conferences that it would be very interesting to know what treatment the patient had had before she had come under the care of Dr. Adams.

Mr. Lawrence: "As a doctor, a Harley Street specialist, who has ended up in that box and said that another doctor formed a murderous intent which he carried into effect on an old lady of 81, have you seriously asked for that information from those who are conducting the matter for the Crown?"—"No. I did not regard it as my duty to ask them to find out facts of that sort. The information and the expression of opinion that I have given is on the facts which have been presented in this court."

"Yes, I dare say, but you are not forgetting for one single moment, are you, the conclusions which you put before the jury yesterday of murder in this man's mind and the execution of murder in the five days at the end of her life?"—"No, I haven't forgotten that for a moment."

Further pressed as to why he had not sought the information, the witness said that in the first place he had been told it was not available; secondly, it would not have materially influenced the answers he had given in respect of the addiction.

Mr. Lawrence: "It would be most important to know, would it not, before damning Dr. Adams's treatment from the start, as you did yesterday, to know what had happened in Cheshire?"—"It would be interesting to know what had happened in Cheshire, yes."

"And so far you do not know what that information is, do you?"—"I do not, no."

Beginning of the Illness

Mr. Lawrence then produced copies of the nurses' notes taken on the case in the Neston Cottage Hospital in Cheshire from the outset of the patient's illness. These would fill the final gap going back to the moment when the stroke had occurred. The reports, starting in June, 1948, indicated hemiplegia, paralysis of the left side, 2 gr. of "luminal" administered. Temperature was 99° F., pulse 72, respirations 18. The witness agreed that luminal was a synthetic barbiturate. The night report for June 26 showed that another 2 gr. of luminal had been given and that the patient had complained of pain in the left arm in the early morning. Special injections and special sleeping tablets had been given on the next two days with very little effect, it being a reasonable inference that the tablets were barbiturates. The day report for June 27 said: "Patient very distressed and complaining of severe pain." Two "veramon" tablets had been given which the patient had been unable to swallow and ½ gr. of morphia had been given at 11.30 a.m., after which the patient had slept. A Dr. Turner had been informed of the position. Morphia, ½ gr., had been given every day for the remaining eight days of the patient's stay in the hospital.

Having put the details of the report to the witness, Mr. Lawrence said: "Now, Dr. Douthwaite, she was in that hospital under the care of a Dr. Turner and apparently with a consultant doctor, Dr. Pemberton, at the early stages?"—"Yes."

"For ten days or thereabouts?"—"Yes."

"With day and night nurses?"—"Yes."

"From those records of that ten days three things at least are clear, are they not: first of all, she was a very ill woman?"—"Yes."

"Secondly, she complained of severe pain?"—"Yes, on June 27."

"And thirdly, that after two nights of attempting to give her sleep and sedation by barbiturates, the doctor at the hospital resorted to morphia?"—"Yes."

"And every night for the rest of her stay in that hospital under those doctors she had morphia?"—"Yes."

The witness pointed out that it was important to remember that the barbiturates had been luminal, but agreed that 2 gr. was a quite good dose. There was some record of the patient having slept after the morphine injections.

Asked about the stroke which the patient had suffered, he confirmed his previous evidence that no doctor should give morphine to a patient with a stroke except if a patient had acute mania. In such a case there should be one single injection. He agreed that, although the doctor in Cheshire had been adopting a course of morphine injections night after night, there had been no suggestion of acute mania or of the rare condition, the thalamic syndrome.

Mr. Lawrence then asked: "Does the field of condemnation that you are spreading from that witness box extend to include Dr. Turner for having given this patient morphia after this stroke?"—"If that was the treatment for the stroke, yes."

"We are left with this, are we not, that three doctors—two other doctors who are not in dock on a charge of murder at all, two doctors in addition to Dr. Adams—gave, and deliberately gave, this particular patient, who had had a stroke, injections of morphia, not a single injection but night after night?"—"Yes, the first being given when pain was reported."

"But you can't shelter behind that, can you?"—"I'm not trying to shelter behind anything."

"Because the morphia goes on night after night, but, as you pointed out just now, there was only one complaint of severe pain?"—"Yes."

He agreed that as a general principle only the man on the spot with the patient in front of him could judge the full and true picture. The general practitioner on the spot had to exercise the best judgment he could.

Mr. Lawrence: "He has not got to be the perfect physician?"—"No."

"—the ideal that is stored up somewhere in Harley Street, has it?"—"No." The patient was not addicted to morphia to any degree on leaving the hospital after having nine daily injections of ½ gr. morphia. It was possible that a person might become addicted in less than a fortnight or three weeks. He agreed that the patient's prognosis at that time in terms of expectation of life might reasonably be six to twelve months.

The witness was then shown the list of prescriptions beginning on July 7, 1948, at the Esperance Nursing Home, Eastbourne, upon her return from Cheshire. They showed that for the next 12 months the patient's treatment had included the administration of tincture of nux vomica, sodium barbitone, syrup, chloroform water, hyperdoric morphia, veramon, a sedative mixture containing morphia, sodium bromide, ammonium bromide, and chloral hydrate; vitamin-B ampoules, pethidine tablets, "allonal" tablets (containing barbiturate with amidopyrine), right up to June 13, 1949, when Dr. Harris had been continuing the prescriptions of morphia and heroin. It was not unreasonable to assume, he agreed, that for some months after the stroke the patient had been suffering pain somewhere.

Making Life Bearable

Heroin, he agreed, had some slight sedative quality, but was notably a pain-killer which left the patient in a state of euphoria. The first object of a general practitioner's treatment for what he could reasonably expect to be the remaining months of Mrs. Morrell's life would be to try to restore her health if possible. The doctor would also try to make life as bearable as possible for the patient. He agreed that, short of a miracle, no doctor in his senses could think that he could restore a woman of 79 or 80 to her pre-stroke health after there had been a brain lesion, as indicated in Mrs. Morrell's case; but making the patient's life as bearable as possible, he said, was a side consideration.

Mr. Lawrence: "Well, you say it is a side consideration, but let us face it, Dr. Douthwaite, not from the consulting room in Harley Street, but let us face it from the angle of the general practitioner in the provincial town."—"Yes, I am quite aware of that."

"Nurses in 1950, after the war, were pretty scarce, were they not?"—"Yes."

"At a time when nurses are not going to put up with an infinity of trouble and difficulty?"—"True."

"If the patient's life is made as bearable as possible for her she is in a condition which enables her to be bearably nursed by them, then that latter factor redounds in favour of the patient, does it not?"—"Yes."

"If she was not up and about in the day-time she would get bedridden too soon?"—"Yes."

"And if she did not get sleep at night she would wear herself out with exhaustion?"—"Yes."

"Exhaustion would lead to collapse, and with an aged woman like that collapse might very well contain the risk of a premature death?"—"Yes."

"Now, whatever you may say about the use of these drugs, morphia and heroin, the fact is this, is it not, recorded in these notebooks: that, broadly speaking, until September, 1950, this woman was being got up and about during the day-time?"—"Yes, I can't remember up to what month that was, but I naturally accept your word."

"So far as sleep was concerned at night, she was having a regular routine injection at 8.30 of ½ gr. morphia and 1/3 gr. heroin, and during that period she was being assisted further to sleep by slight additional doses of barbiturates when necessary?"—"Yes."

"That is the broad picture?"—"Yes, I agree."

He agreed that if there was any clotting after an operation it started usually in a vein rather than the arteries. In extreme cases after strokes such as the patient had had there could be an almost completely or perhaps wholly changed personality manifesting itself in behaviour changes.

Mr. Lawrence: "Do you agree with me now that before you can pass any judgment upon Dr. Adams at any stage of the matter in relation to a murder charge it is necessary to try to see the picture of his treatment of Mrs. Morrell as a whole right from the start?"—"Yes."

"And indeed more than that, to go back, as we have been able to go back, to what happened before he took her over?"—"Yes."

The witness agreed that between June, 1949, and August, 1950, there were indications that efforts were made by Dr. Adams to keep the patient on the move during the daytime and to encourage her to take an interest in outside events.

Withdrawal Symptoms

The witness was then referred to his previous evidence that certain symptoms consistent with withdrawal symptoms had manifested themselves on the occasions when there had been reductions in the drug dosages. Mr. Lawrence said at least one instance of a reduction followed by a good day, and not withdrawal symptoms, had not been referred to.

"It would be perfectly fair to balance that against what you said yesterday in regard to the instances you referred to?"—"Perfectly fair. Let me make it clear. I did not pick out these instances."

"Who did?"—"My attention was drawn to them by the Attorney-General and I agreed; but I had not been through these trying to find evidence to support one way or the other. I had merely studied them. There may be many other instances you can produce like that. I do not doubt it."

"Let me understand this. You and I are agreed, I think, that we ought, in order to try and find out what is the real truth of this case, to look at it as a whole?"—"Yes."

"And not be over-selective and picking out individual bits here and there?"—"Yes."

"But trying to take the big view?"—"Yes."

"Do I understand that it was no part of your expectation when you went into the box yesterday to give evidence that your attention would be drawn to selected instances like this?"—"I had no doubt it would be."

"And you had no doubt what they were to be, had you?"—"That I am not prepared to say."

"You are not prepared to say?"—"That is to say, I was not certain what they would be, but I knew they would choose some."

"But did you realize that it was not fair to pick out those selected instances, that it was not a proper and fair way to put it?"—"I did not think it was my duty to point out whether it was fair or not."

"You agreed yesterday with the expression of opinion that my client intended to kill her and killed her?"—"Yes, I did, and I expressed that view in the last few days of September."

"I suppose you realize that there is a heavy responsibility on any doctor who expresses that view about another?"—"Yes."

"Are you really saying that yesterday you did not think it was part of your duty to correct any false impression which was made by any part of your evidence?"—"If I thought any false impression was to be gained from my evidence, I should have corrected it at once."

"But drawing attention to one or two selected things and ignoring other things was giving a false impression, was it not?"—"Yes, but I realized that you would go through this, or I presumed that was the natural course of events, and that it was for the two counsel on one side and the other to lead me on to express a view on the days when drugs were given, and I thought that was my duty."

"Do you know there is no burden of proving anything in this case, from start to finish, on the defence?"—"No, I did not know that."

"If the result of this little discussion is that I may now disregard altogether that part of your evidence where your attention was drawn to those selected instances, may we pass from it?"—"I am not prepared to say you may disregard it. In so far as instances were drawn to my attention on which I was asked whether they were consistent with withdrawal or increase of drugs, then I meant it."

After the luncheon adjournment Mr. Lawrence continued his cross-examination about addiction and withdrawal symptoms. Dr. Douthwaite said that if a patient was obviously dying it was ridiculous to worry about addiction. If the strong probability was that the patient would not live for more than a month or two, and if the drugs were in fact indicated for that condition, again one need not worry about addiction. If the prognosis was very doubtful as regards time, whether it was a matter of six months or five years, then addiction should be carried in mind the whole time.

The witness agreed that on the second day on which Dr. Adams was carrying out his "murderous" intent the night nurse, on his instructions using her discretion, had given an injection which contained atropine—an antidote to morphia. However, it was an extremely weak antidote and the usual reason for giving it with morphine was to reduce mucus in the throat or lungs.

Last Days of Life

Dr. Douthwaite was recalled on Friday morning, March 29, for the resumption of cross-examination by Mr. Lawrence. Counsel took the witness through an analysis of the treatment given to the patient during the last few days of her life.

Mr. Lawrence: "Now just let us pause there. That has brought us to the night of Friday to the Saturday. If, as I am postulating, the doctor wanted to give as peaceful and helpful nights as possible for this patient at this stage in her illness, he was not doing too badly so far, was he, on those two nights?"

— "He certainly obtained some sleep."

On the Saturday the doctor had varied the treatment from heroin hourly to "Patient may have $\frac{1}{2}$ gr. morphia with $\frac{1}{2}$ gr. heroin hourly if necessary." The subsequent record showed that the patient had not received anything like that dosage in fact. There had been no morning injection, the patient having been asleep when the doctor had called; the $\frac{1}{2}$ and $\frac{1}{2}$ had been given at 1 p.m., another injection in the afternoon; the patient had been quiet until 4.30, then became restless and excited, and had received another $\frac{1}{2}$ and $\frac{1}{2}$ at 4.45. There had been no sleep since 12.30 midday. In the evening the doctor gave 1 gr. each of morphia and heroin. The patient then slept from 7.30 to 10 p.m. At 10.45 Dr. Adams gave $\frac{1}{2}$ gr. heroin and $\frac{1}{2}$ gr. morphia injection, a reduction by half of the previous injection. The nurse gave injections at 1 a.m., 2 a.m., 3.40 a.m., of 1 gr. heroin and $\frac{1}{2}$ gr. morphia, $\frac{1}{2}$ and $\frac{1}{2}$, and 1 gr. heroin respectively, but the nurse had recorded "no sleep." On the last complete day of her life, Sunday, November 12, she received a special injection from the doctor at 11.15 a.m. and slept for two hours, at 2.35 she had $\frac{1}{2}$ gr. hyperdure morphine and $\frac{1}{2}$ gr. heroin from the nurse, the same injection being repeated at 5.25. It seemed from the records that on that last day the drugs were no longer producing sedation and sleep. At 7.30 Dr. Adams had given an intramuscular injection of 2 c.c. paraldehyde with no apparent effects. At 10.30 Dr. Adams injected paraldehyde 5 c.c. The remaining entries were: "11.30, very restless; 12.30, restless and talkative, and very shaky; 12.45, seems a little quieter, appears asleep; respiration 50; 2 a.m., passed away quietly."

Dr. Douthwaite said: "In these last few days, in my view, there was a steady accumulation of morphia and heroin in the body, because this woman—and I think it is common ground—was dying and therefore all the natural functions were depressed. Therefore, the effect of these drugs was slowed down." If Dr. Adams had allowed for that accumulation it would not have been necessary in the last two or three days to keep up more than a minute quantity.

Summarizing his questions, Mr. Lawrence then said: "I am not inviting a Harley-street opinion upon the skill as a doctor of a general practitioner, but after that rehearsal I have put before you—I know what your opinion has been over these last days—I want you to consider this. At least it is a possible alternative view on these reports, is it not, that this general practitioner was following a consistent course with these drugs to produce the results which it was his duty to produce, and that when he found he could not do it on the last day and night he tried to turn to something else?"

— "Yes. He produced what he wanted to produce, or the result that he wanted to produce."

"That is sleep and sedation and the avoidance of restlessness and excitability?"

— "Yes, certainly the avoidance of restlessness, and sleep."

Re-examined by the Attorney-General, Dr. Douthwaite agreed that if the whole or the major part of the heroin and morphine prescribed between November 8 and 12 had been administered to Mrs. Morrell it would have caused death.

The Attorney-General: "Is there any evidence that you have heard in this case, apart from the stroke, to indicate that apart from being an old lady Mrs. Morrell was suffering from any physical degenerative condition?"

— "No."

"Which called for morphia?"

— "No. I think really 'physical degenerative condition' must be interpreted as the degeneration natural to old age, in which case the answer is that morphine should not be given."

Counsel then took the witness through the nurses' records from November 9 to 13 and the witness agreed that the general effect was that the patient had had adequate sleep during that time and that there was no justification for heavy drugging during the day-time. The normal sleeping hours of a bedridden lady of 81 would vary between five and six per night.

Mr. Justice Devlin: "Dr. Douthwaite, how far has this sleep been secured by the increase in the dosage of drugs?"

— "I was wondering the same thing, my lord. I have no doubt that it played a part."

The Attorney-General: "So far, at any rate, is there any shortage of sleep at night time apparent such as would justify procuring drugged sleep at all costs in the daytime?"

— "No, there is not."

The Attorney-General concluded: "Has anything been said in this court, any evidence you have heard, affected your opinion as to the cause of death to Mrs. Morrell?"

— "No."

"To what do you attribute her death?"

— "To drugs, morphia and heroin, possibly assisted by paraldehyde. In the absence of paraldehyde, in my opinion, morphia and heroin administered in the last few days would have killed her."

Judge's Questions

Mr. Justice Devlin then put a number of questions to the witness. He said:

"Dr. Douthwaite, I want your help, and it may be to a quite considerable extent. In due course I expect I shall direct the jury that before they can convict an accused they must be satisfied that he committed an act of murder, and that means, in the circumstances of this case, that he either administered the drugs himself, intending them to kill her, or he gave directions or instructions to the nurses which he hoped and intended, if carried out, would kill the patient, Mrs. Morrell. I should like you, if you would, to help me by directing your general evidence to each of those individual acts. Your evidence covers the period from November 8 to 13 for this purpose, and during that period I think I am right in saying that Dr. Adams paid Mrs. Morrell 17 visits."

— "Yes."

"And on all or most of those occasions he either administered drugs himself or he left directions for the nurses as to what they should do?"

— "Yes, my lord."

"If the case for the Crown is right, then one or more of those acts amounted to murder. I should like to be able, when the time comes, to direct the jury, or assist the jury, by pointing out to them precisely what in relation to each act it is that forces you, as you put it in your own words, to postulate that murder was being committed, or attempted."

The Judge reminded the witness that the first of the 17 visits mentioned had been at 7.40 p.m. on November 7, when $\frac{1}{2}$ gr. morphine and $\frac{1}{2}$ gr. heroin had been given, an increase of $\frac{1}{2}$ gr. of morphine. "Are you forced to postulate murder in relation to that dose?"

— "Not that single dose, my lord."

"Do you mean that you might be forced to postulate it in relation to the doses that come after?"

— "In the first place, the doses which had gone before, and, to be exact, the doses which were not given of morphia, from the 1st to the 5th, when only heroin was given—I think those dates are right—by withdrawing morphia for 5 days in a woman who had been having it regularly, it would have diminished any likelihood of producing a comfortable sleep by virtue of the morphine if the morphine was capable of producing sleep after she had received it for so many months. Furthermore, the tolerance to the morphine, which certainly was acquired, although not a great tolerance because it was not a high dose, would fairly rapidly diminish, and at the end of 5 days, although I am not suggesting the tolerance would have disappeared, it would have been reduced. That was my first point—to draw your lordship's attention to the 8th, at what I regarded as rather a critical date, because that morphine withdrawal was not replaced by any

adequate substitute. In other words, she was deprived of a drug to which she had become accustomed and lost some of her tolerance. Then it was returned, and on the 6th we get a small dose, a $\frac{1}{4}$ of morphine, which would be more effective now because some of the tolerance had been lost. On the 7th it jumps to $\frac{1}{2}$ of morphine from $\frac{1}{4}$, a big jump, and on the 8th it goes to 2. I wondered what was a possible reason for stopping this morphine, and that is why I didn't make up my mind on the probable desire to terminate her life until I saw the substitution was returned on the 6th followed by a rapid increase, together with large doses of heroin. For that I could not find any explanation. Because clearly this was not an attempt, or it seemed to me, this was not an attempt to wean her from her drug addiction on late realization of what was happening. If it had been so, why should not the heroin, which all doctors know is a more dangerous drug, had been reduced first rather than the morphine? Then, to complete the answer to your lordship's question, my conclusions after that were based on the rather rapidly mounting doses of the last few days."

"Are you saying that morphine was deliberately withheld in order that it might be reintroduced?"

— "That is how it appears to me, my lord, because I can see no other reason for it. There was no attempt at substitution."

The witness went on to say that the variation in drugs suggested by defending counsel amounted to variation without substitution.

The Judge: "When you are dealing with another doctor, the very last thing you think of normally is murder?"

— "Yes."

"You explore every other possible hypothesis and reject it and say it cannot be sustained before you come to the conclusion that it is murder?"

— "Yes."

Dr. Douthwaite agreed he had criticized Dr. Adams' treatment as being wrong.

Mr. Justice Devlin: "He embarked on a wrong line of treatment from the very beginning?"

— "In my opinion he did."

"But murder is not suggested as an explanation of that?"

— "No, my lord."

After further questions on the doses of morphine and heroin the Judge then asked about the injection of paraldehyde on the fifteenth visit:

"I think you said at one time that it made her death more certain, if it was not already certain?"

— "Yes, my lord."

"Well, was it in your view certain already?"

— "It was."

"In a matter of days?"

— "Yes, my lord."

"Is it your view, then, that paraldehyde was given to accelerate it?"

— "Yes, my lord."

"And would have that effect?"

— "And would have that effect."

"But again you are forced to draw the conclusion that Dr. Adams gave the paraldehyde because he was tired of waiting for the heroin to take effect, to bring about a quick and immediate result?"

— "Yes, my lord."

"That is the conclusion you draw medically?"

— "Yes, my lord."

"Would 2 c.c. be enough for that purpose?"

— "No, my lord. 2 c.c. is a small dose and I would not be prepared to say that 2 c.c. would make any difference, even though she was heavily drugged, and, in my opinion, suffering from obvious signs at least of heroin poisoning."

"So that medically you cannot find any reason for the 2 c.c. dose?"

— "No, my lord. It occurs to me that it may well be that he tried to mask those conclusions."

"For a quite innocent purpose?"

— "It could be for a quite innocent purpose."

"And it could not have been for a wicked purpose?"

— "2 c.c., no. I do not regard the administration of 2 c.c. as in any way sinister or of any significance."

"But 5 c.c.?"

— "5 c.c., that brings in the probability of a further depression of this respiratory centre which now must have been (if I may use the term) on its last legs."

"Do you find yourself forced to postulate that the 5 c.c. of paraldehyde was given to kill?"

— "Yes, I do, my lord."

"Although 2 c.c. was not given to kill, and could have been given for an innocent purpose?"

— "It could have been given for an innocent purpose."

"But you find yourself forced to exclude the possibility that the 5 c.c. might have been given for an innocent purpose?"

— "I do, my lord."

"Why?"

— "Because it would necessarily—and I think a doctor must know it—have aided or accelerated death from this heroin depression of the respiratory centre. 2 c.c. is too small to produce that effect."

"What about 3 c.c.?"

— "3 c.c., it might. We are getting up to just a level where it is getting dangerous on this picture."

"4 c.c.?"

— "Yes, decidedly dangerous, my lord."

"So if the dose had been 3 c.c. you might well have said that it was for the same innocent purpose as the 2 c.c.?"

— "Yes, I might have, yes."

"And might have been in the circumstances quite the correct thing to do?"

— "No, my lord."

"To stop convulsions?"

— "No. I hope I haven't suggested that if the treatment was just to stop the convulsions that was a suitable thing to do, because the only way . . ."

"No, you have not suggested it. I was putting the question to you. You said it could have been done for an innocent purpose, but you certainly never suggested that it was the right thing to do."

— "Thank you, my lord."

"But it could have been done for an innocent purpose?"

— "It could have been done."

"And 3 c.c. could have been done for an innocent purpose?"

— "Conceivably, yes."

"But 60% more means murder?"

— "Yes."

"Does it matter really, then, in your view, whether the second injection of paraldehyde, about which there has been a lot of dispute, was or was not given?"

— "No, it doesn't affect my view."

The witness said that if there had been a post-mortem on the body the quantities of heroin and morphia in her would have been detected, he believed with reasonably certain accuracy. He preferred not to express an opinion on how long those traces would be detectable; most of it would be detected in a matter of some weeks, but it might be much longer.

After Dr. Douthwaite left the witness-box Mr. Thomas Reid was recalled to produce and explain a graph of the dosages as shown by the nurses' reports on the same basis as graphs to be produced by Dr. Ashby. After he had explained these and been subjected to a limited cross-examination by Mr. Lawrence, the witness withdrew and was replaced by Dr. Michael George Corbett Ashby, who said he practised from 148, Harley Street. His qualifications included M.B., B.Ch., M.R.C.P. He had at one time been medical registrar to Sir Russell Brain, was appointed to consultant status in 1949, since when he had been neurologist to the Whittington Hospital and to five other hospitals in north-west London. His task was to produce certain graphs which he had prepared based on the record of prescriptions.

The Attorney-General put to the witness that it was common ground that morphine and heroin were dangerous drugs. Dr. Ashby assented, but Mr. Lawrence denied that it was common ground.

The Attorney-General: "They are dangerous drugs under the Dangerous Drugs Act, at any rate?"

— "Yes."

"Are you aware of any reason for prescribing morphia and heroin for a patient if they are not intended to be used on that patient?"

— "I can think of no legitimate reason."

Before the court rose Mr. Justice Devlin told Mr. Lawrence that he would consider any application for the recall and further cross-examination of Dr. Douthwaite in view of that witness's last answer to his lordship.

Theory of Murder

On Monday, April 1, Dr. Douthwaite was recalled, at the resumption of the hearing, on the application of Mr. Lawrence, who proceeded to further cross-examination.

He suggested that the witness's "theory of murder" was made up of two limbs—first, that Dr. Adams had withdrawn the morphine on October 31, 1950, for a time in order to reduce to an appreciable degree her tolerance to it; secondly, that, having reduced the tolerance, he had reintroduced morphine on November 6 and thereafter gave increased doses of it in conjunction with heroin in order to bring about a fatal result. Dr. Douthwaite accepted that the two limbs were mutually interdependent. He agreed that, looking at the picture as a whole, there had been an increase of drugs in the last fortnight right up to the time when they had been abandoned and paraldehyde used, but maintained that the picture of such a dosage, even in the case of a patient with inoperable cancer, would have been one suggesting a desire to terminate life.

"It would be quite impossible to say from the picture of the dosage alone that it was a case of murder with intent to kill?"

— "If leading to the death of a patient suffering from pain is precisely the same thing as murder—and that is not for me to

say—I think it would." He agreed it would not be so if the dosage of the last few days were considered isolated from all the previous weeks of drugs accumulating.

"You would not be forced or driven to go into the witness-box and say that the general practitioner who followed that course in that case was a murderer, would you?"—"I would say that faced with a woman in terrible pain he was giving large doses of drugs and those doses of drugs, as set out here, would have caused death."

"You would not say that in those circumstances you were forced to say that that general practitioner was a murderer?"—"No."

The Judge: "Would you say you were forced to conclude he intended to kill?"—"Yes, my lord. Earlier on, when I was asked what my conclusions were from these drugs, I deliberately said my conclusions were that they were given to terminate life. I said that deliberately because I don't know, it's not my business to know, whether that is synonymous with murder. I never introduced the word 'murder' myself, but learned counsel did so, and I take it he meant that was synonymous. In fact I thought he obviously wouldn't deceive me. I was giving that opinion on these drugs administered to an old woman who was not in agonizing pain."

The Judge said he was anxious that there should not be introduced any questions which might be partly questions of law. It might be, as a matter of law, and it might be, as a matter of medical practice, that if a doctor gave drugs knowing that they would shorten life but gave them because they were necessary to relieve pain he was not committing murder.

Mr. Lawrence: "Postulating that this is not a case of extreme pain, or inoperable cancer, but is a case of the terminal stages of senile disintegration with the brain affected by a long-standing arteriosclerotic condition, and postulating that in the last days that patient was suffering acute distress, a lack of sleep, if a doctor were to give the level of drugs indicated in those nurses' reports over the last days, can you imagine that he would be dealing with it in the same way as the general practitioner who was dealing in the same way with the acute pains of the final stages of cancer?"—"No."

"Why not?"—"Because there is a profound difference between the acute pains of inoperable cancer and the terminal pains of arteriosclerosis."

The witness denied that his theory in relation to the withholding of the morphine for five days in the last fortnight of the patient's life was an afterthought, but agreed that it had occurred to him after he had first given evidence at the trial.

Towards the end of his further cross-examination Mr. Lawrence summarized his questions in this form:

"The picture, then, as a whole, is this: a doctor who begins the medication of his patient in a totally wrong way?"—"Yes."

"Due not to any intention to kill but, I suppose, to ignorance or stupidity, or something of that kind?"—"Have I said that? I must start thinking again."

"If you do not want to be asked about it I will not press it."—"Well, I think if I give the answer it will not be helpful to you, and I would rather not be pressed on it in that case."

"Very well then. He starts with a wrong type of medication?"—"Yes."

"It is clear that he goes on with that for years?"—"Yes."

"It is clear—we are all agreed about this—that the woman was in the terminal stages of her life in this last fortnight?"—"Yes."

"Dying anyhow?"—"Dying anyhow?"

"She was dying?"—"Well, she was dying."

Mr. Justice Devlin: "Do you mean she was dying before November 1?"—"Yes, my lord."

Mr. Lawrence: "If what we read in the day report of October 9 is right, where the nurse rang up Dr. Adams and he diagnosed a possible further stroke, if that was in fact another stroke, to some degree, that would certainly bring the final end of her life nearer, would it not?"—"Yes, I think it would." A second stroke would make the prognosis worse.

"The truth of all this matter is this, Dr. Douthwaite, that you first of all gave evidence on one basis to support a charge of murder and then thought of something else after you had started?"—"That is quite likely. In fact, I think it is probable. I had been turning it over in my mind, but at what time it crystallized and became clear I do not know."

"Yes, I think we understand that; but that is your personal view, is it not?"—"Yes."

"You can conceive it quite possible, can you not, that a reasonably minded physician of equal eminence, if I may say so, might by no means find it necessary to postulate an intention

to terminate life on the basis of the same evidence as you have?"—"Certainly. I have always agreed that there would be contra-medical opinion. I am expecting it."

Accumulation of Drugs

After further questions from the Attorney-General the Judge asked Dr. Douthwaite:

"Do I understand this to be right: first, that no single injection given by itself was large enough to drive you to postulate as a medical man that there was an intent to kill by that injection?"—"That is true, yes."

"Secondly, that no instructions that were given to the nurses were such as to drive you to that conclusion, by those instructions alone?"—"I agree, my lord. I mean there were none."

"By those instructions alone Dr. Adams intended to kill?"—"There was no indication that by those instructions alone Dr. Adams intended to kill."

"Whether the intent to kill was formulated first at the end of October or the beginning of November or whether it was formulated first on November 8, it depends on what has been called the accumulation theory?"—"The production of death?"

"Your inference that there was an intent to kill depends on the attribution by you to Dr. Adams of the knowledge that a single drug, not dangerous in itself, would be lethal because of the accumulation of drugs already in the body?"—"Yes, my lord."

"And that is so, as I say, whether one starts with an intent to kill on November 1 or whether it is November 8?"—"Yes, my lord."

"That knowledge and the attribution of that knowledge to Dr. Adams is essential in both cases?"—"Yes, my lord."

By his last answer to Mr. Lawrence, said the witness, he had meant that doctors of skill frequently disagreed and he would be surprised if some eminent doctor did not disagree with him on some points.

"On this particular point, if another doctor were to say he disagreed entirely with your views about accumulation, would that be a genuine skilled view to the contrary?"—"I can only say I would be astonished if he does. I certainly could not agree with him. I really would be astonished if he said that."

A view contrary to his own on the subject of accumulation, due to error, ignorance, or incompetence, could, however, be honestly held by another doctor. But he postulated an intent to kill because he was unable to conceive of a man with Dr. Adams's qualifications and special knowledge of drugs having such ignorance or being ignorant of drugs of that sort. In the case of a general practitioner the patient's death might be due to error, ignorance, or incompetence on the doctor's part, but in the case of a general practitioner with anaesthetist's qualifications such as Dr. Adams had it could not be due to such things.

The Judge: "It must follow, must it not, that if Dr. Adams were to go into the witness-box and say, 'I disagree entirely with this view,' he would be guilty of perjury, would he not?" He would be saying he held a view that in your opinion he could not possibly hold?"—"You have put to me a very difficult point, my lord. If he went into the box and said he did not agree with the opinion I have given..."

"On the accumulation theory?"—"On the accumulation theory, he would then be suggesting that he had not knowledge of it."

"Your answer would be, leaving out perjury, that he could not honestly say that?"—"Yes."

"That is getting near to perjury—he cannot honestly say that?"—"That I believe."

"If any other doctor with Dr. Adams's qualifications goes into the witness-box and says the same, your answer would be the same, would it not—that he could not honestly say that?"—"That would be my answer, yes."

"Then it does not leave any room on this matter of accumulation for any view to the contrary which is based on error, ignorance, or incompetence?"—"No."

He told the judge that if he had seen the patient in October, 1950, he would have expected her to live only for a matter of a few weeks, probably not more than two months.

"If one were to take the lower estimate of that, is Dr. Adams saying to himself, 'She can only live for, let me say, three weeks anyway?' He would be embarking on a course on November 1 that in fact took thirteen days to bring about her death and which probably he would have estimated would take about thirteen days, since he had to withdraw the morphia, reintroduce it, and step it up to overcome the tolerance?"—"He might well have, my lord."

Dr. Douthwaite then left the box.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending March 16 (No. 11) and corresponding week 1956.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 100 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES in Countries and London	1957					1956

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenza pneumonia.
‡ Includes puerperal pyrexia.

Vital Statistics

Industrial Accidents and Diseases

The number of workpeople (other than seamen) in the United Kingdom whose deaths from accidents in the course of their employment were reported in February was 102, compared with 85 in the previous month and 106 in February, 1956.

The numbers of cases of industrial diseases in the United Kingdom reported during February, 1957, were as follows: lead poisoning 1, epitheliomatous ulceration 6, chrome ulceration 2; total 9. There was one death from epitheliomatous ulceration due to mineral oil.—*Ministry of Labour Gazette*, March, 1957.

Deaths from Accidents

In England and Wales in the month of January 1,280 deaths from accidents were registered. These included 667 home accidents, 385 road accidents, 50 other transport accidents, and 178 other accidents. These figures, and the numbers of deaths in broad age groups, are in a new table, to appear monthly, in the *Registrar-General's Weekly Return*, No. 12.

Infectious Diseases

The largest fluctuations in the notifications of infectious diseases in England and Wales during the week ending March 16 were increases of 202 for dysentery, from 1,214 to 1,416, 185 for whooping-cough, from 2,995 to 3,180, and 98 for scarlet fever, from 837 to 935.

The notifications of measles numbered 24,825, 12 fewer than in the preceding week; the largest variations in the local returns were increases of 276 in Lancashire, from 3,951 to 4,227, 212 in Nottinghamshire, from 306 to 518, 158 in Cumberland, from 461 to 619, 128 in Glamorganshire, from 249 to 377, and 119 in Surrey, from 1,400 to 1,519, and decreases of 393 in London, from 2,225 to 1,832, 268 in Essex, from 1,912 to 1,644, 144 in Durham, from 1,511 to 1,367, 126 in Yorkshire North Riding, from 375 to 249, 119 in Cheshire, from 912 to 793, and 114 in Gloucestershire, from 437 to 323. A small rise in the incidence of scarlet fever occurred in most areas; the largest was 20 in London, from 54 to 74. The largest increases in the notifications of whooping-cough were 54 in Lancashire, from 221 to 275, and 41 in Hertfordshire, from 62 to 103; the largest decrease was 40 in London, from 189 to 149. 3 cases of diphtheria were notified, being 3 fewer than in the preceding week.

38 cases of acute poliomyelitis were notified, and these were 3 fewer for paralytic and 8 more for non-paralytic cases than in the preceding week. The largest returns were Hertfordshire 9 (Barnet U.D. 5, Stevenage U.D. 2), London 6 (Wandsworth 3, Lewisham 2), and Lancashire 4.

The rise in the number of notifications of dysentery was due to an increased incidence in established outbreaks rather than to new outbreaks; the largest rise was 98 in Yorkshire West Riding. The chief centres of infection during the week were Yorkshire West Riding 333 (Rotherham C.B. 98, Sheffield C.B. 54, York C.B. 40, Leeds C.B. 32, Worsborough U.D. 26, Bradford C.B. 18, Wakefield C.B. 17, Wetherby R.D. 12), Lancashire 170 (Blackburn C.B. 25, Ashton under Lyne M.B. 19, Stretford M.B. 16, Urmston U.D. 15, Liverpool C.B. 15, Kirkham U.D. 10), Surrey 82 (Surrey M.B. 32, Hambledon R.D. 17), Kent 80 (Deal M.B. 59, Chislehurst and Sidcup U.D. 12), Bedfordshire 77 (Luton M.B. 58), Middlesex 71 (Enfield M.B. 30, Hayes and Harlington U.D. 23), London 66 (Islington 13, Hackney 11), Durham 65 (Blaydon U.D. 16, South Shields C.B. 14, Stanley U.D. 11, Gateshead C.B. 10), Warwickshire 59 (Coventry C.B. 29, Birmingham C.B. 19), Hertfordshire 41 (Welwyn Garden City U.D. 38), Nottinghamshire 38 (Basford R.D. 16),

Northumberland 34 (Blyth M.B. 17, Newcastle upon Tyne C.B. 15), Cheshire 30 (Hyde M.B. 9), Berkshire 26 (Reading C.B. 25), Essex 26 (Thurrock U.D. 13), Staffordshire 25, Yorkshire North Riding 23 (Middlesbrough C.B. 23), Carmarthenshire 23 (Llanelli R.D. 14), and Oxfordshire 21.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the years 1948-56 are shown thus -----, the figures for 1957 thus ———. Except for the curves showing notifications in 1957, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Week Ending March 23

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 822, whooping-cough 2,932, diphtheria 3, measles 27,179, acute pneumonia 695, acute poliomyelitis 37, dysentery 1,317, paratyphoid fever 3, and typhoid fever 1.

Universities and Colleges

UNIVERSITY OF OXFORD

Dr. F. G. Hobson has been appointed to the council of St. Luke's Homes, Ltd., for four years from February 18, 1957.

In Congregation on March 2 the following degrees were conferred:

D.M.—M. G. Ellis, M. A. Peyman, Sabine J. Strich.
B.M.—D. H. G. Ogg.

UNIVERSITY OF CAMBRIDGE

Dr. C. C. D. Shute, University Lecturer in Anatomy, has been elected into a Josephine Rebecca Wolf Fellowship at Christ's College.

In Congregation on February 9 the degree of M.B. was conferred on A. C. Fernando (by proxy) and on T. Buchan.

C. H. Kinder, R. B. McGrigor, and C. H. Talbot have been approved at the examination for the degree of M.Chir.

UNIVERSITY OF LONDON

The following have been reappointed representatives of the University on the governing bodies of the institutions indicated in parentheses: Sir Francis Fraser (Board of Management of the London School of Hygiene and Tropical Medicine); Professor A. A. Moncrieff, Professor J. Z. Young, F.R.S., and Mr. R. C. Davenport (Court of Governors of the London School of Hygiene and Tropical Medicine); Professor G. R. Cameron, F.R.S. (Royal Veterinary College).

The following have been recognized as teachers of the University in the subjects indicated in parentheses: *Institute of Psychiatry*, Dr. B. G. C. Ackner and Dr. W. L. L. Rees (*Mental Diseases*); *University College Hospital Medical School*, Dr. W. B. Balderston (*Dental Surgery*); *St. George's Hospital Medical School*, Dr. G. R. F. Hilson (*Pathology*); *Institute of Diseases of the Chest*, Dr. K. F. W. Hinson (*Pathology*); Dr. J. R. May and Dr. R. W. Riddell (*Bacteriology*); *Postgraduate Medical School of London*, Dr. J. P. Payne (*Anaesthetics*), Dr. R. E. Steiner (*Radiology*), and Dr. I. D. P. Wootton (*Pathology (Chemical Pathology)*); *London Hospital Medical College*, Mr. G. C. Tresidder (*Surgery*); *Guy's Hospital Medical School*, Dr. G. R. Webster (*Pathology (Chemical Pathology)*); Dr. G. W. Garland has been granted probationary recognition for two years from November, 1956, as a teacher of obstetrics and gynaecology at St. Thomas's Hospital Medical School.

Medical News

"Food and Health."—World Health Day is celebrated annually on April 7 to commemorate the foundation of the World Health Organization in 1948. This year the theme is "Food and Health," and the Food and Agriculture Organization is joining W.H.O. as co-sponsor. Special messages for the day have been prepared by the two directors-general. Dr. M. G. CANDAU, director-general of W.H.O., writes: "Without enough of the right kinds of food nobody can be healthy. This simple truth holds the explanation of much of the misery from which mankind suffers. A vicious circle has arisen—poor health impairs productive capacity, low production of foodstuffs brings under-nutrition, more sickness, and less productive power. Health means more than simply the absence of disease and infirmity, and enough food does not mean just sufficient to maintain life." Mr. B. R. SEN, director-general of F.A.O., states: "We can legitimately hope that we have seen the last of famine. The existence of reserve stocks of food, modern transport facilities, and experience in famine relief are among the safeguards at our disposal, and any recurrence of famine and its tragic consequences on a large scale would be a disgrace to humanity."

Sir Geoffrey Keynes.—At its recent meeting the Osler Club presented Sir GEOFFREY KEYNES with a drawing of himself on the occasion of his 70th birthday. The Club was fortunate enough to persuade that master-orator Sir GORDON GORDON-TAYLOR to acclaim the new septuagenarian. "As regards yourself," Sir Gordon said in the course of his tribute, "by some alchemy of fate a distinguished surgeon emerges effulgently as the complete man of letters. Nowhere in the history of surgery has such a combination of qualities been mingled in one person at so high a level of excellence."

Library for Birmingham Medical School.—Sketch plans have been approved for the first stage of the medical school library. It will be sited opposite the medical school and will house over 90,000 volumes. Building is expected to start in June. The first stage, which should be completed by the end of 1958, will consist of the lower-ground and ground floors, together with the shell of the first floor. Stage II, consisting of the completion of the first floor and the addition of second and third floors, which will include a large lecture theatre, will be put in hand as soon as funds are available.

Scottish Hospital Endowments Research Trust.—The Trust has issued its first report, covering the period from its constitution on January 12, 1954, until the end of July, 1955 (H.M.S.O., price 1s. 3d. net). The Trust administers some 22% (on an income basis) of the endowments of the former voluntary hospitals in Scotland. Its funds amounted to nearly £2.5m. at the close of the period reviewed, yielding an annual income of £94,000. Under the terms of the Hospital Endowments (Scotland) Act, 1953, these funds are to be used for the support of research "into any matters relating to the causation, prevention, diagnosis, or treatment of illness or mental deficiency or to the development of medical or surgical appliances including hearing-aids." Before making grants the Trustees are required to consult with the Advisory Committee on Medical Research in Scotland. The first report includes a statement on the Trust's policy regarding grants. Its funds should not be considered as relieving universities or hospital boards of their responsibilities for research. The Trustees have decided therefore, as a general principle, to favour applications for support of clinical or experimental investigations only after the completion of any preliminary work. Major pieces of equipment, purchased by the Trust, are to remain Trust property. The report has appendices giving the statutory background of the Trust, conditions applicable to grants, the Trust's financial statement and investment portfolio, and a list of grants already awarded.

Technical Colleges and Radiological Protection.—The MINISTER OF EDUCATION has written to local education authorities advising them on radiological protection in technical colleges. In colleges where radioactive materials are used competent safety officers should be appointed, "hot" laboratories should be kept separate, and proper storage places and mechanical ventilation should be installed where required. There is also advice on the screening of x-ray apparatus. Colleges are asked to inform the Minister before starting instruction or research with a radiation hazard.

Society for Social Medicine.—The society's first annual meeting will be held in Birmingham from September 24 to 26. The meeting will include scientific sessions as well as the usual business meeting. The Society for Social Medicine was formed last December under the chairmanship of Professor W. J. E. JESSOP, professor of social medicine at Trinity College, Dublin. At present the society has 72 members, drawn mainly from doctors and statisticians working in university departments of social medicine. The annual meeting will be limited to members of the society, but any interested medical practitioner may attend the scientific sessions. Further information about the society may be obtained from the hon. secretary, Dr. ALICE STEWART, 8, Keble Road, Oxford.

Lord Cohen in U.S.A.—Lord COHEN OF BIRKENHEAD is paying a short visit to America. In New York he will be the guest of the New York Academy of Medicine, where he will give a dinner address and speak at a luncheon. On April 7 he will address the annual meeting of the American College of Physicians in Boston, and on April 9 will read a paper on "Observations on Carotenaemia." While at this meeting he will be made an honorary Fellow of the College.

London University.—Dr. KATHARINE LLOYD-WILLIAMS, dean of the Royal Free Hospital School of Medicine, has been elected dean of the Faculty of Medicine of the University. She succeeds the late Professor W. G. BARNARD for the remainder of the period 1956-8. Dr. C. F. HARRIS has been reappointed deputy Vice-Chancellor for the academic year 1957-8. The following have been recognized as teachers of the University: Dr. M. A. PARTRIDGE (mental diseases, St. George's Hospital), Dr. J. H. PATERSON (neurology, St. George's Hospital), Mr. J. S. TOMKINSON (obstetrics and gynaecology, Guy's Hospital), Dr. M. SCHACHTER (University College), and Dr. M. L. THOMSON (applied physiology, London School of Hygiene and Tropical Medicine).

"Cantabartians."—The annual dinner of the Cambridge Graduates Club was presided over this year by Sir HENRY DALE, O.M., described during the evening by Dr. GEORGE GRAHAM as "the most distinguished person we have ever had in the club." Sir HENRY said he had not stayed long at Bart's, and had had to miss being house-physician to Dr. Gee when he was offered a George Henry Lewes Studentship. Gee had said to him then that he hoped that some day medicine would become an experimental science. These and other reminiscences of Sir Henry Dale's were much enjoyed by those whom Sir LANDSBOROUGH THOMSON, replying for the guests, described as "Cantabartians."

Faculty of Anaesthetists.—An election of two fellows to the Board of the Faculty of Anaesthetists took place at the Royal College of Surgeons on March 20. Dr. H. J. BRENNAN, director of the department of anaesthetics at the Manchester Royal Infirmary, and Dr. H. H. PINKERTON, consultant in charge of the department of anaesthetics at the Western Infirmary, Glasgow, were elected, each for a period of eight years. Dr. H. C. CHURCHILL-DAVIDSON, of St. Thomas's Hospital, London, was re-elected to the board for a period of four years.

Aberdeen University.—Dr. M. C. MACNAUGHTON has been appointed lecturer in obstetrics and gynaecology. He graduated at Glasgow in 1948.

Leeds University.—Dr. G. J. R. SOUTTER has been appointed lecturer in paediatrics and child health from May 1.

Mass Radiography at Glasgow.—By the end of the third week of the city's campaign 426,525 people had been radiographed. The weekly figures so far have been: first week, 142,000; second week, 151,000; third week, 133,000. The campaign is for five weeks in all.

Decimal Coinage for India.—Banks closed all over India on April 1, according to Reuter, to allow a change to a decimal coinage system. In future the rupee will consist of 100 instead of 192 pice.

Sir Geoffrey Jefferson, F.R.S., emeritus professor of neurosurgery at Yale University, is to receive the university's honorary LL.D. at the Founder's Day celebration on May 15.

Professor J. F. Fulton, Sterling professor of the history of medicine at Yale University, is among those on whom it is proposed to confer the honorary degree of D.Litt. of Oxford University.

Professor A. W. Downie, F.R.S., professor of bacteriology at Liverpool University, is to receive the honorary degree of LL.D. of Aberdeen University at the summer graduation ceremony.

Miss Margaret Fairlie, professor of obstetrics and gynaecology at St. Andrews University from 1940 to 1956, is to receive the honorary degree of LL.D., St. Andrews.

Dr. Mary Crosse, lecturer in child health at Birmingham University, is visiting Turkey and Greece for a month, under the auspices of the British Council.

COMING EVENTS

Recent Trends in Medicinal Chemistry.—Symposium on April 16 at Manchester University arranged jointly by the Chemical Society, Institute of Petroleum, Royal Institute of Chemistry, and Society of Chemical Industry. Apply by April 9 to Dr. M. T. G. Burrows, Murgatroyd's Salt & Chemical Co. Ltd., Elworth, Sandbach, Cheshire.

Wessex Rahere Club.—Spring Dinner at Royal Clarence Hotel, Exeter, on April 27. Details from Mr. A. D. BATEMAN, F.R.C.S., 11, The Circus, Bath.

Leonard Parsons Memorial Lectures.—Professor RUSTIN McINTOSH, of the Babies Hospital, New York, will lecture at the Birmingham Medical School on May 7 and 8 at 4 p.m. His subject will be "Growth and Development."

Harben Lectures.—Professor P. DRINKER, of Harvard, will deliver this year's Harben lectures at 5 p.m. on May 13, 14, and 15 at the Royal Institute of Public Health and Hygiene, 28, Portland Place, London, W.1. His subject will be "Air Pollution and the Public Health."

Dental Implant Society.—Professor T. TALMAGE READ will read a paper on superiosteal dental implants, followed by a film, at the Royal Society of Medicine, May 15, 8 p.m. Medical practitioners are invited. Apply to the hon. secretary, Dental Implant Society of Great Britain, 109, Harley Street, London, W.1.

European Organization for Research on Fluorine and Dental Caries Prevention.—Fourth meeting, Malmö, June 15-17. Details from Professor SYRIST, Royal Dental School, Malmö, Sweden.

NEW ISSUES

Ophthalmic Literature.—The new issue (Vol. 10, No. 3) is now available. It contains a comprehensive selection of abstracts of the literature on ophthalmology and related subjects. Six issues and a volume index each year; annual subscription £4 4s. (or in combination with *British Journal of Ophthalmology*, £7 7s.); single copy 25s.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

Abstracts of World Medicine.—Issued in the first week of each month, this journal contains abstracts of important papers selected from the current medical literature of the world. Annual subscription £4 4s., single copy 8s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Tuesday, April 9

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Professor H. J. Shaw: Radical Surgery in Cancer of the Extrinsic Larynx and Laryngopharynx.

SOCIETY FOR CULTURAL RELATIONS WITH THE U.S.S.R.—8 p.m., Professor Fedor Syrovatko (Moscow): Soviet Work in the Relief of Pain in Childbirth.

WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Dr. C. C. Edwards: neurological demonstration.

Wednesday, April 10

●CAMBRIDGE MEDICAL SOCIETY.—At Corpus Christi College, 7.30 for 8 p.m., dinner.

LONDON UNIVERSITY.—At Middlesex Hospital (Clinical Lecture Theatre, First Floor Crosspiece), W., 4 p.m., special university lecture in medicine by Professor R. M. Jones (Toronto): Cancer of the Lung—Certain Considerations in its Diagnosis.

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—3.30 p.m., Mr. F. M. Brownlee, A.M.I.H.E.: Hygiene and Public Health in the Municipal Baths Department (illustrated).

ROYAL MEDICO-PSYCHOLOGICAL ASSOCIATION, PSYCHOTHERAPY AND SOCIAL PSYCHIATRY SECTION.—At 11, Chandos Street, W., 8 p.m., Dr. E. F. Carr: Group Therapy in a Mental Hospital. (Open to members and guests.)

Thursday, April 11

ALFRED ADLER MEDICAL SOCIETY.—At 11, Chandos Street, W., 8 p.m., Dr. J. Cowie: The Delinquent Girl.

BRITISH INSTITUTE OF RADIOLOGY.—8 p.m., Dr. Macdonald Critchley: Clinical Aspects of Tuberculous Sclerosis; Dr. J. J. Y. Dawson: Tuberculous Sclerosis with Special Reference to Pulmonary Changes; Dr. P. H. Whitaker: Radiological Changes in Tuberculous Sclerosis.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Professor A. A. Jefferson: Pituitary Chromophobe Adenoma and Rathke Pouch Cysts.

Friday, April 12

BIOCHEMICAL SOCIETY.—At Department of Biochemistry, Oxford University (Friday and Saturday, April 12 and 13), 11 a.m., 361st meeting, jointly with Société Belge de Biochimie—Belgische Vereniging voor Biochemie. BRITISH INSTITUTE OF RADIOLOGY.—3 p.m., meeting of medical members. FACULTY OF RADIOLOGISTS.—At Royal College of Surgeons of England, 5 p.m., Robert Knox Memorial Lecture by Dr. E. Rohan Williams: Multiple Myeloma.

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—3.30 p.m., Dr. I. Friedmann: Advances in Chemotherapy in Ear, Nose, and Throat Diseases.

INSTITUTE OF NEUROLOGY.—5.30 p.m., Dr. E. J. M. Campbell: Pulmonary Physiology and Artificial Respiration.

KENT AND CANTERBURY HOSPITAL.—8 p.m., clinical meeting. SOUTHEAST-ON-SEA GENERAL HOSPITAL.—At Out-patients' Hall, 8.30 p.m., Sydney Body Lecture by Sir Hugh Lindsay, LL.D., F.R.S., M.P.: Human Relations in and Around the Health Service.

APPOINTMENTS

CARTER, KENNETH, M.R.C.S., L.R.C.P., Scientific Director, Ames Company, Inc., Elkhart, Indiana, U.S.A.

EAST ANGLIAN REGIONAL HOSPITAL BOARD.—T. J. K. Merritt, M.B., B.S., D.P.M., Senior Registrar, Department of Child Psychiatry, Ipswich and East Suffolk Hospital; E. F. Southill, M.B., B.Chir., F.R.C.S., Senior Surgical Registrar, United Norwich Hospitals; Mary M. Berrin, M.B., B.Ch., D.A., Registrar in Child Psychiatry and Mental Deficiency, Little Plumstead Hospital Group; K. J. Millar, M.B., B.S., Surgical Registrar, West Suffolk General Hospital.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Crawford.—On March 22, 1957, to Mary, wife of Dr. W. Cowan Crawford, 58, Pottery Road, Warley, Birmingham, a son—Alan.

Gillespie.—On March 10, 1957, at 2, Cavendish Road, Hull, Yorks, to Dorothy, wife of Ross Gillespie, M.B., Ch.B., a sister for Jean, James, and David.

Norman.—On April 1, 1957, to Dr. Rebe Rainsbury, wife of Dr. L. I. Norman, of 34, Court Road, Eltham, a second daughter.

Shinton.—On March 24, 1957, to Margaret (formerly Hyde), M.B., Ch.B., and Neville Keith Shinton, M.B., M.R.C.P., a second son.

Stephenson.—On March 24, 1957, to Anne (formerly Conley), M.B., B.S., wife of Kenneth D. Stephenson, M.B., B.S., of Stanhope Road, Darlington, Co. Durham, a daughter.

MARRIAGES

Trewby.—Huxley-Williams.—On March 30, 1957, at Hong Kong, Lieutenant-Colonel H. F. Trewby, A.M.I.Mech.E., R.E.M.E., to Rosemary Huxley-Williams, M.R.C.S., L.R.C.P., D.A.

DEATHS

Carmichael.—On March 15, 1957, in hospital, Exeter, Henry Carmichael, M.B., C.M., late of Wandsworth, London, S.W., aged 84.

Hovenden.—On March 14, 1957, at Putney Hospital, Gerald Stanley Hovenden, M.D., of Glebeholme, Barnes, London, S.W., aged 87.

McMahon.—On March 10, 1957, at 31, Church Road, Whitechurch, Cardiff, Glam., Leo Luke McMahon, M.B., B.S.

Stevenson.—On March 11, 1957, at Cambridge, Mabel Geraldine Stevenson, M.D.

Symons.—On March 8, 1957, at Gwendron, Fermanagh, Guernsey, Angelo Nelson Symons, O.B.E., M.R.C.S., L.R.C.P.

Thompson.—On March 6, 1957, in a nursing-home, Frank Stuart Corbett Thompson, O.B.E., M.B., C.M., Lieutenant-Colonel, I.M.S., retired, late of Bengal, aged 84.

Weedner.—On March 14, 1957, at White Gables, St. Brelade, Jersey, Robert Joseph Weedner, M.B., B.S.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Milk on Continental Holiday

Q.—What risk is there of diseases such as tuberculosis and brucellosis from milk and milk products in countries in Western Europe, such as France, Spain, and Italy? Does the risk justify taking any special precautions, especially so far as children are concerned, and, if so, what is advised? Are T.A.B. and B.C.G. inoculations recommended?

A.—In the countries mentioned, and, it may be added, Portugal, Morocco, and Algeria, the incidence of enteric fever is higher—in some much higher—than in Great Britain, and the administration of T.A.B. vaccine is a wise precaution before visiting them, particularly for a stay of some length and in a country district. Cities are safer, because their milk is almost all pasteurized and sanitation generally is under closer control. Brucellosis and tuberculosis are also risks, varying much with locality and difficult to assess. There should be no hesitation at the beginning of any considerable stay, particularly with children, in inquiring about the source of the milk supplied and whether it is pasteurized: if not, and if the quality of the source is doubtful, it may be advisable to have it boiled for the benefit of young children consuming a good deal (the temperature of boiling is quite unnecessarily high, but ignorant people cannot be trusted to do anything less). Whether to immunize with B.C.G. in these circumstances involves the whole question of what should be the scope of this method of vaccination. In Scandinavian countries Mantoux-negative schoolchildren all receive B.C.G. at an early age, and there is much to be said for this, rather as a protection against contact with human disease than against the usually lesser risk of milk-borne infection.

Apomorphine Treatment of Alcoholism

Q.—What are the details of the treatment of alcoholism with apomorphine? How successful is it?

A.—The endemic problem of the compulsive alcoholic and the drug addict is hardly touched on in our medical schools or textbooks. The continual drinker should be treated in a hospital or nursing-home, but those with an intermittent craving may be given oral treatment at home between attacks. Successful treatment makes the patient lose his compulsion to drink, and, unless he returns to taking the alcohol (or drug) he no longer needs, no further treatment will be necessary. Here it is possible to give only a brief outline of the treatment.

Treatment in Hospital.—This should not take more than ten days; six or seven days are generally enough. The dosage should start with apomorphine gr. 1/20 (3.2 mg.) intramuscularly and increase by gr. 1/20 (3.2 mg.) two-hourly, each dose being followed in a few minutes by a drink of 2 oz. (57 ml.) of half-and-half gin or whisky and water (whatever the addiction, even if it is to morphine), until a vomiting dose is reached. The dose of apomorphine is then varied so as to achieve a satisfactory vomit and sleep between injections, which are continued two-hourly for about 48 hours. No food or other drink is given during this stage. During the next 48 hours apomorphine at half the previous highest dose is given three-hourly, the dose being gradually reduced to just below the nauseating level; alcohol is now stopped and food and soft drinks are allowed.

Treatment at Home.—Here the patient is immediately

cut off drink, and apomorphine is given sublingually at a dose just below the nauseating level and is continued two-hourly for two days.

Vitamin Supplements for Babies and Young Children

Q.—What vitamin supplements are advised for a breast-fed baby, and for how long should they be continued?

A.—The standard vitamin supplements given to babies, whether breast- or bottle-fed, are vitamin A 3,000-5,000 units, vitamin D 600-900 units, and vitamin C 25 mg. Breast milk contains just enough of these vitamins to protect the baby only if the mother has been receiving a satisfactory diet and if the baby is taking its feeds well and getting some exposure to sunlight. In Britain one cannot count on enough sunlight to form sufficient vitamin D to give a baby protection from rickets. Hence, if the infant is not taking full feeds, or is ill, it may be deficient in these vitamins.

Apart from the standard supplements noted above, a normal breast-fed baby does not need supplements of other vitamins, unless it is ill, when the addition of the B-group of vitamins is advisable. This applies particularly to prolonged gastrointestinal disturbances.

The absolute need for vitamin supplements once the baby is on a full mixed diet is dependent very much on the quality of the diet and, to a small extent, on the amount of sunshine to which the child's uncovered skin is exposed. But it is generally—and wisely—recommended that children should continue to receive supplements of vitamins A, C, and D until they are 5 years old. The supplements can do no harm, and there is always some risk of at least a vitamin-D deficiency in a rapidly growing child if extra D is not given. It may in fact be wise to continue to give A and D vitamins, at least during winter, until the age of about 12 years. One teaspoonful daily of the Government fortified cod-liver oil is adequate, the dose starting at the age of about 4 weeks with one drop and being doubled every day or two until the full amount is reached. For those babies who will not tolerate this or whose mothers object to the smell and staining properties of cod-liver oil, there are many reliable concentrated preparations. Vitamin C can be given from about the same age in the form of Government concentrated orange juice, or as ascorbic acid pills, fresh orange juice, or rose-hip syrup.

Storage of Inflammable Liquids

Q.—What legal regulations govern the storage of petroleum ether, benzene, toluene, and similar inflammable liquids in chemical laboratories?

A.—Petroleum ether, benzene, and toluene are all "petroleum spirit" within the meaning of the definition for petroleum spirit in the Petroleum (Consolidation) Act, 1928. The provisions of that Act therefore apply to these inflammable liquids. Except in quantities not exceeding three gallons (13.5 litres) and when kept in receptacles not exceeding one pint (570 ml.) in capacity, a licence must be obtained from the local authority for the storage of these petroleum spirits. The local authority may attach to the licence such conditions as they think expedient as regards the safe keeping of the petroleum spirit. The licence may include conditions concerning the nature of the goods with which the petroleum spirit may be kept, for instance.

There are also inflammable liquids with low flash-points which are not petroleum spirit, and the above-mentioned Act does not apply to them. But, if such liquids are kept, the local authority may agree that they should be kept with the petroleum spirit and under the same conditions.

Petroleum spirit intended for use in motor vehicles, motor boats, aircraft, and certain engines may be kept in quantities in excess of three gallons (13.5 litres) under certain specified conditions. This exemption, however, does not apply to the storage of petroleum spirit in chemical laboratories.

Post-coital Pain in Hip

Q.—What are the likely causes of pain in a man's hip and thigh after intercourse? The pain invariably follows intercourse and occurs the next morning—sometimes on getting up and sometimes later—and lasts about three hours before passing off. The patient in question had a non-specific urethritis several years ago. Physical examination is negative.

A.—This pain may be a muscular reaction to some faulty posture during coitus, or it may well be psychological in origin. Clinically and pathologically the spermatic tract must be considered as a single unit consisting of the testes, epididymes, vasa deferentia, ampulla, seminal vesicles, and ejaculatory ducts which empty the seminal fluid into the posterior urethra at the verumontanum during ejaculation. Complete or partial blockage of the spermatic duct from whatever cause may result in spermatic colic which is characterized by sudden, sharp pain at the end of coitus. The close anatomical relationship of the seminal vesicle and ampulla to the corresponding ureter facilitates the spread of inflammatory changes from the former, and this may lead to periureteritis and ureteric colic.

That there is a close association between non-specific urethritis and arthritis is well known, the latter usually occurring when fibrous change takes place in the spermatic tract, and many authors have recorded involvement of the lumbosacral and sacro-iliac joints in this condition.

No Diastolic Reading

Q.—In measuring the blood pressure, sometimes after the systolic reading has been taken the sounds show no alteration right down to a zero reading. Why is this, and how should the diastolic pressure be ascertained in such cases?

A.—There are two conditions in which the Korotkoff sounds may persist right down to the lowest levels. One is aortic incompetence, and the other thyrotoxicosis. Apart from these, nervousness in perfectly healthy people may make the diastolic reading very difficult. This nervousness may not cause the heart rate to increase or the vigour of the contraction to be more pronounced, although there is usually a tendency to thump. This difficulty in taking the diastolic pressure may not persist and the sounds will change if the patient becomes more composed. On another occasion a normal reading may well be found. Usually on very careful auscultation a slight change in the character of the sounds can be detected where the diastolic reading really is. Otherwise, if the sounds go right down to the bottom, then no diastolic reading can be made. The reason for these abnormal diastolic phenomena is not known.

NOTES AND COMMENTS

Alopecia Areata.—Dr. J. T. INGRAM (Leeds) writes: I hope that most dermatologists will disagree with your expert who says that "only local remedies are worth trying in alopecia areata" ("Any Questions?" March 16, p. 658). Alopecia areata is a symptom, not a disease. There is nothing local to treat, and it is probable that all local treatments are worthless. Unless management and treatment are along general lines they are more likely to be harmful than helpful. Fortunately the majority of patients with alopecia areata recover in spite of treatment.

Dr. F. F. HELLIER (Leeds) writes: I cannot disagree too strongly with your expert's opinion that "only local remedies are worth trying in alopecia areata." Local remedies will only make growing hair grow faster and will not directly affect the underlying restraining influence which is arresting hair growth. What this is we do not know, but there is little doubt that in many patients it is associated with nervous stress, anxiety, or shock. It may be that reassurance and a bottle of hair tonic will help the patient's anxiety so that the hair is allowed to grow again, and in this way local treatment may be of value—in a psychological way.

OUR EXPERT replies: I do not question Dr. Hellier's assertion that there is a systemic underlying factor in causing alopecia

areata. However, I agree with Dr. Hellier that we do not know what it is, and we do not, therefore, know how to remove it with treatment. In many patients, it is true, there is associated nervous stress, but in far many more there is none, and the systemic factor remains quite unidentifiable.

Otitis Media Due to Gram-negative Organisms.—Dr. E. N. WHITMAN (Medical Department, Burroughs Wellcome and Co. (U.S.A.) Inc.) writes: This is in regard to the answer to the question on local therapy in otitis media due to Gram-negative organisms ("Any Questions?" December 15, 1956, p. 1441). The only antibiotics mentioned in the answer were chloramphenicol, oxytetracycline, streptomycin, and neomycin. This answer is of concern to me, since I feel that it might possibly be misleading to doctors of limited experience in this field. As you know, much recent work has amply demonstrated that most cases of otitis are caused by Gram-negative organisms, and between 50 and 60% of these are caused by *Pseudomonas aeruginosa*. In addition, it has been repeatedly demonstrated that the most potent antibiotic against this organism is polymyxin B. For that matter, comparing the *in vitro* potency of the antibiotics mentioned in the answer with polymyxin B, the latter emerges far superior. Wright, Potee, and Finland¹ found that almost all strains of *Pseudomonas aeruginosa* were inhibited by 6.3 mcg. or less per ml. of polymyxin B. In comparison the other antibiotics mentioned required the following concentrations in mcg./ml. to inhibit 80-90% of the strains tested: oxytetracycline, 100 mcg./ml.; neomycin, 200 mcg./ml.; streptomycin, 400 mcg./ml.; and chloramphenicol, more than 400 mcg./ml.

So far as clinical work is concerned, Benton² states that "the most frequent organism found in pure culture was *Pseudomonas aeruginosa*" (47 out of 110 cases). He goes on to state that "polymyxin was found to give the quickest and most satisfying results, and it is therefore the drug of choice in cases of gram-negative otitis externa." Branca³ recommends the use of "aerosporin" otic solution: "This preparation contains polymyxin, which is most effective against *Pseudomonas* and gram-negative organisms. It also contains acetic acid, which helps restore the normal pH of the canal."

3. Branca, H. E., *A.M.A. Arch. Otolaryng.*, 1956, 63, 459.

OUR EXPERT replies: The original question referred to otitis media, but did not specify whether acute or chronic. Your correspondent, Dr. Whitman, appears to refer to cases of otitis externa, in which I quite agree that polymyxin B gives excellent results. In acute otitis media the infection is predominantly by Gram-positive organisms, and systemic antibiotics are employed. In chronic otitis media Gram-negative organisms are more commonly found, but topical application of antibiotics is often disappointing, and for this reason the application of classical surgical principles of cleanliness and promotion of drainage was given priority.

Books of "Any Questions?" and Refresher Course Articles.—The following books are available through booksellers or from the Publishing Manager, B.M.A. House. Prices include postage. *Any Questions?*, Volumes 2 and 3 (8s. each); *Refresher Course for General Practitioners*, Volumes 2 and 3 (26s. 6d. each inland, 26s. overseas); *Clinical Pathology in General Practice* (22s. 3d. inland, 21s. 9d. overseas).

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 4499. TELEGRAMS: *Altology, Westcent, London*. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Director, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 4499. TELEGRAMS: *Britmedad, Westcent, London*.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 4499. TELEGRAMS: *Medisecra, Westcent, London*. B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ACETAZOLAMIDE
Lederle

In conditions where excess fluid accumulates in body tissues, prompt dispersal measures are called for. In such cases, by inhibiting carbonic anhydrase, DIAMOX acetazolamide produces prompt copious diuresis. It has proved its ability to control body-fluid balance in cardiac oedema, glaucoma and epilepsy. Published reports also show satisfactory results from DIAMOX in toxæmia and oedema of pregnancy, premenstrual tension, renal oedema, emphysema and drug-induced oedema. DIAMOX is a welcome departure from the mercurials and is well suited to long-term maintenance of ambulant and out-patient cases.

TABLETS of 250 mg.

Bottles of 25, 100 and 1,000

PARENTERAL Vials of 500 mg.

LEDERLE LABORATORIES DIVISION

Cyanamid OF GREAT BRITAIN LTD., London, W.C.2

WARD, CASSENNE LTD.

3 to 5 times more
active than hydrocortisone
or cortisone.

DELTALONE

BUFFERED TABLETS

REGD.T.M.

MAJOR INDICATIONS:
*Rheumatoid Arthritis,
Severe allergies.*

The antacids and the protective coating covering the Deltalone crystals increase therapeutic advantages by lessening the risk of gastric disorders.

DELTALONE

REGD.T.M.

BUFFERED TABLETS: At 5 mgm. or at 1 mgm.

ADVANTAGES:

—Better gastric tolerance,
due to the addition of
antacids. These counteract
the gastric hyperactivity
often caused by these
corticoids.

—a protective coating which
covers each hormone
crystal individually.

*No sodium or water
retention when usual
therapeutic doses are prescribed.*

FORMULA:

Prednisone (Delta-1-Cortisone)
Aluminium hydroxide
Magnesium trisilicate

WARD, CASSENNE LTD.

116 Victoria Street, London, S.W.1

The graph above is of an experiment to measure the effect of Transvasin on skin temperature on a subject. The red line plots the skin temperature before and at intervals after a single application of one inch of cream (0.924 grams) from a tube of Transvasin. The black line gives similar information with regard to the application of a plain vanishing cream used as a control. Skin temperatures were measured with an electro-thermo couple every five minutes for two hours. Photographs show the affected area before application; three minutes and thirty minutes later.

COMPOSITION OF TRANSVASIN

Salicylic acid tetrahydrofurfuryl-ester		14%
Nicotinic acid ethyl-ester		2%
Nicotinic acid n-hexyl-ester		2%
p-Aminobenzoic acid ethyl-ester		2%
Water-miscible base ad		100%

Transvasin

Transvasin is a registered trade mark of Lloyd-Hamol Ltd

IT is generally agreed that cases of soft-tissue rheumatism and of many types of arthritis benefit by hyperaemia of the affected tissues. Transvasin, which contains two quick-acting esters of nicotinic acid, induces such a deep and prolonged hyperaemia at the same time as it produces superficial erythema.

In addition to the esters of nicotinic acid, Transvasin contains the fat- and water-soluble esters of salicylic and p-aminobenzoic acids. Both these well-tried analgesic drugs are readily conveyed through the skin in therapeutic quantities and enable an effective concentration to be built up where they are needed.

Transvasin is now being widely prescribed, with successful clinical results. Since a very small quantity is sufficient for each application, the cost of treatment is extremely low.

Transvasin is available in 1 oz. tubes, basic N.H.S. price 2/6 plus P.T., and is not advertised to the public. Samples and literature will be gladly sent on application.

CANCER—A BIOLOGICAL APPROACH*

III. VIRUSES ASSOCIATED WITH NEOPLASTIC CONDITIONS

BY

Sir MACFARLANE BURNET, M.D., F.R.S.

Walter and Eliza Hall Institute of Medical Research, Melbourne, Australia

There is still an active body of opinion that would regard cancer as a parasitic disease due to infection of cells by extrinsic viruses. Such an attitude has the great attraction that it suggests straightforward approaches to the prevention of cancer by immunological methods and holds out more hope of an eventual effective chemotherapy. As various writers have pointed out, the claim that some neoplastic processes are due to virus infection is not inconsistent with a recognition of the overriding importance of somatic mutation. Any claim that all cancers are of infective character is unjustified and frankly absurd in the present state of knowledge.

It has never been easy to define a virus, and the recognition of provirus in bacteria, with the convincing evidence that it is intimately built into the host's genetic mechanism, has now made it even more difficult. Any definition must cover the fact that there are two very different systems from each of which by appropriate manipulations a continuing sequence of typical virus infections may be produced. These are respectively the infective particle and the infected host cell.

A virus, in the conventionally understood form of a population of infective virus particles, can be defined as a self-replicating agent or organism smaller than bacteria and capable of multiplication only within living susceptible host cells. It may be desirable to add certain qualifications when we have to discuss demonstrable or hypothetical self-replicating subcellular entities. A virus particle must be shown to carry specific patterns in protein and nucleic acid which are different from those of the host cell and which are not derived genetically from the host species or any species related to it.

At a certain stage of infection, host cells may contain no virus demonstrable by the classic method of breaking up the cell and inoculating the product into other susceptible cells. There is other evidence that at this stage the cells do not contain formed virus particles. Under certain circumstances this phase may be prolonged. Its existence can be recognized either by providing a situation where infective virus particles will develop and be identified by standard methods or by demonstrating specific virus antigen in or liberated from the cells.

In general a virus (in the sense covering both the infective and vegetative phases) can be recognized only if it produces cytopathogenic effects in some type of host. It is by no means necessary, however, that intracellular

production of virus or virus constituents should always be associated with observable cellular changes.

Much of the discussion of a virus theory of cancer has been based on these difficulties of definition. The essential problem, however, is to decide whether the virus theory of cancer provides ideas which will allow (a) more effective generalization as an aid to the understanding of cancer, or (b) effective approaches to prevention or cure that would not be available if other views were held.

The incentive to consider whether all malignant neoplasms are the result of virus infection is derived from the fact that active proliferative lesions may be experimentally produced in birds and mammals by infection with a few typical viruses. The epidemiology of these conditions in nature is consistent with transfer of virus from one host to another by one of the classical methods. There are many other types of neoplasm in which there is no such association with overt virus infection. It is the contention of those supporting the virus theory that in this latter group virus is present, but, because it is normally in the vegetative phase or for other technical reasons, it cannot be observed by conventional techniques.

In this discussion we may deal with the relevant data under four headings: (1) The character of proliferative lesions produced by unequivocal viruses such as fibroma and fowlpox viruses. (2) The significance of the complex of conditions in fowls which includes lymphomatosis and filterable sarcomata. (3) The development of malignant lesions from virus-produced papillomata. (4) The changed susceptibility of proliferating or neoplastic tissue to virus multiplication and damage.

Proliferative Lesions Produced by Virus Infection

It is a commonplace that the gross effect of virus infection in vertebrate tissues is to produce varying degrees and mixtures of cellular proliferation and cellular necrosis. This can be seen in almost diagrammatic form in the lesions produced by different viruses on the chorioallantois. Typical strains of fowlpox give grossly proliferative lesions without necrosis. A neurotropic strain of vaccinia will give a pock with only a thin margin of hyperplastic and proliferating cells and a broad central crater of necrotic material (Beveridge and Burnet, 1946).

Fibroma virus in rabbits may be taken as typical of viruses with predominantly proliferative lesions. Morphologically it is a large pox-type virus; it is presumably spread by biting insects, and is in every sense a thoroughly "typical" virus. The characteristic lesion is composed of healthy-looking fibroblast-like cells and contains much infective virus. Antibody production can be demonstrated,

5023

*Parts I and II of this paper were printed in last week's issue (p. 779).

and presumably as a result of an immune response the fibromatous lesions regress within a month or two and leave a solid immunity to reinfection. There is no evidence that malignant change ever occurs in the lesions.

This condition poses the general question of how or why a virus induces a cell type to proliferate, in this case almost like a neoplasm. Answers can fall into two categories. The first is to be satisfied with obtaining an accurate range of experimental data on the extent of proliferation produced on different types of tissue by the viruses selected for study and to look for any correlations with other observable qualities of the viruses and cells concerned. The second is to regard the proliferative lesion as a deviation from the normal control of form exercised by the organism as a whole and to use the phenomena in an attempt to understand both the nature of virus action on the cell and the process by which control of the cells' growth is lost during the active phase of the lesion.

In the present discussion we are concerned especially to see in what ways the simple proliferative lesion produced by fibroma virus can provide helpful analogies to what occurs in tumour production. In the fibroma lesion there is no evidence for or against the occurrence of a somatic mutation allowing release of a specific control. We must assume the release of a control, and the simplest hypothesis is that the virus after entering the cell uses, binds, or inactivates a component of the cell which plays an essential part in the process of control. Of the available suggestions the most attractive is to use Weiss's concepts of cellular interactions and to suggest that this type of virus infection results in the cell losing its normal function of maintaining or liberating the markers which convey information of its presence to adjacent cells. These would leave the infected cell representing a (non-existent) gap, which adjacent cells would replicate to fill and in their turn be infected. On this view one could have a mass of cells all "unaware" of the existence of any contiguous cell and therefore proliferating at the maximal rate allowed by nutritional and other still existent controls. An essential feature of this hypothesis is that the same result would appear if the control affected by virus infection were abrogated as a result of a corresponding somatic mutation.

The Shope Papilloma and its Malignant Changes

The naturally occurring virus papillomata of cotton-tail rabbits seem to result from simple transfer of virus from an affected animal to a mildly traumatized area on a susceptible one. The lesions contain infective virus and large amounts of a DNA nucleoprotein, which appears to represent the effective virus. The number of such nucleoprotein particles is, however, enormously larger than the number of minimal infective doses. The lesions are papillomata resulting from proliferation of skin epithelium with various secondary changes. Specific antigen is produced with demonstrable antibody response, and some of the growths regress slowly.

The main interest of this virus in relation to neoplasia depends on two findings: (1) Infection of domestic rabbits gives rise to large papillomatous lesions in which little or no virus can be demonstrated. It has been held that this provides a prototype of the condition present in those cancers where no virus can be isolated. (2) The lesions produced either in cotton-tails or domestic rabbits frequently become carcinomatous, especially if the skin involved has been treated with a chemical carcinogen as well (Rous and Kidd, 1938).

The non-infective character of the lesions in the domestic rabbit would be best interpreted as a stabilized vegetative phase in which specifically patterned virus components are being produced but for one reason or another are not being fabricated into complete infective virus. From analogy with the findings in regard to non-infectious haemagglutinin in influenza virus infections it may be that the essential defect is an unbalanced production of virus protein without equivalent replication of the DNA component. The

point of special importance is that the proliferative character of the lesion, which is as marked in domestic rabbits as in cotton-tails, must depend on the earlier stages of the process of virus replication, since the fabrication and liberation of complete virus particles does not occur. With the proliferation of infected but otherwise undamaged cells, virus patterns in DNA and protein will be distributed to descendant cells and will be enabled to exert in them whatever deviation of control is needed to maintain the proliferative process.

In cotton-tail rabbits many of the growths fail to regress, and about 25% become frankly malignant. With the change to carcinoma, virus can no longer be found in the growths (Syverton *et al.*, 1950). Extensive studies have been made in domestic rabbits of the capacity of the virus to provoke carcinomata in skin areas converted to a pre-cancerous state by treatment with tar. From the history of a transplantable carcinoma V2 produced in this way, it appears that, though no free virus was present, all rabbits bearing the tumour for its first 22 passages developed antibody against papilloma virus. After 46 passages, however, the capacity to produce antibody had disappeared. This tumour was dependent on the existence of vegetative virus, but when the appropriate somatic mutation arose the continuation of virus action became both unnecessary and impossible.

Avian Lymphomatosis and Related Conditions

In domestic fowls, and perhaps in other birds, there is a wide range of neoplastic processes involving mesenchymal cells from which with varying degrees of difficulty non-cellular infectious material can be obtained. The epidemiology of the group is still rather obscure, but everything points to the conclusion that viruses of this complex do spread by one process or another from bird to bird. The viruses concerned are highly labile genetically, and it is perhaps best to regard the most extensively studied types, the Rous sarcoma and Beard's erythromyeloblastosis, as laboratory variants rather remote from natural strains.

It has been known for many years that Rous tumours vary greatly in their filterability. Duran-Reynals (1953) considers that this is largely related to the age of the host. In very young birds haemorrhagic necrotic lesions with much filterable virus is the rule. In old birds slower-growing tumours containing no extractable virus are commonly found. These are just as effective stimulants to antibody formation as are tumours that provide free virus.

Probably the most rewarding way to look at the lymphomatosis viruses of birds is to recognize the different requirements for cell-to-cell transfer if a proliferative process is involved. The standard teaching on the natural history of viruses is that we have a regular alternation of phases. The infective particle, the conventional "virus," is a unit specifically evolved to transfer infection to a new host cell. It is immaterial whether this is another cell of the same host organism or a cell of another individual in which infection is being initiated. Within the susceptible cell we have the vegetative phase, in which replication of all the specifically patterned components needed for infective virus is going on. It has been one of the important recent findings of virology that it is by no means inevitable that initiation of cellular infection must be followed by the production and liberation of a new brood of infectious virus. With highly virulent types, and especially those adapted to specially susceptible laboratory hosts, this condition may be approached.

In nature probably a very large proportion of cells into which virus enters support only a limited phase of the process of replication and produce no infective virus. Under most circumstances this will entail the elimination of the virus concerned, but conditions may be different if the completely infected cell proliferates as a result of some change induced by the infection. The vegetative virus can then progressively infect more and more cells, either descendants or conceivably by some form of cytoplasmic fusion with cells of other lines. If at the end of such an internal spread opportunity arises for the production of a

proportion of infective particles that can reach new individual hosts, there is a clear possibility that the mechanism may have survival value for the virus. As in so many other areas of biology, we find what looks like a degeneration put to biological service and providing a new niche for survival.

The status of the Bittner milk agent in relation to mammary cancer in mice is not yet clear. If it is introduced very early in life it gives rise to mammary cancer at a late stage in mice whose inheritance and endocrine experience are appropriate. There are suggestions that it may arise spontaneously, and there is no doubt that mammary carcinoma can arise in its absence. It is an interesting point, possibly due to an inability of the virus to become implanted unless it enters the body at a stage when immunological tolerance can develop, that no antibodies against the virus have been detected in mice. The general picture one receives is of a virus of very low grade that has found a way of persisting in mouse tissues analogous to that of lymphocytic choriomeningitis virus. As such it has an opportunity to act as an effective link in a chain of abrogated controls leading to the development of mammary cancer.

The other alternative, which is equally applicable to the virus that can transmit leukaemia to mice inoculated on the first day of life (Gross, 1954), is that these mouse agents are not descendants of autonomous viruses, but represent pathologically active subcellular organelles whose pattern has been derived relatively recently from a mouse genetic mechanism. This has been a common speculation for many years, but no one has been able to provide definitive criteria which will establish such an origin.

A point relevant to the lymphoma-leukaemia group of conditions in domestic fowls and laboratory mice is the possibility that there seem to be rather numerous strains in both species in which the overall genetic control of lymphoid cell proliferation is abnormally weak.

Changed Susceptibility of Proliferating Cells to Virus Attack

In recent years the oncolytic action of certain viruses has raised hopes that eventually we may see therapeutic use of viruses which, while lethal for tumour cells, have no action on normal tissues. There are other changes in cell circumstances that may lead to increased susceptibility to virus action, and it is perhaps significant that two of them are associated with diminished control of growth. Virus fibroma lesions in rabbits are infected and rapidly destroyed by some of the encephalitic viruses, including Semliki Forest and MVE, which have no more than trivial action on rabbit tissues generally (Ginder and Friedewald, 1951). Monkey kidney cells *in vivo* do not support multiplication of poliovirus and suffer no damaging effect (Kaplan, 1955). When prepared for tissue culture they represent the medium of choice for growth and recognition of the virus. The HeLa strain of human cancer cells is susceptible to a wide range of viruses, and it is usual to find that transplantable mouse tumours are more susceptible to many viruses than normal mouse tissues.

Koprowski (1955) has introduced an important new point in showing that when an ascites tumour broadens its range of hosts—that is, loses an antigenic individuality marker—it concomitantly develops an increased susceptibility to the cytopathogenic action of several viruses. It may be significant, too, that rapidly growing embryonic tissues where control obviously takes a different form to that of the adult are highly sensitive to virus action. And one may wonder whether in the central nervous system, with its undue susceptibility to many viruses, there may be another clue to this general problem.

When increased susceptibility to viruses becomes evident it is to their necrotic action, not to their effect in increasing proliferation. If simple proliferation is, as we have suggested, due to the relaxation of what might be called proximity control, then it appears that when this control is lost there is no other point at which a number of viruses (of the arthro-

pod-borne group) can be checked once they enter the cell. For reasons that we have discussed in relation to the typical "tumour viruses" the block which tends to be associated with proliferative rather than necrotizing action must lie at a stage just before the completion of virus replication. It is of considerable interest that at the present time there is a strong tendency for virologists to regard the final fabrication of virus as a function of the cell surface. This is particularly well established for influenza virus. In the allantoic cavity the whole process takes place on the free surface of the cell. This is the only surface where there is not a constant proximity to the living surface of other cells. It is too early to make any hints on how a proximity control might also function as a barrier preventing the completion of virus particle production, but it is hard to believe that it will not eventually be found to do so.

Development of Malignant Characters by Cells in Tissue Culture

One of the most decisive arguments against a necessary part being played by viruses in carcinogenesis is derived from the findings that pure cell lines maintained in tissue culture can become malignant. Many examples of this have recently been reported in strains of fibroblasts from mice or rats, but perhaps the most interesting report is that of Earle's group (Sanford *et al.*, 1954). They established a line of fibroblasts from a single cell and from this line developed eight clones which were studied for their capacity to produce sarcomata when inoculated at various stages of culture into mice of the homologous strain. After several passages six of the eight clones had given typical tumours. The most consistently active of these, Line VII, and a strain which had produced no tumours, Line III, were then selected for detailed study. Line VII produced sarcoma in 97% of the mice inoculated, Line III in only 2 out of 146 inoculated. If x-irradiated mice were used, however, over 40% of tumours were obtained from Line III, and these tumours could subsequently be passed in normal mice. The two lines, VII and III, in addition to this difference in transplantability also showed clear differences in cellular morphology. The phenomena are what would be expected on the hypothesis of somatic mutation, but would require a fantastic series of secondary *ad hoc* assumptions to be interpreted as manifestations of virus infection.

Although the evidence can naturally never be complete there is very much to suggest that all, or almost all, of the cell lines derived by virologists from normal human tissues become malignant as they develop facility to grow indefinitely in tissue culture. It is characteristic that at this stage they become susceptible to practically the same range of viruses as HeLa cells and lack any special susceptibility for viruses which naturally infect their cells or origin.

Summary

The general picture emerging from this discussion of the "cancer viruses" is that these represent simply one rather potent means by which what is functionally equivalent to a somatic mutation can be produced. In the well-studied rabbit papilloma there is good evidence that when malignancy is fully established virus cannot grow in the tumour cells. The analogy with azo-dyes and the development of hepatoma is extraordinarily close.

Where a virus produces a proliferative lesion a unique opportunity exists for the development of a situation which probably arises commonly enough in other types of virus infection but cannot be demonstrated. This is the persistence of a "vegetative state" in which production of virus antigen goes on, presumably with replication of the associated nucleic acid more or less in tempo with cellular multiplication, but no production of infective virus. Since in these proliferative lesions infected cells are the progeny of infected cells there is no necessity for the production of infective particles to transfer infection from one cell to another. In all probability any low-grade virus which can

find a cell, either normal or one or more stages on the way to loss of control, in which it can produce proliferative effects will have some or all of the qualities of a cancer virus. Probably all viruses have some capacity to provoke proliferation—the uniform structure of the chorioallantoic lesions speaks for this—but the converse claim that all proliferative processes are due to viruses is quite untenable.

IV. PRACTICAL APPLICATIONS

The only social justification of generalization in science is to provide firmer basis for human action. If the picture of somatic mutation as the basis of malignant disease is correct what are the implications at the practical level? More specifically, does it provide leads regarding research which might eventually allow the development of new techniques for the prevention, diagnosis, or cure of cancer?

Prevention

One of the most heartening developments in medicine has been the recognition that a very large proportion of lung cancer has a definable aetiology and, in principle at least, is preventable. This underlines the potential importance of continued search for aetiological agents of environmental origin. If a somatic mutation cannot be reversed it is of the utmost importance that the conditions under which it is either provoked or given the conditions to allow it to prosper unduly should be understood and counteracted.

Despite continuing assertions that there is as yet no absolute proof of the significance of cigarette smoking, the available evidence suggests that the position in regard to lung cancer is, in fact, relatively clear.

There are two types—one described as adenocarcinoma, which occurs with equal frequency in males and females and for which there is no evidence of environmental influence; the second, comprising squamous-celled and anaplastic carcinomas, is that which is responsible for the recent great increase in lung cancer. This increase is real and is directly related to two environmental factors, cigarette smoking and the degree of urbanization of the environment. A good case can be made for Stocks and Campbell's thesis (1955) that the effective cause of lung cancer is the amount of common carcinogen, 3:4-benzpyrene, in the air inhaled, including of course air inhaled while smoking. In non-smokers there are nine cases of urban lung cancer to one in the country. The ratio diminishes as smoking increases until for heavy cigarette smokers the same high incidence is found in the country as in the town. The preventive approach is therefore quite clear-cut and probably socially impossible to implement. Cigarette smoking needs to be rendered unpopular by every acceptable means, and the greatest attention must be paid to reducing the products of incomplete combustion of fuel that are liberated into the air. It is a good rule that smoke, whether from a factory chimney, a diesel exhaust, or a cigarette, is dangerous and undesirable.

There are a number of other indications of environmental factors being important in the production of cancer, and there may well be some more unpleasant surprises in store for us. There is, for instance, much interest in but no solution of the fact that Indonesians have far less gastric cancer than Europeans or Chinese and much more liver cancer. The suggestion that dietary factors are involved is insistent, but no one has provided a likely answer in any detail.

More immediately important is the part played by ionizing radiation, whether from x rays, from atomic explosions, or from the entry of radioactive material into the body. When dealing with fair-skinned people, one could add the ultra-violet component of sunlight as a penetrating radiation so far as the superficial cells of the body are concerned. The high incidence of relatively mild and tractable skin cancer in regions like Queensland, where there is plenty of sunshine, has been well known for years.

One of the important aspects of the somatic mutation theory of cancer is the way it brings into the same focus the

two important harmful effects of ionizing radiation, carcinogenesis, and genetic damage. Whether acting on the nuclei of germ cells or on the nuclei of the somatic cells of the body, the effect of radiation is the same—random damage to a relatively large assemblage of complex genetic mechanism. It is as if a bullet were fired at random into an automatic telephone exchange. The results would have only a very small relationship to the size or speed of the bullet, but, depending on wholly accidental factors as to where the hit occurred, they might range from no functional effect at all through various types of minor or major malfunction to complete breakdown. As we have discussed, the only type of somatic mutation in man that can be observed is one leading in the direction of cancer. Many other types undoubtedly occur, but there can be no overt evidence of their presence. Germ-cell damage also has only a limited number of ways in which it can be recognized; like damage to somatic cells, it is in general only recognizable when it is of minor degree allowing the production of offspring in whom a specific defect can be recognized. Just as genetic damage may only become manifest in distant generations so somatic damage may have no immediate effect but may lead to the accumulation of a stock of mutant cells all one or more steps nearer to malignant change.

There is no doubt that every type of ionizing radiation has a measurable mutagenic power and that the effect is cumulative—that is, it is just as dangerous to receive 365 units of radiation in 1-unit doses daily over a year as to receive the full dose in a minute. It is impossible, therefore, to say that any dose of radiation is harmless. On the other hand, very high doses are needed to produce malignant change in a large proportion of animals experimentally exposed. Radiologists in the early days were occupationally liable to skin cancer. Now with better protection but much more powerful machines they are still subject to an undue mortality from leukaemia (March, 1950). Large therapeutic doses of x rays, notably for ankylosing spondylitis (M.R.C., 1956), have been shown to be responsible for the development of leukaemia in a significant proportion of cases.

Increasing Exposure to Ionizing Radiation

The only fully established chronic effect of the atom-bomb explosions over Japan was the development of leukaemia in a proportion of the survivors some years later. At the present time leukaemia is the only form of malignant disease other than cancer of the lung that is showing a steady increase. Much thought is being given to the possibility that some, or all, of this increase can be ascribed to increasing exposure to ionizing radiation. There have been two disquieting recent reports. First, that children of mothers who were exposed to diagnostic x rays of the pelvic region during the relevant pregnancy show a much higher incidence of leukaemia and other forms of malignant disease than a control series (Stewart *et al.*, 1956); and, second, that in comparing the history of patients with myelogenous leukaemia with those suffering from chronic lymphatic leukaemia the former group showed a significantly greater amount of exposure to diagnostic x rays (Faber, 1956). These results make it urgent to extend such studies so as to obtain as soon as possible a sound assessment of the danger associated with diagnostic and therapeutic exposures to x rays. It may turn out to be trivial, but equally it may come to be regarded as of sufficient importance to demand revolutionary changes in radiological practice.

Other indications of the carcinogenic activity of ionizing radiation in man can be found in the recently described cases of carcinoma of the thyroid in children treated locally with x rays on the assumption that an enlarged thymus was responsible for symptoms (Clark, 1955). Equally relevant is the classical account (M.R.C., 1956) of the occurrence of bone sarcomata in technicians using radium paint in the manufacture of luminous watch-dials, etc. Extremely minute amounts of radium were involved. Since one of the important products of atomic fission, ⁹⁰Sr, is, like radium,

selectively concentrated in the bones and has a half-life of 28 years, an increasing incidence of bone tumours may be one of the first indications of a dangerous increase in fission by-products.

A full-scale atomic war would have social consequences that would end scientific medicine for generations, and it would be useless to attempt any discussion of its medical sequelae. It is legitimate, however, to consider the implications of the inevitable great increase in the industrial use of nuclear power and the wide distribution of radioactive isotopes which is bound to accompany it. All recent reports stress the problems associated with the large amounts of radioactive waste products that have to be disposed of in the plants for chemical treatment of metal "fuel" that has been used in reactors. So far methods of dealing with such problems seem to have been adequate, and it may be possible to continue to enforce the necessary discipline and control in the future. There is a real risk, however, that as more and more reactors are brought into production all over the world familiarity will result in relaxation of precautions and minor and major accidents increase. Already in Australia we have heard of industrial capsules of cobalt-60 being left for uninstructed adults or children to handle, in one case with the subsequent development of severe lesions.

There is unanimity of authoritative opinion that the global concentration of fission products from test explosions of atomic weapons, plus the limited release of radioactive material from industrial reactors, is at the present time and in the foreseeable future far below the danger level for genetic damage. There is much less evidence about the possible effect of the ⁹⁰Sr, which is selectively concentrated in bone, or ¹³¹I, which, although an isotope of short half-life, may be concentrated sufficiently in the thyroid to produce serious local effects. It would seem highly desirable that careful watch should be kept on the incidence of tumours of bone and of the thyroid during the next decade. These, plus leukaemia, would be the most likely conditions to indicate that the liberation of radioactive material was becoming positively dangerous to health.

From the more general point of view, the last approach to the (partial) prevention of cancer seems likely to be a concentration of research on the mechanism of chemical carcinogenic action. The production of a somatic mutation is in itself unimportant unless conditions are such as to allow an extensive replacement of normal cells by descendants of the mutant type. It may emerge that there are ways by which these conditions can be controlled even if mutation is inevitable. There is, for instance, much to suggest that any form of chronic irritation and inflammation which gives rise to an increased turnover of epithelial cells in one of the vulnerable regions will increase the likelihood of the appearance of malignant change. Appropriate treatment of such conditions may well have an important place in the prevention of cancer.

Diagnosis

The problem of early diagnosis is an extremely difficult one, and if the somatic mutation hypothesis is correct it may, in principle, be even insoluble. Modern studies on the survival time of patients treated in various ways suggest that for many types of cancer the end-result depends on the type of malignant cell and is virtually uninfluenced by the particular form of treatment adopted (Jones, 1956). The only justification for special measures of early diagnosis is a reasonable certainty that the prognosis will be improved by such diagnosis. In view of the universal practice of excising or destroying all small lesions known or suspected to be early cancer, it may be quite impossible ever to make such an assessment. The invariable finding that very early lesions give much better survival rates than more advanced ones is by no means an adequate basis for demonstrating the importance and effectiveness of early diagnosis. If every malignant growth represents the result of a final mutational change occurring in one of numerous cells which have reached by successive mutation the penultimate stage, then

effective treatment may well demand the excision of all these immediately vulnerable cells as well. Where the process of carcinogenesis has been confined to a limited region—clay-pipe cancer of the lip might be taken as a typical example—this may be very readily accomplished. In other situations it may be quite impossible simply because of our inability to recognize cells in the vulnerable state.

One of the academic and perhaps practical problems of the future is to find means of recognizing the extent to which intermediate changes on the road to malignancy have occurred. From the nature of the problem the only hope of recognizing such changes is the histochemical one. Mutations can give rise to general effects only when the mutant type constitutes a significant proportion of the order of 10% or more of the cells of its type in the body. A means must be available by which a much smaller proportion of aberrant cells can be recognized, and histological methods of some sort are the only ones that are at present conceivable.

It is the great virtue of Green's immunological approach that it more than any other theory of cancer provides indications for the direct experimental study of its implications. If the process is to a large extent a loss of serological markers, these changes can in principle be recognized by the use of Coons's (1954) methods with fluorescent antibody as used, for instance, by Weiler (1956) in the study of rat hepatoma. In the field of human pathology, very much might be expected from the production of a series of fluorescent antisera rendered specific by appropriate absorption, against as many organ-specific human antigens as it is practicable to prepare.

Conventional methods of histological examination for the detection of pre-cancerous change will always have their value, but if direct serological indications can be obtained it is most important that they should be elaborated immediately. It is a possibility that such studies would allow concomitant changes to be recognized which would eventually allow the use of simpler histological methods for their detection. The application of fluorescent antibody studies to exfoliated cells might add a further diagnostic criterion to this method of clinical study.

Curative Treatment

If somatic mutation is the key to the understanding of cancer there are grave restrictions to the possibilities of prevention and cure. Nature has only one way of eliminating harmful mutants—by genetic death. Mutation being basically a random process, there is no conceivable way by which a cell can be induced to undergo a specific back-mutation to eliminate the change. Even if in a sense carcinogens act by enforcing a specific mutation by loss, there is still no conceivable way by which the loss of genetic material can be replaced in the cells concerned. Therapy along somatic-genetic lines is therefore unthinkable.

Any therapeutic approach must be indirect and based on some exploitation of a physiological difference between the cancer cell and normal body cells. The chemotherapeutic approach to date has been almost wholly along such lines and suffers from one overwhelming intrinsic disadvantage, which may be put in oversimplified form—namely, that all anti-cancer drugs are also carcinogens. As has been discussed in regard to Law's (1952) work, the situation is analogous to that found with antibiotics and staphylococci. Every effective antibiotic is capable of assisting the emergence of a bacterial pathogen resistant to its action. Once a malignant process is well established, the cell population has become genetically heterogeneous, and though 99% of the cells may be susceptible to some antimetabolite and immediate benefit result, experience to date has confirmed the theoretical prediction that elimination of all cancer cells will be impossible and that sooner or later a new generation of cells resistant to the formerly effective agent will become clinically evident.

A slightly more hopeful approach, which, however, is so dependent on the body's own resources that it has never

been seriously propounded, is the immunological one. It is generally regarded as axiomatic that, since a cancer cell is of the body's own pattern, no effective immunological action against it is possible. In view of recent work, it is, however, conceivable that in many instances there is sufficient antigenic difference to be effective. In terms of the immunological ideas discussed in Part I, cell components, normally non-antigenic, may become so either by modification of antigenic pattern through the action of chemical agents capable of being bound to the component, including perhaps viruses or their products, or by being brought into a new relationship to the scavenging cells of the body. Somatic mutation with malignant or pre-malignant changes might allow either of these conditions to arise. If in terms of Green's theory the loss of self-markers is an important step in the progressive abrogation of control, it may become important to know whether the loss of an antigenic pattern with this effect is or is not associated with the emergence of a new and therefore foreign antigenic pattern. Green's view would be that a carcinogen plus host protein produced a new antigen but that malignancy is associated with the shedding of the new antigen by somatic mutation. Loss of any antigenic pattern may, however, be associated with the emergence of another.

It is by no means inconceivable that small accumulations of tumour cells may develop and because of their possession of new antigenic potentialities provoke an effective immunological reaction, with regression of the tumour and no clinical hint of its existence. It has also been suggested that the result of surgery for cancer may to a large extent be determined by the degree of resistance, presumably immunological in nature, against the tumour cells. Black *et al.* (1954) found a sharp correlation between the degree of lymphocytic infiltration in the tumour removed at operation and the likelihood of "cure" following surgery.

What is to be sought is some means whereby the protective mechanism of the body has its reactivity against minor deviations from self-patterns made more sensitive—the converse of the effect of cortisone in damping down immunological reactivity. One would guess that the desired capacity is determinable only by genetic means, but this is not necessarily so, and from many points of view research along these lines might be particularly valuable for its practical potentialities.

The use of specific antigens for immunization against cancer can be ruled out from the most elementary consideration of the position.

The orthodox treatment of cancer has always been based on a more or less clearly visualized somatic mutation theory. The objective has been first to excise from the body all cells which have taken on the new genetic behaviour, and, if that is impossible, to use any agent known or presumed to have a differentially destructive effect on the malignant cells. When eradication of the malignant cells is impossible there still remain medical and surgical measures which by one or another form of symptomatic relief will do much to make the final stages of disease more tolerable.

Under the circumstances theoretical considerations can have no special significance at the therapeutic level. The most satisfactory application of the very simple principles outlined above will have to be worked out on an empirical basis for each particular type of tumour and every possible opportunity taken to assess the results of treatment objectively. The only satisfactory way is to follow the after-history of treated patients till their death.

To one not directly associated with the surgery of malignant disease it is extraordinarily difficult to gain a clear picture of how much effect modern surgical and irradiation therapy has had on the death rate from cancer. The overall mortality statistics show little or no effect, and some recent analyses (Jones, 1956) of adequately studied series of some of the commoner types of tumour have found it very difficult to show that therapeutic action has greatly modified survival time. On the other hand, there is no doubt that published results of treatment for early cancer of lip, skin,

breast, and cervix uteri show quite gratifying five-year survival percentages.

Perhaps the most pertinent query that is raised by this theoretical discussion is in regard to the use of various forms of ionizing radiation in treatment. Is it or is it not established that radiation influences the survival rate beneficially? There is no doubt that appropriate dosage will cause differential destruction of large numbers of malignant cells. On the other hand, there is also a markedly destructive effect on cells of the lymphocytic series that would mediate any immunological resistance, and there is the carcinogenic effect of irradiation on normal cells. Obviously the practical usefulness of radiation therapy can only be established empirically.

Conclusion

There is little ground for optimism about cancer. Everything suggests that, somatic cells being what they are, the impact of the environment must inexorably lead to an accumulation of mutant cells, some of which will have malignant descendants if life persists long enough. Both the genetic character of the cells exposed and the intensity and type of the mutagenic stimuli from the environment will play a part. At the present time two types of environmental stimuli—the carcinogenic hydrocarbons from incomplete combustion processes and ionizing radiation—are steadily increasing in importance. It may eventually be possible to recognize other specific agents as being responsible for certain types of cancer which have not shown any special change of incidence in recent years. From the very nature of the processes concerned it is difficult to envisage effective means of utilizing such knowledge for the prevention of cancer. We are not likely to ban cigarette smoking and the use of diesel engines on the roads, or to stay the development of nuclear energy, just because these aspects of our mode of living indubitably increase the incidence of cancer.

We must work toward prevention and be prepared not only for failure but for a sharp increase in the incidence of cancer with the further elaboration of modern technology. If so, the medical problem of the future will be very largely to clarify the immense complexities that arise when we try to adopt the orthodox maxim, "Recognize the cancerous lesion as early as possible and excise it."

If what can legitimately be called pre-cancerous lesions are an inevitable development with increasing age it will need the greatest skill and judgment to devise and implement a policy which will provide the "greatest good to the greatest number." On the one hand, there are sound psychological, social, and economic reasons against the use of cancer-detection clinics to carry out relevant periodical examinations of all persons over the age of 40. There is, too, the underlying uncertainty regarding what is the real prognostic significance of borderline lesions—for example, intra-epithelial carcinoma in biopsies of the cervix uteri—and even greater doubts about the ability of any treatment to deal effectively with cancers whose histological character is undubitably malignant. All these points have to be weighed against the desire of all concerned to find and treat malignant growth at the stage at which it can be eradicated.

It would probably be wise to conclude that the diagnosis and treatment of cancer is one of those social problems that must be allowed to develop their own current solution under the various pressures of advancing knowledge, of changing public opinion, and of the

enthusiasm and influence of advocates of this or that approach. A final solution will probably never be possible.

At the meeting of the council of the Royal College of Nurses last month final approval was given to a new training scheme which would lead to State registration and the health visitor's certificate. It is being organized by the College with the help of King's College Hospital. A four-year course is envisaged (excluding six months' training for part I midwifery). An introductory term at the Royal College of Nursing would be followed by three years' training at King's College Hospital. Then would come seven months of more specialized training at the College as a health visitor, leading to the health visitor's examination. To ensure continuity and integration of study, one health-visitor tutor at the College would be responsible for the students throughout; during the hospital period she would remain in contact with them in co-operation with the hospital sister-tutors. She would undertake certain lectures at the preliminary training school of the hospital, and also join in the case-study discussions. The scheme is now to be submitted to the Royal Society of Health and the Ministry of Health, with a view to beginning the course in September, 1958.

LONG-TERM RESULTS IN EARLY CASES OF RHEUMATOID ARTHRITIS TREATED WITH EITHER CORTISONE OR ASPIRIN

A THIRD REPORT BY THE JOINT COMMITTEE OF THE MEDICAL RESEARCH COUNCIL AND NUFFIELD FOUNDATION ON CLINICAL TRIALS OF CORTISONE, A.C.T.H., AND OTHER THERAPEUTIC MEASURES IN CHRONIC RHEUMATIC DISEASES*

A comparative study of the value of cortisone and aspirin therapy in early cases of rheumatoid arthritis was started in 1951 by the Joint Committee of the Medical Research Council and Nuffield Foundation on Clinical Trials of Cortisone, A.C.T.H., and Other Therapeutic Measures in Chronic Rheumatic Diseases. The findings during the first and second years of therapy have already been published (Joint Committee, 1954, 1955). Although the therapeutic trial in its original form was not continued after the second year, most of the 61 patients originally taken into the trial have been followed by the physicians at the five participating centres, and a review of the condition of these patients at between three and four years from the start of therapy has provided some interesting information. The patients originally admitted to the trial form a well-defined and homogeneous group of early cases, since only patients with a disease duration of not less than three and not more than nine months were included. In addition the patients had to have a polyarthritis of rheumatoid type affecting at least four joints, with bilateral involvement of hands, feet, ankles, or wrists, and they had to be between 17 and 59 years of age at the time of entry into the trial. The sheep-cell agglutination test was carried out during the first year in 53 of the 61 patients studied and a positive result was recorded at least once in three-quarters of them.

Completeness of Follow-up

The number of patients available for assessment during the three to four years of study is shown in Table I. As previously reported, 3 of the 31 patients allocated to aspirin were lost during the first year of therapy. One woman aged 60 who did well emigrated to New Zealand. A woman aged 53 had a psychological breakdown after three months of therapy and declined to return. And a man aged 48 whose condition was deteriorating felt he was deriving no benefit from the tablets after six months. During the second year there were no losses, but during the third year five patients were lost sight of. In two women aged 45 the disease had been in complete remission throughout most of the second year, and they were untraceable at the

*The members of the Joint Committee are: Lord Cohen of Birkenhead (chairman), Dr. E. G. L. Bywaters, Dr. W. S. C. Copeman, Sir Charles Dodds, Dr. J. J. R. Duthie, Professor A. Bradford Hill, Mr. H. Osmond-Clarke, Professor F. T. G. Prunty, Dr. J. Reid, Dr. H. F. West; Professor J. H. Kellgren and Mr. W. A. Sanderson (joint secretaries).

The Subcommittee and participating centres were: Professor J. H. Kellgren (chairman), Rheumatism Research Centre, Manchester; Dr. E. G. L. Bywaters, Postgraduate Medical School of London and Canadian Red Cross Memorial Hospital, Taplow; Dr. W. S. C. Copeman, West London Hospital; Dr. J. J. R. Duthie, Northern General Hospital, Edinburgh; Dr. H. F. West, Sheffield Centre for the Investigation and Treatment of Rheumatic Diseases; Professor A. Bradford Hill; and Professor F. T. G. Prunty.

The results of the trial were analysed by Dr. J. T. Boyd, of the Statistical Research Unit of the Medical Research Council, London School of Hygiene and Tropical Medicine, and the Subcommittee is greatly indebted to him for his work.

three- to four-year follow-up; one had been treated with cortisone, the other with aspirin. One man aged 58 who was receiving cortisone (75 mg. daily) developed haematemesis and melaena, for which gastrectomy was performed at another hospital. After this, cortisone was stopped and

TABLE I.—Number of Patients Available for Assessment and Drugs Actually Taken at Different Stages of the Trial

Drug Taken	Treatment Groups											
	Cortisone				Aspirin				Total			
	Start	1 Yr.	2 Yr.	3-4 Yr.	Start	1 Yr.	2 Yr.	3-4 Yr.	Start	1 Yr.	2 Yr.	3-4 Yr.

None	—	—	3	6	—	—	3	3	—	—	7	9
Total	30	30	30	27	31	28	28	26	61	58	58	53
Not known	—	—	—	3	—	3	3	5	—	3	3	8

the patient was not seen again. A woman aged 60 was found to have a peptic ulcer during the third year of therapy, when on a cortisone dosage of 62.5 mg. daily; cortisone was gradually withdrawn under corticotrophin (A.C.T.H.) cover, but she had a severe flare-up of her arthritis, became seriously disabled, and was transferred to a long-stay hospital. Finally, a woman aged 58 who was receiving aspirin fractured her femur in a car accident, and was admitted to another hospital, where she was also receiving treatment for rheumatoid arthritis and anaemia at the time of the follow-up.

Thus of the eight patients not available for follow-up, two on aspirin and two on cortisone were lost because they did badly or developed serious complications. In one on cortisone and one on aspirin the disease had gone into complete remission during the second year. And two from the aspirin group were lost through unconnected events—namely, emigration and a motor-car accident.

Therapy

At the start of treatment all 61 patients were admitted to hospital for one month, but subsequently they were mainly treated as out-patients, though a small number were readmitted from time to time if the physician-in-charge considered this advisable. Other measures, such as splintage and physiotherapy, were prescribed throughout as indicated.

Details of the dosage of cortisone and aspirin employed in the trial were described in the previous reports. During the first year of therapy both substances were given in 12-week courses, but during the second year treatment was continuous at a dosage determined by the patient's physician, who was asked to employ the minimum dose that would produce maximum functional efficiency and relief of symptoms without producing serious side-effects.

During the third and fourth years treatment was left to the discretion of the physician, though the hope was expressed that, where possible, the patient should be encouraged to continue on the treatment originally allocated at the start of the trial.

The changes in treatment that took place during the period of observation are shown in Table I. At the end of the second year and at the three- to four-year follow-up there were three patients in the aspirin group and five in the cortisone group who were receiving no tablets because their disease was in full remission. One patient in the cortisone group was receiving no tablets of any kind in spite of continuing disease activity. By the end of the second year one patient in the cortisone group and four in the aspirin group were receiving other medicaments, such as tab. codein. co. or phenylbutazone, but by the last follow-up there were nine patients from the original cortisone group who were receiving other treatments, and seven of these were receiving aspirin, one was having phenylbutazone and one tab. codein. co., whereas from the original aspirin group 19 were still receiving aspirin, three phenylbutazone, and one gold.

Thus, of the 53 patients still available for follow-up at three to four years, 27 were originally started on cortisone and 26 on aspirin, but at the last follow-up only 12 were still taking cortisone, whereas 26 were taking aspirin, seven patients having been transferred from cortisone to aspirin, while none had been transferred from aspirin to cortisone. The mean daily dosage during the first and second years was 80 and 75 mg. for cortisone and 4.5 and 4.5 g. for aspirin.

At follow-up the mean daily dosage for those patients receiving the same tablets as at entry into the trial was 66 mg. for cortisone and 3.5 g. for aspirin.

Apart from two patients lost to follow-up through peptic ulceration, only four had their cortisone stopped because of undesirable side-effects. These were mainly not dangerous, consisting of dizziness, hypertension, headaches, dyspepsia, moon-face, etc.* The remaining six who had changed from cortisone to other tablets had done so because they were either deriving little benefit from cortisone or because they had discovered that other tablets were more effective, or for various reasons which were not clear. The small number of patients still on cortisone at the three- to four-year follow-up precludes a comparison between cortisone and aspirin therapy at this stage, but the status of patients originally allocated to the two treatment groups has been compared at three to four years after the start of therapy and the progress of all the patients admitted to the trial has been reviewed.

Assessments

Of the detailed assessments used in the first two years of the trial, some, including tenderness and range of movement in certain specified joints, were not universally recorded thereafter. Comparisons at three to four years have therefore been based upon a clinical statement of progress in general terms, such as functional capacity, disease activity, and remission rate, and also on radiological changes in the hands and feet, and laboratory findings such as sedimentation rate and haemoglobin level.

Results

The general functional capacity of the patients originally allocated to cortisone and aspirin therapy is shown in Table II. The two groups were very similar at the start.

TABLE II.—Number of Patients With Given Functional Capacity at Different Stages of the Trial

Grade	Treatment Groups											
	Cortisone				Aspirin				Total			
	Start	1 Yr.	2 Yr.	3-4 Yr.	Start	1 Yr.	2 Yr.	3-4 Yr.	Start	1 Yr.	2 Yr.	3-4 Yr.

Total	30	30	30	27	29*	28	28	26	59*	58	58	53

* No record was made at the start of treatment for two patients on aspirin; subsequently these two patients appear in Grades 1 and 2.

Both improved considerably by the end of the first year and the position was virtually unchanged during subsequent follow-up. If we consider the eight patients lost sight of, it seems probable that at least two of them would have been in grade 1 or 2—that is, with virtually normal function—and at least two would have been in grade 4 or 5—that is,

*One man aged 43 whose rheumatoid arthritis went into complete remission during the second year of cortisone therapy developed nephritis (Ellis type II) shortly after stopping cortisone. Lupus erythematosus cells were looked for on several occasions with negative results, and after being invalided by his nephritis for most of the third year he eventually recovered.

seriously disabled—while the remaining four might have been in any grade. Thus the results on the whole may not be quite as good as the three- to four-year follow-up suggests. Whether the patients were treated with cortisone or aspirin initially appears to have been immaterial.

The number of patients in whom the disease was recorded as being in complete remission is shown in Table III. It will be seen that the numbers in remission increase

TABLE III.—Numbers of Patients (a) Reported by Physicians as Being in Remission and (b) With Given Clinical Assessment of Activity, at Different Stages of the Trial

Characteristic and Grade	Treatment Groups											
	Cortisone				Aspirin				Total			
	1 Yr.	2 Yr.	3-4 Yr.	1 Yr.	2 Yr.	3-4 Yr.	1 Yr.	2 Yr.	3-4 Yr.	1 Yr.	2 Yr.	3-4 Yr.

Total	30	30	27	28	26	26	58	58	53	30	30	27

steadily each year, and if we were to add the two patients lost to follow-up who had been recorded as in remission during the second year the final remission rate would be 14 of the original 61, or 23%. At three to four years the remissions are distributed equally between the cortisone and aspirin groups, and there is clearly nothing to choose between the two treatments in this respect. The total number of patients showing a period of complete remission at some stage was actually 18, but four of them were known to have relapsed by the last follow-up.

A clinical assessment of disease activity based largely upon examination of the joints was also recorded by the physician in charge of the patient; the results are shown in the lower half of Table III. This shows a slight inconsistency in that only 11 patients were stated to have inactive disease at follow-up, but the general picture is the same and there is little to choose between the cortisone and aspirin groups.

The mean haemoglobin levels and sedimentation rates in the two treatment groups at the various assessment times are shown in Table IV. The advantage shown by the cortisone group at the end of the first year's treatment was subsequently lost, and at follow-up the mean haemoglobin in the cortisone group was only 0.5 g.% higher than that of the aspirin group, while the mean sedimentation rate was 8 mm. higher in the cortisone group. The distribution of sedimentation rates at follow-up in the two groups is shown in Table V.

give a rate of 40% for inactive disease in 84 patients at a mean follow-up period of two and a half years. In this series of 53 patients the proportion of patients in remission at three and a half years was 23%. Detailed comparisons are, however, of doubtful value, since the dividing line between inactive and slightly active disease is difficult to define and the difference between "complete remission" as used in this series and "partial remission" is far from clear and almost certainly not uniformly applied in different centres. In general terms, however, it may be said that in a quarter of the patients in this series the disease went into remission, in a similar proportion of patients the disease remained very active, while in the remaining half the disease remained slightly active. Only a quarter of the patients became seriously disabled. This approximates to the expected results that could be derived from previous follow-up studies (Short and Bauer, 1948; Ragan, 1949; Duthie *et al.*, 1955).

Whether the patients were originally given aspirin or cortisone therapy appears to have been immaterial to the outcome. With the passage of time seven patients were transferred from cortisone to aspirin therapy whereas none were transferred from aspirin to cortisone. Serious complications of therapy were infrequent in this series, but were encountered only in patients on cortisone therapy. Though there is no significant difference between the two treatment groups at follow-up, the changes in therapy do suggest that with the passage of time both patients and physicians have in some cases come to prefer aspirin to cortisone therapy.

Conclusions

Certain conclusions can, we think, justifiably be drawn from this study. Firstly, the introduction of cortisone has not materially affected the prognosis of patients developing rheumatoid arthritis for the first time. Secondly, in early cases there appears to be little difference between the therapeutic effect of aspirin and cortisone, but in the long-term management of the disease, at least during the first four years, medication with aspirin is more often likely to prove satisfactory than medication with cortisone, though there are certainly some patients who feel they derive more relief from cortisone than from aspirin.

NOTE ON THE SHEEP-CELL AGGLUTINATION TEST

BY

J. H. KELLGREN, M.B., F.R.C.P., F.R.C.S.

Professor of Rheumatology and Director of Rheumatism Research Centre, University of Manchester

Results of the differential sheep-cell agglutination test were finally obtained from all patients except the three lost to the trial in the first six months. The cases admitted at Edinburgh, Sheffield, and Manchester were tested by the method of Ball (1950), the test being regarded as positive if agglutination occurred in a titre of 1:32 or higher when read at 18 hours. The cases admitted at Hammersmith and West London were tested by the original method of Rose *et al.* (1948), in which the test is regarded as positive if the two titres recorded show a ratio of 1:16 or higher. Only single tests were done in six patients, and, of these, four were positive. The remaining 52 patients were tested on several occasions throughout the period of observation. Of the

58 patients tested the results were positive on all occasions in 26, sometimes positive and sometimes negative in 20, and negative only in 12. The distribution of test results in the patients originally allocated to cortisone and aspirin therapy is similar, as shown in Table I. The tests were not

TABLE I.—Results of Differential Agglutination Test in Patients Originally Allocated to Cortisone and Aspirin Therapy

Results of Test	Treatment Groups		
	Cortisone	Aspirin	Total
Positive { Multiple tests ..	11	11	22

done systematically at set time intervals in all patients, so that no precise statement can be made about the behaviour of the test during the period of observation in the group as a whole, but such information as is available does not suggest that the titre values tend to rise with the passage of time. Indeed, 17 patients showed a steady fall in titre values, whereas only four showed a persistent rise, while in the remaining 31 with repeated tests titres remained unchanged or fluctuated up and down.

The 12 patients in whom only negative tests were recorded are of special interest, since in this small group there were seven remissions and no relapses, so that they account for half of the total remissions at follow-up. There is also some relationship between the sheep-cell test and the development of x-ray changes in the last available films of the hands and feet as shown in Table II, in which the gradings

Total ..	12	20	26	58

* All patients tested and x-rayed have been included.

for porosis and erosion found in either hands or feet, whichever was the higher, have been added and then divided by 2. It will be seen that six of the seven patients with x-ray gradings of less than 1 had only negative tests, and no patients with only negative tests had an x-ray grading of over 2½, whereas 16 of the 27 patients with x-ray gradings of 2½ and more had persistently positive tests.

In the small series studied in this trial the prognosis of patients giving only negative results in the test was much better than in those giving only positive results, but there appeared to be no difference between those giving only positive results and those giving both positive and negative results in the test. Among the patients in whom the test was always negative there were several with severe widespread polyarthritis and high E.S.R. on entry into the trial, so that the negative tests and good prognosis cannot be entirely explained in terms of trivial disease. Whatever the explanation may be, it is clear that in therapeutic trials in rheumatoid arthritis the sheep-cell test should be performed on several occasions in all patients, and those giving only negative results in this test should be studied separately.

FOETAL POST-MATURITY AND PROLONGATION OF PREGNANCY

A CRITICAL STUDY OF THE INCIDENCE AND SEQUELAE OF INDUCTION OF LABOUR FOR POST-MATURITY IN BRITISH HOSPITALS, WITH REMARKS THEREON

BY

F. J. BROWNE, M.D., D.Sc., F.R.C.S.Ed.
F.R.C.O.G.

Emeritus Professor of Obstetrics and Gynaecology, University of London; Consulting Obstetric Surgeon, University College Hospital, London

In 1922 W. J. Ballantyne and I published a paper entitled "The Problems of Foetal Post-maturity and Prolongation of Pregnancy." The opinions expressed were founded largely on the experience gained by the performance up to that time by one of us (F. J. B.) of over 500 post-mortem examinations of stillbirths and neonatal deaths. We emphasized the absence of any reliable criteria, clinical or pathological, for the diagnosis of post-maturity in the foetus or newborn child, but among our conclusions were the following: (1) the dangers to both mother and child are undoubted: they are chiefly associated with difficulty in the passage of the child; and (2) the treatment is prevention of post-maturity by induction of labour at or soon after the carefully calculated period of full-time gestation.

At that time induction of labour was the method of treating disproportion in Britain, and it was because of the fear of disproportion and difficult labour that we advocated it.

In this paper, which represents a somewhat new approach to the problem, the incidence and sequelae of induction of labour for post-maturity, as revealed in all the hospital annual clinical reports available to me—namely, 32 reports from 20 hospitals—are reviewed.

Incidence of Induction of Labour

Table I shows most of the essential details, and it will be observed that, with one or two exceptions, all the reports are of recent date. Each hospital is designated by a capital letter, and where a number is attached to a letter (for example, A1), it indicates reports of succeeding years from the same hospital.

Only inductions done after the 40th week are included and those in which there are no additional indications for induction, such as toxæmia, disproportion, and so on. Caesarean section rates for all the hospital deliveries are included because a high rate might sometimes compensate for a low induction rate.

It will be evident that there are wide differences in the incidence of induction for post-maturity. In hospital K during the year from July 1, 1949, to June 30, 1950, it was not done once in 4,949 deliveries, whereas in hospitals L and O it was done in 3%, and in hospitals G and A4 in 2.7% and 2.1% respectively. In hospital K, in which there were no inductions for post-maturity, the stillbirth rate was the seventh lowest in the series, and in hospital R, in which induction was done very seldom (0.11%) the stillbirth rate was the third lowest. In neither of these hospitals was the stillbirth rate done for post-maturity. Examination of the stillbirth records of hospital K shows that no stillbirths resulted in women who had gone beyond 40 weeks' gestation, so that no babies were lost through failure to induce. The caesarean section rate in this hospital was 1.8%, the lowest in the entire series.

It will be noted that some hospitals with a low induction rate for post-maturity had a very high perinatal mortality rate. This, however, seems to be due to other causes. Thus in hospital F, with 2,641 deliveries and no inductions for post-maturity, 75% of the patients were "non-white," and

N.N.D. = Neonatal deaths. P.N.M. = Perinatal mortality.

the average antenatal attendance was 3.6 per patient. Of the 96 stillbirths, approximately half were emergencies, and only seven had exceeded 42 weeks' gestation, estimated from the first day of the last period. Particulars of these are as follows.

Case 1.—Emergency, 48 weeks; had been in labour five days with membranes ruptured 48 hours; transverse lie; internal podalic version; breech extraction; ruptured uterus; dead birth.

Case 2.—43 weeks; concealed accidental haemorrhage; weight 8 lb. 4 oz. (3,740 g.); dead born.

Case 3.—44 weeks; spontaneous delivery; foetal heart not heard; dead born: 5 lb. 5 oz. (2,420 g.). No post-mortem examination.

Case 4.—47 weeks; toxæmia; inertia; difficult instrumental delivery; 9 lb. 5 oz. (4,220 g.).

Case 5.—Emergency, 43 weeks; diabetic; arrested shoulders; 9 lb. 3 oz. (4,170 g.).

Case 6.—Emergency, 43 weeks; hysterectomy for intrauterine sepsis; weight of baby unknown.

Case 7.—43 weeks; deep transverse arrest; "failed forceps"; internal podalic version; breech extraction; dead born; 7 lb. 3 oz. (3,260 g.).

Apart from associated conditions, such as disproportion, concealed haemorrhage, diabetes, in only one of these seven (Case 3) could it be said that the foetal death might have been due to post-maturity, but as no post-mortem examination was done the particulars are not sufficient to justify a decision either way.

Hospital N had 2,043 women admitted to its wards in 1954, and of these 1,354 were "coloured" and 689 "natives"; 466 received antisyphilitic treatment, and the average number of attendances at the antenatal clinics was only 3.2 per patient. In hospital P with only one induction for post-maturity, the perinatal mortality was 14.7%. The maternal death rate was 11.7 per 1,000 births, and the average antenatal attendance was only 2.5 per patient.

Though the proportion of white and non-white patients in this hospital is not stated, it is notable that all the seven maternal deaths occurred in "coloured" women. None of the stillbirths were over 40 weeks, and therefore none would have been saved by induction. In hospital M, with only one induction for post-maturity, though again the proportions of white and non-white patients are not stated, all three maternal deaths occurred in non-white women, including two Bantus. The antenatal attendances averaged 4.5 per patient, and none of the stillbirths were over 40 weeks.

It is well known that stillbirth rates are much higher among "non-white" women. Edith Potter (1954) states that in 1950 the perinatal mortality in the United States was 66.7 per 1,000 births amongst non-white women and 39.7 per 1,000 among whites.

It will be evident, therefore, that there is no reason to believe that the high foetal and neonatal mortality in these three hospitals was due to their low induction rates. In fact, all the evidence is against it. Further, in hospital L, where the induction rate for post-maturity was 3%, and the highest in the series, the perinatal mortality was 6.3%—the fifth highest in the 32 reports.

Parity.—Clifford (1954) writes as follows: "In general, post-maturity constitutes no obstetric problem to the multiparous woman. In these women, although the incidence of postmaturity [defined by him as over 300 days from the first day of the last period] is 5%, the foetal and neonatal mortality is no higher than in the full-time infants." Yet in the present series, out of 384 inductions for post-maturity in which parity is stated, 261 (68.0%) were done in multiparae.

Sequelae

Induction-Delivery Interval.—In 24 cases this was over two days. Individual durations in these were as follows (in days): 19, 10, 7 (2 cases), 6, 5 (3 cases), 4½, 4 (5 cases), 3½ (2 cases), 3 (3 cases), 2½ (3 cases) 2½ (2 cases). In many cases the interval was shortened by caesarean section. The time elapsing between artificial rupture of the membranes and the onset of labour is not recorded in any of the reports, most of which were compiled in compliance with the directions for a standard report issued by the Royal College of Obstetricians and Gynaecologists, London, which does not require this particular detail. There can be no doubt, however, that the interval was often long, and that this can be dangerous to the foetus is well known. Gibson (1952), in a review of 843 surgical inductions in Belfast, done during 1946–50, found that intrauterine death occurred in 25% of the cases in which the latent interval exceeded 72 hours after artificial rupture of the membranes, probably from anoxia caused by excessive retraction of the uterus.

Caesarean Section.—In induced cases the caesarean section rate was 6.2%. This may not seem unduly high, but it should be remembered that none of the women who were subjected to it had any abnormality except that they had passed their expected date of delivery, because inductions for post-maturity in which there was an additional indication for termination of pregnancy have been excluded. Some of the caesarean sections, too, were done on young primigravidae, and not infrequently resulted in the birth of a quite small baby. Examples of this are:

1. Primigravida aged 23, supposed to be at the 45th week; induction-delivery interval not stated. Caesarean section for foetal distress; baby weighed 5 lb. 10 oz. (2,550 g.).
2. Primigravida aged 21, 41 weeks. Lower-segment caesarean section; weight 6 lb. 2 oz. (2,780 g.).
3. Primigravida aged 21, 42 weeks. Prolapsed cord, L.S.C.S.; weight 5 lb. 9 oz. (2,525 g.).
4. 1-para aged 22, 42 weeks; L.S.C.S.; weight 6½ lb. (2,950 g.).

The usual indication for caesarean section was uterine inertia or disordered uterine action, causing prolongation of the first stage of labour and foetal distress. The average weight of the babies born by caesarean section was 7½ lb. (3,400 g.), but ranged from 5 lb. 9 oz. to 10 lb. 2 oz. (2,525 to 4,590 g.).

Stillbirths.—There were 10 stillbirths, including 1 craniotomy.

Other Complications.—There were two cases of constriction ring, one of prolapsed cord, three of genital tract infection, including one case of hyperpyrexia in the first stage of labour, and one maternal death.

This patient, aged 42, had had four full-time confinements without any abnormality. The first day of her last period was stated to be April 18, 1955. She was seen 13 times in the antenatal clinic, when her blood pressure and urine were always found to be normal. External version was done for a breech presentation at 32 weeks. Vaginal examination at 40 weeks revealed an "unripe" cervix. Surgical induction, by stripping the membranes, was done at 10 a.m. on February 22, 1956, for "prolonged gestation," 44 weeks and 2 days having elapsed since the first day of her last period. The cervix was rigid, and while dilating it with the finger a slight tear was caused in it. The foetal head was then at the level of the ischial spines, and the patient's condition was good and the foetal heart sounds were regular and clear. Labour began 24 hours after induction and proceeded normally until 29½ hours after induction, when, at four fingerbreadths dilatation, she complained of severe pain in the left side of the chest, became cyanosed, with stertorous breathing, and died in 10 minutes—that is, at 3.25 p.m. on February 23. Post-mortem caesarean section was done, but the baby was dead. It weighed 7 lb. 5 oz. (3,345 g.).

At post-mortem examination of the mother no naked-eye abnormality was found. The following was the report on the microscopical examination: "In some of the small veins are linear refractile pink-staining structures and occasional basophilic amorphous masses. The significance of these is uncertain, but they may be amniotic emboli. The rest of the parenchyma is normal. Similar amorphous material is present in some small blood vessels of the kidneys, suprarenals, and ovaries." The provisional diagnosis of the cause of death was "amniotic embolism." Whether or not the induction contributed in any degree to the death it is not possible to say. The case is simply recorded.

Discussion

Perusal of the recent literature reveals considerable divergence of opinion on the importance of post-maturity as a cause of foetal and neonatal death, and indeed on the question whether it is a clinical entity at all. In the United States of America, D'Esopo and Marchetti (1942) reviewed 1,000 consecutive foetal deaths occurring in the six years 1935–40 at the New York Lying-in Hospital, and the Sloane Hospital for Women, New York, and do not mention post-maturity as a cause. Necropsies were done on 89% of Potter and Adair (1943), in a "clinico-pathological study of perinatal mortality" in the Chicago Lying-in Hospital during the 10 years 1931–41, in which there were 27,321 births, the 10 years 1954 and 1955 there were in the Chicago Lying-in Hospital 6,593 births. The stillbirth rate was 1.5% and the perinatal mortality 2.7%, both of which included all the foetuses and infants weighing 400 g. and over. Dr. two-year perinatal mortality over 2,500 g. was 1%. Dr. Potter, in sending me these figures in 1956, wrote as follows: "I have never found any evidence in our own material that post-maturity contributed to any death. Many years ago we used to deliver occasional babies for supposed post-maturity, but in several years we have had no caesarean sections or inductions performed for that indication. In fact, I have a strong feeling that one of the reasons for our reduction in mortality has been related to the decrease in induction."

Clifford (1954), the well-known Boston paediatrician, on the other hand, believes that it is an important cause of both foetal and neonatal deaths, but only in primigravidae. He states that 1 in 10 post-mature primigravidae (over 300 days) loses her baby, and that of primigravidae over 26 years old 1 in 3 who became post-mature will do so either before or after birth. In multiparae he finds that post-maturity is in

general unimportant, neither the foetal nor the neonatal mortality being any higher than in mature infants.

Among British writers there is a similar though much less sharp difference of opinion. Latto (1951), in 4,653 deliveries in Oxford, found 171 post-matures—that is, 42 weeks or more since the first day of the last period. Among these there were nine stillbirths, and of these only one could, in his opinion, be attributed to post-maturity. In this case the baby was born 15 days after the expected date and weighed 4 lb. 2 oz. (1,900 g.). The placenta was small and infarcted, and weighed 318 g. Latto blamed post-maturity and a small placenta for the stillbirth.

Gladys Hill (1952) (London) reviewed 115 cases of post-maturity (16 days or more over the expected date). She states: "The findings suggest that post-maturity *per se* does not affect adversely the mother, her labour, or her infant." McKiddie (1949) (Aberdeen, Scotland) found that foetal distress in labour occurred twice as often in post-mature cases as in those that were merely mature, but failed to find any correlation between its incidence and the degree of post-maturity. Neither was there any significant difference between the neonatal death rates in post-mature infants and those at term.

Opinion in Britain and elsewhere has been much influenced by the work of Walker and his colleagues (Walker and Turnbull 1953, 1955; Turnbull and Walker, 1955) in Aberdeen; they found that the stillbirth rate increased significantly after the 41st week. Walker put this down to anoxia, as he found that the oxygen supply of the foetus even in a clinically normal pregnancy falls gradually up to the 40th week and rapidly thereafter. At 43 weeks all foetuses have a low oxygen supply, and practically no reserve to meet the stress of labour. The rise in the death rate after the 40th and 41st weeks is due primarily, he says, to a rising incidence of "unexplained deaths"—that is, death *in utero* when there is no clinical abnormality of pregnancy or labour to explain it. Walker (1954) says: "Deaths of this type are common at 40 to 41 weeks, but by 43 weeks, in primigravidae and multigravidae, they are the highest single cause of death . . . by the 42nd and subsequent weeks at least one-third of all deaths are unexplained."

Rathbun (1943), of Boston, however, did not find any higher incidence of unexplained foetal deaths in post-mature cases either before or during labour (Table II).

TABLE II.—Incidence of Unexplained Deaths in Mature and Post-mature Cases Before and During Labour (After Rathbun, 1943)

	Mature		Post-mature	
	No.	%	No.	%
Deaths before labour:				
No cause	12	16.0	5	18.5
Cause apparent	7	9.3	5	18.5
Deaths during labour:				
No cause	7	9.3	3	11.1
Cause apparent	49	65.6	14	51.9

"However," he writes, "failure to appreciate the fact that labour may be more difficult may cost the baby its life, or even the mother hers." Rathbun concludes: "It would seem that post-mature infants are no more inclined to die for no apparent reason than term infants."

Clayton (1953) stressed the frequency of unexplained intrauterine death before the onset of labour when there is no question of post-maturity, and says it is seen nearly as often before the 42nd week as after it.

Even if we assume that there is a higher incidence of unexplained deaths during labour in post-mature cases, it would seem that as they are due to anoxia there may be another explanation of their occurrence than mere post-maturity—namely, the greater size of post-mature babies and consequent longer and more difficult labours. Rathbun found that the mean weight of mature babies of primiparae was 7 lb. 3 oz. (3,260 g.), and of multiparae 7 lb. 10 oz.

(3,460 g.). In post-matures the corresponding figures were 7 lb. 12 oz. and 8 lb. 4 oz. (3,515 and 3,740 g.).

Cope (1956) found that the average birth weight of 1,000 post-mature infants was 8 lb. 2 oz. (3,685 g.), whilst a sample of 200 merely mature infants (confined between the 273rd and 287th days) had an average birth weight of 7 lb. 8 oz. (3,400 g.). These figures are statistically significant.

Karn *et al.* (1951) found that the mean weight of the first-born males at 280 days was 7 lb. 2 oz. (3,230 g.), and increased to 7 lb. 12 oz. (3,515 g.) at 310 days. The mean weight of first-born females was 7 lb. (3,175 g.) at 282 days and 7 lb. 10 oz. (3,460 g.) at 316 days.

Rathbun also found that labour was longer in post-mature women. At term the average duration was 14.9 hours in primiparae and 8.8 hours in multiparae. In post-matures the corresponding times were 18.2 and 10.5 hours.

Walker (1954) found that the incidence of difficult labour in primigravidae rises steadily from the 37th to the 44th week. At the 40th week only 3.1% of all cases have a major degree of difficulty in labour or delivery, but by the 44th week the figure rises to 13.7%. This rise is, he says, "due mainly to an increase in uterine dysfunction of severe degree, but mechanical difficulty also increases, and is made clinically more important by the less efficient contractions." Clifford, Reid, and Worcester (1951) found that the average duration of labour in primigravidae whose babies were alive at the start of labour and yet were stillborn was 34 hours. The average duration of labour in primigravidae whose infants survived was 17 hours.

In passing it may be remarked that this continued growth of the foetus when pregnancy is prolonged after 42 weeks, which must be due to the passage of nutrient materials in solution across the placenta from the maternal to the foetal circulation, is difficult to reconcile with placental insufficiency and its inability to allow the passage of oxygen. It will be recalled that no greater degenerative changes have ever been found in post-mature than in mature placentas (Reynolds, 1937–8; Masters and Clayton, 1940).

As for the occurrence of unexplained intrauterine death before the onset of labour, it is well known to occur not infrequently when there is no question of post-maturity. In 14 of the hospital reports previously cited, I have found 72 unexplained intrauterine deaths before the start of labour, all under 40 weeks' gestation. In 60 of these post-mortem examinations had been done and the cause of death was usually put down as "asphyxia." Of the 72 deaths, 1 was at 28 weeks, 1 at 29 weeks, 5 at 30 weeks, 1 at 31 weeks, 4 at 32 weeks, 6 at 33 weeks, 7 at 34 weeks, 7 at 35 weeks, 7 at 36 weeks, 6 at 37 weeks, 18 at 38 weeks, and 9 at 39 weeks. Possibly they can be explained by the observations of Robinson (1921), professor of anatomy in the University of Edinburgh, who showed that in ferrets, on which his observations were made, a certain percentage of deaths are "normal" and are to be expected. They are not due to environment, or to any abnormality in the mother during pregnancy, because two or three foetuses in a uterine horn may survive and one die. Robinson concluded that the fault lay in the ovum or sperm or both, and that the embryo or foetus died because it was inherently unfitted to survive beyond a certain intrauterine age.

Compensatory Mechanisms in Anoxia

Accepting the findings of Walker and his colleagues that there is a gradual decrease in the oxygen passing from the maternal to the foetal blood, consideration must be given to certain compensatory mechanisms that nature develops to mitigate its harmful consequences to the foetus. These are at least five: (1) The foetal red blood cells and haemoglobin increase in proportion to the fall in the oxygen supply. If the pregnancy is prolonged beyond 40 weeks, foetal haemoglobin still continues to rise (Walker and Turnbull, 1953). (2) The nature of most of the foetal haemoglobin is different from that of the mother; it has a higher affinity for oxygen and so can take up oxygen more easily from the maternal

blood (Barcroft, 1946b). (3) Anoxia increases the amount of carbon dioxide produced by the foetal tissues, and this by raising the acidity of the blood automatically favours the dissociation of oxygen from haemoglobin and its transfer to the foetal organs, the increase in dissociation being in direct proportion to the partial pressure of carbon dioxide in the blood (Fulton, 1955). (4) The foetal arterial blood pressure rises (Barcroft, 1946a). (5) The foetus seems to have greater tolerance of oxygen lack than has the adult. There is evidence that this is due to a partial anaerobic metabolism which requires less oxygen per unit of energy, and that it persists for some time after birth. Its persistence probably accounts for the fact that, whereas the adult animal cannot stand deprivation of oxygen for more than three minutes newborn animals can survive it for times varying from seven minutes (guinea-pigs) to 50 minutes (rats). Many isolated observations suggest that a similar immunity to oxygen lack exists in the newborn infant (Wilson *et al.*, 1948).

That these compensatory mechanisms are often effective even if the stay of the foetus is prolonged long after 43 weeks is shown by the observation that in all the cases of post-maturity allowed in the English courts not one baby was born dead. A well-known example is that of Gaskill v. Gaskill in 1919, in which the baby was born 331 days after the last cohabitation. Adding 14 days—the usual time elapsing between the first day of the last menstrual period and ovulation—the length of gestation, counting from the first day of the last period, was 49 weeks and 2 days. The baby was not weighed at birth, but was said to be unusually large, and labour was prolonged. It was alive and well. A more recent case was that of Wood v. Wood (1947), in which 346 days had elapsed from the date of the last cohabitation. Adding 14 days, we get 51 weeks and 3 days since the first day of the last period. Again the baby was born alive and well.

It is no answer to these examples to say that the decisions of the courts were at fault. Any woman whose character and conduct can withstand scrutiny and cross-examination in, in each case, three of the highest English courts of law must indeed be without reproach.

It is interesting to reflect that if these two women had been cared for in almost any of the hospitals listed in Table I, labour would have been induced at the 41st or 42nd week and no action for divorce would have been brought on account of the unusual prolongation of pregnancy.

Normal Duration of Pregnancy

After deducting all cases in which the date of the beginning of the last menstrual period was doubtful, or whose gestation period counting from that day was greater than 313 days or less than 251 days, Sutton (1945) found that in 2,293 women the average length of gestation was 283 days, and this was the day on which the greatest number of babies were born. Only 5%, however, were born on that day. The term "average" or "mean" implies a "scatter" on either side of the mean. An important question is, "How large can that scatter be before a birth occurring on a day within it becomes premature or post-mature?"

The standard deviation in Sutton's cases is ± 9.3 days (the 10th day), and only 64% of the births took place between the 273rd and the 293rd day, and 36% took place outside these limits. We must certainly, therefore, regard at least these two days as within the normal range. Thus a baby born on the 273rd day is not necessarily premature, nor one born on the 293rd day necessarily post-mature.

These data show that there may be quite considerable variations in different individuals in the length of time that the foetus and placenta (for the placenta is part of the foetus and should therefore mature at the same rate) take to reach maturity. This suggests the possibility, to put it no stronger, that cases of so-called post-maturity are really instances of slow maturation. This conception would explain the well known fact that there are no reliable criteria, clinical or anatomical, of post-maturity in foetus or placenta. Even by x-ray examination of the centres of ossification before or after birth, or actual measurement of the ossific centres at

post-mortem examination, it is impossible to tell the foetal age within one month (Ballantyne and Browne, 1922).

All young women do not reach maturity and puberty at the same age. Clow (1927), in an English public school for girls, found that in 2,600 girls the most usual age of puberty was 13 years (in 34% of cases). The age of onset of menstruation was, however, 16 years in 14.41%, 17 years in 0.35%, and 18 years in 0.17%. Yet all were healthy girls. She concluded that it is not justifiable to regard a case as one of primary amenorrhoea, or to attempt to interfere with the natural course of events, so long as growth in weight and height continue. The Medical Women's Federation of Great Britain (1933) found that in 1,000 women the age of onset of menstruation varied from 9 to 21 years. In approximately 13% menstruation began after 17 years.

Seeing that there are such variations in the length of time taken to reach maturity in healthy girls, why should we expect it to be otherwise in the unborn child? Just as girls may continue to grow until menstruation starts, so we would expect the foetus to continue to grow *in utero*.

Fallacies in Menstrual Data

It is a commonplace that in the inquiry into a case of possible post-maturity a careful scrutiny of the menstrual history is essential, and especially of the possibility that conception may have occurred in a very long menstrual cycle. While the average length of the cycle is 28 days considerable variations from this mean are common. Gunn, Jenkin, and Gunn (1937), in an investigation of menstrual periodicity, found that in 209 apparently healthy women whose menstrual records were reliable the length of the cycle varied by more than 13 days in 30%. In one case the successive periods were 42, 58, 87, 54, 48, 56, and 36 days apart. If conception had occurred in the 87-day cycle the duration of the pregnancy, reckoned from the first day of the last period, would have been 59 days longer than it would have been in a 28-day cycle—that is, 342 days. In other words, the patient would have seemed to be 59 days (8½ weeks) post-mature, whereas, assuming that ovulation occurred 14 days before the next period was due, she was only at term. Such abnormally long intervals can never be entirely excluded, for they may occur in a woman whose cycles have hitherto been no longer than usual. If she were examined early in pregnancy suspicion might be aroused by discrepancy between the size of the uterus and the menstrual dates, though here again there are many well-known pitfalls.

As, however, the average weight of the post-mature child is greater than that of the merely mature child, and as this greater weight must be due to the longer stay of the foetus in the uterus, it is unlikely that conception in a long menstrual cycle accounts for many cases of post-maturity.

Summary

A review of hospital reports shows that there are very large variations in the frequency of induction of labour for post-maturity without any significant differences in the perinatal mortality rates. In certain hospitals the induction rate is 30 times that in others in which induction for post-maturity is done.

In one hospital with approximately 5,000 deliveries in a year it was not done once, yet the stillbirth rate was the seventh lowest in the 32 hospital reports, and the caesarean section rate was 1.8%—the lowest in all the reports. There were no deaths from post-maturity either before or during labour.

The complications occurring in 596 surgical inductions for post-maturity are reviewed. They include long induction-delivery intervals and a high caesarean section rate (6.2%), the sections being usually done for prolonged labour due to disordered or abnormal uterine action.

It is suggested that many cases of so-called post-maturity are really examples of slow maturation of the foetus and placenta, and that as good or better perinatal mortality rates can be got in these cases without induction.

Others may be due to the occurrence of conception in a very long menstrual cycle.

The higher foetal mortality in post-mature as compared with term babies can be adequately explained by the larger size of the infants in the former and the longer duration of labour.

If, because of the larger size of the baby, there is disproportion, the case should be treated by trial of labour. Induction of labour is not the modern treatment for disproportion, at least in primigravidae.

"The Health of Scotland" was the theme of a speech made last week by Mr. J. NIXON BROWNE, M.P., Joint Parliamentary Under-Secretary of State for Scotland, at the annual conference of the Scottish Branch of the British Red Cross Society. In 1949-50, the first full financial year of the National Health Service, £40m. was spent on the Service in Scotland; in 1956 the figure was £53m. Since 1949 the number of staffed hospital beds had risen from 58,700 to 63,000. Of these about 40% were reserved for mentally ill and mentally defective patients. In 1956 hospital out-patients numbered 7½ million, compared with 5 million in 1949; 4½ million pairs of spectacles had been issued since 1948, and 671,827 sets of false teeth since the charges for them were introduced in 1952. The number of family doctors in the Service had risen from 2,314 in 1949 to 2,603 in 1956, and there had been an encouraging growth of partnerships and group practices. The average number of patients per doctor, however, had fallen from 2,147 to 1,980. One feature in Scottish health statistics which had failed to improve much during the last 25 years was mortality among middle-aged males. The two main reasons for this were deaths from coronary thrombosis and from cancer, particularly lung cancer. The health record of Scotland was in some respects worse than that of England. One possible reason which had been suggested for this was that, according to the National Food Survey in 1954, "the Scots were inclined to indulge in a rather less nutritious diet than the English," eating more carbohydrates and less fruit, fresh vegetables, and meat.

SEDATION OF CHILDREN AS OUT-PATIENTS FOR DENTAL OPERATIONS UNDER GENERAL ANAESTHESIA

TRIAL OF METHYLPENTYNOL, BUTOBARBITONE, AND CHLORPROMAZINE

BY

R. GOULDING, M.D., B.Sc.

Lecturer in Pharmacology, Guy's Hospital Medical School

P. J. HELLIWELL, M.B., F.F.A.R.C.S., D.A.

AND

EILEEN M. WILKIN, B.Sc.

Amy, Lady Tate Scholar, Department of Psychology, Bedford College, London

Pre-operative sedation for dental out-patients requiring general anaesthesia is not commonly used, but is strongly advocated by Macintosh and Bannister (1952). It may not be necessary in adults, but the assumption that it is of value in the management of young children is widely held. It has been advocated as a method of reducing the emotional disturbances within a child about to undergo what otherwise may be a very frightening experience and as a way of reducing the outward expression of such emotions. It has also been suggested that the prevention of pre-operative terrors would remove the danger of post-operative emotional upsets.

The value of premedication for child in-patients has long been recognized. Basal narcosis has provided a satisfactory answer to the problem, except in the case of operations on the upper respiratory tract (Barnes, 1952). No safe and effective premedication technique has yet been devised for ambulatory children. Methylpentynol, however, has been claimed in both the medical and the lay press to be the ideal agent for this purpose. The statement by the makers of a brand of methylpentynol that their preparation has the "unique property of allaying fear and apprehension within a few minutes of its administration" suggested that its use as a premedicating drug for children should be carefully investigated.

The investigation described here was designed to study the effect of the pre-operative administration of three drugs to child out-patients attending hospital for dental extractions under general anaesthesia.

Conditions of Experiment

In Guy's Hospital two sessions each week are reserved for children between the ages of 2 and 15 years who require dental extractions under general anaesthesia. The children come from all parts of London and the neighbouring counties and from all classes of homes. A few require teeth extracted because of overcrowding of the mouth, but the majority require extractions because extensive caries has made the conservation of the teeth impracticable. A small number of teeth are removed for the immediate relief of pain.

The children are first seen in the dental department. If they need to have teeth extracted, instructions are given that they should be brought, without having had

breakfast, to the out-patient department at 8.30 a.m. on the day of the first convenient session, accompanied by a responsible adult. On arrival the children are given into the care of a nurse. After going to the lavatory, they wait together in a special room away from their parents for their turn to enter the theatre. The house-surgeon takes each child, in order of arrival, into the theatre, seats him in the chair, examines the mouth, and inserts a prop if it is required. The anaesthetist then takes charge of the child and begins induction of anaesthesia.

A senior dental surgeon is responsible for the surgical work. In selected cases, student dressers carry out the treatment under his instruction and supervision. The anaesthetist, in addition to his primary responsibility to the patient, teaches the practice of anaesthetics to student dressers and in suitable cases directs them to administer the anaesthetic under his supervision. Normally there are two surgical dressers and two anaesthetic dressers present in the theatre. With the addition of a nurse and a surgery assistant, this makes a total of nine persons in attendance on the patient.

After the operation the child regains consciousness in the dental chair. He is then handed over to a nurse, who looks after him and takes him to the recovery room. When the child's condition is satisfactory the recovery-room nurse takes him back to his parent, who has been waiting in the reception hall.

Two essential conditions had to be observed in this investigation: firstly, the obvious one that it should in no way cause any harm to the children; and, secondly, that it should not interfere with the normal conduct of the sessions.

Problem of Assessing Effect of Pre-operative Sedation

An essential requirement of any clinical trial is a criterion by which responses to applied measures may be judged (Gaddum, 1954). There is no yardstick readily available by which the effects of pre-operative sedation can be measured. This is probably because the object of this pre-medication is to modify an emotional state which in itself is unobservable. While it is recognized that mental stress can be manifest in bodily changes such as a faster heart rate, a raised blood pressure, a drying of the mouth, or an outbreak of cold sweating, the interpretation of such physical changes in terms of emotions has so far proved impossible. The claims that certain drugs dispel anxiety and apprehension have not therefore been based on objective studies.

An assessment of the degree of anxiety in a patient may be made at an interview. The reliability of the assessment will depend upon the extent to which the subject can communicate his feelings, the length of the interview, and the experience and prejudices of the interviewer. Because so many of the children were of an age at which they were unable adequately to describe their feelings, and since the necessary interviewing time could not be fitted into the normal programme of working of the children's extraction sessions to cover a large number of children, such a technique could not be used here.

Preliminary observations in the theatre revealed that, from the point of view of the anaesthetist and the surgeon, the principal advantage of pre-operative sedation was that it would reduce disturbed behaviour in the patients, thus facilitating the induction and maintenance of anaesthesia. If it is assumed that the patient's lack of co-operation arises from apprehension, then it is fair to judge the effectiveness of the pre-operative sedation by the way in which it influences the behaviour of those receiving it.

Even if the direct relationship between fear and truculence is denied, a harmless drug promoting co-operative behaviour before operations would be of considerable value.

We therefore decided to make an arbitrary scale of behaviour, with calm co-operation at the top, violent obstruction at the bottom, and one intermediate grade. By this scale the behaviour of each child was to be recorded before and after premedication. If the sedation were effective the children at the top of the behaviour scale on arrival would stay there as the time of operation approached. Those who were lower down the scale on arrival might be expected to be upgraded with the passage of time.

Preliminary Trial of Method of Assessment

A preliminary trial of the behaviour-grading procedure was made by one observer (A. C. K.) watching a series of 114 children undergoing dental extractions as described above. The behaviour grading was made at two distinct stages: firstly, immediately the child entered the theatre, and, secondly, when the presentation of the anaesthetic was begun, which is presumably a time of increased stress.

The children who appeared unmoved by the proceedings were graded calm. Those who were overactive or obviously tense, who sobbed, cried, or indulged in delaying tactics, but who yielded readily to suggestion, were put in the disturbed category. Children who refused to co-operate or were actively obstructive were classified as turbulent. The method was found to be practicable, and the results obtained are shown in Fig. 1. It can be seen that with the approach of the anaesthetic some of the calm children became disturbed and some of the disturbed became turbulent.

FIG. 1.—Behaviour shown at two stages by 114 unpremedicated children who were about to receive a general anaesthetic.

When two observers (A. C. K. and A. C.) in the theatre made independent assessments of pre-anaesthetic behaviour in terms of the scale, their ratings for each child observed were found to be in close agreement. It was concluded, therefore, that the procedure as outlined was relatively free from personal bias in a clinical assessment of behaviour.

Selection of Drugs

The neurophysiology of apprehension and anxiety is obscure. Rational pharmacology is therefore impossible and drug treatment is largely empirical. If it is assumed that fear is a function of mental activity, then a drug which depresses the central nervous system should logically promote tranquillity.

Methylpentynol.—Those concerned with the clinical investigation of methylpentynol as a hypnotic have observed that "one of the most valuable characteristics of the drug was to produce a state of quiescence accompanied by mental relaxation and a diminution of restlessness." Brookfield (1955), Trotter (1953), Nebel (1953), and Simmons (1954) have claimed good results from methylpentynol given to adults and children prior to dental extractions undertaken with general anaesthesia, and Bourne (1954) has written similarly about his experiences with methylpentynol in obstetrics. Simmons (1954) and Gusterson (1955) were

enthusiastic about the value of this drug before tonsillectomy, but Rendell (1954), Butler (1955), and Rollason (1955) reported otherwise. Because of its alleged clinical virtues and because it appeared to be a very safe drug, it was chosen for use in the present study with children. The dosage adopted—namely, 75 mg. per stone (11.8 mg. per kg.)—was arrived at from the manufacturer's advertised dosage of 250 mg. for a 5–10 years' old child.

Butobarbitone.—This barbiturate is often employed as a pre-operative sedative in dental surgery. For full basal narcosis the accepted standard dosage of a barbiturate such as butobarbitone is 40 mg. per stone (6.3 mg. per kg.). For the sedation of ambulatory patients there is no agreement about dosage. It was arbitrarily assumed, and subsequently confirmed, that 20 mg. per stone (3.1 mg. per kg.) would be a dose which could be given without danger of delaying the patient's recovery and discharge.

Chlorpromazine.—This drug, closely related chemically to the antihistamine promethazine ("phenegan"), is said to be of "unusual interest in psychiatry." In overactive and excitable patients it is said to promote resignation without clouding of consciousness—the so-called "medical leucotomy," and is being widely used in psychiatric practice. Its use as an oral premedicant does not appear to have been studied. In a single dose it has a wide therapeutic ratio and it is unlikely to give rise to those toxic complications encountered with prolonged administration. Its choice in the present investigation seemed, therefore, justified. The dosage, however, had to be arbitrarily adopted, since there was no precedent to serve as a guide. The manufacturers suggested a dosage of 2.5 mg. per stone (0.4 mg. per kg.) as being completely safe, although possibly below an effective level. This amount was given in the pilot trial, and, in view of the lack of evidence that the drug was acting, the dosage was doubled for the full-scale trial.

Design of Clinical Trial

The hospital dispenser prepared four solutions as nearly as possible alike in appearance and taste. One was a placebo and the other three contained the various drugs in such a concentration that the appropriate dose of each could be given by measuring 1 ml. per stone (0.16 ml. per kg.) body weight. Each solution was given a code letter by the dispenser and he alone knew the distribution.

At each session the children were received by one of us (R. G.). A serial number was entered on the patient's record ticket and a note made of the behaviour grading according to the scale described. The child was then weighed and given one of the preparations according to weight. The allocation of the solutions was randomized and the time of administration was recorded together with the other details.

Two observers in the theatre, one a psychologist and one a physiologist, working independently of each other and of the observer in the waiting-room, made two serial classifications of the behaviour of each child according to the scheme described above. Along with their assessments, they noted any particularly interesting events and recorded the type and duration of the anaesthetic. The anaesthetics in this series were either nitrous oxide and oxygen from a standard Walton apparatus or vinyl ether using the Oxford modification of the Goldman inhaler.

In the recovery room a nurse kept a third set of records in which she noted the time when the patient was fit to return to his escort and go home, and the reason for any undue delay in discharge.

Finally, all these records were passed to a secretary who, having obtained the key of the code from the dispenser, transferred all the data to punched cards.

Results of Pilot Study

As a practical test of the design of the trial, a pilot study was carried out. The results are charted in Fig. 2. Examination of this figure suggests that the distribution of

behaviour was identical in the first three "treatments," but that in the fourth, given chlorpromazine, disturbed behaviour was more frequent—possibly because nine of these children were under 6 years of age. The method, having been tested and found satisfactory, was then used on a larger series of patients.

FIG. 2.—Behaviour shown at three stages by 133 children who were about to receive a general anaesthetic. The children are grouped according to their premedication.

Results of Trial

Of the 410 children premedicated and observed as described, 357 were watched by both A. C. K. and E. M. W. in the theatre. Table I shows the distribution of the children among the four treatments and the interval of time between swallowing the solution and entering the theatre. The children for whom this time interval was less than 15 minutes have been excluded from the results.

Table II shows the age distribution of the remaining 338 children according to the treatments they received. In each treatment the age distribution is approximately the same.

TABLE I.—Distribution of Premedication Intervals for 357 Children Arranged in Four Treatment Groups

	Interval in Minutes Between Having Treatment and Entering Theatre						Total
	0-14	15-29	30-44	45-59	60-74	75-89	
Placebo	4	31	34	14	6	2	91
Methylpentynol	7	27	36	10	10	1	91
Butobarbitone	2	27	34	16	8	2	89

TABLE II.—Distribution of Age by Treatment Groups in Children Who Had Their Premedication more than 15 Minutes Before Entering Theatre

	Age in Years						Total
	2	3	4	5	6	7-13	
Placebo	3	7	13	10	10	44	87
Methylpentynol	5	7	11	10	9	42	84
Butobarbitone	3	8	9	9	12	46	87
Chlorpromazine	4	5	9	6	6	50	80
Total	15	27	42	35	37	182	338

The behaviour gradings for the four groups at the three stages of observation are shown in Fig. 3. No differences between the four treatments are obvious, but the charts may conceal improvements or deteriorations in the behaviour of individual children. In order to study the change of individual behaviour with time, the following method of analysis was used.

Fig. 4 shows the change in behaviour with time of children who were graded "calm" on arrival. Those who were still graded "calm" on entry to the theatre are shown in Fig. 4, a. It can be seen that most of them remained calm

FIG. 3.—Behaviour shown at three stages by 338 children who were about to receive a general anaesthetic. The children are grouped according to their premedication. The distribution of the three types of behaviour was similar in all four groups.

FIG. 4.—Subsequent behaviour of children graded calm on arrival at the waiting-room. A, B, C=times of grading as in Figs. 2 and 5. Pbo.=placebo; Mpn.=methylpentynol; Btbn.=butobarbitone; Cpzn.=chlorpromazine.

on the presentation of the anaesthetic, but about 15% of them showed disturbed behaviour. Fig. 4, b shows that the children who were calm on arrival and disturbed on entering the theatre, sometimes improved, but generally remained in the disturbed category. A marked change from "calm" on arrival to "turbulent" on entry to the theatre was shown by only two children (Fig. 4, c).

When the four treatment groups are compared in this way there is still no suggestion of a difference which might be due to the effect of any particular treatment.

The data for the children who were graded disturbed on arrival in the waiting-room are similarly treated in Fig. 5, a, b, c, whilst the progress of those assessed in the waiting-room as turbulent is followed in Fig. 6, a, b, c.

In each treatment, improvements and deteriorations can be seen to have occurred, but there was no suggestion that any of the three premedication treatments was more effective than the placebo.

It was obvious during the trial that disturbed behaviour was much more frequent in the younger children. In Fig. 7 the data for each treatment group are presented in two sets—one for the children up to and including 6 years of age, and the other for the older ones. Within one group, no significant differences were found, but between the two age groups a marked difference in the distribution of types of behaviour was revealed.

Whereas in the older children roughly two-thirds were graded calm throughout the period of observation, in the younger group only about one-third maintained that standard of behaviour.

Comparison of Findings of Two Independent Observers

Whilst it is reasonable to assume that the design of the trial precluded the possibility of an observer being biased for or against any particular drug, one observer might have made subjective errors so that his results were unreliable. The probability that two independent observers would both repeatedly make the same subjective errors in the conditions of this study is small. If agreement is found between the assessments of two independent observers watching the same event the results can therefore be taken as reasonably reliable.

Table III is an attempt to show the extent of agreement between two such observers. There is close agreement between two observers in grading calm or turbulent children, but two observers in grading the children on entry to the theatre in a higher grade than A.C.K. This tendency, however, was not maintained at the second grading.

FIG. 5.—Subsequent behaviour of children graded disturbed on arrival at the waiting-room. Explanations as in legend to Fig. 4.

FIG. 6.—Subsequent behaviour of children graded turbulent on arrival at the waiting-room. Explanations as in legend to Fig. 4.

and the differences were small in proportion to the agreements, and varied evenly on either side. Where disagreements occurred they were distributed evenly among the treatment groups.

We do not feel that the disagreements were serious enough to invalidate the method. When the observations of E.M.W. were analysed in the same way as A.C.K.'s in Fig. 3, the distribution of behaviour was the same.

Discussion

The absence of any measurable effect on behaviour in the medicated children may be due to various causes.

Firstly, dosage may be a critical factor. The distributors of methylpentynol recommended in their advisory leaflets that for pre-anaesthetic medication a child of 5 years of age should receive 250 mg. This age group proved almost modal for the children with whom we had to deal and this standard was accordingly taken as a basis. If a child of 5 years weighs, on an average, a little less than 3 stone (19 kg.) (Sutcliffe and Canham, 1950), then the dose adopted was worked out at 75 mg. per stone (11.8 mg. per kg.) of body weight. For butobarbitone no recognized figure was available. 30 to 40 mg. per stone of body weight is employed for full basal narcosis—a state to which it would be dangerous to proceed with ambulant out-patients. 20 mg. per stone (3.1 mg. per kg.) of body weight appeared to be about the largest dose which could be given under these circumstances. The fact that there was no evidence of excessive sleepiness in the children receiving this drug suggests that more might have been given. The problem with a barbiturate of this sort, however, is to settle on a dose which achieves sedation without at the same time impairing co-operation. The danger of restlessness with butobarbitone described by some authorities (Lucas, 1954) served as a further caution against the use of this drug, though fortunately we did not encounter this complication.

For chlorpromazine there was no precedent. The dose of 5 mg. per stone (0.8 mg. per kg.) of body weight was used for the trial proper, at which level no undesirable side-effects were seen.

That the doses used in this trial, particularly of methylpentynol and chlorpromazine, were inadequate is a possible criticism. But other workers (Trotter, 1953) have claimed undoubted success, at least with methylpentynol, at a dosage no greater than that which we followed.

Absorption of the drug must also be taken into account. Data relating to those children who received their medication less than 15 minutes before the induction of anaesthesia were excluded from consideration. As the drugs were all administered in fluid form on an empty stomach, reasonable absorption should have taken place by this time, allowing for the excitement due to the occasion. The manufacturers of methylpentynol have stated, moreover, that 10 to 20 minutes before operation is an adequate interval.

To be examined also are the standards of assessment by which the behaviour was judged. They may not have been sufficiently delicate or precise. Yet by reference to these standards a contrast in behaviour between the various age groups was strikingly demonstrated, while the findings of the two independent observers closely agreed. The criteria were therefore adequate in certain respects, and it is clear that by such yardsticks, whatever changes may have been brought about among the younger children, these were never sufficient to give them the poise of the more mature subjects.

It is clear that, within the conditions of this trial, methylpentynol, butobarbitone, and chlorpromazine could not be distinguished from a placebo by their effect on the behaviour of out-patient children about to undergo general anaesthesia for dental extractions. What, in fact, seems to be much more important than attempted pre-anaesthetic sedation by means of drugs is the age of the children concerned. Those over 6 behave in an almost unexceptionable manner, and for them premedication is almost unnecessary. From observations made in a clinical trial, a value may be ascribed to one or more drugs which, in fact, ought rather to be ascribed to age differences, unless these are carefully taken into account as well.

We would make it clear that our study has been concerned with behaviour—not anxiety. The latter is much more difficult to assess, and we wonder, for reasons already set out in the introduction to this paper, whether other workers are entitled to draw conclusions about anxiety when

FIG. 7.—Behaviour shown by the younger and the older children before general anaesthesia.

TABLE III.—Comparison of Findings of Two Observers who were Assessing the Behaviour of 390 Children About to be Anaesthetized. The Percentage Occurrence of Agreements and Disagreements Between the Observers are Shown, Taking A.C.K.'s Assessments as the Baseline. Agreements are Shown in BOLD TYPE

A. C. K.'s Observations		How E. M. W. Graded the Same Children		
Grading	No. of Children	Calm %	Disturbed %	Turbulent %
Observations at Child's Entry to the Theatre				
Calm	273	99	1	—
Disturbed	87	29	63	8
Turbulent	30	—	23	77
Observations at Beginning of Presentation of Anaesthetic				
Calm	222	91	9	—
Disturbed	110	13	77	10
Turbulent	58	—	21	79

Recovery Period

Careful attention was paid by the nurse in charge of the recovery room to any unusual behaviour on the part of the patients throughout the trial. There was no evidence that the medication either caused any unusual behaviour or delayed their recovery to a stage when they were fit to leave the hospital.

during a trivial procedure when he had successfully withstood a suprapubic prostatectomy so recently. This patient was premedicated with atropine 1/100 gr. (0.65 mg.). The cyprane inhaler was at no time set beyond the third mark.

Case 6

A healthy man aged 40 was admitted to hospital for block dissection of glands of the right side of the neck. He was premedicated with papaveretum, $\frac{1}{2}$ gr. (22 mg.), and scopolamine, 1/150 gr. (0.43 mg.). Anaesthesia was induced with thiopentone and suxamethonium. The throat was sprayed with lignocaine 4%, a No. 9 plain endotracheal tube passed, and a throat pack inserted. Anaesthesia was maintained with nitrous oxide, oxygen, and trichlorethylene. Following the adoption of a 15–20-degree foot-down tilt and intermittent doses of hexamethonium bromide to a total of 100 mg., the blood systolic pressure was stabilized at a level of 85 mm. Hg. While the dissection proceeded round the subclavian vein a small puncture was made in the vessel, but this was rapidly sealed without entry of air. When dissection had proceeded to the level of the hyoid bone respiration suddenly and dramatically ceased. Carotid pulsation was no longer visible and the apex beat was absent. Immediate artificial ventilation with 100% oxygen in the head-down position was performed and cardiac massage was instituted within $1\frac{1}{2}$ minutes of arrest. The heart was restarted within 30 seconds, and respiration began within a further minute, with restoration of systolic blood pressure to the previous level. The operation was completed under nitrous oxide, oxygen, and intravenous pethidine without further incident. The patient was conscious and rational on termination of the anaesthesia.

The hypotension in this case was never marked and in fact the blood pressure remained at a stable level for 45 minutes, never falling below 80 mm. Hg systolic. The dramatic nature of the collapse is in marked distinction to the usual manner in which death occurs during hypotension (Committee upon Deaths Associated with Anaesthesia 1953). Coronary thrombosis, whether due to the hypotension or occurring as a primary condition, can presumably be excluded by the rapid response of the heart to cardiac massage and the subsequent uneventful recovery. Air embolism is not consistent with the suddenness of the collapse and the equally rapid and complete recovery.

Case 7

A healthy young primigravida aged 30 was admitted to hospital for lower uterine segment caesarean section for contracted pelvis and foetal distress. Premedication was by atropine, 1/100 gr. (0.65 mg.). Anaesthesia was induced with thiopentone and maintained with nitrous oxide, oxygen, and trichlorethylene. After delivery of a live infant the uterus was well retracted and the blood loss was within normal limits. As the abdomen was being closed cardiac arrest occurred. Resuscitation restored a feeble pulse and spontaneous respiration but the patient failed to regain consciousness and died two hours later. Necropsy revealed no cause of death.

Haemorrhage in this case was by no means excessive and up to the time of arrest the patient gave no cause for concern to either surgeon or anaesthetist.

Comment

Cardiac arrest occurring during trichlorethylene anaesthesia is not necessarily cardiac arrest due to trichlorethylene. Before the drug is incriminated certain conditions must be fulfilled. (1) The pattern of arrest must be essentially similar in all cases. (2) Other possible causes of arrest must be absent. (3) The technique of administration of the drug must be beyond reproach, avoiding both anoxia and overdosage.

In each of the cases reported above the clinical picture has been essentially the same, displaying the features originally described by Snow when he first reported primary

cardiac failure under chloroform anaesthesia. Recovery without cardiac massage does not preclude the diagnosis of cardiac arrest in those cases exhibiting the classical features—namely, pallor, apnoea, and absence of pulse and heart sounds. This has recently been demonstrated conclusively by Johnstone (1955) who also showed that resuscitative measures short of cardiac massage may suffice under certain circumstances.

In four of our cases arrest occurred during induction and before surgery had been started. In the remainder the picture is more complicated, but for the reasons given with each report we feel that trichlorethylene was responsible for the arrest which occurred.

In one case trichlorethylene was administered from a cyprane inhaler, a method commonly used both in this country and abroad. In the other cases administration was from the chloroform bottle of the standard Boyle machine, the oxygen varying between 25 and 30% and the minute flow being 7 to 8 litres. Only minimal quantities of trichlorethylene were added, the lever being never more than half-way open and the plunger fully elevated. Enderby (1944) has condemned the use of the chloroform bottle on the Boyle machine for the administration of trichlorethylene. He maintains that even in the minimal position the concentration of trichlorethylene administered is excessive for maintenance of anaesthesia, while anything approaching the maximum concentration is in excess of that required to anaesthetize any patient. Within these limitations, however, the Boyle bottle is still commonly used, and without it the use of trichlorethylene for anaesthesia would virtually cease in this country.

Reassessment of the Place of Trichlorethylene in Modern Anaesthetic Practice

Trichlorethylene, being a powerful analgesic, neither irritant nor explosive, has been widely used in the following circumstances: (1) As a supplement to nitrous oxide and oxygen in the production of light anaesthesia without anoxia. Since after-effects are minimal its popularity became rapidly established in dental, casualty and obstetric practice. (2) To produce the analgesia of Gray's triad (Gray and Rees, 1952) in conjunction with thiopentone, nitrous oxide, and a muscle relaxant. In this respect it is used in lower abdominal surgery and in such operations as herniorrhaphy and haemorrhoidectomy, where some relaxation is desirable but assisted rather than controlled respiration is indicated. (3) As a suitable agent for maintenance of anaesthesia when the explosion hazard is present. (4) As an analgesic vaporized by air.

Hunter (1944) has suggested that the use of trichlorethylene as a routine supplement to nitrous oxide and oxygen should cease. To facilitate the introduction of ether, vinyl ether anaesthetic mixture is just as effective and much safer to the cardiac rhythm. For maintenance of light anaesthesia the trichlorethylene may well be replaced by minimal ether, the increased incidence of post-operative vomiting which may ensue being a small price to pay for the increased safety of the agent used. Since the introduction into anaesthetic practice in this country of intravenous pethidine (Mushin and Rendell-Baker, 1949) this drug has largely supplanted the more toxic volatile anaesthetics, and it may well be that alphaprodine hydrochloride ("nisentil"), at present under investigation, will prove even more satisfactory in this respect.

For dental and casualty anaesthesia Bourne has recently advocated the use of cyclopropane and oxygen; where the explosion hazard is present the oxygen is diluted with nitrous oxide. While this technique has still to stand the test of time the results so far are encouraging. Another suitable alternative for this type of anaesthesia is vinyl ether anaesthetic mixture. In obstetrical anaesthesia the skilful use of ether dispenses with the need for trichlorethylene, and indeed in a recent report Lock and Greiss (1955) condemn its use as an anaesthetic in obstetrics under any circumstances. Similar

considerations apply when reviewing the choice of analgesic agent for use with a relaxant in lower abdominal surgery.

The use of diathermy precludes the employment of any inflammable agent, but once again the introduction of pethidine has reduced the indications for trichlorethylene in this sphere.

The use of trichlorethylene as an analgesic vaporized by air in the apparatus commonly used to date is obviously not without risk. Whether these dangers have been completely overcome by the introduction of thermostatically controlled vaporizers remains to be seen.

Conclusions

Pharmacologically, trichlorethylene bears a strong resemblance to chloroform, and while it is not suggested that the incidence of cardiac arrest is at all comparable it may well be that the occurrence is not so rare. Reported cases are indeed few, but it is possible that this is due to a natural reluctance to publicize mishaps. When cardiac arrest occurs during anaesthesia many possible factors may be implicated. As this is an infrequent occurrence in the clinical experience of any one anaesthetist, and as trichlorethylene is reputedly a safe anaesthetic, it is not surprising that the blame in these cases is apportioned elsewhere and the incident passes unrecorded. This is well seen in Case 6 of our series, where if death had occurred the exclusion of air embolism or coronary thrombosis would have been virtually impossible.

We feel that the place of trichlorethylene in modern anaesthesia is very limited, and in the absence of strong indications for its use other, and safer, agents should be employed. When it is used, however, the possibility of cardiac arrest should be borne in mind and the risk balanced against the advantages to be gained. There is still a place for a safe non-inflammable volatile anaesthetic agent should such be discovered.

Summary

A critical survey of the literature pertaining to cardiac arrest during trichlorethylene anaesthesia is presented. Seven previously unpublished cases are reported. The aetiology of the cardiac arrest in these cases is discussed and the possible role of trichlorethylene is emphasized. The scope of trichlorethylene in modern anaesthetic practice is reassessed and the employment of alternative agents whenever possible is recommended.

We are indebted to Dr. R. W. Cope for making available to us further details of the cases already reported by him. We are grateful to our colleagues whose cases are included in this report, and no less to those whose cases have for various reasons been omitted. Finally, we thank Dr. A. C. Forrester and Dr. D. M. Armstrong for their encouragement in the preparation of this paper.

ADDENDUM.—Since this paper was prepared the Committee upon Deaths Associated with Anaesthesia has produced a further report (*Anaesthesia*, 1956, 11, 194). In this report nine cases of primary cardiac failure are mentioned and a typical case history is given. This type of death accounts for 1.5% of the cases where the anaesthetic is considered to have been responsible for the fatality.

AN OBSCURE CASE OF RUPTURED DIAPHRAGM

BY

HUGH REID, M.D., F.R.C.S.

Senior Surgeon, Royal Infirmary, Liverpool

The following case of herniation of the stomach into the left pleural space may be considered rare enough to be placed on record.

Case Report

A man aged 54 was admitted to hospital as an emergency case on April 26, 1956. He was too distressed to give a history; he was gasping for breath, cold sweat was running down his face, and his extremities were blue and cold. It was noted that the heart pulsations were over to the right of the sternum, the trachea was also displaced to the right, the left chest was moving poorly and air entry could not be heard.

The history relevant to this episode is that he had been admitted to hospital as an acute abdominal emergency on September 9, 1954, and a diagnosis of perforation of a diverticulum of the pelvic colon was made. At operation the peritoneum was found to be full of foul-smelling fluid and a large, immovable inflammatory mass was felt in the pelvic region. Left iliac colostomy was performed and the abdomen drained. After a stormy convalescence, complicated by bilateral bronchopneumonia, he left hospital a month later.

On September 5, 1955, he was again admitted and a diagnosis of right-sided subphrenic abscess was made. At operation, after resecting the 12th right rib, foul-smelling pus was evacuated from the anterior superior space beneath the diaphragm and the space was drained for 15 days. He was discharged 21 days after his operation, and he remained at home, reporting to hospital occasionally, until the catastrophe here reported.

Immediately after the present admission a skiagram of his chest showed almost complete collapse of the left lung, with displacement of the mediastinum to the right, apparently due to an extensive hydropneumothorax (Fig. 1). On viewing the skiagram, the Senior Medical Registrar (Dr. D. C. Watson) passed a needle into the chest posteriorly,

FIG. 1.—Extensive hydropneumothorax with collapse of the lung.

and drew out with great difficulty a small quantity of inspissated pus, but could get no more. When I saw the patient a short time later the picture had not changed except that he was more restless and was grunting with distress. I passed in a long wide-bored needle posteriorly for 2 in. (5 cm.), but no fluid was encountered here.

I then passed a needle anteriorly into the third interspace, above and external to the nipple line, and drew out very easily a syringe of fluid resembling dark beef-tea; this looked like stomach contents, and indeed it was strongly acid to litmus paper. A rubber catheter was inserted in this situation, by means of a trocar and cannula, and attached to a suction apparatus, which aspirated 50 oz. (1,420 ml.) of fluid. At once his condition improved strikingly; a skiagram now showed that the drainage tube was in a large cavity and that the left upper lung had begun to re-expand.

Underwater drainage was continued and a Ryle tube was passed down the oesophagus, being left in for two days while fluids were given by mouth. Nine days later (May 4) he was fit enough to have a barium meal, and this showed that the cavity in which the catheter was lying was the stomach, and that the stomach was within the thoracic cavity (Fig. 2).

On May 9, the catheter being still in the stomach, a barium meal showed that that organ was folded transversely on itself within the thorax, the pylorus and duodenum cap were pointing directly downward, and the stomach was emptying fairly freely into the small bowel.

The patient's general condition now being quite good, it was decided to open the thorax, return the stomach to the abdomen, and repair the diaphragm.

Operation.—On May 11 the chest was opened through the bed of the eighth rib on the left side. The stomach was found to be lying in the pleural cavity, with the fundus and anterior wall pressed up against and adherent to the thoracic wall anteriorly. Posteriorly the stomach was firmly adherent to the lung and to a dense inflammatory mass at the back of the chest wall. Considerable difficulty was found in separating the stomach from this mass, and a little pus was encountered in doing so. The diaphragm consisted merely of a ledge of tissue adherent all round to the stomach. The cardio-oesophageal junction was in its normal position, being held by the crus of the diaphragm. After

FIG. 2.—Barium in stomach showing position of this organ in chest. Draining-tube still in place. Note position of cardio-oesophageal junction.

FIG. 3.—Chest condition five and a half weeks after operation. Anterior-posterior view.

adhesions had been separated, the stomach was pushed down through the large aperture in the diaphragm into the abdominal cavity. The aperture was then drawn together by stay sutures and repaired by means of a tongue of intercostal muscle and by sutures of stainless-steel wire. The chest wound was closed, leaving two drainage-tubes for underwater seal drainage, one anteriorly and one posteriorly.

His post-operative course was smooth and without untoward incidents. A skiagram of the chest taken on May 19 showed that the lung had expanded well but there was some residual inflammatory reaction in the left lower lobe and in the pleura at the base of the pleural cavity. A later skiagram June 27 (Fig. 3) showed satisfactory clearing of the chest with no residual pockets.

Five and a half weeks after repair of his diaphragm the patient left hospital in very good condition.

Discussion

Even with this patient's previous history before us, the true nature of the condition was not at first recognized. On admission he appeared to have a spontaneous pneumothorax.

The first pleural paracentesis passed into a mass of old inflammatory tissue and drew off a very small amount of inspissated pus, suggesting an empyema. The skiagram, however, showed a large space filled with gas and air, with an almost completely collapsed lung, and the clue to the diagnosis was given only after a needle in the third intercostal space drew off the dark fluid described. The surprising feature is that passing a large needle through the chest wall into the stomach did not produce leakage of stomach contents into the pleural cavity.

After drainage of the intrathoracic stomach in this way the lung rapidly expanded, the stomach descended towards the abdomen, and the patient was able to eat and drink without discomfort.

After operation there was very little discharge from the two drainage-tubes, and no loculations of fluid or air were left in the pleural cavity.

The sequence of events leading to rupture of his diaphragm is shown in his history. First, the peritoneal catastrophe of a ruptured diverticulitis, then a subphrenic abscess, which presented on the side opposite to the subsequently

ruptured diaphragm. It is probable that there was a left subphrenic abscess at about the same time and that infection from this site tracked up through the foramen of Blakdale into the chest. This would account for the inflammatory mass at the posterior aspect of the left chest at the site of the first paracentesis and for the subsequent softening, and finally the rupture, of the diaphragm and the sudden passage of the stomach into the chest.

EFFECT OF CHLORPROMAZINE ON RENAL HAEMODYNAMICS AND FUNCTION IN CONGESTIVE HEART FAILURE

PRELIMINARY REPORT

BY

G. SZABÓ, M.D., D.S.Med.

F. SOLTI, M.D.

J. RÉV, M.D.

AND

K. MEGYESI, M.D.

From the 1st Medical Clinic, University of Budapest

On the basis of an earlier observation of ours that chlorpromazine ("largactil") has a marked diuretic action in cases of congestive heart failure we investigated 12 cardiac patients and, for comparison, 6 normal persons for the effect of chlorpromazine (25 mg. intravenously) on diuresis, sodium excretion, glomerular filtration (endogenous creatinine clearance), and renal plasma flow (para-aminohippuric acid clearance).

Results

After the intravenous injection of the above dose an immediate increase in diuresis was seen in oedematous cardiac patients, reaching its maximum within about half an hour. The rise averaged two or three times the initial value, and in our 12 cases the average of the maximal diuresis rose to four times as much. Even the lowest values due to chlorpromazine were much higher than those observed in the control periods (Tables I and II).

Sodium excretion varied together with the diuresis, rising upon administration of chlorpromazine in general to more than twice that observed in the control periods. The peak values in some of the experiments reached three times those of the control periods. In the chlorpromazine-treated cases even the lowest sodium excretion was significantly higher than the control values.

The glomerular filtration rate also increased as the result of chlorpromazine, though by no means to the extent seen in diuresis and sodium excretion. In the periods after chlorpromazine administration the glomerular filtration rate was some 20 to 50% higher than the control values, the rise being statistically significant in only the first two periods after administration of the drug. The maximal glomerular filtration rate values in the periods after chlorpromazine were on the average 86% higher than in the controls. The minimal values were 9.5% lower than the control values, and are not statistically significant.

Chlorpromazine produced an average rise of 30% in the renal plasma flow, but this rise, except for the first period after administration, cannot be regarded as statistically significant. The average of maximal values due to chlorpromazine exceeded the controls by 69%, the difference being highly significant. The mean of the lowest values was actually 12% lower than the controls, but from the standpoint of statistical analysis was not substantially different.

Comment

From the above, therefore, it appears that in congestive heart failure chlorpromazine has a pronounced diuretic and

saluretic action. This effect could be explained by alterations of renal haemodynamics—that is, to be due to the rise of renal plasma flow and filtration rate, resulting in the changes of water and salt reabsorption. This possibility is not in the least excluded by the fact that the rise in glomerular filtration and renal plasma flow was much less than that in water and sodium excretion. Against this view, however, stands the fact that the changes in glomerular filtration and plasma flow were not always followed by similar changes in water and sodium excretion. It is to be noted in our experiments that out of 45 post-chlorpromazine clearance periods water excretion rose considerably in 11 cases, and sodium excretion in 7, in spite of a significant fall in glomerular filtration rate and renal plasma flow.

In six normal persons chlorpromazine had no consistent effect on renal function. Diuresis increased in three cases, decreased in two, and in one was unaltered. Glomerular filtration decreased in three cases, and showed no change in the other three. The renal plasma flow diminished in three cases, was unchanged in one, and showed a slight but inconsiderable rise in the other two. Sodium excretion decreased in two cases, and did not alter in three.

Our results will be communicated in detail in the *Acta Medica Academiae Scientiarum Hungaricae*.

PERICARDITIS AND ELECTROCARDIOGRAPHIC CHANGES IN REITER'S SYNDROME

BY

G. W. CSONKA, M.D., M.R.C.P.

Consultant Venereologist, Addenbrooke's Hospital, Cambridge

AND

J. K. OATES, M.B., M.R.C.P.Ed.

Physician to M.R.C. Investigation of Non-specific Urethritis

Reiter's syndrome is a condition which has been known for many years, but has been studied in detail only during the last ten to fifteen years. It presents with non-gonococcal urethritis, polyarthritis, conjunctivitis, and sometimes iritis, a characteristic balanitis, or eruption on the skin (keratoderma blennorrhagica), and the syndrome may show all these features or only two or three.

Several authors have described evidence suggesting cardiac involvement in the course of these infections, but, as one would expect with a non-fatal condition most commonly affecting young people, post-mortem evidence is lacking.

Electrocardiographic changes suggesting myocarditis were reported by Gadrat and Morrell (1935), Bang (1940), Candel and Wheelock (1945), Feiring (1946), Paronen (1948), Lövgren and Masreliez (1949), Trier (1950), Shapiro *et al.* (1949), and Weinberger *et al.* (1952). Paronen also recorded seven cases which developed pericarditis with an audible friction rub out of a total of 308 patients suffering from the syndrome. Lever and Crawford (1944) recorded a case of a 35-year-old man who, during the fourth month of a severe attack of Reiter's disease, complained of substernal oppression and whose electrocardiogram showed changes suggestive of recent myocardial infarction. An electrocardiogram earlier in the attack had been normal. He died four days later, but a post-mortem examination was not carried out.

Mayne (1955) described a case of Reiter's syndrome with electrocardiographic changes suggesting pericarditis

which at the time of publication had persisted unaltered over the unusually long period of 15 months. He also recorded a further case of a man aged 30 with Reiter's syndrome who had electrocardiographic changes strongly suggestive of anterior myocardial infarction. Neither of these patients had any symptoms of cardiac disease.

Present Series

In 128 cases of complete Reiter's syndrome, mostly in men between 20 and 35 years of age, clinical evidence of heart disease developed during the attack in only two patients, both of whom suffered from pericarditis. Six patients had complained of transient chest pain, which was thought at the time to be due to connective-tissue involvement. In view of our later experience it is possible that some of these patients may also have had pericarditis.

Electrocardiography now forms a routine part of our investigation of all patients with Reiter's syndrome, and 4 out of 25 cases have shown abnormal tracings. The case histories of these four patients illustrate some of the cardiological abnormalities which may be found in Reiter's syndrome.

Case 1

On admission to hospital a West Indian man aged 38 gave a history of urethral discharge and polyarthritis for a month. His urethral infection had been treated originally by his own doctor with a course of a sulphonamide, but recurred two weeks later, together with terminal haematuria. Many joints of both arms and legs were involved, and there was also pain in the lumbar region and marked plantar fasciitis and swelling of the Achilles tendons. For the first week

FIG. 1.—Case 1. Heart enlarged. Screening showed this to be of left ventricular origin.

FIG. 2.—Case 1. Prolonged P-R interval of 0.28 second and ST elevation in L I, V I, V II, V III, and V IV.

there was a slight pyrexia of up to 100° F. (37.8° C.). The patient complained of transient central chest pain soon after admission, but on clinical examination no cause for this was detected. Treatment with salicylates and bed rest

FIG. 3.—Case 2. Elevation of ST segment in L I, L II, and CR leads.

FIG. 4.—Case 2. ST elevation much less marked in L I, CR IV, and CR VII.

did not improve his condition, and fever therapy with intravenous *E. coli* vaccine was tried. After three injections there was considerable symptomatic improvement and he was discharged from hospital.

He had contracted gonorrhoea eight years previously, and this was followed by the development of a urethral stricture. He gave no history of rheumatic fever or previous joint or heart disease. The Wassermann and Kahn reactions were negative and the gonococcal fixation test was strongly positive. The E.S.R. was 80 mm. in one hour, haemoglobin 106%, white blood cells 5,250, with 57% polymorphonuclear leucocytes. A mid-stream specimen of urine showed a few pus cells and was sterile. X-ray examination of the

chest showed the heart to be enlarged, with some prominence in the region of the left ventricle (Fig. 1). The affected joints showed no abnormality. The blood pressure was 150/100.

After leaving hospital he had intermittent pain in various joints and was readmitted with renewed swelling of the same joints as on the first occasion and also of the right elbow. Slight urethral discharge was present, and microscopically showed polymorphonuclear leucocytes and red blood cells but no gonococci. The prostatic secretions contained a considerable excess of polymorphonuclear leucocytes. He developed a mild symptomless bilateral conjunctivitis, which subsided in a few days. A routine electrocardiogram taken on the same day (Fig. 2) showed a prolonged P-R interval of 0.28 second and ST elevation in leads I, VL, V1, V2, V3, and V4. Radiographs of the heart were similar to the previous film, and screening gave no additional information. Nine days later he complained again of central substernal pain, which continued for two days. During this time a pericardial friction rub was heard, but the electrocardiographic tracing showed no change. His joints improved slowly and he was discharged three weeks later. Further electrocardiograms were taken at monthly intervals, but these still showed no change. He was well enough to start work again, and the only abnormality found on clinical examination was minimal stiffness in the knees and several fingers, together with the evidence of chronic prostatic infection.

Case 2

A man aged 24 was admitted to hospital complaining of thick urethral discharge, of soreness of both eyes, and pain in the left heel for one week. He denied sexual intercourse. Polyarthritis developed and affected both knees, ankles, left shoulder, several metacarpophalangeal and proximal interphalangeal joints, and the second, third, and fourth metatarsophalangeal joints of both feet. His illness lasted approximately 14 weeks, and during this time he also suffered two attacks of conjunctivitis and two of iridocyclitis. Lesions of keratoderma blennorrhagica appeared on the palms, soles, genitalia, and limbs.

For the first 14 days he had intermittent pyrexia of up to 100° F. (37.8° C.). For the next six weeks he ran fever of up to 101° F. (38.3° C.) in the evenings, falling to 99.5° F. (37.5° C.) in the mornings. He complained on several occasions of attacks of pain in the chest. Throughout the course of his 14-weeks stay in hospital he showed tachycardia of 95 to 115 beats a minute. No other abnormal physical signs were detected in the cardiovascular system on clinical examination. An electrocardiogram taken 10 weeks after admission showed slight elevation of the ST segment in leads I, II, CR1, CR4, and CR7 (Fig. 3). A tracing taken 10 days later showed much less ST elevation in leads I, CR4, and CR7 (Fig. 4). X-ray examination of the chest showed nothing abnormal. The E.S.R. was 100 mm. in one hour, falling to 40 mm. shortly before discharge.

Case 3

A man aged 33 (a patient of Dr. D. Lewes) had suffered an attack of Reiter's syndrome for some two to three months, the only residual finding being the presence of bilateral calcaneal spurs. Eleven months later he suffered a further attack, this being characterized by joint pains, conjunctivitis, and a transient macular rash. He ran a fever of up to 100° F. (37.8° C.). He also complained of pain in the chest, and on examination was found to have a pericardial friction rub. The electrocardiogram showed ST elevation in leads I, II, V1, and V2 (Fig. 5). The chest x-ray picture was normal.

During the next seven days his fever settled and the pericardial rub disappeared. A further electrocardiogram taken 13 days later (Fig. 6) showed the T wave to be flat in lead II and very low in leads I and III.

FIG. 5.—Case 3. RT deviation in LI, LII, V1, and V2, with reciprocal ST depression.

Case 4

A 33-year-old man complained of dysuria, frequency, and haematuria 21 days after sexual intercourse. There were no ocular or arthritic symptoms. Shortly after admission he had a rigor and his temperature rose to 102° F. (38.9° C.). There was diffuse tenderness in the hypogastric region, and the urine contained many polymorphonuclear leucocytes and red blood cells. No organisms were seen. Clinical examination of the cardiovascular system showed no abnormality and the x-ray picture of the chest was normal. Three specimens of urine were cultured, but no organisms were grown. An intravenous pyelogram showed no abnormality. On receiving treatment with oxytetracycline he improved rapidly.

An electrocardiogram taken on the fourteenth day of the illness showed the following changes: slight ST elevation

FIG. 7.—Case 4. ST elevation in LII, LIII, LIII R, and CR7. ST depression in LI.

FIG. 6.—Case 3. Tracing normal 13 days later than in Fig. 5.

of electrocardiographic changes in abacterial pyuria has been found in the literature.

In Case 1 the condition was thought to be rheumatoid arthritis at the time of the patient's first discharge from hospital. Arthritis following genital infection and classical rheumatoid arthritis are dissimilar in many respects, but it seems clear that both may cause cardiac involvement. Sokoloff (1953) showed, in a study of 101 post-mortem examinations of patients with rheumatoid arthritis, that pericarditis was a very common finding and that the diagnosis of pericardial disease had rarely been made during the lifetime of the patients. His figures for pericarditis for which no cause other than rheumatoid arthritis could be found were 24.8% of 101 cases, as against 2.2% of 1,154 controls. There are no post-mortem studies of Reiter's syndrome comparable to those in rheumatoid arthritis, but findings in the present series and those described in the literature suggest that low-grade pericardial involvement is not at all uncommon and may be clinically silent.

In view of this evidence there is a good case for employing electrocardiography and careful cardiac assessment as a routine in the investigation of Reiter's syndrome, and attention is also drawn to the possibility that pain in the chest may occasionally be due to pericardial involvement, a fact which is likely to be obscured by the widespread aches and pains which are characteristic of the syndrome. An unusual feature was the persistence of the electrocardiographic changes for six months in Case 1; this tallies with Mayne's experience, for his patient had shown unchanged electrocardiographic tracings for

FIG. 8.—Case 4. S wave in CR1 with ST elevation and inversion of T wave. Slight ST elevation with T wave inversion in LII and LIII. T wave inverted in LIII R and CR7.

in leads II, III, LIII R, and CR7 (Fig. 7). When repeated two weeks later the tracing showed inversion of the T wave in leads II, III, LIII R, and CR7 (Fig. 8). The patient now had no symptoms of any kind, and his urine was normal macroscopically and microscopically.

Discussion

From a study of the present series of patients and the literature it appears that clinically obvious cardiac involvement is uncommon in Reiter's syndrome, but electrocardiographic changes may be more frequent. Most of the previously reported cases have been of this nature, and overt pericarditis with an audible friction rub appears to have been reported only by Paronen (1948).

Case 4 was not characteristic of Reiter's syndrome, but of acute urinary infection of unknown aetiology following sexual exposure. As cultures and microscopy of the urine failed to demonstrate the presence of micro-organisms, it must be classified as a case of abacterial pyuria. Well-marked electrocardiographic changes suggestive of pericarditis developed. It may be that this type of genital infection is caused by the aetiological agent which is responsible for Reiter's syndrome, as suggested by Harkness (1950). Moreover, abacterial pyuria is sometimes closely associated with a typical attack of the syndrome. No reference to the development

at least 15 months up to the time of writing. The remote possibility that constrictive pericarditis may develop later must be borne in mind.

Summary

Three cases of pericardial involvement in Reiter's syndrome are described.

The symptoms of this complication are not always prominent, and for this reason electrocardiography should be a routine procedure in cases of Reiter's syndrome.

A case of abacterial pyuria with pericarditis is also reported.

This work was undertaken as part of the M.R.C. research on non-specific urethritis with a grant-in-aid from the National Institute of Health of the United States Public Health Service Contract No. E652. We thank Dr. C. Young, of St. Mary's Hospital, and Dr. David Lewes, of Bedford General Hospital, for permission to study their patients, and Dr. William Evans, Mr. A. J. King, Dr. G. L. M. McElligott, and Dr. Wallace Brigden for their valuable help.

Medical Memorandum

Strangulation of Umbilical Hernia in Children

The infantile type of umbilical hernia is rightly regarded as a benign condition and complications are very rare. A few cases of spontaneous rupture have been reported (MacLean, 1950; Strange, 1956), but strangulation of bowel in such a hernia is even more uncommon. Indeed, Browne (1952) wrote that he was unable to find a record of such an occurrence, and Woods (1953) could find no case in the records of the Bristol hospitals.

I have been able to find only two reports of strangulated umbilical hernia in children. Miller (1932) included one child of 2 years of age in his series of 60 cases of strangulated umbilical hernia seen at the Massachusetts General Hospital from 1911 to 1930; and Crump (1952), in his series of 329 cases of umbilical hernia in American Negro children, mentioned a case of strangulation in a 17-months-old girl.

Two cases of strangulated umbilical hernia have been seen at this hospital during the last six years, and in view of the rarity of the condition a brief report is considered justified.

CASE 1

A boy was admitted to hospital with oedema and albuminuria when he was 2 years old. He was found to be suffering from the nephrotic syndrome. Soon after admission he developed gross ascites, and the presence of a large umbilical hernia was recorded in the case notes. During the next two years numerous abdominal paracenteses were necessary to relieve the distress caused by large accumulations of fluid in the peritoneal cavity. He never showed evidence of renal insufficiency.

When he was 4 years old he was readmitted to hospital with a two-days history of abdominal pain and vomiting.

Examination showed that the umbilical hernia, which had previously been easily reducible, was hard and could no longer be reduced. Apart from some oedema his general condition was good, although he was noticed to have muscular twitchings. As his serum calcium was found to be low he was given intravenous calcium chloride and the twitchings ceased. An intravenous transfusion of glucose water was started pre-operatively.

Under general anaesthesia an incision was made around the protuberant umbilical mass. The underlying tissues were dissected until a loop of bowel was seen which was constricted by a defect in the linea alba. The bowel was congested, but was considered to be viable. The constricting ring was divided, following which there was a gush of fluid from the peritoneal cavity. The child's condition rapidly deteriorated and he died a few minutes later. No cause for the sudden collapse and death was found at necropsy.

CASE 2

A boy, who had been born three months prematurely, was seen as an out-patient when he was 3 months old on account of umbilical and right-sided inguinal hernias. Adhesive strapping was applied to the umbilical hernia, but it is not known how long this was maintained. It was proposed to repair the inguinal hernia when he was older.

Two months later, however, he was admitted to hospital as an emergency because for nine days he had been having attacks of screaming during which he drew up his legs, and his mother noticed that the umbilical swelling had increased in size and had become bluish in colour. The baby had vomited a little and had been constipated.

On examination his general condition was very good and he weighed 12½ lb. (5.8 kg.). There was a large bluish protrusion at the umbilicus which could not be reduced. The inguinal hernia was easily reducible.

An operation was performed at once, and the hernial sac was found to contain a loop of very oedematous but viable bowel and a mass of omentum in which there was a haematoma. The obstruction was relieved and the baby made a rapid recovery.

Two weeks later he was readmitted because the inguinal hernia had become incarcerated. This was successfully relieved by operation.

COMMENT

In Case 1 there was presumably a congenital weakness of the umbilical scar, and raised intra-abdominal pressure, due to the large accumulation of ascitic fluid, resulted in herniation through the scar. The natural tendency for this type of hernia to resolve spontaneously in children (Woods, 1953) would also be unlikely to occur because of the constant increase of pressure in the abdomen. Local distension of the loop of bowel in the hernia, or adhesions due to the many paracenteses, may have been the factors precipitating the strangulation. No cause for the sudden collapse and death of the patient was evident at necropsy, but it may have been due to the sudden release of fluid from the peritoneal cavity.

The umbilical hernia of Case 2 was the usual infantile type, and there appeared to be no factor precipitating the strangulation.

It has been shown that adhesive strapping hastens the resolution of large umbilical hernias (Haworth, 1956), and the fact that strangulation does very rarely occur is perhaps an additional reason for strapping these cases.

Case 1 was admitted under the care of Mr. R. B. Zachary and Case 2 under Mr. W. J. Lytle, to both of whom I am grateful for permission to publish.

Reviews

ENZYME, ANTIGEN, AND VIRUS

Enzyme, Antigen, and Virus: A Study of the Macromolecular Pattern in Action. By F. Macfarlane Burnet, Kt., F.R.S., F.R.C.P. (Pp. 193 + viii. 18s.) London: Cambridge University Press. 1956.

Those who knew that Sir Macfarlane Burnet was preparing a sequel to the monograph *Production of Antibodies*, which he published with Dr. F. Fenner in 1949, have awaited its appearance with the certainty that it would stimulate, and a fair expectation that in places it would irritate, its readers. As the title *Enzyme, Antigen, and Virus* and the subtitle "A Study of Macromolecular Pattern in Action" imply, in this new essay Burnet undertakes a much wider approach to the biosynthesis of specific protein than in his earlier monograph. He first discusses recent work on adaptive enzyme and antibody production in the light of current knowledge of ribose nucleic acid structure and its relationship to protein synthesis. In this light it is possible to put forward a much more definite, though admittedly still speculative, hypothesis about the nature of the protein replicating units in terms of ribose nucleic acid templates—templates whose pattern can, under certain circumstances, in turn be influenced by protein molecules. In many other respects the conclusions of the first monograph still stand, and in fact some, such as the prediction of immunological tolerance, have since been splendidly verified experimentally. After a short digression on the possibility that loss of "self-markers" is the basis of malignancy in cancerous cells, the last chapters deal with virus multiplication. The bacterial viruses containing deoxyribose nucleic acid are set aside as belonging to a class of their own, and not necessarily related to the common theme of this essay. For the growth and reproduction of the influenza virus, however, a detailed hypothesis is constructed capable of accounting for all the main experimental phenomena, including various grades of incompleteness, genetic interactions, and the existence of ribose nucleic acid only in the virus. The interpretation is unorthodox, but very stimulating.

Although there may be several people who might have written an essay on any two of the subjects of this book, it is probably safe to say that only Sir Macfarlane Burnet could have written an essay on all three such as to interest workers on protein synthesis, adaptive enzymes, immunology, and viruses alike.

J. H. HUMPHREY.

TECHNIQUES WITH VIRUSES

Diagnostic Procedures for Virus and Rickettsial Diseases. Second edition. By the Committee on Diagnostic Procedures for Virus and Rickettsial Diseases of the American Public Health Association. (Pp. 578 + xv; illustrated. No price.) New York: American Public Health Association. 1956.

Eight years have passed since the publication of the first edition of this book, which is an indispensable guide to anyone running a virus diagnostic laboratory. In thickness the second edition is nearly twice the first (578 against 347 pages), yet some material has been condensed. There are new chapters on general principles (Lennette), ECHO viruses, tissue culture methods (Melnick), Coxsackie viruses (Dalldorf and Sickles), and miscellaneous virus diseases (Hilleman). Most of the others have been largely rewritten and many appear under new authorship.

Individual experts have been given free rein, and this has the rather unfortunate result that such things as the complement fixation test are described in some detail, but with variations, in several chapters. Melnick's paper on tissue culture techniques will be useful to many readers, though it would appear from the 61 references that the author does not read, or disregards, other than American literature. It is indeed amazing to realize that eight years ago tissue culture played almost no part in diagnostic procedures for

viruses. The adenoviruses (A.P.C.) are considered under "atypical pneumonia": one would think they deserved a chapter of their own. Only the yellow fever chapter remains practically as in the first edition; the important discovery of haemagglutination by this virus is not mentioned.

Obviously many experts will have their favourite methods, and all the authors can do is to describe precisely at least one method which they have found to work. This has been well done, and most authors give attention also to the interpretation of results and the avoidance of pitfalls. Quite apart from its immense value to the laboratory diagnostician, the book will prove a useful source of information and references to all who try to keep abreast of work on the viruses affecting man.

C. H. ANDREWES.

GLAUCOMA

Glaucoma. Transactions of the First Conference, December, 1955, at Princeton, N.J. Edited by Frank W. Newell, M.D. (Pp. 251; illustrated. \$4.50.) New York: Josiah Macy, Jr. Foundation. 1956.

This is an account of a conference held by leading ophthalmologists and medical scientists on the causes of glaucoma. In the words of the chairman, the subject is one which shows "all kinds of unusual and interesting features that are of interest not only to ophthalmologists but to the psychiatrist, to the internist, and to the gynecologist." The discussion is recorded in the form of free questions and answers, and contains many irrelevancies. It is not easy to read. Indeed, the clinical ophthalmologist might search in vain for any clear summary of the latest scientific discoveries, but the research worker should enjoy the finer points of discussion and will appreciate the illustrations of experimental work and the bibliographies. The editors invite criticism of the style of publication, and there is no doubt that the interposition of the headings would enable the reader to follow the trend of the argument more easily, and much of the discussion could be omitted. The text contains a description of the causes of angle-closure glaucoma and of the factors which lead to a blocking of the angle—that is, in the breaking down of a prodromal attack of glaucoma. There appears to be general agreement about the mechanical blocking of the flow of aqueous—by pressure on the root of the iris and by the relative pupillary block. The hydrostatic and osmotic pressure which contribute to the maintenance of intraocular pressure are also discussed, and an extensive account is given of the effects of electrostimulation of the diencephalon—upon blood pressure, cutaneous vessels, and intraocular pressure. The change in resistance to outflow of aqueous which can be caused by the perfusion of some substances such as hyaluronidase in the excised eye, and by the systemic administration in the intact animal or subject, is described in detail, and with particular reference to the nervous and chemical reactions which may occur in the trabeculae of the angular tissue.

D. R. CAMPBELL.

MYOTONIA

Dystrophia Myotonica, Paramyotonia and Myotonia Congenita. By Dr. J. G. Y. De Jong. (Pp. 255; illustrated. Dutch florins 19.50.) Assen: Koninklijke Van Gorcum and Comp. N.V. 1956.

This monograph gives a comprehensive review of the literature concerning myotonia and a detailed account of 43 personal cases of dystrophia myotonica discovered in 11 families, and of 23 of paramyotonia, all occurring in a single family. Translation from the Dutch has probably resulted in loss of clarity, for many of the arguments are difficult to follow, particularly in the section on pathogenesis. The symptomatology of dystrophia myotonica and its endocrine aspects are discussed exhaustively, with a wealth of illustrative detail from the author's own cases, while pathology is also fully considered. In discussing heredity the author rightly stresses the importance of personal examination of whole families, in view of the existence of abortive cases, but fails to mention the important work of Bell on this subject. Throughout, the book is marred by an uncritical repetition of much that has been written before, with little

attempt at clarification and integration; for instance, the brief section on electromyography could do little more than confuse the uninformed reader. Furthermore, it abounds in dogmatic statements based upon impression and personal opinion rather than upon scientifically valid evidence. For example, one reads that "in complete penetration of the gene of dystrophia myotonica, oligophrenia appears." And in considering the vexed question of the relationship between dystrophia myotonica, paramyotonia, and myotonia congenita the author rightly stresses the differences in natural history between the three conditions, but it is difficult to see upon what evidence he bases his categorical assertion that they are entirely different diseases, as his own series includes no cases of myotonia congenita. In a long discussion of pharmacology and treatment it is suggested that growth hormone and insulin may be of value, but this advice appears to rest upon the uncontrolled observation of improvement in a single case. Despite these criticisms one must pay tribute to the author's industry, for the book contains much useful information and will be a valuable source of reference, as most of the important facets of this group of conditions receive detailed consideration.

JOHN N. WALTON.

BRITISH SURGICAL PROGRESS

British Surgical Practice. Surgical Progress, 1956. Under the general editorship of Sir Ernest Rock Carling, LL.D., F.R.C.S., F.R.C.P., F.F.R., and Sir James Paterson Ross, K.C.V.O., M.S., F.R.C.S., F.A.C.S. (Pp. 396 + vii; illustrated. 47s. 6d.) London: Butterworth and Co. Ltd. 1956.

This is the annual supplement to *British Surgical Practice* for the year 1956. As in previous years, the volume consists of original articles, critical surveys, and abstracts. The articles deal with a variety of subjects, the first and longest being an account of spontaneous intracranial haemorrhage by J. M. Potter. Other subjects comprise cancer of the maxilla, atresia of the oesophagus, repair of the cardia, some plastic procedures, distribution of paralysis in poliomyelitis, rectal prolapse, parotitis, traumatic paraplegia, congenital deformities of the thorax, and transplantation of the ureters into the ileum. Of the critical surveys, the most important is that by C. F. Scurr and G. S. W. Organe on hypothermic anaesthesia, in which the advantages and dangers of that procedure are well indicated. The abstracts cover a wide ground and are of varying importance; I wish it might have been possible to include details of the technique used in resection of abdominal aneurysms. Altogether the whole volume will be of great assistance to busy surgeons who are trying to keep up to date with the latest advances.

ZACHARY COPE.

COAGULATION DEFECTS

The Laboratory Diagnosis of Coagulation Defects. By Pietro de Nicola, M.D. (Pp. 240 + xv; illustrated. 57s. 6d.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1956.

This further monograph in the American Lecture Series maintains the high standards of many of its predecessors. It is written by a recognized authority on haemorrhagic disorders and blood coagulation, and he has succeeded in presenting his material in a format suitable not only for the laboratory worker in this field but also for clinicians, physiologists, and pathologists with a less specialized interest. The publication of this book is timely; the number of papers on blood coagulation in recent years is enormous, and each is written in a terminology peculiar to one group of workers. The resulting confusion has in some measure been reduced by this particular account of the subject.

The book contains five chapters, the first on the physiological basis of the laboratory tests, while Chapters II and III deal with the application of these to the diagnosis of haemorrhagic syndromes. Chapter IV enumerates the technical details of each of the tests. Useful diagrams help the reader to follow the description of these technical procedures. On page 63 the term "adsorbed serum" in the account of the thromboplastin generation test should read

"serum". Chapter V summarizes the author's conclusions. The bibliography at the end is good, but a little difficult immediately to follow, being divided into parts, each with a series of numbers, covering individual sections of the book.

A. S. DOUGLAS.

HEALING OF WOUNDS

The Mechanisms of Healing in Human Wounds. By Shattuck W. Hartwell, B.S., M.S., M.D., Ph.D., F.A.C.S., F.I.C.S. (Pp. 166 + xii; illustrated. 34s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1955.

This monograph presents a practising surgeon's mature conclusions on the healing of wounds. Over the past 30 years the author has made numerous experimental and clinical studies of this subject, and these are summarized here in a readable and attractive form. The approach is teleological and qualitative, and though the style is discursive this is not inappropriate in a monograph.

On the basis of extensive histological studies of human wounds in various stages of healing, the author draws attention to the difference between repair of human skin and that of animals (upon which textbook descriptions commonly rely). The dense subcutaneous fatty layer which binds human skin to underlying structures has no counterpart in laboratory animals. To this difference the author ascribes his observation of a type of primary healing peculiar to man (and possibly the pig). This contrasts with "primary healing" in laboratory animals, which is more akin to secondary healing in man. Repair is considered as a cellular activity—the cells of the epidermis having a propensity to migrate so as to cover surfaces. In deeper tissues wandering cells thought to be derived from lymphocytes are responsible for the deposition of collagen. When there is a "space effect" due to dead material, fluid, or air, secondary repair occurs, with increased vascularity, fibrinous exudate, and eventual bridging of the gap by collagen. Filling in of the "space" continues until limited by an epithelial layer. The author reviews the healing of different human tissues and discusses appropriate treatment in the light of the principles he describes. The book does not claim to be exhaustive; chemical factors, for instance, are dismissed in half a page with the robust clinical justification, "The clinical surgeon is not yet in a position to alter them as might be indicated even if he could investigate them." It is also not always clear which statements are based on observation and experiment and which are matters of opinion. Nevertheless, student, surgeon, and research worker will find in this book an infectious enthusiasm for this important subject, and may with profit be led to reflect on the processes which surgery affects and induces.

J. P. BULL.

HEAD INJURIES

Head Injuries and Their Management. By Francis Asbury Echlin, M.D., C.M., M.Sc., Med.Sc.D., F.A.C.S. (Pp. 127 + x; illustrated. 24s.) Philadelphia and Montreal: J. B. Lippincott Company. London: Pitman Medical Publishing Co. Ltd. 1956.

The preface and introduction set out the purpose of this brief monograph. The contents more than justify this purpose in 107 small pages. At first I carried this little book around in my pocket and read it at odd intervals as the author and publishers obviously intended. It deserves much more than such peripatetic attention. Later it won a place by my chair near the fire at home. It is light in the hand, but at intervals should be laid down as one remembers various patients with head injuries of the types it describes so clearly. The book ends with an excellent bibliography covering world literature, and has a good index.

In every way this is a first-class book, short, clear, and concise. The subject is not an easy one to teach or to understand. On this account alone this work can be recommended to teachers, undergraduates, and all in any way responsible for the care of this common group of injuries.

WILLIAM GISSANE.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY APRIL 13 1957

"NOTHING WHATEVER ON THIS MATTER OF SPENS"

The consultants and specialists of this country, through their Standing B.M.A. Committee, last week endorsed the Council's recommendation to boycott the Royal Commission in present circumstances. This decision was backed by an overwhelming majority after a careful and thoughtful discussion lasting about three hours, during which the Central Consultants and Specialists Committee was addressed by Sir Russell Brain. The C.C.&S. Committee represents some 20,000 doctors working in the hospital service of this country, and its decision last week means that the Council of the B.M.A., under its chairman Dr. S. Wand, can now go to the Special Representative Meeting in May with the consultants, the general practitioners, and the medical officers of health solidly behind it. The final responsibility for policy rests, of course, with the Representative Body. But unless there is a radical change in the present position the R.B. is unlikely to act otherwise than in full support of the Council's recommendation.

If anyone still has any doubt of the wisdom of this recommendation it should be removed by a reading of the debate in the House of Lords last week. Lord Moran went straight to the heart of the matter by attacking, with cogent argument, the terms of reference of the Royal Commission.

"If the Royal Commission interpret their terms of reference," he said, "so that they are not required to pay regard to what has happened in the past, if they are going to make a fresh start dealing merely with future scales—if, in a word, they are going to ignore these obligations, then I say deliberately that they are wasting their time; they will not allay the discontent among the doctors, nor will they provide a lasting solution of this question of remuneration."

Asking that even at this late hour the terms of reference should be changed, Lord Moran remarked: "I press this matter because, with the present terms of reference, we shall get nowhere." And it is precisely because of this that the B.M.A. Council is

recommending to the Special Representative Meeting that in present circumstances the Association should not co-operate with the Royal Commission. It would be futile to co-operate if "we shall get nowhere": we should end up in Erewhon. It would be stupid, and even dangerous, because we should be attempting to co-operate on terms of reference that had been settled by one side only to the present dispute—the Government, the employer of doctors in the N.H.S. The terms of reference are the Government's terms of reference, and, in Lord Moran's words: "Apparently the findings of this Royal Commission are to be taken seriously only if they are in the Government's favour." The considerations with which the Commission will examine the doctors' case "boil down to a specific comparison with other professions." Lord Moran ended his analysis of this by saying, "It is surely quite wrong." Lord Jowitt and Lord Conesford also both agreed that this wrong could not be made right "by an exchange of letters or anything of that kind." The words of the terms of reference are there for all to read. The profession has been informed with customary curtness that they exclude medical officers of health, although according to the words used they should be included. This arbitrary dismissal of a section of the medical profession is surely in itself enough to convince doctors that they should not—in present circumstances—co-operate with the Royal Commission. To do so would be to betray some of our colleagues.

What kind of defence did the Earl of Home put up for the Government in reply to Lord Moran and other critics? He began by saying that, "It is the first time it [the State] has had to work out a relationship with one of the great skilled professions, and inevitably, I suggest, it must take time. . . ." But the apparent task of the Royal Commission is to work out the relationship of the medical profession, not with the State, but with other professions and with "connected occupations." Lord Home, having said he does not believe it is possible to insulate one profession against the effects of inflation, then goes on to make the following statement: "But, short of the happy day when we achieve a halt to inflation, the best we can do is to try to make as sure as we can that no section of wage earners or salary earners is put at a relative disadvantage with regard to any other section of comparable skill and attainment." This is getting very near to Spens. In the face of the approaching nationalization of—in Lord Home's words—"one of the great skilled professions," the two Spens Committees, in their recommendations, took into account the past financial expectations of doctors, postgraduate training and

qualification, and the desirability of maintaining the proper social and economic status and power to attract suitable recruits. Their specific recommendations were to be adjusted in "direct regard not only to estimates of the change in the value of money but to the increases which have in fact taken place since 1939 in incomes both in the medical and in other professions"—to quote the Consultant Spens Report. It is necessary to go on repeating these recommendations, as, with Lord Moran, we believe they "cannot be thrown upon the dust-heap just because they have subsequently proved inconvenient," though we think Lord Moran is not right in thinking that a section of the medical profession wants to bind the Government in perpetuity to a "literal interpretation of Spens," especially as he interprets this as follows: "That every rise in the cost of living will be met by a rise in the salaries of doctors." The present claim is based on a rise in cost over five years, and even then the Chairman of Council, Dr. Wand, has made it clear that the profession is not insisting on its pound of flesh according to the bond, but is willing—and even anxious—to submit the whole matter to arbitration. Lord Jowitt urged this course in the debate in the House of Lords last week, but, in urging doctors "to stop all this talk of a strike and to accept the principle of arbitration," he seems to have forgotten that it is the profession itself that has ceaselessly been urging this principle. The Government reply in the Lords debate was completely unsatisfactory: at the end of it Lord Moran said, "I go away by the same door by which I came in, with no surety about the awards, and nothing whatever on this matter of Spens." That is why the profession must have nothing to do with the Royal Commission in present circumstances.

WITHDRAWAL FROM SERVICE

Support for withdrawal of general practitioners from the N.H.S. in the absence of a satisfactory settlement of the claim or of arbitration is coming in from all over the country. And the most encouraging support has come from the recommendation of the Hospital Medical Staffs Defence Trust that consultants and S.H.M.O.s should contribute 5% of their hospital remuneration to a special fund for assisting general practitioners in their action. In some divisions, as in the correspondence columns, there has been criticism of the scheme for withdrawing from the N.H.S. No one can pretend to like the idea or to be happy in seeing a skilled and learned profession resorting to this measure in defence of its rights and in pursuit of its just claims. But that it has been forced to consider such a step is the most powerful

indictment there could be of the parlous position in which it finds itself as a nationalized profession controlled in the details of its employment by party politicians. Medicine is, in fact, no longer a free profession. It has sacrificed so much that it seems of little account to sacrifice one of the few things left to it—what is called "dignity." But when a monopoly employer repudiates a contract, refuses to discuss terms, refuses to negotiate, denies us the ultimate resort to arbitration, sets up his own apparatus of determining terms—what possible courses of action are open to the few thousand he employs? Our negotiators presented to the Ministry of Health last year a carefully argued case based upon expert economic and legal advice. All the Minister of Health did was to reject it without even considering it. Words, written and spoken, have simply had no effect upon the profession's masters. Nor have they taken any heed of the criticism and advice they have received in the Press and in the House of Commons and the House of Lords. So the profession has, with the greatest reluctance, been driven to resort to a threat of withdrawal from the N.H.S. on the part of general practitioners. When this present grave and deepening crisis is past it may be hoped that a National Health Service will be evolved that will make this kind of thing highly unlikely. The B.M.A. is not a moment too soon in its decision to set up a wide-ranging inquiry into all aspects of the N.H.S.

PULMONARY ARTERIAL PRESSURE

The blood pressure within the lesser circulation excites increasing attention. The introduction of cardiac catheterization has allowed accurate measurement of vascular pressures within the lung, and disorders of the pulmonary circulation have been extensively studied during the last ten years. The average normal blood pressure in the pulmonary artery is 16/7 mm. Hg, the maximum normal is 30/15 mm. Hg, with reference to the sternal angle,¹ when measured by a cardiac catheter introduced into the pulmonary artery via an arm vein, and connected to a suitable manometer. The pulmonary artery pressure depends upon the output of the right ventricle and the resistance to flow offered by the pulmonary vascular bed. The resistance is normally low, so that the increase in cardiac output on effort is not accompanied by any increase in pressure in the pulmonary circuit.^{2,3} Pulmonary hypertension, by definition, exists when the pulmonary arterial pressure exceeds the maximum normal value (30/15 mm. Hg), and can result from either considerable increases in pulmonary blood flow (as in congenital heart disease with left-

to-right shunt) or from an increase in resistance within the pulmonary vascular bed, or from a combination of both factors.

Pulmonary hypertension resulting from an increase in pulmonary vascular resistance may be due to an increase in left atrial pressure, as in mitral stenosis and left ventricular failure, or to an increase in precapillary or arteriolar resistance due to narrowing of these vessels, which may be organic or functional, or a combination of both. The factors responsible for pulmonary vasoconstriction are imperfectly understood. Evidence from animal experiments,^{4,5} and from clinical studies of the effect of ganglion-blocking agents on the pulmonary circulation,⁶⁻⁸ suggests that such vasoconstriction is neurogenically maintained, though this has been denied.⁹ The pulmonary vascular resistance may be modified by other drugs. A rise in pulmonary arterial pressure due to an increase in resistance can be produced by drugs such as noradrenaline, while tolazoline, aminophylline, and acetylcholine can cause a fall in pressure.¹⁰ Many drugs, especially ganglion-blocking agents, also cause a fall in both systemic and pulmonary resistance. Caution is thus needed in ascribing a reduction in pulmonary resistance to the blocking of a neurogenic mechanism by such drugs, unless the fall in pulmonary resistance is greater than the fall in systemic resistance. Undoubtedly factors of a local nature may also be implicated, especially hypoxia due to a low tension of alveolar oxygen. Pressure in the pulmonary arteries increases after hypoxia, and this hypertension is usually considered to be due to an increase in vascular resistance,^{11,12} though an increase in flow may also be responsible.³ Pulmonary precapillary resistance increases in severe mitral stenosis, in certain types of congenital heart disease (notably patent ductus arteriosus and ventricular septal defect), in chronic pulmonary disease, and when the small vessels are obstructed by thrombo-embolic lesions or neoplastic or other emboli. The condition known

as idiopathic pulmonary hypertension is characterized by a striking increase in arteriolar resistance, leading eventually to failure of the right ventricle. The causes are not fully understood, but in most cases there is intrinsic obstruction of the small pulmonary arteries.¹³⁻¹⁵

Respiration also may influence the pulmonary arterial pressure. Since the pulmonary artery pressure reflects the stroke output of the right ventricle, and since the flow rises in inspiration and falls in expiration, the pulmonary arterial pressure will vary similarly, though during quiet respiration the pressure swing is very small. Respiratory activity may also influence resistance to blood flow through the lungs, for the changes in intra-alveolar pressure during breathing act on the pulmonary capillaries, causing variations in the pulmonary vascular resistance and hence the arterial pressure.¹⁶ Rodbard and colleagues¹⁶ have recently studied the respiratory fluctuations of pulmonary arterial pressure in a number of patients with various cardiovascular disorders. They noted that the swings of pulmonary artery pressure with respiration were increased in patients with pulmonary hypertension due to left ventricular insufficiency, mitral stenosis, or cor pulmonale, but fluctuations were within the normal range (average 5 mm. Hg) in patients with ventricular septal defect and pulmonary hypertension, and in those with pulmonary stenosis. They were unable to explain these differences, but noted that in the group with wide respiratory swings of arterial pressure there was usually pulmonary hypertension and congestion. It is known that the lungs are unduly stiff and the work of breathing is increased in mitral stenosis,^{17,18} and this might exaggerate the normal respiratory swing in pulmonary arterial pressure. Rodbard and colleagues¹⁶ believe that in chronic pulmonary disease the greater resistance to air flow and the reduced lung compliance cause an increase in the respiratory excursions and therefore the fluctuations of arterial pressure. By contrast, no such respiratory anomalies have been noted in pulmonary stenosis or severe pulmonary hypertension with ventricular septal defect, and patients with these disorders were found to have normal respiratory fluctuations of pulmonary arterial pressure. These authors suggest that the assessment of the degree of fluctuation of the pulmonary arterial pressures with respiration might form a useful test for distinguishing cases in which the pulmonary vascular resistance is increased at arteriolar level from those in which it is increased at post-capillary level. However, this is probably an oversimplification of the problem, since in many circumstances both pre- and post-capillary increases in resistance are present, as

frequently occurs in mitral stenosis. This work is valuable in drawing attention to the influence of respiratory factors on the pulmonary arterial pressure in health and disease, but much has still to be learnt before the story of pulmonary hypertension is complete, and all the factors affecting pulmonary resistance are fully understood.

HAZARDS FROM AGRICULTURAL CHEMICALS

The use of pesticides in agriculture increases at this time of year. In May and June the most dangerous pesticides such as parathion and dinitro orthocresol (D.N.O.C.) are dispersed in the greatest quantities. But on a smaller scale many insecticides, herbicides, fungicides, and rodenticides are applied for a much longer season in food stores, glasshouses, or in the open.

The same pest may be successfully attacked by chemicals ranging in their toxicity to man from the very dangerous to the virtually harmless, though factors other than danger to the user must determine the choice of any particular material in agricultural work. As a result of a co-operative effort by many people, including the manufacturers, distributors, and officials of the Ministry of Agriculture, Great Britain has had in recent years a good record in the safe use of the more dangerous pesticides. Before jumping to the conclusion that the regulations controlling the use of these materials are superfluous, it is as well to consider what happens elsewhere. In Germany W. Reinl¹ has assembled records of 28 cases of poisoning by organo-phosphorus insecticides among agricultural workers in 1950-5. These included 1 fatal, 3 severe, 7 moderate, and 17 mild cases of poisoning. An analysis of the symptoms showed that headache, dizziness, weakness, nausea, and vomiting were most frequently seen. Though contraction of the pupil has often been cited as a characteristic sign of poisoning by organo-phosphorus insecticides, it was noted in less than a third of these cases. There is indeed a recent report² of two patients with severe parathion poisoning who had dilatation of the pupils when first seen, and this led to some hesitation in making a diagnosis. Full atropinization saved these cases, and atropine must be given in large doses to all suspected cases of poisoning by organo-phosphorus insecticides. If a mild case responds well to atropine the patient must be kept under observation for 12-24 hours, because a single dose of atropine may be of only temporary benefit. The chemicals that can reverse the inhibition of cholinesterase caused by these compounds are still being studied,³ but specific recommendations for their use have not yet been made.

There is no specific treatment for D.N.O.C. poisoning. Cases are most likely to occur in hot weather when farm labourers are working long hours with weed-killing sprays on cereals. The chlorinated hydrocarbon group

of insecticides continue to be used with complete safety in agriculture. Endrin poisoned people who ate contaminated flour,⁴ and dieldrin when carelessly used has poisoned public health workers.⁵ Despite dramatic signs of poisoning, such as convulsions, no deaths were reported, and the margin of safety is apparently wide. Fluoroacetamide, a slightly less toxic derivative of fluoroacetate, is now on the market for anyone to buy, but it is sold as a very dilute solution containing acetamide, which is an antidote to the poisonous effects of fluoroacetamide in rats.⁶

Antibiotics, including penicillin and streptomycin, have been used for some years in agriculture as supplements to pig and poultry feeds.⁷ More recently sprays containing streptomycin have been applied to a number of different crops in the United States to control plant diseases due to micro-organisms. It seems to be generally accepted that the hazards of handling these antibiotics as agricultural sprays are negligible, and there have been no reports of ill effects among agricultural workers. But since nurses handling antibiotics may become sensitized to them this might be a risk also run by men handling concentrated sprays for crops. Whether or not resistant strains of bacteria can develop in persons coming into only casual contact with antibiotics remains to be seen. If preparations containing antibiotics of the type used in clinical medicine are introduced into agricultural practice in Britain, bacteriologists might look for evidence of any harmful developments.

The doctor with agricultural workers among his patients would do well to ask about possible exposure to toxic chemicals when cases of vague illness are reported to him. It may be helpful to ask to see the pesticide container, for the labels of all reputable brands contain much useful information on the properties of their contents. These pesticide containers are an obvious hazard if left within the reach of children who cannot read the labels.

HYPERGLOBULINAEMIA

Many pathological states are associated with increased levels of serum globulin, and clinicians have long used the erythrocyte sedimentation rate, which is in part dependent upon the globulin level, as an index of organic disease. Certain disorders, such as multiple myeloma, sarcoidosis, kala-azar, and some collagen diseases, may be associated with striking hyperglobulinaemia, but the question remains, How informative is precise measurement of the degree of hyperglobulinaemia as an aid to diagnosis? Using the salting-out technique of C. Cohn and W. Q. Wolfson,¹ which gives results in close agreement with the electrophoretic pattern,² A. R. Feinstein and R. G. Petersdorf³ have correlated in 394 patients the clinical diagnoses with the degree of hyperglobulinaemia. They found that when hyperglobulinaemia exceeded 5 g. per 100 ml. nearly half the patients were suffering from one of the diseases known to be associated with a raised level of serum globulin, and that the chances of the patient

having multiple myeloma, sarcoidosis, or a collagen disease were almost 1 in 2. A moderate degree of hyperglobulinaemia with the level of serum globulin ranging from 4.2 to 5 g. per 100 ml. was attributable to these conditions in only about 1 patient in 10, whereas a third of the patients had liver or neoplastic diseases, and the remainder usually had acute or chronic infections. Lesser degrees of hyperglobulinaemia (3.9 to 4.2 g. per 100 ml.) were found in a wide variety of conditions. Fewer than 1 in 10 had multiple myeloma, sarcoidosis, or a collagen disease, and though all had organic disease more than half had conditions not specifically associated with hyperglobulinaemia. From these findings it can be deduced that, when the diagnosis is not clinically obvious, hyperglobulinaemia exceeding 5 g. per 100 ml. should direct investigations towards confirming the presence or absence of myeloma, sarcoidosis, or one of the collagen diseases. Hyperglobulinaemia of 4.2 to 5 g. per 100 ml. will suggest cancer, liver disease, or infections. Lesser degrees of hyperglobulinaemia give little clue to the best lines of further investigation, and serve only to indicate the existence of organic disease.

POST-MATURITY

It is perplexing to all who practise midwifery that, whereas to some doctors post-maturity poses a difficult and not uncommon problem, others dismiss prolongation of pregnancy as of little or no clinical importance. This division of opinion is reflected in the figures collected by Professor F. J. Browne from 20 hospitals over the last decade, figures which he discusses in an article at p. 851 in this issue. For example, in one hospital in which the total deliveries for 1954 were 1,027, 31 women were induced for uncomplicated post-maturity, while in another hospital there were no such inductions among 4,949 deliveries in 1949-50. The difference was apparently not due to resort to elective caesarean section for post-maturity in the second hospital, for its section rate was less than half that in the first. Indeed, the suspicion arises that the more inductions performed the higher the section rate may be, for 6.2% of all the women induced for simple post-maturity were eventually delivered abdominally.

It seems reasonable to regard the perinatal mortality as a good yardstick by which to measure any adverse effects of prolonged pregnancy, but again opposite conclusions can be drawn from different published reports. In one hospital in Professor Browne's series in which there were no inductions for post-maturity the perinatal mortality was low and there were no stillbirths in pregnancies prolonged beyond 40 weeks; while in the hospital where the induction rate was 3% the total foetal loss was relatively high. Discrepancies might arise partly because conditions in different hospitals are never exactly the same; the logical approach, therefore, would be to compare the results of intervention and non-intervention in a single hospital. This was in fact done

by D. Racker and his colleagues,¹ and their figures showed a lower foetal mortality in the group induced soon after term than in the group allowed to await the spontaneous onset of labour. After discussing the many variables concerned, physiological and clinical, Professor Browne offers certain conclusions. He suggests that many cases of so-called post-maturity are really examples of slow maturation of the foetus and placenta, and that to induce labour in these cases may do nothing to improve the perinatal mortality rate. Others may be due to the occurrence of conception in a very long menstrual cycle; but even when the date of isolated insemination is accurately known the conception-to-delivery interval varies widely—from 235 to 298 days according to E. J. Farris.² Finally, Professor Browne believes that the higher foetal mortality in post-mature babies compared with those born at term can be adequately explained by the larger size of the infants and by the longer average duration of labour in the former group.

The debate continues. And in post-maturity, as in most problems in medicine, the opinion and practice of the individual doctor is likely to be coloured by his personal experiences, and in particular to be influenced by an otherwise unexplained stillbirth or neonatal death, even though such occur also at or before term. For the present, perhaps, an old rule of thumb provides as good a guide to maturity as any: if the cervical canal is taken up and the external os is not closed, the patient is near, at, or after term.

TREATMENT OF PARKINSONISM

The syndrome of Parkinsonism is a challenging problem to the physician. Treatment of this distressing condition began on an empirical basis, and there it still remains. The only real progress has been an increase in the number of drugs available. Solanaceous alkaloids were first given for Parkinsonism so long ago as 1882, but they have never been thoroughly satisfactory because, though they may control the symptoms, their effect is transient, and attempts to extend it by increasing the dose cause severe side effects to appear. The action of many drugs may be prolonged by prescribing them on a form which lengthens the period of absorption from the intestine by several hours, and solanaceous alkaloids have been specially prepared in this way for an investigation into the treatment of Parkinsonism.¹ The preliminary report suggests that this classic treatment may return to favour in modern form.

It has been found that synthetic compounds with anti-acetylcholine and antihistamine activity can favourably influence the Parkinson syndrome. One of the first to be tried was diphenhydramine hydrochloride ("benadryl"). Slight modifications of structure have produced

more powerful analogues, the most active of which has the formula β -dimethylaminoethyl-2-methylbenzhydryl hydrochloride ("disipal"). In the clinic where this compound was investigated disipal is regarded as the best drug with which to begin treatment of new patients.² Ethopropazine hydrochloride ("lysivane") has also been shown to produce beneficial results when given by itself.³ Benzhexol hydrochloride ("artane") is more popular in the U.S.A. than in Britain.⁴⁻⁶ Although it has useful therapeutic properties it has been reported to cause severe mental disturbance.⁷ The activity of caramiphen hydrochloride ("parpanit") has been assessed as equivalent to that of the solanaceous alkaloids,⁸ but some clinicians have found it to be one of the least effective of the drugs commonly prescribed. Phenindamine tartrate ("thephorin") has been said to be the most potent of the antihistamine compounds given for Parkinsonism.¹ Another drug for which good results have been claimed is procyclidine hydrochloride ("kemadrin"),⁹ but it has not achieved any great popularity. A recent addition to the range of drugs has been reported from America. It is a synthetic compound named "cogentin," and has the tropine part of atropine united with the benzhydryl part of diphenhydramine. It is said¹⁰ to have a "prolonged potent anticholinergic, antihistaminic action" and was administered to 302 patients with various forms of Parkinsonism. Of those who began treatment four years ago 57% have experienced benefit with few side effects.

The aetiology of Parkinsonism is still obscure, and any classification provides little more than a convenient nomenclature. Similar presenting symptoms may have different causes requiring different treatment, and it is unlikely that maximal improvement will be obtained through the use of any drug by itself. There is no easy road to success; the only way is to persevere with various combinations of drugs until one is found which gives the individual patient the greatest relief. Frustrating as this approach may appear at times to be, there can be few experiences more rewarding to the physician than to see a patient who was helpless from severe Parkinsonism restored to normal activity.

THE NEW ESTIMATES

Total expenditure on the Health Service in Great Britain is approaching £690m. That figure takes into account payments from all sources, rates as well as taxes, patients' charges as well as the contribution from the national insurance fund. A similar gross figure for 1949-50, the first complete year of the Service, was £450m. But as the Minister of Health explained in the House of Commons recently, this increase of 53% is largely due to the rise in prices, of goods and services, in the intervening period. If prices had remained constant, expenditure on the Health Service would have gone up by only 15% in the last seven years. In other words, the real resources used by the Service have increased by 15%; but, as the country's total resources have expanded even more, the proportion taken by the Service has actually dropped slightly.

It is nevertheless the huge gross total of the Service that has prompted the Government to place more of the cost on to national insurance contributions instead of on to the taxpayer or the patient. At present, the share of the contributions from employer and employees that is credited to the Service is £40m., or approximately one-seventeenth of its cost. In 1949-50 the £40m. represented one-eleventh of the cost, and when the Service was being planned it was estimated that one-fifth of the cost should be met by insurance contributions. As the alternatives for meeting the higher cost are increasing the already onerous burden on the taxpayer and raising charges to patients, the Government has proposed instead to double the amount that will come from the national insurance fund. At £80m. this would meet between an eighth and a ninth of the gross total.

Even so, the amount to be met by the taxpayer would be £510m. A year ago, the taxpayer's bill was estimated at £502m., but supplementary estimates in February raised it to £529m. If, therefore, the proposal to increase the insurance contribution goes through, the taxpayer will be saved nearly £20m. in this financial year. Nearly £1m. of this saving will go to meet the 10% increase in the salaries of junior hospital staffs that came into force on April 1.

Within the Service the estimates¹ are remarkable for the comparative stability shown by the individual items—with the one exception of the hospitals. In fact, the pharmaceutical service actually shows a small fall, from £59.4m. to £57.6m., in its net cost. But this reduction has been achieved only by the expedient of charging patients a shilling for each item on the prescription instead of for each form. This has increased patients' payments for drugs from £8.8m. to £13.4m., and had it not been for this increase the pharmaceutical service would have cost nearly £3m. more.

The rise of nearly £3m. in the dental service can be explained by a bigger demand for treatment. But the increase in the cost of the executive council services as a whole—just over £3m.—is completely dwarfed by the rise in the cost of the hospitals. Some of this, £5.6m., is on capital account and represents the carrying out of the hospitals' building programme. But a sum twice as big is needed for the estimated extra cost of maintaining the hospitals in the new financial year compared with the year just ended. The additional £11m. will bring the total advances to hospital boards for hospital maintenance to £371.5m., or about 54% of the total gross cost, compared with 45% in 1949-50. Presumably this growth in the hospitals' share of Health Service resources is largely inevitable. But it is worth emphasizing, as we have done before, what a large proportion of the hospitals' costs is accounted for by the salaries and wages of staffs other than doctors and nurses. Doctors' salaries are estimated at £39m. in 1957-8 and nurses' at £90m. But all other salaries and wages, excluding the central administrative expenditure of management committees and boards, amount to £108m.

AGEING AND OLD AGE

SYMPOSIUM AT LIVERPOOL

[FROM A SPECIAL CORRESPONDENT]

An opportunity for people of different disciplines but with a common interest in the problems of ageing to compare their views was afforded by a recent symposium organized by the Department of Studies in Psychological Medicine of Liverpool University. The symposium was held in the University Department of Civic Design on March 23. The joint chairmen were Dr. S. BARTON HALL and Dr. F. HOPKINS, and the speakers included a psychologist, a medical officer of health, and a psychiatrist.

Too Old at 25

The need to regard ageing as a continuous process which starts soon after maturity is reached was stressed by Dr. ALASTAIR HERON (Liverpool), deputy director of the Medical Research Council Group for Research on the Occupational Aspects of Ageing. In the past too much attention had been paid to the end product of the ageing process rather than to the process itself, he said. There was little justification for the view that ageing begins at some arbitrary point such as the age of 65. There were other crucial ages, and some of us had already passed them. Muscular strength would appear to be at its maximum in the late twenties, while some signs of hearing loss were often apparent in the early forties. Similarly deterioration occurred throughout life in visual perception. These physiological changes were paralleled by changes in mental capacity. There was a slow but steady fall in the average score on standardized intelligence tests after the age of 25, while the prolongation of reaction time in the elderly was almost certainly due to differences in the way the ageing individual coped with incoming information. Emotional differences demonstrated on projection tests such as the Rorschach and the thematic apperception test might represent changes in our attitudes and values as we grew older.

Practically all the available data on these mental and physical changes had been obtained by comparing groups of different ages on a single occasion. This, of course, provided no satisfactory evidence on age-changes but only on age-differences, and there was thus a need for intensive longitudinal studies in which the same people were followed throughout life. Such studies did not produce information quickly, and the subjects might well outlive the experimenter. This difficulty could be overcome to some extent by following groups of people of different ages over a period of years. That was what members of the M.R.C. Group at Liverpool were now doing. They were studying the auditory, visual, and intellectual responses of a sample group of volunteers.

Dr. Heron ended his address by referring to the problem of the ageing industrial worker. This was of particular importance nowadays. Physical efficiency was likely to be affected less than mental efficiency, but forms of work where speed was important put a special strain on the elderly. Automation would also pose many problems for the middle-aged worker, as the new electronic devices put a premium on mental rather than manual skills. At present training in industry was "youth-oriented," but training schemes for the middle-aged were also wanted if the latter were to keep up with industrial change.

Services for the Aged in Liverpool

Professor A. B. SEMPLE (Liverpool) discussed the social problems of the elderly as seen in a large city. Isolation, economic difficulties, inadequate diet and housing, and the absence of employment were, in his view, the most important. Physical disability had a particularly bad effect on those who lived alone, as after a time they limited their journeys and eventually did not go out at all. This led them to restrict their diet to milk and bread, commodities usually delivered to the door. In these circumstances home visiting became

very necessary, and in Liverpool they had a friendly visitors service, so that every old person could have a regular visitor if he wanted. This was supplemented by a scheme whereby a friend or neighbour acted as a "signaller," whose job it was to inform the health department if the old person needed help. The domestic-help service also devoted much of its time to the elderly. Here the aim was to get the old person to live as normal a life as possible by taking him shopping and cooking a meal with him in his own home. This was often preferred to having a meal brought to the door by a mobile service.

There was not nearly enough suitable housing for the aged, continued Professor Semple, and, although housing authorities were aware of the problem, they had not yet shown a very realistic approach to it. It was important to restrict accommodation in residential hostels to those who did not need nursing care; if nursing was needed then the proper place was a bed in a hospital for the chronic sick. Lack of mental and physical effort quickened the pace of degeneration, and there was much to be said for a system of employment for the elderly as a health project. Similarly, the value of maintaining outside interests as a preventive against social isolation could not be over-stressed. Such interests were best established in youth or middle age, when enthusiasm was greater and active participation easier.

Importance of Accurate Psychiatric Diagnosis

Professor MARTIN ROTH (Newcastle upon Tyne) spoke on mental disorder in the elderly. This was one of the few forms of mental illness, he said, which we could be reasonably certain had increased in prevalence during the last fifty years. Even so, the increase might well be more apparent than real and due to the greater tendency nowadays to admit to mental hospitals old people who formerly would have survived at home.

It was of primary importance that the diagnosis of mental illness in later life should be accurate. A distinction was usually possible between a gradually developing senile psychosis and an arteriosclerotic psychosis, a condition in which about half the cases showed focal symptoms and signs in addition to dementia. No longer should it be accepted that mental disorder in old people was necessarily always due to arteriosclerotic or degenerative changes. Affective illness in old age had the same good prognosis as it had in young people and responded well to electric convulsion therapy. It was also important to differentiate between delirious states and dementing processes. If the picture was a delirious one then there was generally some specific illness the active treatment of which might decide whether the patient lived or died. A patient who presented as a deluded dement might, for instance, really be suffering from cardiac failure, the treatment of which could ultimately lead to his discharge from hospital. The mortality from delirious states in old age was high, so when there were delirious features a particularly careful search should be made for any specific physical factor which might be treatable.

The electroencephalogram gave some help in differentiating the forms of mental disease in old age. In affective psychosis at all ages the electroencephalogram was essentially normal, while in cases of senile degeneration there might be little change apart from slowing of the alpha rhythm to 6-8 cycles per second. It was in the differential diagnosis of confusion and dementia that the electroencephalogram was most useful, some 40 to 50% of confused cases showing high-voltage, rhythmic, slow waves, predominantly from the frontal region. In arteriosclerotic psychosis such changes were absent in a quiescent phase, but during a phase of acute confusion there might be similar changes, though often with minor asymmetries such as a focal abnormality; or these might develop as the confusion died down.

Unsolved Questions

Dr. R. KEMP (Liverpool), in the discussion, asked whether old people could not be adopted in the same way as children,

but Dr. P. SHAW (Nottingham) said that in Nottingham boarding out had failed to work. It was even more difficult to match old people with a family than it was to match children with foster-parents. They had found in Nottingham that an occupation-centre and day-hospital were of great value, particularly in relieving families of the burden of old people during the day. This had made it possible for many elderly psychiatric cases still to be cared for at home.

Dr. W. E. KERSHAW (Liverpool) said that in most biological systems protected from severe hazards mortality rose with age in such a manner that the logarithm of its rate had a linear relation to time. Because of their concern in tropical medicine with such factors as the fertility of insect vectors, the capacity of a vector to support a parasite, its flight range, and its ability to take repeated blood meals, they had investigated the survival of various physiological functions. All had shown a similar pattern of survival, with the logarithm of the mortality rate linearly related to time. They would like to know more about the relation between failure of physiological functions and death, and data derived from the psychological assessment of the elderly and from the development of psychiatric conditions in old age would probably yield information of value.

Many other points were raised in the discussion. It was generally agreed that some form of residential accommodation half-way between a hostel and a hospital was required for the elderly psychiatric patient, where he could receive nursing care. No one could explain why women live longer than men, although some speakers thought that endocrine factors were responsible. This discrepancy often leads to hostels for the elderly having a preponderance of contented women and a minority of discontented men. Why do some people grow old gracefully and remain mentally alert even in their nineties? This was still a puzzle, and, although many speakers thought that it was a matter of personality and temperament, on the whole the meeting felt that there was much more to it than that. Obviously much more data and research are needed in this field, and more meetings of interested workers as at this successful symposium.

Nova et Vetera

THE GREAT FAMINE

The Great Famine lasted from 1844 to 1850, and was a tragedy for both Ireland and England. This book,* which examines its historical, social, economic, political, and medical aspects, is written by a group of scholars predominantly, if not all, Irish. It is judicious and moderate in tone, singularly impartial, and points out that English handling of the problem was dictated by humanitarian principles and advanced for the time. But it was misdirected by ignorance of Irish conditions and difficulties, and based on economic theories which were quite inapplicable to Ireland. The British Government hesitated and delayed, and 4,000,000 persons were brought to the verge of starvation, while thousands died of famine and fever.

It was not until 1847 that soup kitchens and depots for free food were set up; relief works were a failure and badly administered. Too often the famine-stricken men died at their work. Disastrous too were the wholesale evictions which followed when the famine ceased. Unwilling emigrants were driven out of Ireland, mostly to America, by the hundred thousand, cherishing animosity for the Anglo-Irish land-holding classes and for the government which had done nothing to prevent their expulsion.

The cause of the famine was a fungus disease of the potato due to *Phytophthora infestans*, which appears in the

**The Great Famine: Studies in Irish History, 1845-52*. Edited by R. Dudley Edwards and T. Desmond Williams. (Pp. 517+ xvi; illustrated. 30s.) Dublin: For the Irish Committee of Historical Sciences by Browne and Nolan Ltd. 1956.

form of black spots on the leaves, with, on the under surface, a whitish mould containing the spores. These are conveyed by wind, rain, and insects. The potato was almost the sole food of one-third of the population and a main article of diet of a much greater number.

In Chapter V Sir William MacArthur, with his wonted literary skill and erudition, graphically describes the medical history of the famine. The diseases which followed in its train were typhus, relapsing fever, dysentery, scurvy, and famine dropsy, while in 1848-9 there was an outbreak of imported cholera. Sir William MacArthur considers that nearly a million persons died from famine and its consequences during the whole famine period. He describes the medical organization and arrangements that were made, the provision of fever hospitals, and attempts to limit the spread of infection. But, he adds, in the absence of modern knowledge of louse-borne infection and its prevention "no board of health at that date, even if given dictatorial powers and unlimited funds, could have brought the epidemic to a speedy and dramatic end." Finally he quotes that great Irish physician William Stokes, who said: "We cannot be suddenly wise. Nations as well as individuals must purchase experience, even though the cost be ruinous. And whatever fault we may find with the methods adopted for relief to the sufferers in the famine of 1847, we must applaud the intention, and be grateful for the efforts that were made."

ARTHUR S. MACNULTY.

Reports of Societies

DISORDERS OF THE PANCREAS

DIAGNOSTIC FEATURES

The Section of Medicine of the Royal Society of Medicine discussed the diagnostic features of some pancreatic disorders on March 27. Dr. C. E. BEAUMONT, president of the Section, was in the chair.

Relapsing Pancreatitis

Dr. T. C. HUNT (St. Mary's Hospital) confined his remarks to chronic relapsing pancreatitis, a relatively uncommon disease but one extremely difficult to diagnose. There were several reasons for this difficulty, he said. Chronic pancreatitis probably embraced a number of syndromes with a broad spectrum of symptomatology. It was often associated with—and mistaken for—gall-bladder disease, peptic ulceration, and neurosis. Nor were there any precise diagnostic tests on which the clinician could rely. Relapsing pancreatitis came to light most commonly in the middle forties, though it could occur at the extremes of life. Men and women were equally affected. There was often a long history of recurrent symptoms, of which pain was the most outstanding, before the diagnosis was made. The pain was severe, usually continuous, but it might be spasmodic and difficult to distinguish from colic. In the majority of patients it was situated in the centre of the abdomen and radiated through to the back. It never radiated into the neck or arms, an important point in differentiation from myocardial infarction. A characteristic feature was that sitting up often relieved the pain. Loss of weight and vomiting were common, but, in contrast to peptic ulcer, vomiting did not relieve the pain. Attacks of pain lasting only a few days and failing to respond to alkalis were other useful diagnostic points.

It was not sufficiently realized that chronic pancreatitis might be a cause of gastro-intestinal bleeding, though it was difficult to explain why this should happen. The classical triad of steatorrhoea, glycosuria, and pancreatic calcification was diagnostic, but quite uncommon. Chills, mental and physical fatigue, but excessive alcohol intake might be

precipitating factors, but, although patients tended to avoid fats, there was no evidence that they played any part in causing the disease.

Cancer of the Pancreas

Mr. RODNEY SMITH (St. George's Hospital) spoke about some of the surgical problems in the diagnosis of carcinoma of the pancreas and chronic pancreatitis. The common textbook description of painless jaundice as the presenting symptom of carcinoma was erroneous, he said. In fact pain was very common and occurred as the first symptom as often as jaundice. Those cases in which pain was absent, however, had the best prognosis so far as surgery was concerned. The jaundice was not necessarily progressive, and intermittent relief could result from sloughing of necrotic areas of carcinoma. A distended gall-bladder was not always palpable, so that failure to palpate this organ did not rule out the diagnosis. Radiological examination of the duodenum, with special attention to the mucosal pattern, could sometimes be helpful. In a very few selected patients with obstructive jaundice transhepatic cholangiography, combined if necessary with a barium meal, was of value, though there was a definite risk of leakage of bile into the peritoneal cavity.

Even at operation the diagnosis could be difficult, especially if the tumour was small and eminently suitable for resection. A hard pancreas could be due either to carcinoma or to chronic pancreatitis. It might well be necessary to open the duodenum, and even to perform a transduodenal biopsy of the pancreas, in order to make a definite diagnosis. Biopsy should never be attempted through the pancreas itself because of its unreliability and the risk of producing a fistula. Inspection of the common bile duct could yield valuable information. It was usually dilated, thin, and translucent in neoplasm; often thickened, white, and with adherent peritoneum in chronic pancreatitis.

Chronic Pancreatitis

Chronic pancreatitis, continued Mr. Rodney Smith, could present in many different ways. At one extreme was the patient suffering recurrent acute attacks with pain, fever, leucocytosis, and a raised serum amylase, and at the other the syndrome of chronic pain with calcification of the pancreas. In between were the difficult cases, where the serum amylase was normal and tests of pancreatic function were of no help. Laparotomy was often the only conclusive investigation. The surgeon exploring the abdomen must be prepared to give a definite answer on whether chronic pancreatitis was present, and should make every effort to demonstrate the cause.

In chronic pancreatitis the pancreas was hard and rounded, with adherent peritoneum and peripancreatitis. The biliary system should be explored, and a case could be made out for operative cholangiography and pancreatography. Reflux of bile into the pancreatic duct was common, and Mr. Rodney Smith showed a ciné film demonstrating this by means of diodone injected into the bile duct. Interestingly enough, as he pointed out, the patient experiences pain immediately the dye enters the pancreatic duct. This did not appear to be due to a rise in pressure, since secretin, which increases the pressure in the duct system, caused less pain provided the pancreatic reflux was reduced as a result. Similarly splanchnic block would inhibit pain but had no motor effect on any hypothetical sphincter.

"Mucosis" and Other Pancreatic Disorders of Childhood

Dr. MARTIN BODIAN (Great Ormond Street) reviewed the necropsy material from children dying with diseases of the pancreas. Fibrocystic disease was by far the commonest, but he stressed that the pancreas was only one among a number of organs involved in a widespread disorder of mucus secretion (inherited as a recessive characteristic), which he called "mucosis." For some reason the mucus

was more viscid than normal, and this led to its retention, pseudocyst formation, with subsequent atrophy and necrosis of secretory elements and fibrosis. Ultimately the pancreatic remnant became embedded in a thick layer of fatty tissue. It was important to realize that there was no atresia of the pancreatic duct in this condition. Similar changes occurred throughout the alimentary tract and its adnexa and in the lungs—in fact, in any organ containing mucus-secreting glands. The salivary glands, for example, were involved, though this produced no symptoms. Obstruction of biliary ducts within the liver led to focal biliary fibrosis, and later to more generalized cirrhotic changes. A curious feature, so far unexplained, was that the sweat contained increased amounts of sodium and chloride. Involvement of the lungs was probably the most important single factor, because of the susceptibility to every variety of respiratory infection. The introduction of antibiotics had done much to prolong the life of these children.

By contrast with fibrocystic disease, other pancreatic conditions were uncommon in childhood. Congenital hypoplasia and cystosis might rarely be the cause of symptoms of pancreatic insufficiency. Interstitial pancreatitis could be produced by various factors, of which congenital syphilis was the commonest. Occasional cases were caused by virus infection, vascular disease, and ascending infection of the pancreatic duct associated with gastro-enteritis.

Reflux of Bile

In the discussion which followed it was agreed that reflux of bile into normal pancreatic ducts did not cause trouble, so that chronic pancreatitis must result from the effect of reflux on passages which had already been damaged during the initial attack. Sphincterotomy might relieve symptoms, but if after a suitable interval there was no improvement division of the common bile duct and its insertion into some other part of the small bowel might have to be considered. None of the speakers had much faith in the value of secretin tests or serum amylase estimations in diagnosis; the latter might not rise even in acute pancreatitis.

Preparations and Appliances

METAL CATHETER GUIDE

Mr. J. D. HENNESSY, urological registrar, United Birmingham Hospitals, writes: The whistle-tip type of catheter has now largely replaced all other types of urethral drainage of the bladder following retropubic prostatectomy and other open operations on that organ. It more readily facilitates the removal of any clot formed in the bladder. It is our custom to use a No. 22 or No. 24 Charrière neoplex catheter. On occasion, however, we have found difficulty in passing this catheter beyond the membranous urethra and have had to resort to using a Tieman catheter.

A brass guide shaped like the tip of a Tieman catheter has been made in the hospital workshop and attached to the whistle-tip catheter (as illustrated). In our last thirty retro-

pubic prostatectomies this has been found an excellent method of guiding this catheter into the bladder, the guide then being removed.

A similar fitting could easily be made to suit the funnel-shaped open end of a urethral catheter so as to guide it in a retrograde fashion along the urethra during a suprapubic operation for those who wish to use such a method.

I thank Dr. L. T. Clarke for stimulating thoughts in this direction, Mr. W. H. Biffen for the manufacture of the instrument, and Mr. T. F. Dee for the photograph.

LATHAM TUTOR FOR HOLGER NIELSEN METHOD OF ARTIFICIAL RESPIRATION

Dr. M. A. DOBBIN CRAWFORD, medical officer, Ministry of Supply, writes: Recovery from asphyxia often depends upon the immediate application of artificial respiration, and the efficacy of this treatment rests largely upon the skill of the operator. The recent enthusiastic adoption of the Holger

Nielsen method of artificial respiration has not resulted in its comprehension by the majority of first-aiders; they lack a precise, controlled technique.

A simple apparatus, of great use in training, has been devised to instil control of rhythm, posture, and the weight to be applied. A surface model in wood, of the head, arms, and upper chest, is so made that pressure upon the region of the shoulder-blades is recorded on a dial visible to the operator in a mirror, and the dial is calibrated to indicate the proper weights. The posture of the casualty is correct; the arms lift at the shoulder and are jointed at elbow and wrist. Perfect timing and rhythm can be practised *ad lib.*, without a demer from the casualty, and the proper weight to be leaned upon his back will soon be

appreciated by the attentive student. The Latham tutor has been seen and approved by Dr. K. W. Donald, secretary of the Resuscitation Committee of the Medical Research Council.

This apparatus is readily portable, neatly packed in a light wooden cover. It has been invented by Mr. A. H. Latham, a voluntary and experienced first-aid, who has gained his instructor's certificate and is on the staff of the Ministry of Supply. It is being manufactured by Messrs. Siebe, Gorman and Co. Ltd., Neptune Works, Davis Road, Surbiton, Surrey.

Correspondence

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

Premature Induction in Haemolytic Disease of Newborn

SIR,—Dr. O. D. Fisher's communication (*Journal*, March 16, p. 615) does no more than confirm that premature induction of labour leads to a reduction in the number of stillbirths but to an increase in neonatal deaths from this cause. His series does not provide a valid comparison between the use of premature induction and spontaneous delivery in the management of Rh iso-immunization. Although clinical assessment was carried out in each case, we are not told the criteria for selection and are left to surmise to what extent induction was determined because of admission to Professor Macafee's unit. If the groups "induced" and "spontaneous" are indeed comparable must one imagine that increased need for exchange transfusion in the induced group was a consequence of induction? It is implied that the more severely affected cases were induced, but we can only guess how this was achieved and how the optimal time for induction was determined. Surprisingly, 28 out of 76 induced cases were delivered after 38 weeks' gestation, but 22 (including 7 of the 12 stillbirths) out of 63 spontaneous cases were delivered before this time. Only 4 out of 17 stillbirths occurred before 36 weeks. This suggests that some early stillbirths were delivered elsewhere, for superficially it would seem that 143 cases represent less than 70% of the number expected in Belfast alone in the five years under discussion.

In a disease so diverse in effect individual cases have little meaning when related to the problem as a whole—e.g., in cases 1 and 2 it is quite likely, having reached 37 weeks' gestation, that the result would have been similar if spontaneous delivery had been allowed. That Dr. Fisher himself found it difficult to decide the optimal time for induction is illustrated by his other case history.

Before embarking on a policy of premature induction one must weigh the probable reduction in the number of stillbirths against the increased neonatal loss. We found that 268 stillbirths occurred in 1,692 cases of haemolytic disease between 1948 and 1956, an incidence of 16%, which corresponds with other estimates.^{1,2} We found, moreover, that 50% of these (taking into account those foetuses dead or hydropic although not delivered) occurred before 35 weeks' gestation, and therefore premature induction at this time can at best provide only half of the answer to this problem. If, e.g., one were to induce 100 immunized Rh-negative mothers at 35 weeks' gestation one might prevent eight stillbirths, for which reward 92 mothers and babies would have been exposed to the risks of premature induction, and, to quote Fisher, the babies exposed to "the hazards of prematurity." It would only require a neonatal death rate similar to that of Fisher (15%) to mean that this had been in vain.

An alternative approach is to reserve premature induction for cases where stillbirth is almost inevitable, but as yet there is no certain method for predicting this. We have found the previous obstetrical history of value, for, although the overall risk of stillbirth is 16%, the risk in a mother developing antibodies for the first time is only 8% and where a previous baby has been mildly affected only 2%. Having analysed 896 cases observed by us in the past four years, we find that 70% of all cases of haemolytic disease fall into this category, and it is doubtful whether premature induction is ever justified in such families. At the other extreme the risk of stillbirth following stillbirth or very severe disease is between 50% and 80%. These account for 10% of all cases of haemolytic disease, and in these we feel that premature induction is justified.⁴ In the remainder,

preceded by disease of sufficient severity to have required treatment, the risk of stillbirth is 20%–27%, and these (20% of all cases) provide food for thought. It is especially in these that a further method of assessment, whether by antibody titrations, tests on liquor amnii, or other method, is needed.

The time at which stillbirth occurs must also be taken into account, and this varies, the chance of the pregnancy reaching 35 weeks satisfactorily being only 30% following multiple stillbirths but 70% for "first affected" stillbirth. The nearer a pregnancy approaches term satisfactorily the less the risk of stillbirth, so that the later induction is delayed the greater its apparent benefit unless early stillbirths are taken into account. Induction at 37 to 38 weeks can possibly prevent 40% of all stillbirths, but less than 30% of those with a bad obstetrical history.

We still require an accurate method of forecasting stillbirth in haemolytic disease, and, having forecast it, a better method than premature induction to forestall it.—We are, etc.,

Deformities of the Chest

SIR,—Your annotation on deformities of the chest (*Journal*, March 16, p. 637) comments on the little work which has been done in Britain on this subject. After referring to the suggestion of H. A. Brodtkin^{1,2} that funnel chest and pigeon breast might be due to congenital weakness of the anterior segment of the diaphragm the annotation states: "His arguments, though interesting, are mainly theoretical and proof should be forthcoming before they are accepted. It should be possible to learn something from post-mortem studies. . . ."

In his Hunterian lecture at the Royal College of Surgeons of England, May 17, 1956, Mr. E. F. Chin discussed the surgery of funnel chest and congenital sternal prominence.³ I carried out a histological study of muscle biopsies from the anterior portion of the diaphragm taken by Mr. Chin at operation and compared the findings with biopsies from normal controls in the same age group. The histological picture has done a great deal to confirm Brodtkin's work. In the cases of funnel chest the anterior portion of the diaphragm proved to be grossly deficient in muscle, and the most common change was a marked increase in fibrous tissue. Some cases showed complete replacement of the muscle by fibro-fatty connective tissue. These findings are illustrated in Mr. Chin's paper, and, in our opinion, they fully explain the clinical findings in these cases. I would submit therefore that the congenital defect in the development of the diaphragm suggested by Brodtkin has now been fully proved.—I am, etc.,

Southampton.

Chemotherapy in Primary Tuberculosis

SIR,—I was interested to read the comments of Dr. F. J. Bentley (*Journal*, March 9, p. 584) on my recent article on this subject (*Journal*, February 9, p. 324). I am in entire agreement that a major planned trial is called for. As I stated, "The results obtained in the present relatively small series of cases . . . cannot take the place of an adequately controlled large-scale trial."

In recent years treatment of primary tuberculosis in the Indian and Eskimo child has been carried out on a large scale in this country, and it is the general opinion among workers in the field that the clinical course now very closely

resembles that in the white child. In view of this, despite the smallness of the group, and with the reservations mentioned, I feel that it is justifiable to conclude that there is no obvious increase in the natural frequency of segmental lesions as a result of antimicrobial treatment. As Dr. Bentley has reported a 10% incidence of haematogenous complications in children under 2 years of age suffering from a primary infection,¹ it would appear to me unwise to discourage the use of isoniazid in any of this group in view of its excellent reputation in the control of haematogenous spreads unless the results of a controlled trial should show a very real increase in segmental lesions among cases who receive chemotherapy.—I am, etc.,

Neodymium 3-Sulpho-isonicotinate and Blood Coagulation

SIR,—Professor R. B. Hunter and Dr. W. Walker have reported (*Journal*, January 26, p. 227) that they have found haemoglobinaemia in all of four patients who received daily injections of neodymium 3-sulpho-isonicotinate 5 mg./kg. for more than five days. It is not stated, however (as I have heard by personal communication from Dr. Walker), that the haemoglobinaemia was demonstrated only by spectroscopic methods. It may be remembered that the principal bands for neodymium (594–562, 534–498 m μ) are the same as those of oxyhaemoglobin (578 and 542 m μ). It is therefore not possible to show by simple spectroscopy that neodymium will produce haemoglobinaemia. There is also no evidence that it was possible to convert the pigment into reduced haemoglobin, methaemoglobin, and haematin with the corresponding changes in the spectrum.

German authors have seen haemoglobinaemia or haematuria in only some of many thousands of patients, which is similar to the observations following the application of heparin or dicoumaroles, where it is thought that these effects are associated with a greatly prolonged clotting-time rather than being caused by the anticoagulant itself. The proof of a drug-induced haemoglobinaemia is also difficult, because destruction of erythrocytes at venepuncture or on sharp centrifuging of the blood can result in haemolysis.

I believe that it is not justified to draw conclusions from such obviously inadequate experiments and results as regards the clinical application of neodymium sulpho-isonicotinate, a remedy in clinical use for seven years.—I am, etc.,

Hamburg.

E. VINCKE.

Natural Childbirth

SIR,—I have no desire to enter into any controversy regarding the merits and demerits of training programmes for natural childbirth. In my letter (*Journal*, December 29, 1956, p. 1545), I merely wished to add support to Dr. Constance Beynon's¹ contention that it is now time to take stock of the situation regarding the value of these training programmes. I would, however, like to correct certain misunderstandings created in the mind of Dr. J. G. Scott (*Journal*, February 9, p. 343) by my letter.

First, I have a very great respect for Dr. Read's work and consider that he has done us obstetricians a very great service in helping to wean us away from "unnatural childbirth." With most new ideas, however, the pendulum has always a tendency to swing too far due to excess of enthusiasm, and it is necessary to check it before any actual damage is done either to patients or to the nation's purse. Secondly, in more than twenty years of obstetric practice, I have yet to come across an "unsophisticated girl" who has had any education in preparation for labour during pregnancy by a midwife, whether "native" or foreign, excepting those girls who have already been attending antenatal clinics. These girls receive a certain amount of simple but very valuable instruction by the health visitors during

their home visits. On the other hand most "sophisticated" girls have usually read various books as well as articles in magazines on this subject. Thirdly, my experience with women who have already had some training in "natural childbirth" is chiefly limited to those who have had their training in the U.S.A. I can only say that I am glad to know that the pendulum has not yet swung so far in Britain. When it does, Dr. Scott will have experiences similar to mine.

Finally, I would like to suggest to Dr. Scott that in medical science clinical impressions are not enough. A study of the survey of 2,994 parturients by Mr. C. W. F. Burnett² should provide him with considerable food for thought.—I am, etc.,

New Delhi, India.

Termination of Pregnancy

SIR,—The paper by Dr. James Arkle on termination of pregnancy on psychiatric grounds (*Journal*, March 9, 1957, p. 558) contains a number of inaccuracies respecting religious legislation in the matter of abortion. He says that "the ancient Hebrews, too, allowed the operation if the husband agreed," but the text, Exodus, Ch. xxi, v. 22, which he alleges in support does not say this. It refers (whether in the Hebrew or the Septuagint text) to an accidental abortion. In fact, the sacred writings of the Jews contain no other enactment about abortion.

Dr. Arkle is at pains to show that the distinction between a formed and unformed foetus, which eventually appeared in ecclesiastical legislation, was based on the Septuagint version of the Old Testament which embodied this distinction in the translation of the passage of Exodus referred to. He goes on to state that Tertullian's elaboration of this distinction was translated into Latin by St. Jerome. As Tertullian wrote in Latin, this is obviously not the case. The distinction of the formed and unformed foetus was part of current "science" at least from the time of Aristotle (fourth century B.C., some little time before the Septuagint translation was made) onwards. From the beginning, Christian tradition and legislation condemned all direct abortion, irrespective of the point of evolution of the embryo or foetus. When eventually the distinction between a formed and an unformed foetus made its appearance in Canon Law, it was merely to make the penalties less severe in the case of an unformed foetus. When "science" showed that there was no such turning-point in the development of the foetus the distinction disappeared from Canon Law as it has from civil law.—I am, etc.,

M. D. NUNAN.

Treatment of Acute Appendicitis

SIR,—I was much impressed by Mr. Eric Coldrey's method of conservative treatment of acute appendicitis (*Journal*, December 22, 1956, p. 1458). Shortly after reading this article I had occasion to treat two patients suffering from this disease.

A European woman, aged 31, presented classical symptoms and signs. Tenderness was both in the right iliac fossa and pelvis. W.B.C. count was 18,000/c.mm. The patient was not anxious to have the operation, as she was due to go in a short while to the U.K. on home leave. The antibiotics used were penicillin and streptomycin given intravenously by continuous drip—the average daily dose being streptomycin 3 g. and penicillin 3,000,000 units. After four days on this drug the signs and symptoms had almost completely resolved and it was possible to allow the patient to proceed to U.K. with instructions to report without delay to her own hospital where the appendix could be removed in the usual way.

The second patient was a young Arab, aged 17 years, with classical symptoms and signs of acute appendicitis. The presence of diarrhoea suggested a retro-ileal position of the organ. It was decided to try conservative treatment and to follow this by operation at a later date. The treatment used was intramuscular penicillin and streptomycin three-hourly at first. The temperature

did not fall rapidly, and therefore spiramycin by mouth was given instead of penicillin after two days. The symptoms and signs disappeared rather more slowly than in the patient who was given drugs by intravenous drip, and the white count, which was originally 18,000/c.mm., fell more gradually to 9,000/c.mm. At operation, a week after admission to hospital, a grossly thickened appendix was dissected out from the posterior aspect of the mesentery, opposite the terminal ileum. There were numerous recent curtain-like adhesions between the caecum and ileum and the parietal peritoneum, which were separated. The notable feature was the absence of pus. There was very little free fluid in the area. The terminal ileum was thickened and reddened, resembling a regional ileitis. Lymph glands were not enlarged. The post-operative convalescence was uneventful.

Certain conclusions can be drawn from these experiences of mine: (1) The antibiotic treatment of acute appendicitis is a successful method of treatment. (2) Formation of adhesions is a noteworthy feature of such cases, and in the case of a pelvic appendix it is easy to understand how a "frozen pelvis" might arise. (3) When the patient lives in a remote and uncivilized portion of the globe and prefers to have the operation of appendicectomy carried out at a surgical centre in which the patient has confidence, it is possible to tide matters over by using the conservative method of antibiotic treatment.—I am, etc.,

Umm Said, Persian Gulf.

Cell Excretion in Normal Urine

SIR,—We were interested to read the paper by Drs. B. J. Houghton and M. A. Pears (*Journal*, March 16, p. 622) on cell excretion in normal urine in adults. We would like to draw attention to the method and findings of Masters¹ and Stansfeld and Webb.² In children they determined the number of white cells per c.mm. in random specimens of urine collected without previous preparation. They gave the following normal values:

Percentage and Total Numbers of Specimens of Urine with 10 or Less W.B.C./c.mm.

	Boys	Girls
Masters	100% (70)	92% (50)*
Stansfeld and Webb	98% (1,142)	84% (1,067)

* Catheter specimens.

With this method the rate of urinary excretion need not be determined. The technique is simple and speedy, and we think it is the method of choice in children.—We are, etc.,

Medical Advice in the Lay Press

SIR,—Dr. M. B. Matthews's letter (*Journal*, March 16, p. 647) deserves serious attention. The treatment of medical matters in the lay press has a number of disturbing features. Apart from the one he has mentioned, there is the stream of medical misinformation and ludicrous advice poured out by some Sunday and weekly papers in response to their readers' insistence on knowing how to keep fit. There are the odd pronouncements of our courts of law on questions of aetiology and pathology, which are presented in a way that gives the deliberations of the bench equal authority with scientific observation and experiment. Lastly, and more than offsetting all our propaganda against disease, there are the campaigns of advertisers which create illness in healthy people. At least six of these are constantly before the public, and a new one has been added this week.

The responsibility for this state of affairs rests inescapably with our profession. Circulation of lies and rumours is the inevitable result of public ignorance, and, notwithstanding the work of the British Medical Association and others in the field of popular medical journalism, it is still evident that the ordinary person has difficulty in getting the

information he wants. "My doctor never tells me anything" is the common complaint, nor is pressure of work the only reason for this neglect. We often underrate the patient and doubt his ability to grasp elementary ideas of pathology, and so we withhold explanations which we are sure he will not understand. But experience with non-medical students has suggested that the laity can be taken much further into the complexities of medical thought than has generally been admitted, and that the promotion of our citizens to adult status might be advantageous to both curative and preventive medicine. There seems to be room for more writing on medical topics addressed to the "pelican"-reading classes, and a need also for a monitoring organization that will scour the popular press and issue counterblasts to some of the more dangerous nonsense which is now being printed.—I am, etc.,

Sheffield, 10.

P. E. BROWN.

Poliomyelitis Vaccine

SIR,—Would there be any chance of answers from some official source to the following questions, which must be in the minds of many general practitioners? (1) Is the rate of manufacture of poliomyelitis vaccine really the maximum possible, and are developments being pushed forward with all speed? (2) If the vaccine was only effective up to half the official claim, then in view of the gravity of the problem one would have expected frank progress reports at frequent intervals. Why the long silences and the almost casual references to production difficulties? (3) Why is only one firm in this country at work on the vaccine, and what are the real reasons for this monopoly? Are the profit margins too low to make rapid expansion economic? Is there unwarranted red-tape bedevilling the work of the bacteriologists? Could this responsible firm not do much better if left to itself, as is done with so many vital drugs and vaccines? (4) Is there any real sense of urgency in the mind of the Government at all, or is the general attitude of frustration in connexion with the vaccine a true reflection of the official mind?

There is undoubtedly grave disquiet in many of our minds, and the questions here put forward are genuine ones. I know nothing whatever of what is going on, and my doubts arise solely from past experiences. I think in terms of officially disclosed history relating to shells, tank components, and other military urgencies in peace and war, and wonder whether this vaccine would not flow with far greater fluidity to where it is urgently needed if perchance there was a "former naval person" writing memoranda which demanded to know the full reasons, and at once. There can be many valid reasons for everything done and not done in this connexion, but what exactly are they? We are the people who should say whether they are justifiable reasons or merely officially convenient excuses.—I am, etc.,

St. Ives, Cornwall.

L. P. LOCKHART.

Multiple Sclerosis

SIR,—The publication of Dr. Douglas McAlpine's paper on multiple sclerosis (*Journal*, March 2, p. 475) is greatly to be welcomed for various reasons. It emphasizes the importance of clinical study above all in general practice, where cases of this disease are first encountered. It summarizes most of our existing knowledge, scanty though it admittedly is, and it constitutes an appeal for a fresh outlook.

In 1916 James Dawson¹ published in Edinburgh a monumental contribution to the study of the histology of disseminated sclerosis. Like most pioneers in medical research, Dawson was working entirely alone, without financial backing or endowment. He was of course restricted by the limitations of technique then available. Subject to this reservation, his work remains as an invaluable milestone in the progress towards truth. In 1920 Professor J. Cruickshank² published the result of his studies on Lange's colloidal gold reaction in general paralysis, and considered that the reacting substance resided in the globulin fraction. In

a control series he detected a similar colloidal gold curve in some cases of disseminated sclerosis. In 1921 I published a paper based on the cerebrospinal fluid picture in disseminated sclerosis confirming the high incidence of positive colloidal gold curves in a series of cases and recording progressive modification of such curves during treatment by intravenous "neosalvarsan."

In the years between, much experimental work has been done in this country and in the United States without results of real value. My findings in the cerebrospinal fluid and their modifications under salvarsan therapy led to the following personal contacts. When Dawson of Edinburgh was dying I was determined to ascertain his real opinion. He told me that all his studies on the histological changes convinced him that this disease was based on the activities of a specific infective agent. Subsequently Sir Henry Head very kindly invited me to discuss these matters with him, and we were both agreed that multiple factors must be invoked in any illness. As a result of a direct question I expressed the view that allergy was probably the most important single factor, and I hypothecated an allergic reaction to an unknown infective agent as suggested by Dawson. In explaining the basis of remission, Sir Henry Head advised me strongly never to forget that "the nervous system is 50% overwired."

In 1947 a team of seven research workers published a paper³ on a disease of the nervous system occurring among research workers on swayback in lambs. Of these research workers, four had the misfortune to develop a disease of the central nervous system clinically indistinguishable from disseminated sclerosis. It has always seemed to me personally that this incident has been misinterpreted. The occurrence of four cases of disseminated sclerosis in a team of seven research workers is too high a percentage incidence to be based on a coincidence. It seems equally obvious that they could not have developed a trace-element deficiency. They were personally employed in field and laboratory work under conditions in which they were theoretically exposed to the same infections as those to which sheep are exposed. Should these cases prove ultimately to be identical with true disseminated sclerosis, the whole incident constitutes a most valuable and interesting line for further intensive research which might throw a flood of light on the exact nature of the precise aetiological factors involved.

It appears to me that it is more than time that attention was drawn to the fundamental principles which should govern any line of treatment in medicine. To be justifiable, any treatment should conform to the following criteria: it should be rational, safe, and acceptable to a physician were he himself in the patient's condition. In recent years these principles are often disregarded. Gold, a deadly tissue poison, is still recommended in the treatment of rheumatoid arthritis. The possible development of such grave complications as acute yellow atrophy, agranulocytosis, nephritis, or thrombocytopenic purpura is disregarded. The reader will find a vivid, horrifying, and accurate description of a case in Dr. G. E. Beaumont's *Applied Medicine*.⁴

Cortisone, introduced with world-wide publicity as a cure for rheumatoid arthritis, has failed to cure a single case. Its possible and deadly potential side-effects have been studied and published by Dr. Duthie.⁵ These side-effects have been disregarded and ignored. In the interval there can be few remaining diseases in which cortisone has not been tried, so far without proved success.

The very large group of cases suffering from thyrotoxicosis has for many years been treated with brilliant success following on subtotal thyroidectomy. With adequate preparation and specialized surgical skill such treatment has proved safe and successful. This rational and safe treatment is now in danger of being abandoned for the administration of radioactive isotopes. Potential genetic dangers (to the patient) are disregarded. The possible future development of cancer can be excluded only by the passage of time. In the meantime, myxoedema or occasional deaths are referred to as possible side-effects. Such experimental treatment should,

in the light of our present knowledge, be restricted to animals, if the Home Office were to approve of the experiments in question. As a profession we should return to the attitude of asking ourselves the question, "What is true?" rather than, "What is new?" We should also return to the pursuit of truth within the limits of the Hippocratic Oath.

Finally, I would like to pay tribute to the recent publication on multiple sclerosis by McAlpine, Compston, and Lumsden.⁷ Reviews on monographs at this high level should not be anonymous. This book contains a wealth of information for the future research worker not to be found in any other volume of comparable size.—I am, etc.,

Glasgow, C.3.

The Hurt Brain

SIR,—I am astonished at Dr. Humphry B. Kidd's implication (*Journal*, March 16, p. 645) that I was advocating treatment of neurosyphilis other than by penicillin (*Journal*, February 16, p. 399), and can only conclude that he has completely misunderstood my comments.

I am satisfied that penicillin is the treatment of choice in neurosyphilis, but am not convinced that the patient can be cured by a total of 10 injections of the antibiotic, as was suggested in the television programme under discussion. The mere reversal of pathological findings in the cerebrospinal fluid does not constitute a complete cure of the disease. All venereologists will agree that it is now no longer justifiable to use a potentially dangerous treatment like induced malaria, except in a few particular types of case. It is surprising that Dr. Kidd should use arsenicals and bismuth at all in these enlightened days. One presumes the arsenical was a pentavalent one with its risk of optic nerve damage, since the trivalent arsenicals, being incapable of reaching the cerebrospinal fluid, have long been known to be useless in neurosyphilis.—I am, etc.,

Liverpool, 3.

E. E. PREBBLE.

SIR,—I wish to protest against the way in which exaggerated statements about the treatment of neurosyphilis have been attributed to me in the correspondence under this heading (*Journal*, March 16, p. 645).

I have written about my experience and that of others with the use of penicillin and have emphasized the need for subsequent supervision and for giving adequate time for clinical recovery. I have never stated that penicillin is the only remedy. I have never stated that if it fails nothing else will work—though, in fact, probably the best remedy then would be more penicillin given under more effective conditions. As regards arsenicals and bismuth, in referring to the absorption of inflammatory products from the brain after penicillin treatment, I wrote: "I know of no evidence that arsenical or bismuth therapy has any effect in hastening absorption or is of any value once the infection has been overcome" (now italicized). I have never made the statement that arsenicals and bismuth were of no value in the treatment of neurosyphilis.

Every treatment of neurosyphilis, and particularly of general paralysis of the insane, at the present time is subject to great limitations; I have tried to analyse the reasons for these, and I would be the last person to suggest that one's obligations to the patient were satisfied by the administration of ten injections of penicillin.—I am, etc.,

London, W.1.

Prevention of Tetanus

SIR,—I have read with interest the very helpful paper by Drs. H. J. Parish, L. J. M. Laurent, and N. H. Moynihan (*Journal*, March 16, p. 639). This paper, however, does not make clear the best procedure to adopt when immunizing with diphtheria-pertussis-tetanus and T.A.B.T. vaccines.

In the case of the triple vaccine the makers recommend three injections at intervals of one month to six weeks. This would appear to provide immunity to tetanus for six months only, as the third dose would have been given less than six months after the second injection. If this assumption is correct, the best routine for the triple vaccine would appear to be as follows:

Interval:	1st dose	Combined diphtheria-pertussis vaccine
4 weeks	2nd "	Triple vaccine
4 "	3rd "	
6 months	4th "	Tetanus toxoid

This routine would comply with the authors' definition of complete immunity.

If, however, the doses of triple vaccine were given at intervals of four to six weeks, when would the authors advise giving a boosting dose of tetanus toxoid—presuming that the interval of 4–5 years, which would elapse before the diphtheria booster is usually given, is too long for effective protection against tetanus?

Immunization against tetanus combined with T.A.B.T., where only two injections are given, appears to be subject to the same conditions. Is it that the synergistic action of these combined vaccines is such that the disadvantages in the spacing of the third dose of triple vaccine and the absence of a third dose with T.A.B.T. are immaterial, and that full immunity against tetanus is in fact conferred?—I am, etc.,

Portsmouth.

E. D. B. WOLFE.

Visceral Lesions in Herpes Zoster

SIR,—Dr. R. Wyburn-Mason's comprehensive account of the localization of the visceral lesions of herpes zoster (*Journal*, March 23, p. 678) is most instructive. The fact that intestinal involvement usually causes constipation is particularly interesting, since one might expect the inflammatory spasm to have an irritative rather than a "paralytic" effect. The only example of the syndrome which we have recognized did, in fact, have diarrhoea as the dominant symptom. As this is apparently exceptional, we have summarized the history of this patient, who presented as ulcerative colitis.

A woman, aged 64, developed a painful rash on her right thigh in August, 1954. She lost her appetite, and two weeks later began to have diarrhoea and vomiting, accompanied by pain in the left lower abdomen. The vomiting ceased after four days, but she continued to pass five or six watery blood-stained motions daily. On entering hospital a week after the onset of diarrhoea, the patient was feverish—temperature 100° F. (37.8° C.), slightly anaemic, and tender in the left iliac fossa. A herpetic eruption involving the right second lumbar segment was almost healed. No pathogens were grown on stool culture, and sigmoidoscopy on two occasions revealed no abnormality. A barium enema showed left-sided colitis, this part of the colon being contracted, with mucosal irregularity and absent haustration. The diarrhoea continued for four weeks and then ceased abruptly, and the fever settled in six weeks. In the seventh week another barium enema showed that the abnormality was less extensive. The splenic flexure and upper few inches of the descending colon were rigid and narrowed and their contour was slightly irregular. The same localized changes were found when the barium enema was repeated two months later. The patient remained well and has had no further bowel disturbance.

Absence of proctitis and rapid permanent recovery are unusual in acute ulcerative colitis. We therefore suspected that the bowel lesion in this case was a herpetic manifestation, having previously seen cystitis and pleurisy complicate the disease. This interpretation seems to have been correct, since Dr. Wyburn-Mason points out that the portion of the colon which was affected is innervated from the appropriate

(L.2) segment. The transition between the normal and abnormal colon was radiologically very striking, and it appeared to coincide proximally with the territorial limit of the inferior mesenteric artery. The latent interval between the onset of the rash and the diarrhoea presumably indicated, as it does in typhoid fever, the time ulceration took to develop. The fact that this "symptomatic" colitis did not relapse, in spite of radiological evidence of scarring, does not support the suggestion that classical ulcerative colitis originates from a non-specific insult to the colon.—We are, etc.,

Athlete's Foot

SIR,—The two very interesting articles, one by Miss Mary P. English (*Journal*, March 30, p. 744) and the other by Mr. J. C. Gentles (p. 746), as well as your annotation (p. 755) on the same subject, have prompted us to search through our case records for evidence of the spread of tinea pedis in families. Among an approximate total of 352 patients presenting with tinea pedis confirmed by culture we note at least 5 cases of spread of infection due to *T. rubrum*, 2 due to *T. mentagrophytes* var. *interdigitale*, and 2 due to *E. floccosum*. The various relationships of the patients concerned were as follows: husband and wife, father and son, father and daughter, brother and sister, and sister and sister. In one family *T. rubrum* was isolated in culture from the father and his son, whereas *T. mentagrophytes* var. *interdigitale* was cultured from the mother. We also have no doubt that many more such cases of transfer of infection to contacts in families occur than is generally recognized.—We are, etc.,

Leeds.

J. T. INGRAM.
C. J. LA TOUCHE.

Lung Cancer

SIR,—Is it not highly probable that most of the lung cancer to-day is attributable to our modern tarred roads? Forty years ago both were very rare, yet smoking was very common—five cigarettes for a penny. Is tobacco more likely to cause lung cancer to-day than it was then? The same applies to air pollution by chimney smoke. Non-smokers get cancer of the lung. Before we make smoking illegal—as some people would like—and before I resign from the B.M.A. because the *Journal* advertises cigarettes, I would have to be convinced that the very frequent inhalation of tar dust over a number of years was not the most likely cause. In fact, I wonder that any of us who live on and use the main roads escape. I would be very pleased if any of your readers could disprove this, as it is rather alarming.—I am, etc.,

Clent, Worcs.

J. MILLAR SMITH.

Herpes Zoster and Chicken-pox

SIR,—Two cases of herpes zoster in children aged 5 occurring recently in my practice have made Dr. R. M. McGregor's article (*Journal*, January 12, p. 84) and correspondence about zoster very interesting to me. One occurred in a child who had varicella when aged 2 months, the other had a very mild eruption while in hospital for tonsillectomy at 3 years old. The sister of the first case developed a rash indistinguishable from varicella 20 days after the zoster rash appeared, without any other known contact with varicella. Only the second child had pain, and that not severe.

I do not feel confident in putting forward any definite proposition in a disease of such variable severity, but could it be that zoster may affect those people whose immunity to varicella has worn thin, either due to an attack before the age when immunological mechanisms are fully developed, or only after a relatively long lapse of time? This might account for the clinical impression that zoster is commoner with increasing age and explain why it is more frequent in the ages prone to neoplastic disease, and so gave rise to the ground of Dr. McGregor's interesting inquiry.—I am, etc.,

M. J. F. COURTENAY.

Obituary

D. W. G. FARIS, C.B.E., LL.D., M.B., D.P.H.

Dr. Desmond Faris, who was the first dean of the faculty of medicine in the University of Malaya, died at Hove, Sussex, on March 20. He was 55 years of age.

Desmond William George Faris was born on April 30, 1901, and was educated at Epsom College and at the London Hospital, qualifying in 1924 and graduating M.B., B.S. in the following year. Entering the Malayan Medical Service in 1926 as a health officer, he took the D.P.H. a few years later and became chief health officer at Singapore. During the war he was interned by the Japanese in Changi camp, where his efforts to maintain the health of his fellow prisoners were notably successful. He was appointed C.B.E. in 1946. He had been principal of the King Edward VII College of Medicine at Singapore for some time before the founding of the University of Malaya in 1949, and he was appointed the first dean of the faculty of medicine, holding the post until last year. Dr. Faris is survived by his widow and by a son, who is at the London Hospital, and a daughter who is a student of radiotherapy at the Middlesex Hospital.

D. E. C. M. writes: Of those who have served in the Malayan Medical Service and have known and loved that country, none was more devoted than Desmond Faris. Whether as a health officer, as a lecturer in public health, as dean of the faculty of medicine, or as acting vice-principal of the university, whatever he undertook he did with all his might. Nothing showed forth the man more than his willingness to undertake the thankless task of watching over the health of his fellow internees at Changi Prison and Sime Road. Much as he hated it, he undertook duties which demanded unceasing vigilance, endless improvisation, and, most distasteful of all, constant and close contact with our Japanese guards. That we eventually came through that period without experiencing any of the many epidemics which could so easily have been disastrous was in no small measure due to his work and constant endeavour. There can be few who cannot call to mind the picture of him, crowned with an ancient straw hat, bustling about the camp and poking into all sorts of corners at all times of the day.

He took over the duties of dean of the faculty of medicine when the University of Malaya was founded, and in those early formative years gave devoted service. It was no easy task, for there was no well-drilled machinery which merely had to be kept running. Each day brought new problems, for which there were no rules or precedence. To Faris, with his scrupulous regard for detail, his ceaseless questing for the right answer, and his desire to build up an efficient administration, it was a constant source of worry and strain. His latter ill-health was largely due to the pressure under which he worked during this strenuous and difficult time. His work was not in the glamorous light of the public eye, but what he did for the faculty and the university will be of lasting merit. He well deserved the award of the honorary LL.D. which he received at the time of his retirement, and he was proud of such a distinction. He looked forward to his retirement and longed to be again with his family. It is tragic that he should have had so short a time with them. Kipling is not a popular poet in these days, yet how well he described the aspirations and burden of Faris:

"Fill full the mouth of Famine
And bid the sickness cease."

R. H. DALE, M.B., F.R.C.S.Ed.

We much regret to announce that Dr. R. H. Dale, plastic surgeon to the City and St. Paul's Hospitals, Saskatoon, died suddenly on April 3 at Saskatoon, at the early age of 47.

Robert Henry Dale, the third child and only son of Sir Henry and Lady Dale, was born on January 28, 1910. Educated at University College School and Trinity College, Cambridge, he went on to St. Bartholomew's Hospital for his clinical work. He qualified in 1934, and later graduated M.B., B.Chir. Having held the posts of house-surgeon to Sir Girling Ball and house-surgeon to the orthopaedic department at his teaching hospital, he became resident surgical officer at the County Hospital, Lincoln. Having taken the Fellowship of the Royal College of Surgeons of Edinburgh in 1937, he went into a surgical practice at Grantham, where he was elected to the staff of the local hospital. Early in the war his partner, being then unmarried, joined the Army Medical Service, leaving Dr. R. H. Dale, like many others, to take double duty and to deal with air-raid emergencies in Grantham, which had become an important munitions centre. He received, indeed, what might have been a serious injury when a spurt from a thermite incendiary bomb fell upon the dorsum of his foot. When his partner was released he himself joined the Royal Air Force and served for 18 months at Halton, with the rank of squadron leader. He returned to Grantham, where he had built up an increasing surgical connexion as a member of the staff of the Grantham Hospital. He realized, however, that, with the National Health Service impending, there were senior claims to his for consultant appointments there, and, being reluctant to have his activities limited to general practice under the conditions of the National Health Service, he sold his practice early in 1948 and accepted an offer from Sir Archibald McIndoe to become surgical registrar at Queen Victoria Hospital, East Grinstead. During the next few years he gained wide experience of plastic surgery and published a number of papers on the subject, including one in this *Journal* on the treatment of hydrofluoric-acid burns. His paper on electrical accidents in the *British Journal of Plastic Surgery* (1954-5, vol. 7, p. 44) was a very useful and well-illustrated report on an important topic. He remained at the Queen Victoria Hospital till 1953, by which time he was holding a multiple senior registrarship at East Grinstead, the Royal Northern Hospital, and St. Charles's Hospital, Notting Hill. No consulting appointment, however, being available for him, his senior registrarship came to an end in 1953, so that his specialist career with the National Health Service was terminated. He accordingly determined to make another fresh start overseas, and found that there was an opportunity for one with his special experience at Saskatoon, whither he migrated in June, 1953. In less than four years he had built up there, at several hospitals in the city, and especially at the new University Hospital when it was opened in 1955, a practice and a reputation in plastic and traumatic surgery which had extended to a wide district in western Canada. It had, indeed, become excessive in the irresistible pressure of its demands, so as to leave him no adequate reserve for rest and recreation. He had just undertaken a book on the plastic surgery of the hand, in collaboration with Mr. Patrick Clarkson, of London, and had become secretary and treasurer for the current year to the Canadian Association of Plastic Surgeons. His last

letter showed that the hard winter and overwork had made him feel abnormally weary. He was found dead in bed on the morning of April 3, and necropsy revealed a coronary occlusion as the cause.

Dr. Dale leaves a widow and three children, and to them and to his mother and father we extend our deep sympathy in their loss.

Dr. W. E. LINDSAY, formerly dean of the faculty of medicine in the University of Saskatchewan, at Saskatoon, in a letter to Sir Henry Dale, wrote:

"In the comparatively short time that he had been here Robin had made for himself an almost unique place in the affections of his colleagues and friends. To this was added a real respect based on the quality of the work he was doing. He had opened up a field that was new in these parts, so that in addition to our grief for the loss of a friend we realize what it means to the school and the hospital, and indeed to the people generally, who had come to recognize his skill and to depend increasingly on it."

H. S. STANNUS, C.B.E., M.D., Ph.D.
F.R.C.P., D.T.M.&H.

The obituary of Dr. H. S. Stannus was printed in the *Journal* of March 9 (p. 589).

Dr. H. E. MAGEE writes: I first met Dr. H. S. Stannus in 1942 and then began a close association for about seven years, after which we met less frequently. We were not only colleagues working together, but very good friends and more. The news of his death, which I learnt only a few days ago, was a great shock and sorrow to me. Our professional association began with his part-time employment by the Ministry of Health to carry out nutrition surveys in various parts of the country on people of all ages and occupations. It was my business to arrange these surveys and to deal with the reports thereon. I had, therefore, much opportunity of appreciating his great skill as a physician and his scientific precision. The clinical assessment of the nutritional state was in those days, as it still is, a subject of some controversy. Stannus fully realized this and set himself out to contribute of his very best to provide reliable information which the Ministry so much needed in those days. For one thing, he addressed himself with great zeal to the cause of folliculosis, which at that time had been attributed by some to deficiency of vitamin A and by others to deficiency of vitamin C. Stannus designed an ingenious method whereby pictorial records could be made of the degree of the condition. The method made it possible, by means of therapeutic trials, to measure the effects of administration of one vitamin and then of the other. His findings showed that neither vitamin was concerned in the aetiology of the condition. Had the result been otherwise, the question of a ration of one or other vitamin would have had to be considered, especially for adolescents, who were chiefly affected. Towards the end of 1943 there were some complaints about the inadequacy of the rations for miners, and fears were expressed about their health. Stannus spent a week in each of the Notts and Leicestershire coalfields, interviewing and examining the miners as they came off their shifts at all hours of the day and night. I was quite convinced that his presence amongst these men with his pleasant manner and great humanity did much to reassure them about their health. At any rate, there were no further complaints from these two areas.

He was a man of refined and artistic tastes, and it was a great joy to drink his excellent sherry in his pleasant and artistically furnished rooms in Harley Street and then to dine quietly with him in his club near by. He was an excellent and very generous host. After medicine, genealogy was his next love. In the course of his inquiries into his own family tree he was able to unearth authentic records of my own. His explorations took him to Dublin Castle, then to south Co. Antrim, where some branches of the Stannus family had settled about the beginning of the seventeenth

century: one family settled at the neck of the Isthmus of Islandmagee. Stannus discovered at Carrickfergus that a Stannus family had saved a Magee family from the massacre of 1642, whereas, according to tradition, only one male member of the Magee clan survived the massacre. This discovery was a great joy to both of us.

Dr. K. SPERBER died at Accra, Gold Coast (now Ghana), on March 3 at the early age of 46 after a long illness. Born in Czechoslovakia on March 16, 1910, Karel Sperber graduated in medicine at Prague University in 1935, and took the equivalent of the D.P.H. soon afterwards. After two years' service with the Czech forces he became surgical officer to the well-known works hospital of the Bata Shoe Company, where he first showed his marked capabilities for traumatic and obstetrical surgery, which remained his main professional interests. Soon after the German invasion of Czechoslovakia he made an adventurous escape to England, and in 1940 obtained an appointment as a ship surgeon. On his first voyage to the Far East his ship was sunk off the Straits of Malacca and he was taken prisoner. During the following three months he attended 500 Allied survivors on board German prison ships. In the words of official documents, "his only surgical instrument was a pocket knife and his only medicines a few pills supplied by the enemy." Being of Czech nationality the Germans regarded him as a subject of the Reich serving under an enemy flag, and he was a marked man from the day of his capture. This did not prevent him from putting persistent and effective pressure on the authorities of prison camps in Germany to improve the badly lacking medical facilities for 3,600 Allied internees. In the words of a visiting delegate of the Protecting Power, "he did a most excellent job and was of the greatest value for the spirit of the camp." Eventually, however, he was handed over to the Gestapo and was taken first to the horror camp of Auschwitz and later to Buchenwald. His survival, while great numbers were exterminated in these two camps, was a miracle, even for a man of his physical and spiritual toughness. He escaped from Buchenwald in the last weeks of the war and returned to England. After another period as a ship surgeon he joined the Colonial Medical Service, and served from 1950, first in the Seychelles Islands and later in the Gold Coast. A year ago he set up in general practice in Accra, but his untimely death deprived him of the fruits of hard and conscientious work, in which he persisted almost to the day of his death. Dr. Sperber was appointed an honorary O.B.E. in August, 1946, for his outstanding work for Allied seamen, and some two years later he became a naturalized British subject. He was a man of striking appearance, of indomitable spirit, and with a golden sense of humour. He loved the simple good things in life, above all good company and good stories. He was no classical scholar, but he had a favourite and characteristic Latin quotation, remembered from his early school days: *Amicus fidus rarus est*. To his many friends, now dispersed all over the world, this simple truth will be a measure of their loss. He is survived by his wife, Kathleen, whom he married in 1947. With her he found that haven of cloudless happiness for which he had yearned through years of darkness and horrors.—E. P.

Dr. A. E. KILLON died at his home at Slough on March 11. A native of Chester, Alfred Ernest Killon studied medicine at Liverpool University, afterwards qualifying L.A.H. at Dublin in 1920. He had been in practice in Slough for 18 years and had earned the reputation of being a sincere friend to his medical colleagues and patients alike. He was an accomplished pianist and organist, and possessed a wide knowledge of classical literature. He is survived by his widow.

Dr. HARRY D. FINDLAY writes: Dr. A. E. Killon was a modest, unassuming man who never sought the limelight. For that reason, perhaps, he was less well known to some of his colleagues than his merits deserved. Only those of

us who were privileged to visit him in his own happy home knew the facets of his character that made every one of his patients a personal friend. A wise and kindly man, he was skilled in the arts of music and song. He bore a year of suffering without complaint, and faced the last enemy with a courage that was a revelation and an inspiration. To his widow his colleagues, who were also his friends, extend their deep sympathy.

Dr. G. S. HOVENDEN, who was a general practitioner in Barnes for over fifty years, died at Putney Hospital, after a short illness, on March 14. He was 87 years of age. Gerald Stanley Hovenden was born at Norwood on August 27, 1869, and was educated at the Whitgift School. He qualified M.R.C.S., L.R.C.P. from Guy's Hospital in 1894, taking the London degrees of M.B., B.S. in the same year. He proceeded to the M.D. in 1896. In 1900 Dr. George Rodman, his cousin by marriage, who was in practice in Barnes and East Sheen, invited him and his twin brother, the late Dr. Arthur Hovenden, to join him as partners. This they did and remained in the same practice till Dr. Arthur Hovenden's death in 1946 and Dr. Gerald's retirement a few years ago. During the last war, when his brother's health had broken down and his junior partners were called up, he held the practice together with only part-time assistance. His appearance of being unhurried even when he was doing four men's work is still remembered by his patients. He was a member of the British Medical Association for over sixty years and until recently was a very regular attendant at the Divisional meetings. His presidential address to the West London Medico-Chirurgical Society in 1947 was entitled "Fifty Years in General Practice." In a generation when it was still possible for a general practitioner to claim that he was up to the standard of clinical knowledge and experience in practice. He was a skilled anaesthetist with chloroform and ether; he performed many tonsillectomies and adenoidectomies; he was good at dental extractions; he was a particularly good paediatrician (as he had been a clinical assistant at Great Ormond Street); and he had a large midwifery practice. Dr. Rodman was a pioneer radiologist, and in the early days the practice treated a large number of fractures. Dr. Hovenden was the ideal family doctor. His own family was the centre of his life, and through his kindness and understanding of human problems he became the friend and counsellor to several generations of families in his practice. His unsparring devotion to his patients' welfare inspired complete trust, and his gentle, genial manner and obvious enjoyment of his simple pleasures were typical of a man who was contented with his life. He was also intensely interested in the modern developments—both in medicine and in general affairs—which were growing so rapidly around him; he was, for instance, a pioneer motorist. He loved riding, and up to the last war was a familiar figure in Richmond Park, riding with his family. He was a keen walker and dinghy sailor and enjoyed holidays abroad. He was an excellent bridge and chess player; but the pleasure which he enjoyed from reading—in English and French and German—lasted till a few days before his death. He was married twice and had one daughter and three sons; two of his sons are in the medical profession—one carrying on his father's practice and the other a surgeon commander, R.N.

Dr. A. H. PRICE, who for many years was a well-known general practitioner at Reading, died on March 17 at his home at Twyford, Berkshire. He was 64 years of age. Alfred Henry Price was born at Glenbeigh, Co. Kerry, on April 25, 1892, and was educated at St. Columba's College and Trinity College, Dublin, graduating M.B., B.Ch., with first-class honours in medicine, in 1916. He proceeded to the M.D. in 1919 and in the following year took the D.P.H. He was a notable sportsman in his student days, playing cricket and Rugby football for Trinity College and gaining an Irish cap. After graduation he held a resident appointment at the Adelaide Hospital, and then served in the Royal

Navy until 1919, his wartime duties taking him to China, among other places. He acted for a short time as medical officer to the Canton municipal council, later becoming medical officer to the Dimbulla District Planters' Association in Ceylon. In 1928 he returned to England and joined the late Sir Stewart Abram in partnership at Reading. On the death of his partner, Dr. Price carried on the practice alone until 1947, when he was joined by his son, Dr. H. M. Price. For some time Dr. Price was in charge of the physiotherapy department of the Royal Berkshire Hospital, where previously he had been clinical assistant in the ear, nose, and throat department for 13 years. He was medical officer to Reading School and commanding officer and medical officer from 1943 to 1946 of the Reading Sea Cadet Corps. A member of the British Red Cross Society for 17 years, he was for a time assistant county director. From 1942 to 1946 he was honorary secretary of the Reading Division of the British Medical Association. He had also held office as the honorary secretary of the local medical war committee. Always ready to take an active part in the community he served, he was a keen supporter of the British Legion. For many years he was a churchwarden at St. John's Church, Reading.

Medico-Legal

TRIAL OF DR. J. BODKIN ADAMS

EXPERT EVIDENCE CONTINUED

[FROM OUR SPECIAL CORRESPONDENT]

The trial of Dr. John Bodkin Adams, of Eastbourne, continued before Mr. Justice Devlin at the Old Bailey. Dr. Adams is charged with the murder of a patient, 81-year-old Mrs. Edith Alice Morrell, who died on November 13, 1950. He pleads not guilty.

Sir Reginald Manningham-Buller, Q.C., is appearing for the prosecution with Mr. Melford Stevenson, Q.C., and Mr. Malcolm Morris. Mr. Geoffrey Lawrence, Q.C., is appearing for Dr. Adams with Mr. Edward Clarke and Mr. John Heritage. The Medical Defence Union is acting for Dr. Adams.

On the eleventh day of the trial, April 1, Dr. M. G. C. Ashby was recalled to complete his evidence-in-chief. After questioning the witness about graphs illustrating the prescriptions the Attorney-General asked:

"In your opinion, what would be the effect on a woman of 81 years of age if given morphia and heroin in the quantities shown to have been prescribed between November 8 and 12?"—"I don't think it is possible that she could have survived those quantities without being steadily worked up to that dosage; that is to say, a patient receiving those doses when being treated for the pains of cancer would survive them, but they would have been built up several weeks before. They would have been getting perhaps 3 or 4 gr. of each. What led me to a conclusion about an inability to survive was the very sudden rise in the prescriptions as illustrated on the graph. The two situations are entirely different."

"That is taking morphia and heroin together?"—"Yes."—"If she had had the morphia alone what would have been the effect, in your opinion?"—"I don't think she could have stood such a very sudden increase of such an extent, because again the prescriptions as illustrated on the graph show no previous raising of morphia at all really right back to August 18. So there was no preparation for the big dose in respect of acquired tolerance to very high doses, again differing from the usual cancer patient."

The witness said that the same considerations would apply if the patient had had heroin alone; he did not think she could have survived if, instead of having the heroin and morphia alone prescribed, she had the major part of both. He wished to correct a "slight error" in his previous answer: the heroin was not quite the same as the morphia because, according to the prescriptions as illustrated on the graph, there had been a fivefold increase of heroin for the previous six or seven days. With such an increase it would

be possible that she could have survived what was then more than 12 times as much; the dosage had been raised 18 times after only six days, and he did not think it was possible that a woman of 80 could survive that.

He said that every general practitioner would be aware of such facts in relation to morphia, because it was a drug of almost universal use. Not quite the same could be said of heroin, because there must be many family doctors who virtually never used it except perhaps in a linctus. He had never himself used heroin and morphia together in conditions where there was not severe pain, nor had he seen it used by a colleague in such circumstances.

He said that the complaint of severe pain on June 27, 1948, when the patient had been at the Neston Cottage Hospital, Cheshire, was probably due to arthritis. There was no evidence either way of the incidence of a thalamic syndrome. The pain on June 28 was probably dyspeptic from the distension of the stomach or viscera. Brandy frequently gave relief in such circumstances.

The Attorney-General: On every night while she was in that hospital—we do not know on whose instructions—she was given $\frac{1}{2}$ gr. of morphia. Would that, in your opinion, have produced addiction or not?"—"I do not think it is possible to answer that question with a straight 'Yes' or 'No,' for this reason: that if we assume for the moment that addiction is produced after three weeks it is not rational to say that there is no measure of it after nine days; but it would be very slight, and I don't think the addiction would have reached the degree to which the doctors would have to give any attention to gradually weaning. But I don't think it would be right to say that there would not be the beginnings of addiction in a very mild way in an average patient."

Expectation of Life

He was sure none of the doctors concerned would have agreed to Mrs. Morrell's journey back to Eastbourne had they not thought that she had greatly improved and that her transfer would in no way prejudice her further recovery. After morphia had been given for a week to 10 days every doctor would be thinking in terms of how much further it was right or proper to go on with it, because the dangers of addiction would then be steadily mounting—accepting for the moment the arbitrary figure of about three weeks.

In answer to the judge, he said he did not criticize the giving of morphia at the Cheshire nursing-home, because it was recorded that the patient was in severe pain and no doctor would dispute that morphia was one of the drugs that could properly be given to deal with it, although there might perhaps be better choices. The more important consideration was that during those first few days just after a severe stroke the patient's expectation of life was very poor indeed and the doctors would not be thinking in terms of future addiction; their one consideration would be to ease pain without prejudicing the patient's life. There would be an immense change in the prognosis on July 5, the day she was thought fit enough to return to Eastbourne. The prognosis would then be quite good and she could have been expected to have lived for six months to several years.

Asked by the Attorney-General whether there would be any justification on July 9, 1948, having regard to the previous injections, for injecting Mrs. Morrell each evening with hyperdure morphia just to secure sleep, the witness replied: "Taking into consideration that impending addiction was the overriding consideration at that time, morphia would not be the drug of choice; it would be one of the barbiturates, which are the drugs for promoting sleep."

He could think of no justification for adding heroin to the morphine injection on July 21, 1948, and he thought it enormously increased the already present danger of addiction. The patient would have been firmly addicted, but in no sense unweanable, by the time she left the Eastbourne nursing-home in October, 1948. After further questions on weaning treatment and tolerance, the Attorney-General said:

"What would be the effect on the general physical health of an old lady of 80 or 81 if she was submitted to heroin and morphia injections over a long period?"—"Patients' reactions vary to this, but on an average I think it can be said with assur-

ance that it does have a deleterious effect upon health. But in this patient's case I think it is necessary to add that, speaking from memory, for the first two years, or nearly so, the dosage rate was low, and we know from the nurses' books that, at any rate, until the spring of 1950 she was pretty well. So I think, whatever the average results, the deleterious effect upon Mrs. Morrell was relatively slight. I am talking about health, as opposed to being irritable at times."

Dealing with the injections given on November 6 to 12, he said the patient could not have survived that set of doses as a whole because the increase was very sudden over what she had been getting only a few days before. The jerky spasms and twitchings which had been mentioned in evidence were a very rare phenomenon, but his studies in the matter had not permitted any alternative to the conclusion that they were attributable to heroin. They did not sound in any way like epileptic fits. The most likely explanation was the high level of heroin the patient was having at that time. He did not see the justification for the administration of heroin and morphia on such a scale. In the absence of any doctor's notes about the condition of the patient it was very difficult to say whether something which must have been at least easing her passing was justified at the time or not.

Dilemma

He said he was unhappy about the last five days. He had studied the books and records with great attention to the problem as to what was the latest time at which what had been referred to as "the dilemma" could have been resolved, and his own conclusion had not been in agreement with Dr. Douthwaite's that all was lost by November 1.

The Attorney-General: "When do you think the moment came, so far as you can judge, when it was no longer possible to wean her of the addiction which was resulting from this routine administration by Dr. Adams from the time she came out of the nursing-home?"—"I think there was still a faint chance during the first week of November, and as it was a matter of inevitable death or a faint chance, speaking personally—I wasn't there—but from the record there was a chance which I think should properly have been taken. But in the absence of medical records of the case I think it is really quite impossible to say. I may be weeks wrong in this estimate, but my recollection of these books is that within two weeks of death she was bright and talkative—I think I am quoting correctly from memory. Well, I can't believe that a patient could not stand an attempt at weaning, on the basis we read out this afternoon, even at that stage. What was there to be lost?"

"Would it be right, in your opinion, from what you have seen, to describe the immediate cause of death of Mrs. Morrell as cerebral thrombosis?"—"Well, there was no recorded evidence to suggest it was that."

"From what you have seen and heard, what would you say was the cause of her death?"—"I think that is very complicated, the factors causing her death. The immediate factors, of course, would be the combination of what we refer to as terminal natural causes, like terminal pneumonia, which in its turn would have been fairly directly caused by her being kept under for the last few days. Then I think another very important factor—probably a larger factor—was this patient's very heavy pressure of opiate therapy. Thirdly, the patient's age cannot be ignored. I don't for the moment think of anything else. It is not possible without a post-mortem examination to say with any certainty what the actual final closing act is which ended life in the majority of patients."

Dr. Ashby was recalled on Tuesday, April 2, for the resumption of examination-in-chief. After his attention had been drawn to further of the nurses' reports, the witness was asked:

"If you are giving barbiturates and heroin—and we have heard about heroin producing twitching—what would be the effect of the barbiturates on those symptoms which may follow heroin?"—"I should have expected them to have a considerable influence in suppressing those twitchings, just like they suppress the epileptic phenomena, which are not very different."

"So the cessation of the administration of barbiturates would unmask those other symptoms if they were to be unmasked?"—"I should have thought that was to be expected."

The witness was then taken through the remainder of the reports. He said that by November 12 he did not see any

positive evidence of the agonizing discomfort or pain which would justify easing the patient if she was dying anyway.

He said that the patient's history could be divided into three "chapters"; the first started with the stroke and earlier administration of morphia and heroin which he criticized on the grounds that they had made the patient an addict; the second began in the summer of 1950 when it was clear that the pressure of sedation was being further increased: "I don't think she was getting as much morphia and heroin as she needed, and they were in a spiral and a dilemma, but a solution of that dilemma, instead of being desirable, became obligatory, as a disaster could only otherwise result." Chapter 3 was a matter of circumstances and decisions rather than precise dates, and he regarded it as the time when there was virtually no hope of the patient recovering from the effects of the previous circumstances. The Attorney-General then asked:

"Can you see any reason why this lady of her age should have died on November 13 if the heroin and morphia had not been administered to her?"—"I don't think she would have died. I can see no reason from these reports to have expected her to die. She was sitting up in a chair talking quite brightly only a few days before."

He agreed that the books showed no record of the administration of morphia and heroin on October 26 and 27 but only the "special injection" given by Dr. Adams.

Cross-examination of Witness

Mr. Geoffrey Lawrence: "Dr. Ashby, you say that you do not think Mrs. Morrell would have died by November 13, 1950, if she had not been given the drugs mentioned in the nurses' notebooks; is that right?"—"I did say that, yes."

"You would say also, would you not, that if she had not had the drugs mentioned in the nurses' notebooks—and I mean by that going right back over the regular course of sedation, the whole pattern of treatment and medication—it is quite impossible to say that if she had not had that she would have lived as long as November 13?"—"No, I agree one could not. I don't think the earlier treatment had any great influence on the length of her life and she might have died of natural causes earlier. I would accept that fully."

He did not think her life-expectation was materially altered by the earlier therapy, nor was it any protection against sudden death from natural causes, from anything else like another stroke or a heart attack.

Mr. Lawrence: "There are some limits to the powers of divination of a doctor, are there not?"—"Extremely. We are very limited in our powers, particularly of prophecy about life and death."

"That is exactly what I thought. And equally about what causes death?"—"Yes, particularly immediate, rather perhaps unexpected deaths."

"And it is equally unsafe to be dogmatic, is it not, about how long any given person would have lived but for this or but for that?"—"Certainly. I hope I have not been dogmatic about it."

"Life is so full of chances, is it not?"—"It is."

"And the field of medicine, although gradually being explored, has still many uncharted deserts in it, has it not?"—"Certainly."

"Where there are great gaps in knowledge?"—"Yes."

"And particularly in the relationship of cause and effect?"—"I would agree."

"And therefore, in vitally important matters, a careful and wise consultant would hesitate to be dogmatic?"—"Yes. I have tried to hesitate."

"When do you say that Dr. Adams murdered Mrs. Morrell—or don't you say that?"—"I do not think it is for me to say that. I have done my best to guide the court as to what I think would be the results of certain actions and chemicals; I do not really feel in a position to say that on a certain day or even week Dr. Adams decided to murder Mrs. Morrell. I do not feel that is my duty."

"It may not be what you conceive to be your duty; but you cannot say that, can you, on your review of all the evidence in this case—certainly the nurses' notebooks—that on any day or any week he made up his mind to kill Mrs. Morrell?"—"In respect of the books, and if I may bring in the nurses' evidence, I feel that the instruction to keep her under would have almost certain effects and the dosage of 4 gr., 5 gr., and 3½ gr. of heroin combined with morphia would also have brought certain effects, but I am not prepared to say whether they were instructions of a murderous nature."

Mr. Justice Devlin: "I think you are quite right to leave the word 'murder' out of it, but were they instructions which, in

your view, a general practitioner with Dr. Adams's qualifications would have known would accelerate her death?"—"The instruction to keep her under could not fail to have—I should not say 'could not fail,' but would be almost certain to accelerate death."

"And that is a conclusion which a doctor with Dr. Adams's qualifications would have reached?"—"Yes. I think an anaesthetist is particularly conversant with the dangers of a patient being unconscious or semiconscious."

Mr. Lawrence: "Dr. Ashby, if we are going to talk about instruction which, if executed, would be calculated to shorten life it is vitally important, is it not, that we should be accurate about what those instructions were?"—"It is."

"And try to find out for ourselves in what circumstances they were given?"—"Essential."

Mr. Lawrence suggested that the instruction to keep the patient from being restless was not the same as the instruction *simpliciter* to keep the patient under—"I do not think it is quite the same as had the sentence contained only the instruction to keep her under." It was a fair interpretation of Nurse Randall's note, "It was doctor's orders to keep her from getting restless, to keep her under as much as we could at that stage," to say that in it she had really expressed, first, the object and the purpose of the instruction, and, secondly, the means whereby that object or purpose was to be achieved. If that was so, the question of whether or not it was justified must depend upon the patient's situation as seen by the general practitioner.

No Maximum Dose

The witness emphatically agreed that there might well be circumstances in the situation of a patient which justified the doctor putting the comfort of the patient before the longest possible survival date. The man to judge of that was the doctor in charge of the case—there could be nobody else.

After an initial stroke, in an old person with an arterial condition such as that of the deceased, it was by no means uncommon for a second cerebral vascular accident of some kind to occur; in fact such a patient was more likely to die of a second stroke than by heart failure.

The witness said he did not think any doctor embarking on a weaning process after November 1 would have done so with more than a slim expectation of success.

He agreed with counsel that there was no such thing known in the medical profession as the "maximum" dose in respect of the drugs in question, as such.

Mr. Lawrence: "It is extraordinarily difficult, is it not, if not impossible, to talk about fatal doses in the case of the opiate drugs?"—"Yes."

"So much, indeed all, depends upon the condition of the patient who takes the dose?"—"Certainly."

When passing from non-tolerant people to those who had acquired a tolerance, it was even more difficult to say what the level of a fatal dose would be, although the patient's record should give some information about the response to smaller doses.

"Dealing with tolerant persons, have you heard the view expressed by some authorities that it is practically impossible to kill tolerant patients by means of drugs?"—"Yes. It can be very serious from the doctor's point of view. It is well known that in the very bad painful cases we have to be careful not to start these drugs too soon or the point becomes reached where, owing to extreme tolerance, they are ineffective, and there may be nothing else."

"But all up the scale the field is one of great uncertainty, is it not?"—"Yes."

Heroin was a drug which was notable for the production of a feeling of well-being and would be likely to cope with the tendency to outbursts and lack of co-operation with the nurses which the patient evinced upon her return to Eastbourne from Cheshire.

Mr. Lawrence: "If he had given her morphia by night and securing her sleep at night and her co-operation during the day—what he did was to combine them together?"—"He did, yes."

"Is there any synergistic value in combining these two drugs?"—"I was not aware of a strong synergistic action. Dr. Douthwaite is the great expert. I must say I didn't know it was as strong as he suggests."

"If there is any synergism between these two drugs, then the combination of them in one injection would be getting the most out of the ones you were giving to the patient?"—"Given those premises I would accept that conclusion."

"The disadvantages—and I'm not going to dodge it—are the disadvantages of addiction?"—"Yes. I think at that stage the only disadvantage, except for a small measure of possible deleterious effect. But heavy barbiturates also, if they had been necessary, might also have produced a deleterious effect. I don't think it would be fair to say that only morphia and heroin would have that effect."

He agreed that when Dr. Adams came to say on the form what was the immediate cause of death he would have in his mind the initial stroke in Cheshire, the condition of arteriosclerosis, and his own diagnosis on October 9 of a supervening cerebral vascular accident. The isolation of the immediate cause of death was a very difficult matter. In those circumstances the entry might have been quite an honest one. He agreed that a post-mortem examination would not indicate a patient's degree of tolerance to a drug.

Final Cause of Death

Re-examined by the Attorney-General, he agreed that a post-mortem would show whether there was heroin or morphia in a body, and experts could estimate the amount with considerable accuracy soon after death.

The Attorney-General: "Assume for the moment that she had on November 8 and all the subsequent days the morphia and heroin prescribed for her; in your opinion was that morphia and heroin the cause of her death, or was her death due to natural causes?"—"I think that would have been the cause of her death. As I said before, I don't think she could have survived that dosage, but that dosage might well have killed her by an apparently, as it were, natural cause—I hope I have made that clear—such as thrombosis or terminal pneumonia."

The full dosage of the prescriptions would have caused death from direct suppression of the vital centres; the same result would occur if the major part had been given. He did not think she could have survived the level of the injections given on November 10, 11, and 12 with paraldehyde in addition.

After further questions from the Attorney-General, the Judge asked: "Dr. Ashby, in an important answer that you gave to Mr. Lawrence you said that you could not rule out the possibility that the death of Mrs. Morrell was the result of natural causes?"—"Yes."

"And you gave some further answers to the Attorney-General on the subject of cause of death?"—"Yes, my Lord."

"When you said to Mr. Lawrence that you could not rule out the possibility that death was the result of natural causes, did you or did you not mean to say that you could not rule out the possibility that the death of Mrs. Morrell was not caused by drugs administered by Dr. Adams or under his instructions?"—"I am afraid I did not quite understand your full question, my Lord, but I would like to say this, that my answer to Mr. Lawrence, at that moment I thought he was trying to ask me an entirely unbiased opinion on that last page. He said, if my recollection is correct, looking at the last page—and there were six lines—he then asked me about the patient's death and I did feel that on that page there was nothing which prevented me accepting the possibility of some fatal catastrophe like another heart attack or cerebral thrombosis."

"Yes, but I must put my question to you again . . . "—"Would you please?"

" . . . and get you to understand it if I can because it is important. You said you could not rule out the possibility that death was the result of natural causes?"—"Yes."

"And then in answer to the Attorney-General you spoke about natural causes as having a terminal effect, or words to that effect?"—"Yes."

"So that it might be said that death is the result, in the end, of natural causes but those natural causes, or the operation of those natural causes, were themselves produced by the drugs that were administered by Dr. Adams?"—"Certainly, yes."

"And if that were so then it might be said that, looked at in the ordinary, common-sense way, the cause of death was the result of the drugs administered by Dr. Adams?"—"Yes."

"Now, I think you have said that in your view that was the cause of death?"—"Yes."

"But what Mr. Lawrence was asking you to-day was that he was asking you whether you could rule out the alternative possibility; that is to say, can you rule out the possibility that the death of Mrs. Morrell was not caused, in the ordinary, broad sense of the word, by the drugs administered by Dr. Adams?"

"Well, my lord, in so far as the nurses' reports show that her condition was not all that bad, she did seem to die in the end, to judge by these reports, fairly suddenly. I don't think . . ."

"I do not want, if I can avoid it—because I am not anxious to reopen the whole subject—you to answer that in detail, and that is why I began by asking you what you meant by your answer to Mr. Lawrence when you said that you cannot rule out the possibility that death was the result of natural causes. Did you mean simply that you cannot rule out the possibility that at the end natural causes was the terminal thing that brought about her death?"

"Well, with the greatest respect, my lord, I was just going to make it clear when you intervened."

"I am so sorry. Yes?"

"I think I can only say it in this way, that in so far as the reports do not make it completely certain that she was absolutely dying even six hours before, I do not think it is possible absolutely to rule out a sudden catastrophic intervention by some natural cause. It just is not possible to say this woman could not have had another cerebral haemorrhage at 1 o'clock that morning. There is just no evidence to say that that is impossible. I do not think it ever is possible completely to rule out the possibility, in a patient of 81, of sudden death."

"And in your answer to Mr. Lawrence, then, you meant no more than that you are not prepared to rule out the possibility that some cerebral haemorrhage might have intervened and brought about death?"

"Yes, I could not exclude the possibility of that beyond any shadow of doubt."

"Then you went on to say that Dr. Adams could well have thought that cerebral thrombosis was the immediate cause of death. When you said cerebral thrombosis then had you in mind the original cerebral thrombosis or the bare possibility of some intervening cerebral thrombosis?"

"I meant a terminal cerebral thrombosis."

"A further cerebral thrombosis?"

"Yes, my lord."

Cremation Certificate

On the thirteenth day of the trial, April 3, Dr. Francis Edward Camps was called by the Attorney-General to deal with a point raised by the judge. Dr. Camps, who is reader in forensic medicine at the London Hospital and the London Hospital Medical College, said that if a referee refused to give a cremation certificate, having had the forms duly completed and put before him, he could either order a post-mortem himself or, more commonly, notify the coroner, whereby the examination could be carried out under the coroner's auspices. In either event, as a result of that post-mortem examination, his Certificate F, which would be signed by the pathologist or the doctor carrying out the post-mortem, would supersede the B and C certificates, or, in the absence of the coroner, his certificate would cancel out the other two and his certificate was then accepted by the referee. If a person expressed a definite desire to be cremated, he thought it was obligatory for that to be done.

Under cross-examination Dr. Camps said that the medical referee, having examined the forms submitted to him, could order a post-mortem in his own discretion; but this was usually only done in cases of technical difficulty, such as the person not having been seen within the prescribed time before death. If he communicated with the coroner, the latter would undertake an investigation, statements being taken from the various people concerned, and might then order a post-mortem. In cases of cremation now it was always the practice to order a post-mortem because it was the final act. Having assessed the evidence, the coroner then held an inquest if he thought fit, but he was entitled to sign a cremation certificate, after due inquiry, without an inquest if he was satisfied that there was no suspicion or that death had not resulted from an accident, or anything of that sort.

He agreed, in answer to the judge, that some relatives might very much dislike a post-mortem, and the situation could arise (although he had not personally met it) whereby if the doctor had been left a legacy in the will, the relatives might say, "We would much rather that she was buried, and we believe that that would be her own wish rather than a post-mortem being carried out." His own experience had

been that in such cases the medical referee automatically notified the coroner.

Mr. Geoffrey Lawrence then made a submission in law, in the presence of the jury, that there was no case for the defence to answer.

The judge said, without calling on the Attorney-General to reply, that, after careful consideration, he had come to the conclusion that the matter should be determined by the jury and that he would therefore overrule the submission.

Mr. Geoffrey Lawrence explained that the defence had decided, in all the circumstances, not to call the accused.

Expert Evidence for Defence

He then called his medical witness, Dr. John Bishop Harman, of Harley Street, physician to St. Thomas's Hospital, London, to the Royal Marsden Hospital (formerly the Royal Cancer Hospital), and to the St. Helier Hospital, Carshalton.

It was clear that in June, 1948, Mrs. Morrell had had quite a severe stroke, and, Dr. Harman thought, was in a rather difficult mental condition. Her condition was symptomatic of arteriosclerosis. Pain did not usually accompany a stroke. He nevertheless assumed that the morphine had been given for pain. It was occasionally necessary to use morphine as a sedative in restless people who had had strokes. He was not prepared to condemn the use of morphine in such circumstances.

Asked about the use of morphia and heroin in the treatment of the patient when she had returned to Eastbourne in the mid-summer of 1948, he said that when a doctor took over a patient from another doctor, even though he had known her before her stroke and had visited her in Cheshire, the usual thing would be to continue with the treatment, for a time at any rate, that the other doctor had found necessary.

Mr. Lawrence: "So far as heroin is concerned, have you ever known of its use in cases other than cases of severe pain?"

"Oh, I use it for such, yes."

Dealing with further symptoms of a period of confusion after October 9, he said that, without reading too much into the reports, it was clear that the period lasted for a few days after the acute episode at night and then apparently passed off again. That would, of course, be consistent with a stroke, it would be consistent with more drugs having been given, but he saw no evidence of the latter.

The Cheyne-Stokes breathing, reported on the night of October 14-15, was one of the characteristics of a mild heart failure of a certain type which occurred particularly at night. It was not unusual and might occur in elderly persons for no very obvious reason.

Mr. Lawrence: "On the evidence presented in the report, are you able to take a view, as the other doctors took, that there was a point when clearly she was a dying woman?"

"Yes, I agree to the dates suggested, roughly."

"Dr. Douthwaite suggested November 1, and I think Dr. Ashby put the date later—on the 8th or 9th."—Yes. On the 8th it was much more obvious; on the 1st it was not so obvious. I think it is merely a question of how soon you make your diagnosis."

"Now, what do you say about this omission of morphia and omnopon and the concentration on the heroin at this stage? You have heard what Dr. Douthwaite said; what do you say?"

"Well, I entirely disagree with what Dr. Douthwaite has said on that subject. I agree with Dr. Ashby when he said it struck one as of no particular significance."

"Is it or is it not a variation of the drug?"—Yes.

"That is not such a silly question as it sounds, in view of Dr. Douthwaite's answer to me on that point?"—Well, one does speak of a variation sometimes in quantity, sometimes in kind. This was a change."

He agreed with Dr. Ashby that when the point of no return had been reached the first duty of the doctor was to promote the comfort of the patient. The administration of drugs after that point indicated that they were being given to stop her getting excited, to keep her peaceful, and that they were not working effectively. He was not sure why atropine was given, unless it was to stop mucus and trouble in the throat. The only effect of the paraldehyde given on the last day would be sedative.

Mr. Lawrence: "On the evidence of these nursing reports, is that death a morphine death or not, in your opinion?"—No.

"Why do you say that?"—By far the commonest form of morphine death is death in a coma and from respiratory paralysis. Before respiration completely stops it becomes very, very slow; it may be only ten or six times a minute."

"What, then, in short, is the significance in relation to a possible morphine death, of this record of respirations at 50 an hour and a quarter before she died?"—It shows she was not having the usual effect of fatal doses of morphine before she died."

He said that the time from the respirations having been noted at 50 to the time when she died was much too short for her to have died of morphine poisoning, morphine having been taken seven and a half hours before.

The cause of death might have been a coronary thrombosis. He saw no necessity to link her death with the doses of heroin and morphia, although it was possible that it was so linked. Although they were rather large doses of an hypnotic, which in general was a bad thing, it was just as likely that they did her good and that she would have been worse without them. There was no evidence either way.

He had searched world medical literature dating from 1800 to 1956, more than 10,000 references on morphine and allied subjects, for evidence about morphine convulsions, and had found descriptions of only 18 cases, excluding infants, of which one had been due to heroin, the remainder to morphine—4 in women and the rest in men. Many of the reports had been extremely sketchy, merely referring to Chinese coolies having convulsions with unknown doses. Not all the recorded instances, of course, had been available.

The witness described and demonstrated convulsions, and showed the difference between clonic and tonic movement.

Mr. Lawrence: "On the evidence here, what do you say about the death? Was it a death from the convulsive effects of morphine poisoning or not?"—I found it very difficult to discover the relationship between convulsions and death. Only four of my cases are recorded as having died in fact, though they had convulsions. My impression is that when they die with convulsions they die in a convulsion, but my knowledge of the phenomenon is so slight that I would not suggest that this is invariably so.

"At any rate, as Dr. Ashby said, it is a very rare phenomenon?"—Yes.

Fatal Dose

He said that the conception of a fatal dose was really too simple to have any practical value. Morphine and heroin were absolutely outstanding for variability, especially when tolerance was taken into account.

Mr. Lawrence: "Would you have expected the doses indicated in the nurses' notebooks to have had a fatal result on Mrs. Morrell?"—The whole point of morphine doses is that I would not expect anything. It is much too varied and unpredictable. On this dosage I would not say that death could not occur."

He had been surprised to hear hyoscine mentioned as an alternative drug to morphine and heroin. He certainly would not recommend it if there was a danger of respiratory failure.

It was a fairly general rule that morphia and hyoscine were not used together pre-operatively in patients over 60, because that synergistic combination would be likely to depress respiration. He did not think the use of atropine made much difference either way. He, personally, would have turned to paraldehyde if he had had to turn to something. Dr. Douthwaite's description of it as "an old-fashioned and well-established hypnotic" was rather derogatory; it was an old one in continuous use.

Asked to comment on the "sinister" suggestion of the prosecution about the patient's dependence on the doctor for drugs, he said addicts did develop a strongly emotional relationship to people or places from which they got their drugs, but that did not apply in places, such as China, where supplies were easily obtained. There was no evidence that Mrs. Morrell even knew she was dependent on morphine. He saw no evidence of craving for drugs by the patient.

On the fourteenth day of the trial, April 4, Dr. Harman was recalled to give the remainder of his evidence-in-chief. He said that in his opinion there was no reason why heroin should not be given to elderly people. If there was a danger it must be a very small one which was not obvious to a large number of doctors who used the drugs. He agreed with Dr. Ashby that there was nothing sinister in

the withdrawal of the morphine from the treatment at the end of October and the beginning of November, 1950.

There was nothing astonishing in the direction to the nurses to give morphine and heroin S.O.S. He frequently did it himself. He would leave it to the nurses' discretion.

Witness Cross-examined

Cross-examined by the Attorney-General, he said he had been in general practice for one fortnight. Prior to the case he had made no special study of heroin and morphia.

The Attorney-General: "You are a recognized authority, are you not, on a disease known as Q fever?"—I have described cases."

"And Dr. Douthwaite is a recognized authority in relation to heroin and morphia?"—He is."

"When you have to perform a diagnosis, you seek, no doubt, to take into account all relevant facts and symptoms?"—I do."

"It is very important, is it not, that you should not shut your eyes to the obvious or not give certain factors their full weight?"—It is."

"When were you first asked to consider this case?"—About a fortnight before it opened."

"At the magistrates' court?"—No, here."

"When did you start reading books on this subject to prepare for your evidence?"—During that time."

The regulations, with regard to dangerous drugs, were quite strict. It was important that the drugs should not be left lying about. Doctors would not normally prescribe morphia and heroin for a patient without the intention of using them on that patient. He was unwilling to suggest what would have been the effect if nearly all the drugs prescribed between November 8 and 13 had been administered, but he certainly thought she could have survived that dosage.

The Attorney-General: "If she had these prescriptions given to her in that short period, that would not form a topic of medical shop between you and other doctors?"—Yes, those doses would."

"Have you ever heard of any doses like that being prescribed for a lady of 81?"—Yes."

"A dying lady—not dying of cancer—a dying lady?"

"In the case I am thinking of, the lady was not dying at all."

"Have you ever heard of any prescriptions like that being prescribed for a dying lady of 81?"—I have not heard of an exactly comparable case."

"If this lady was, as you say, dying early in November, the administration of this dosage must have killed her, must it not?"—No."

"It would have been a most remarkable thing if she had survived it, would it not?"—It would have been a thing worth talking about to colleagues."

"As a remarkable thing?"—As a remarkable thing."

He did not agree with Dr. Douthwaite's evidence that each one of the prescriptions prescribed on the last days, if administered on those days, was a lethal dose. Dr. Harman said he had only treated two or three addicts and had never attempted to wean one.

The Attorney-General: "Were the addicts you treated morphia or heroin addicts?"—One was a heroin addict, the others morphine addicts."

"One heroin addict is not a very representative pattern, perhaps, on which to base a general opinion, but was that addict excitable?"—Not at all."

"How many years ago was that?"—It was before the war."

"Is that the last case you have seen of heroin addiction?"—Yes."

"Am I right in concluding that most of the views you have expressed about heroin are views you have formed after reading books for the purposes of this case?"—Yes. That is one of the usual ways of gaining knowledge."

He did not consider that, if heroin was given repeatedly, the patient would probably develop a feeling of great gratitude to the doctor who was giving her such wonderful injections.

"Are you really saying that a doctor who succeeds for two years by the use of these drugs in making his patient feel better would not get a sense of gratitude felt by the patient towards him?"—I think she would get a sense of gratitude from all his attention in general."

He saw no reason why an attempt should have been made to wean the patient, because she was getting along very well and the attempt was not necessarily worth it.

increase the amount of money from his practice he had to take more people on his list. With large lists of 4,000 or more it was difficult to give proper service. When people were paid from public funds it was important to have satisfactory arrangements by which their money could be increased. If they did not get paid extra salaries they paid a concealed tax because they did not get enough to enable them to cope with the increasing cost of living. One had to be careful not to insist that one profession alone should be tied to a regular increase when the cost of living went up. He would not suggest that the profession would not wish to be put in a specially privileged position, but they were in the present frame of mind because they felt they had not been given what they were promised.

Lord HADEN-GUEST said that a doctor was not a man who thought primarily about money or the income he would get, although he wanted an adequate income. A doctor had to live a life dedicated to his profession. It was a profession that needed different treatment from others.

Earl JOWITT said that whatever happened he hoped that the doctors would abandon any idea of what was called a strike. He would pray that we might accept far more generally the principle of arbitration rather than a resort to force or pressure to try to win one's end. "By all means let us not try to talk of strikes, it is beneath the dignity of doctors." If there was to be arbitration, however, as he devoutly hoped there would be, it should start on the basis that the doctors were reasonably satisfied with the terms of reference under which the arbitrator was to act.

Government Reply

The EARL OF HOME, Lord President of the Council, said the House would wish that within the limits of reason and possibility justice should be done to the medical profession, because no body of men gave more indispensable service and none had a greater sense of responsibility. He said "within reason and possibility" because there was a background to the doctor's claim from which neither party could escape. The Health Service was a comparatively novel experiment. The State had no inherent virtues as an employer. It was the first time it had had to work out a relationship with one of the great skilled professions. Inevitably it must take time before a satisfactory code could be finally established.

The eight years of the Health Service had run concurrently with a time of intensifying inflation, when the purchasing power of money had declined and the costs of the professions had been raised. The doctors no doubt felt convinced that they had a case for increased remuneration, both actual and in relation to others. But the taxpayers were also bearing record levels of taxation, and they had an unanswerable case for relief. The Government were responsible to both the doctors and the taxpayers, and they had to try to be fair to all.

He emphasized the complex interrelation of these factors because there was one proposition running through this dispute which seemed to him false. It had seemed to be argued that, because the Spens Committees based their recommendations for remuneration on 1939 prices, therefore subsequent settlements must always guarantee the doctors against the extra costs brought about by inflation.

That was not a tenable proposition. So long as inflation persisted it was impossible to insulate one profession against the effects of it, or to guarantee that all professions should advance in their remuneration with proportionate precision. The remedy—and it was the Government's policy—was to stop inflation. That itself required the restraint of wage and salary earners. Short of the happy day when they achieved a halt to inflation, the best they could do was to try to ensure that no section of wage or salary earners was put at a relative disadvantage with regard to any other section of comparable skill and attainment.

The Spens Reports were accepted by the Government of the day, and were expected to provide a basis for the entry of doctors into the Health Service. Mr. Bevan, when Minister of Health, said in 1950 that the Spens principle

had served its original purpose, and could not be regarded as the basis of remuneration for all time. That was true. What in the Government's opinion was needed now, after eight years of the Health Service, was to determine the proper place of the medical profession in relation to other skilled professions, and when that was done to fix the scale of remuneration after authoritative and up-to-date findings by a Royal Commission. The Government believed that the Royal Commission could be the proper instrument. It could take into account all the circumstances that were relevant, and one of the factors clearly relevant was consideration of the Spens Reports. If the doctors wished to put before the Royal Commission their interpretation of the Spens Reports there was no reason why the Commission should not listen to and consider their views on them. Clearly the Royal Commission would take into account rewards for skill in other comparable professions, and equally the special conditions of a doctor's life.

Earl JOWITT, interrupting, said he had been looking at the terms of reference and he did not think that the Earl of Home was right. It depended on the construction of the terms of reference. The Earl of Home should take legal advice after the debate to find out whether he was right in what he said. The Earl of HOME said he had taken the advice of the Minister of Health, and he was advised that what he had said fell within the terms of reference to the Royal Commission.

He mentioned the 10% increase that had been given to junior hospital staff, and the announcement that was to come soon from the Prime Minister in relation to a further interim increase for senior hospital staff and general practitioners. Against the background of the country's financial position, and taking into account the doctor's claim was of such a size that it would affect the incidence of taxation, he suggested that, both from the point of view of the doctor and of the public, this interim assistance to be followed by a Royal Commission was a fair way of dealing with the problem.

The Royal Commission had already held a number of sittings, and the chairman had every intention that the Commission should act with speed. There had been criticisms that there were no doctors or dentists on the Commission, but the Minister thought that they would be more valuable as witnesses. It had also been asked why there was no direction to take into account remuneration in commerce and industry. The Minister thought that would have meant an immensely long inquiry, and there was a large section where conditions were not directly comparable. On the question of merit awards, he understood that the Commission would normally be concerned with the levels of medical and dental remuneration, and not with the methods as such. Whether they would find it necessary to look at merit awards in order to discharge their terms of reference fully would be for them to decide.

It was the Government's hope that they would be able to move away from the atmosphere of distrust, of accusations of bad faith, of trials of strength, and non-cooperation with the Royal Commission and the Health Service. That seemed to all of them out of character in a profession that recognized everywhere for its sense of responsibility. But it was equally true that the community, who were the new employers, should not trade on the tradition of patience and good will of the doctors. There must be give and take; there must be understanding and sympathy on both sides. It was the Government's desire that there should be a rapid, fair, and comprehensive settlement, and they believed that the Royal Commission was the method which would most surely reach these results.

Lord MORAN, in a final comment, expressed at times with some exasperation, said he was profoundly disappointed in the substance of the reply. He had given the Earl of Home notice of two questions, and neither had been answered in a way satisfactory to the doctors. On the question of merit awards he merely said that it was for the Royal Commission to settle. In other words the remuneration of consultants might be torn up by the roots and much done in the last seven years thrown away.

Vital Statistics

Tetanus in Hospital

Investigations into the tetanus outbreak at the North Staffordshire Royal Infirmary, Stoke-on-Trent (*Journal*, March 16, p. 653), have shown that tetanus spores were widespread throughout the operating-theatre block. This was stated by Dr. E. M. Mackay-Scollay, director of the Stafford public health laboratory, at the inquest held last week on two of the patients who died. The jury returned verdicts that death was due to tetanus accidentally contracted following operations. The other three patients have now recovered.

Dr. Mackay-Scollay said the North Staffordshire Infirmary operating-theatre block comprised three theatres and their ancillary departments. He found evidence of the presence of tetanus spores after examining samples of dust, debris, and wall plasters from the floor of the main theatre corridor, various sites in the annexe, in particular the packing-room floor, a naked electric light bulb in the packing room, the sluice-room floor, and the floor, walls, shelves, and partition in the annexe passage. He also found spores among general floor sweepings of the theatre block, in a storage box for rubber gloves, and on a surgeon's glove contained in a sterilization drum. There was no evidence of whether that drum had been through a process of sterilization or not. Negative results had come from his examination of samples of all batches of opened catgut. Asked whether normal hospital sterilization would kill a heavy concentration of tetanus on a surgical glove, he agreed it was very difficult to kill tetanus spores, but said that if the method employed was adequate they would be destroyed.

At the close of the inquest it was announced on behalf of the hospital management committee that the present theatre block at the Infirmary would not be reopened, and that new theatres costing between £40,000 and £50,000 were to be built. This was "because of the unusual and unpredictable cases of infection by tetanus."

Week Ending March 30

The notification of infectious diseases in England and Wales during the week included: scarlet fever 812, whooping-cough 2,849, diphtheria 6, measles 25,185, acute pneumonia 545, acute poliomyelitis 28, dysentery 1,222, paratyphoid fever 3, and typhoid fever 1.

Infectious Diseases

In England and Wales during the week ending March 23 the largest rises in the notifications of infectious diseases were 2,354 for measles, from 24,825 to 27,179, and 134 for food-poisoning, from 164 to 298; the largest falls were 248 for whooping-cough, from 3,180 to 2,932, 113 for scarlet fever, from 935 to 822, 99 for dysentery, from 1,416 to 1,317, and 75 for acute pneumonia, from 770 to 695.

The largest increases in the incidence of measles were 737 in Yorkshire West Riding, from 2,115 to 2,852, 467 in Warwickshire, from 1,099 to 1,566, 402 in Essex, from 1,644 to 2,046, 278 in Middlesex, from 1,298 to 1,576, 272 in Kent, from 795 to 1,067, 202 in London, from 1,832 to 2,034, and the largest decreases were 361 in Lancashire, from 4,227 to 3,866, 204 in Cumberland, from 619 to 415, and 122 in Surrey, from 1,519 to 1,397. The largest declines in the incidence of scarlet fever were 31 in Durham, from 70 to 39, and 24 in London, from 74 to 50. The only large fluctuation in the returns of whooping-cough was a fall of 68 in Warwickshire, from 148 to 80. 3 cases of diphtheria were notified, the same number as in the preceding week.

37 cases of acute poliomyelitis were notified, and these were 3 more for paralytic and 4 fewer for non-paralytic cases than in the preceding week. The largest returns were Essex 6 (Brightlingsea U.D. 6), Hertfordshire 5 (Barnet U.D. 2), Surrey 4 (Hambleton R.D. 2).

The largest centres of dysentery were Yorkshire West Riding 282 (Rotherham C.B. 63, Leeds C.B. 40, Bradford C.B. 29, Pontefract M.B. 26, Worsborough U.D. 14, York C.B. 12), Lancashire 150 (Liverpool C.B. 24, Blackburn C.B. 23, Stretford M.B. 21, Ashton under Lyne M.B. 15), Durham 111 (Blaydon U.D. 51, Whickham U.D. 19, Gateshead C.B. 12), Surrey 91 (Surbiton M.B. 32, Chertsey U.D. 25, Esher U.D. 17), London 78 (Wandsworth 40), Cheshire 70 (Hyde M.B. 42), Bedfordshire 57 (Luton M.B. 39, Luton R.D. 17), Middlesex 57 (Hayes and Harlington U.D. 21, Enfield M.B. 16), Nottinghamshire 49 (Basford R.D. 20, Nottingham C.B. 10), Shropshire 33 (Oswestry M.B. 20, Oswestry R.D. 12), Kent 32 (Deal M.B. 27), Warwickshire 31 (Birmingham C.B. 14, Coventry C.B. 11), Essex 30 (Hornchurch U.D. 12), Devonshire 27 (Plymouth C.B. 26), Yorkshire East Riding 25 (Kingston upon Hull C.B. 19), and Oxfordshire 21.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1948-56 are shown thus ----, the figures for 1957 ———. Except for the curves showing notifications in 1957, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

England and Wales in 1956

Provisional figures of deaths from certain causes have been announced for England and Wales in 1956 (Registrar-General's Weekly Return No. 13):

Tuberculosis.—Deaths from respiratory tuberculosis numbered 4,851 (against 5,837 in the previous year), giving a provisional death rate of 109 per million persons. This is a decrease of 17% compared with the previous year. Since 1947 the death rate from respiratory tuberculosis has fallen by more than 75%. The death rate from other forms of tuberculosis was 12 per million persons, compared with 15 for 1955.

Cancer.—The provisional death rate for all forms of cancer for men was 2,274 per million population and for women 1,891. The 1955 figures were 2,252 and 1,873 respectively. The rise in the rate for men includes an increase from 693 to 726 per million population for deaths assigned to cancer of the lung and bronchus. The rate for cancer of the lung and bronchus for women increased from 106 per million in 1955 to 111 in 1956. The male deaths from cancer totalled 48,932, of which 15,615, or nearly 32%, were certified as due to cancer of the lung and bronchus. For women, out of a total of 43,769 deaths from cancer, only 2,570, or less than 6%, were ascribed to this cause.

Maternal Causes.—There were 401 deaths from maternal causes (including abortion) last year. In 1955 the total was 439. The provisional maternal mortality rate (including abortion) per 1,000 live and stillbirths was 0.56, the lowest ever recorded. The previous lowest was 0.64 in 1955.

Eire in 1956

The yearly summary for 1956 in Eire shows that the birth rate was 21.0 per 1,000 population, being 0.2 below the rate for 1955. Infant mortality was 36 per 1,000 registered births; this was the lowest rate ever recorded, being 1 below the preceding lowest level of 1955. The death rate was 11.7 per 1,000 population and was 0.9 below the rate for the preceding year. The death rate per 100,000 from respiratory tuberculosis was 19 and 4 from other forms of tuberculosis; these rates were 5 and 1, respectively, below the rates for 1955. Mortality from respiratory tuberculosis has fallen to one-third and other forms of tuberculosis to one-fifth of the level of 1951. Deaths from infectious diseases included 401 from influenza, 153 from gastro-enteritis (under 2 years), 39 from whooping-cough, 20 from acute poliomyelitis, 20 from measles, and 15 from diphtheria. Deaths from malignant neoplasms numbered 4,566 and were 7 more than in 1955. Of these deaths 48% were due to malignant neoplasms of the digestive system and 12% to the respiratory system.

In the December quarter of 1956 the birth rate was 20.3 per 1,000 population and was 0.8 above the rate for the preceding fourth quarter. The infant mortality rate was 35 per 1,000 registered births, being 1 below the rate for the fourth quarter of 1955; it was the lowest rate for any December quarter. The death rate was 10.9 per 1,000 population and was 0.3 above the rate for the preceding December quarter.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending March 23 (No. 12) and corresponding week 1956.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

Medical News

Nuffield College of Surgical Sciences.—The opening of the Nuffield College of Surgical Sciences of the Royal College of Surgeons on April 5 was an event of the first importance for surgical education. The new college is the gift of Viscount Nuffield, made through his charitable trust and King Edward's Hospital Fund for London. It consists of a residential college with room for 80 postgraduate teachers, students, and research workers drawn from Commonwealth countries and other parts of the world who will, it was stated, "gather together for periods of intensive study with all the academic amenities and scientific facilities of the Royal College of Surgeons at their disposal." Great store is set by the fact that the students will be able to mix freely with members of the academic staff of the college and with eminent surgeons of every nationality. The project arose from the desire of Viscount Nuffield and Lord Webb-Johnson—both of whom received an ovation—to create an "All Souls of Surgery." Viscount NUFFIELD asked the President, Sir HARRY PLATT, who was supported by the Council of the College, to accept the new college, and Lieutenant-General Lord FREYBERG, V.C., formally opened the building after addressing a large and distinguished gathering. The accommodation is commodious and consists of large bed-sitting rooms, dining-room, and lounge, and the amenities include a squash court and a billiards-room. Residents pay £7 5s. weekly for full board, except luncheon.

Voluntary Health Insurance.—The British United Provident Association celebrated its tenth birthday with a dinner in London on April 2. The association is non-profit-making and exists to provide insurance against heavy medical and nursing expenses for those preferring private treatment. It could report a most satisfactory expansion during its first ten years. Mr. F. E. WEBB, the general manager, said that when the association started the staff numbered 17: to-day it was over 300. Administration then cost about a quarter of the subscribed capital, whereas last year only a little over 10% of the income. The initial membership was 50,000. During the first seven years 250,000 new members joined, and during the last three years another 250,000, figures which, Mr. Webb suggested, seemed to indicate that the more people knew of the nationalized health services the less satisfied they were with them. Only about 3% of existing subscribers dropped out each year, while new subscribers were joining at the rate of 30,000 a year, mainly through the introduction of existing subscribers. The reason why they had been able to make such a success of health insurance was, he thought, because they had been able to pay out such large amounts to their dependants in benefit. That could only be done if the services were administered cheaply, and that they had been able to do. They were a non-profit-making organization; the governors got no payment for their services; the staff was generously treated, but no one else dipped into the pool, and they had no heavy advertising charges. At the dinner the chair was taken by the chairman of the association, Sir ANDREW ROWELL, and Mr. REGINALD MAUDLING, M.P., Paymaster-General, was the principal guest.

Society of Chiropodists.—Sir ZACHARY COPE proposed the health of the society at the annual dinner, held at the Park Lane Hotel on April 4. He said there were three particular things he liked about the society—its name, suggestive of strength and power; its development during the past years; and the excellent leadership it had had. Sir Zachary recalled an occasion during the first world war when he had had to undertake chiropody himself: it was a good thing, he said, that as a surgeon he was accustomed to the sight of blood. Responding to the toast, Mr. J. R. HALL, the president of the society, said that Sir Zachary had done more for medical auxiliaries than anyone else, and before long they hoped to see the fruition of the tremendous work

he had put in as chairman of the Cope Committees—with the "professions supplementary to medicine" based on the same high standards of education, examination, and ethics as those of the medical profession. Proposing the health of the guests, Mr. D. NEALE mentioned in particular the support the society had had from the Royal Colleges, and in an entertaining reply Sir HENRAGE OGILVIE ran through the changing fashions of surgery in fairly recent years: plastic surgery followed the fashion for orthopaedic surgery set by Sir Robert Jones; then came the thoracic surgeons, the cardiologists, the arterial surgeons, and finally, at their heyday now, the surgical biochemists.

Physical Medicine Dinner.—Dr. P. BAUWENS was in the chair when the British Association of Physical Medicine held its annual dinner on April 5. In proposing the health of the association, Sir CECIL WAKELEY said there was no branch of medicine which had not benefited from physical medicine: "We strip the veins. You get rid of the ulcers." After Dr. BAUWENS had replied, the health of the guests was proposed by Group Captain C. J. S. O'MALLEY. He paid a special tribute to Mr. J. Cyril Butterwick, Prime Warden of the Goldsmiths Company, for the help they had given in connexion with the association's presidential badge, made in memory of Lord Horder. In reply Mr. BUTTERWICK said the Goldsmiths Company was deeply interested in rehabilitation. Metalwork and jewellery-making were good outlets in occupational therapy.

University Apartheid Bill Withdrawn.—On technical grounds, Mr. VIJOEN, the South African Minister of Education, Arts, and Science, has withdrawn the Government's Separate University Education Bill. He originally introduced the Bill in the Union parliament on March 11. The Bill's purpose was to enforce apartheid in South African universities. It deprived Natal University of its medical faculty, the Durban Medical School, and placed it together with Fort Hare University College, and other university colleges for "non-whites" which were to be established, under a government department; their teaching staffs were to become civil servants, liable to dismissal for public criticism of the Government. The Bill made it an offence, punishable by fine or imprisonment, to admit non-Europeans to the two existing open universities—Capetown and Witwatersrand—or to admit Europeans to "non-white" colleges. The Government's proposals provoked a storm of criticism from academic and medical circles in South Africa (see this *Journal*, 1957, 1, 532, 699, and 775). It is understood, however, that the reason for the Bill's withdrawal was not in response to the protests it has evoked, but because the parts dealing with the Durban Medical School and Fort Hare would have had to go before a select committee, which is a lengthy process. According to the Capetown correspondent of *The Times*, the South African Government has not shelved the Bill, but intends to introduce a Bill to establish university apartheid this session and to leave the Durban Medical School and Fort Hare University College until later.

Dr. Cuthbert Lockyer, 90.—This Saturday Dr. CUTHBERT LOCKYER, consulting gynaecologist to Charing Cross Hospital, is 90. His colleagues, friends, and pupils will wish to join us in congratulating him. Besides holding consulting appointments at Charing Cross Hospital, the Samaritan Hospital for Women, the Royal Northern Hospital, and the National Hospital, Queen Square, Dr. Lockyer was a foundation fellow and councillor of the Royal College of Obstetricians and Gynaecologists. On his retirement in 1930 he presented his magnificent collection of obstetrical and gynaecological specimens to his old school, Charing Cross Hospital.

Prophylactic Chemotherapy at Cancer Operations.—In New York last month Dr. WARREN H. COLE described his use of a prophylactic "umbrella" of nitrogen mustard in cases of cancer. The nitrogen mustard is given intraperitoneally (and also sometimes intravenously as well) at the time of operation, and intravenously for three days subsequently. The object is to destroy dislodged cancer cells

before they can take root. Dr. Cole, who is immediate past-president of the American College of Surgeons, was speaking at a conference at the New York Academy of Sciences on March 28-30. With colleagues from the University of Illinois College of Medicine he reported to the Southern Surgical Association last December experimental results supporting this approach. At the conference in New York he gave his preliminary findings in 34 patients with cancer of the colon or rectum. Although operation appears to lower resistance to the toxic effects of nitrogen mustard, Dr. Cole was able to conclude that his procedure was safe for such cases provided certain precautions were observed.

Another Medical Visit to Warsaw.—Three British thoracic surgeons, Sir CLEMENT PRICE THOMAS, Mr. ANDREW LOGAN, and Mr. RONALD EDWARDS, visited Warsaw last week. They took part in a meeting of the Thoracic Section of the Society of Polish Surgeons on April 4-6. They were invited by the Polish Ministry of Health, and their visit was arranged through the British Council.

Chair in New York.—Dr. BRIAN MACMAHON has been appointed to a new Chair of Environmental Medicine and Community Health in New York State University. He qualified in medicine from Birmingham Medical School in 1946, and after holding a Rockefeller fellowship at Harvard returned to Birmingham as lecturer in social medicine.

F.R.F.P.S.—The following were admitted fellows of the Royal Faculty of Physicians and Surgeons of Glasgow at a meeting on April 1: G. H. A. Aponso, A. K. Dutta, S. Janardhana, and G. P. McNicol.

Air Travellers' Society.—On March 27 in London Lord BRABAZON OF TARA inaugurated the International Society of Air Travellers and Air Transport Users. Among the society's objects are the maintenance of a register of doctors living near airfields who are ready to treat its members, and the care of children, the disabled, and the infirm at airports. The society's address is 45, Park Lane, London, W.1.

Dr. Macdonald Critchley has been elected a member of the Norwegian Academy of Science and Letters.

COMING EVENTS

Institute of Diseases of the Chest.—Clinical demonstrations by Dr. F. H. YOUNG at the Institute (Brompton Hospital, Fulham Road, London, S.W.3) on Fridays at 5 p.m. from April 26 to July 5. Open to all medical practitioners without fee.

B.B.C. Programmes on Mental Health.—Series of six features, weekly from Wednesday, April 17, in the Home Service. B.B.C. leaflet, "Mind Out of Balance," available, on receipt of stamped envelope (2d.), from B.B.C. Publications (Mental Health), 35, Marylebone High Street, London, W.1.

Polish Medical Association in Exile.—Annual meeting on April 27 and 28, at 14, Collingham Gardens, London, S.W.5. Details from the hon. secretary at the above address.

Heberden Society.—The Heberden Round will be held at the Rheumatic Unit, Northern General Hospital, Ferry Road, Edinburgh, on May 16 from 10 a.m. Members expecting to attend should notify Dr. J. J. R. DUTHIE as soon as possible.

National Association for the Prevention of Tuberculosis.—Symposium on "Chronic Bronchitis," on May 29, at 3.30 p.m., at the Clinical Science Building, York Place, Manchester, 13. Admission by ticket (price 10s.) available from N.A.P.T., Tavistock House North, Tavistock Square, London, W.C.1.

Second International Congress for Social Medicine.—Vienna, May 30 to June 2. Organized by the International Federation for Hygiene and Prophylactic Medicine, the Austrian Scientific Society, and the Austrian Medical Chamber. The theme of the Congress will be "University and Public Health." Details from the secretariat, 10-12, Weiburggasse, Vienna, 1.

NEW ISSUES

Thorax.—The new issue (Vol. 12, No. 1) is now available. The contents include:

- A SELF-CONTAINED, DISPOSABLE OXYGENATOR OF PLASTIC SHEET FOR INTRACARDIAC SURGERY. Vincent L. Gott, Richard A. DeWall, Mathias Panch, M. Nazhi Zuhdi, William Weirich, Richard L. Varco, and C. Walton Lilehel.
- STENOSING NON-CASEATING TUBERCULOSIS (SARCOIDOSIS) OF THE BRONCHI. K. M. Chinn and J. G. Scadding.
- BRONCHIAL INVOLVEMENT IN PULMONARY SARCOIDOSIS. Vatche V. Kaibian.
- COR TRIANGULUM. N. R. Barrett and John B. Hickie.
- THE POSSIBLE ROLE OF SURGERY IN THE TREATMENT OF ANOMALOUS LEFT CORONARY ARTERY. J. Adley, R. E. Horton, and M. G. Wilson.
- AN UNUSUAL CAUSE OF A CONTINUOUS MURMUR SIMULATING PERSISTENT DUCTUS ARTERIOSUS AND ASSOCIATED WITH OTHER CONGENITAL CARDIAC DEFECTS. A. J. Gunning.
- PERCUTANEOUS LEFT VENTRICULAR PUNCTURE IN THE ASSESSMENT OF AORTIC STENOSIS. Peter Fleming and Ronald Gibson.
- THE ANATOMY OF PHRENIC NERVE TERMINATION AND THE MOTOR INNERVATION OF THE DIAPHRAGM. G. S. Müller Botha.
- RESPIRATORY GRANULOMATOSIS WITH POLYARTERITIS NODOSA (WEGENER'S SYNDROME). N. S. Plummer, J. H. Angel, D. B. Shaw, and K. F. W. Hingray.
- REPORT OF A CASE OF PULMONARY TELANGIECTASIA. G. H. Apthorp and D. V. Bates.
- A CASE OF PERITONITIS-PERICARDIAL DIAPHRAGMATIC HERNIA TREATED SURGICALLY. A. El Sherif and S. El Mallah.
- RELAPSES AFTER RESECTION FOR PULMONARY TUBERCULOSIS. A. M. W. Hekking.
- THE RESULTS OF RAISING THE RESPECTABILITY RATE IN OPERATIONS FOR LUNG CARCINOMA. R. Abbey Smith.
- DRILL BIOPSY IN INTRATHORACIC MALIGNANT DISEASE. Robert Morrison and Thomas J. Deeley.
- EVARTS' GRAHAM.

Issued quarterly; annual subscription £2 2s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked •. Application should be made first to the institution concerned.

Monday, April 15

SOCIETY FOR GENERAL MICROBIOLOGY.—At Royal Institution, 6 p.m. Third Marjory Stephenson Memorial Lecture by Dr. A. Lwoff (Institut Pasteur): The Notion of Vi-us.

Tuesday, April 16

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—3.45 p.m., Erasmus Wilson Demonstration by Dr. H. G. H. Richards: Parotid Gland Tumours. SOCIETY FOR THE STUDY OF ADDICTION.—At 11, Chandos Street, W. 8 p.m., Dr. D. J. Parr: Alcoholism in General Practice. WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Mr. J. Minton: Ocular Manifestations in Clinical Neurology (Part II).

Wednesday, April 17

HARVEIAN SOCIETY OF LONDON.—8.15 p.m., Dr. Katharine Williams: Nuclear Age: Potentiality and Hazard (illustrated by a film "Calder Hall").

Thursday, April 18

HYPNOTHERAPY GROUP.—At Royal Society of Medicine, 8 p.m., clinical evening. Dr. G. J. Ambrose and Dr. A. Fry: demonstration of cases treated by hypnosis and illustration of the different techniques used. KENT PAEDIATRIC AND CHILD HEALTH SOCIETY.—2.30 for 3 p.m., visit to Vocational Guidance Department, National Institute of Industrial Psychology. NORTH-EAST CLINICAL SOCIETY.—At Prince of Wales's General Hospital, N., 2.30 p.m., clinical meeting.

Sunday, April 21

EDINBURGH CLINICAL CLUB.—At Peel Hospital, 3.15 p.m., meeting with Border Clinical Club.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Steele.—On March 31, 1957, at Kuching General Hospital, Sarawak, to Eileen (formerly Selby-Brown), M.B., B.S., and William O. Steele, B.A., of the Education Office, Simanrang, Sarawak, a son—Jonathan William.

MARRIAGES

O'Donoghue—Hanton.—On March 5, 1957, Hugh O'Donoghue, M.B., D.O., of Herbert Park, Dublin, and 72, Warham Road, Croydon, Surrey, to Miriam Hanton, of John Street, Wexford, Eire.

DEATHS

Aubin.—On March 7, 1957, Emile Dupont Aubin, M.D., of Auckland, New Zealand, aged 87.
Esterman.—On March 7, 1957, Tobias Esterman, M.B., Ch.B., of Highgate, London, N.
Farris.—On March 20, 1957, at 55, Hove Park Road, Hove, Sussex, Desmond William George Farris, C.B.E., M.B., B.S., D.P.H., late of Singapore, Malaya, aged 56.
Hunter.—On March 19, 1957, Stewart Hunter, M.B., F.R.C.S.Ed., M.R.C.P., D.C.H., of Christchurch, New Zealand, aged 54.
Nelson.—On March 16, 1957, at Fauvic Nursing Home, Jersey, Channel Isles, Harry Ross Nelson, M.B., Ch.B., D.P.H., late of Uganda, aged 78.
Price.—On March 17, 1957, at Twyford, Reading, Berks, Alfred Henry Price, M.D., D.P.H.
Small.—On March 18, 1957, at 8, Tollgate Road, Rothbury, Northumberland, John Alexander Small, M.B., Ch.B., aged 80.
Taunton.—On March 18, 1957, at Bailiff's Cottage, Chittenden, Four Elms, Kent, Thomas Joseph Taunton, M.R.C.S., L.R.C.P., of 52, Biddulph Mansions, Elgin Avenue, London, W.

Any Questions ?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Treatment of Menopausal Symptoms after Mastectomy for Cancer

Q.—Is it safe to give hormone therapy for severe menopausal symptoms in a patient who has previously had a radical mastectomy for carcinoma of the breast? The symptoms are predominantly psychological.

A.—There is evidence that the relationship of oestrogen to carcinoma of the breast varies according to whether the disease commences before or after the menopause.¹ In the case in question the growth began before the menopause, so the administration of oestrogen in any form with the idea of controlling menopausal symptoms is contraindicated. Since the symptoms are predominantly psychological it must be asked whether it is reasonably certain that their cause is the climacteric. The association could well be fortuitous, and the opinion of a psychiatrist appears to be indicated before any treatment is planned. If it be concluded that the climacteric is to blame, treatment with sedatives or with drugs which convey euphoria may still be better than endocrine therapy. If it comes to hormones, thyroid might be tried and, failing that, methyl testosterone in a dose of 10 mg. daily sublingually. If the latter has a good effect the patient should be gradually weaned from it after an initial four to six weeks' treatment. The dose of androgen advised is small, so virilizing effects are not likely; they are, however, not impossible.

Agricultural Fungicides in Medicine

Q.—To what extent have agricultural fungicides proved applicable to mycotic infections in man, in particular compounds such as allylthiohippurate sodium ("ehesal")? Does the relationship of plant and soil fungi to animal fungi make this a practicable possibility, or are there marked differences in their metabolism that preclude this?

A.—There is no known correlation between the effectiveness of fungicides in agricultural practice and their probable therapeutic value in the fungus diseases of man and the lower animals.

Antifungal compounds used in agriculture have provided material for research in the chemotherapy of the mycoses; but, although such compounds have been found fungistatic to pathogenic fungi *in vitro*, in many instances they have been unsuitable for internal administration because of their high toxicity and for external use because of their irritant or sensitizing properties; and when these objections have not applied the compounds have often proved ineffective *in vivo*. As examples among the organic sulphur compounds used as fungicides in agriculture, some of the derivatives of dithiocarbamic acid have been found fungistatic to *Histoplasma capsulatum* at very low concentrations *in vitro*, but they were too toxic to mice for therapeutic tests *in vivo*. A related compound, tetraethylthiuram disulphide (disulfiram), which was found to have a strong, selective, fungistatic action *in vitro* against *H. capsulatum* as compared with other pathogenic fungi, is relatively non-toxic, but proved ineffective for the arrest of histoplasmosis in experimentally infected mice.

So far as their ecology is understood, many pathogenic fungi appear to be "plant and soil fungi" in natural saprophytic life. Adaptation to parasitic life in animal tissues usually entails drastic morphological and physiological changes, so that sensitivity to a drug *in vitro* may be no

criterion of the reaction *in vivo*. One of the few specifics in medical mycology is potassium iodide in the treatment of sporotrichosis; nevertheless, *Sporotrichum schenckii* can vegetate in a culture medium containing 8% of potassium iodide.

Inheritance of Diabetes Mellitus

Q.—What are the chances of diabetes developing in the children of a normal couple where there is an affected grandparent on each side (the paternal grandfather and the maternal grandmother)? There is no other history of diabetes in either family.

A.—A number of large-scale family studies have been made on the inheritance of diabetes mellitus.^{1,2} These have shown that environmental as well as genetic factors must play a part in causing the disease. In addition there is very probably more than one type of diabetes mellitus, differing in age of onset and sensitivity to insulin, with probably different aetiologies.

Any estimate of genetic risks to the relations of men and women with diabetes must be based on empirical findings. Such risks are available for the sibs and children of diabetics, but not for the grandchildren. However, it is improbable that the risk to the children of this couple is more than 10%.

Drug Rashes

Q.—There seem to be only a limited number of forms a drug rash may take. What is the mechanism of such rashes and what principally determines their form in the individual case—composition of the drug, dosage, or the particular patient?

A.—A clear distinction must be drawn between drug rashes which are a manifestation of toxicity and those which are due to the development of allergic sensitivity. Consideration of the effects of arsenic may help to clarify this. Long-continued administration of arsenic may cause the development of hyperkeratosis and pigmentation in the skin. Arsenic is deposited in the skin and hair, but the exact mechanism of its chronic effect is not known. Arsenical salts may also cause an acute toxic erythematous rash which may progress to a generalized exfoliative dermatitis. This has been shown to be due to the poisoning of the pyruvate-oxidase system necessary for the respiratory metabolism of skin and is reversible by dimercaprol (B.A.L.). In addition sensitization of the body to arsenic may occur and the manifestation may be urticarial, vesicular, or exfoliative.

The majority of drug rashes, however, are due to allergic sensitivity. There are two distinct forms of sensitivity reaction—the "immediate" or "anaphylactic" type, and the "delayed" or "tuberculin" type. The mechanism of the former is fairly well understood. In brief, the body responds to the presence of foreign protein by the production of antibodies. After antibodies have been formed and the patient has been thus sensitized subsequent contact with the original protein will result in combination of antigen and antibody which releases histamine and probably other substances giving rise within a few minutes to an urticarial response. In animals anaphylactically sensitized increasing sensitivity may result in an "Arthus reaction" at the site of the skin test. This is a haemorrhagic and necrotizing lesion and similar lesions can occur in humans.

In the "delayed" type of hypersensitivity antibodies have not been demonstrated in the plasma, the local lesion is essentially a proliferative mononuclear response, and hypersensitivity can be transferred only by cells and not by plasma. The response takes the form of erythema, induration, vesiculation, and tissue breakdown.

While these two types of reactions are considered by some workers to be entirely separate, a unifying view has also been put forward that immunization induces all cells of the reticulo-endothelial system to develop a specific reaction-

capacity to antigen, as shown in the infiltration of "delayed" reactions, and further to develop into plasma cells and subsequently produce free antibody as in the immediate reaction. A further point of controversy is whether all the tissues of the body develop "sensitivity" or whether the reaction-capacity is confined to cells of the reticulo-endothelial system. This is still a matter of investigation, although the explanation of "fixed" drug eruptions is dependent upon a clear answer.

Although some of the common sensitizing drugs are—contain—proteins, many are chemicals of varying degrees of complexity which one would not expect to be antigenic. Recent work suggests that these chemicals react with body protein and this complex stimulates the antibody response. When subsequently the simple chemical is brought into contact with the tissues, reactions of the immediate or delayed types or a combination of both occur. While this is certainly a valid explanation for the sensitizing properties of many drugs, it cannot be said to have been proved for them all.

The form of the drug rash is thus determined to a certain extent by the nature of the drug. It is also affected by the dosage, which, however, is related to the degree of individual susceptibility. Proteins tend to elicit an urticarial type of reaction only. Drugs of a chemical nature tend to produce reactions of the delayed type with vesicular lesions, but frequently mixed reactions occur.

Another factor influencing the reactions is the mode of administration. Local application produces initially only a local reaction, but prolonged administration may cause this to become generalized. A generalized reaction may be evenly distributed or localized to particular areas. Local trauma in the form, for example, of friction may determine the site of a secondary eruption or of the appearance of a rash due to ingested drugs. In some drugs—for example, sulphonamides—exposure to sunlight may be the determining factor of the eruption site, and of course there are chemicals which may cause a pure photosensitivity. The excretion of drugs in the sweat gives rise to a diffuse military appearance. The fairly constant appearance of bromide rashes is probably due to the excretion of bromide in the sebum as well as in the sweat.

In general the individual patient does not have a characteristic response to any one drug. Some subjects become more readily sensitized than others. In addition, the ease with which histamine is released from the skin varies. These factors, however, will tend to give quantitative rather than qualitative differences.

Salve for Vesicles

Q.—I once gave a patient who was exasperated by the itching of a routine revaccination vesicle the only analgesic preparation at hand—a sample intended for aural use. It contained an analgesic, an antiseptic, and glycerin, and relieved the itching. I was, however, surprised to see the patient later the same day, and to be told, "It's gone." The vesicle had, in fact, vanished completely. What is the explanation of this action, and would such a preparation act as effectively on the lesions of smallpox, herpes zoster, or chicken-pox?

A.—It is probable that part of the reaction which follows revaccination is an allergic one because of residual antibody to the primary vaccination. Therefore an analgesic or antihistamine preparation might be expected to relieve the itching and some of the inflammatory reaction, including blister-formation. Relief might also be expected in recurrent herpes.

In treating the lesions of smallpox, zoster, or chicken-pox, it has to be remembered that in all cases the virus is present in the skin lesions, and for two or three weeks antibodies are not produced, so that we might regard these lesions as being uncomplicated by an allergic reaction which depends upon the combination of allergen and antibody. It is probably wiser in these cases to use mild drying antiseptic lotions on the skin. This should prevent auto-inocula-

tion from the lesions, and will also control secondary bacterial infection, which often complicates the pock lesions and leads to greater scarring.

Probing the Unconscious

Q.—What are the pros and cons of the various methods used in psychiatry for uncovering unconscious material?

A.—Three methods are commonly used for uncovering unconscious material: (a) hypnosis and other forms of suggestive therapy; (b) narco-analysis; (c) analysis—such as psycho-analysis (Freud) and analytical psychology (Jung).

(a) *Hypnosis and Other Forms of Suggestive Therapy*: Treatment here is mainly in conditions where the removal of the symptom permits the restoration of normal functioning. Suggestion plays a part in every form of psychological treatment. Its mode of action is obscure. The words "only suggestion" give a false impression of the value. It is a quick method and may remove symptoms before they become established. Often, unfortunately, it produces an attitude of dependence in the patient. Patients should be selected for hypnosis by a doctor with psychiatric experience, as this type of therapy has some dangers.¹

(b) *Narco-analysis*, within its range, can help by effecting abreaction of symptoms in neurosis following trauma and repression of emotion. A drawback is that the patient may disown the uncovered material. (a) and (b) are best used by a psychiatrist skilled in the longer method of analysis.²
