and a submission to that sort of educational autocracy which led Flexner to believe that "the authorities" always know what is good for the student. The third Report of the Fulbright Committee put the opposite view succinctly: "A student's time for the entire course is his own property, to use and to organize as he chooses. That is at once his freedom and his responsibility." It is unfortunately true that the medical student is, in Newman's words, "all too much a schoolboy undergoing a course of technological tuition, even if he is doing it among the gray walls of Oxford or Cambridge." The Cleveland experiment in the U.S.A. has shown that it is possible to devise a curriculum which makes apparent the relevance of basic studies to the practice of medicine, and which brings the student into contact with patients from the outset. It has now been shown that this sort of intelligible, integrated education does not impair success in external examinations of the traditional type. It remains to be seen whether it succeeds in developing those qualities which cannot be measured by examinations: the capacity to understand sick people; the ability to profit by experience; the urge to do the best possible work; and, above all, the spirit which puts "the interest of the individual patient above the claims of gain, of fame, of research, and of the State." This is the true meaning of professional education; it is by the emergence of this spirit that medical education in the past can be judged, and upon its survival the future depends.

TEACHING OF SOCIAL MEDICINE

During the past decade medical schools on both sides of the Atlantic have attempted to make more adequate provision for the teaching of preventive and social medicine. The form which this development has taken has varied from one country to another, and between different schools of the same country, perhaps nowhere more than in Great Britain. Professor F. Grundy and Professor J. M. Mackintosh¹ have undertaken the difficult task of reviewing the trends in Western Europe, and their observations are reported in a valuable monograph published by the World Health Organization. The part of the report which will perhaps be of the greatest general interest is that which describes and interprets the trend of the modern curriculum. What, after a decade of post-war experience, do teachers consider should be taught in social medicine to undergraduate medical students? At the outset it is a relief to learn that there is fairly general agreement that certain subjects should not be included—for example, a detailed knowledge of public health practice and of epidemiology and statistics.

¹ Grundy, F., and Mackintosh, J. M., *The Teaching of Hygiene and Public Health in Europe, 1957*, W.H.O., Geneva.
² McKeown, T., *J. med. Educ.*, 1957, 32, 110.

Yet the syllabus which remains after the exclusions is formidable enough. Very broadly it may be said to be composed of certain elements of traditional public health teaching on which have been grafted three subjects—medical sociology, statistics, and epidemiology—which either were not taught, or were inadequately taught in the past.

The difficulty of carrying out these proposals is a common one in medical education. The teacher who attempts to cover all the subjects suggested, apparently on the best of grounds, soon finds himself in an impossible position. He is like a man who having examined his accounts is forced to the conclusion that although each item of expenditure appears to be unexceptionable the total cost is more than he can bear. Without reference to some general conception of the object of the instruction the teacher cannot decide what should be cut down and what should be left out. It is this general conception which is still notably lacking in social medicine, and when asked to define their aims many teachers still find it difficult to do more than describe their syllabus. The days of searching for a close definition of the subject may be over, but perhaps the time for a more precise statement of aims and objectives has arrived. On the basis of the past ten years' experience it should not be impossible to say in a few sentences what it has never been possible to say in a few words. What is evidently needed is a unifying idea which would either exclude or assemble into a coherent whole the diverse subjects which have been added to the post-war curriculum, some of them, as Grundy and Mackintosh note, for no better reason than that they seemed important, and that "if the student did not receive instruction in a department of social medicine, he would normally not receive it at all."

In a recent discussion of the syllabus in social medicine Professor T. McKeown² has stressed the need for coherence, and has described what he considers to be the necessary conditions for achieving it. These are "exclusions of medical statistics and human genetics, and extension of the instruction, hitherto restricted mainly to preventive measures, to include the curative services." His reason for excluding statistics and genetics is not that these subjects should not be taught, nor even that they should not be included among the responsibilities of the department of social medicine. But they are disciplines in their own right, almost equally relevant to many other subjects in the medical curriculum, and no coherence can be achieved so long as they are included. The extension of instruction to include the curative services has in view what he suggests as the object of teaching in social medicine: "To provide an understanding of the problems confronting us in medicine, and of the means at our disposal for solving them." This is

interpreted broadly as an appraisal of medicine's activities: its achievement, its problems, and its practice. This is an ambitious objective, and whether it will be acceptable to most teachers, or whether if accepted it can be realized, are open questions. But there are two points which most people will be ready to concede. The field of preventive and social medicine is now so vast that its teaching will require both simplification and synthesis if it is to make its full impact. And if any subject can provide for the undergraduate medical student a coherent picture of medical activities, past and present, as a basis for discussion of future development, it will have performed a most valuable service.

MENTAL HEALTH OF STUDENTS

A good deal has been written about student health in the last ten years, particularly since Oxford statistics suggested that the rate of mental breakdown was greater among undergraduates than it is among young men in the country as a whole. The years from 18 to 22, of course, cover part of the period of life when a schizophrenic breakdown or a first endogenous depression is particularly likely to occur, and incipient psychosis is noticed sooner in the communal life of college or hostel than it is in the bosom of the family. There are two main possibilities to account for an excess of mental ill-health among university men. Either those who become students are not a true cross-section of the population of young people, but include an extra share of the odd, the neurotic, and the mentally unstable; or the circumstances of student life are such as to impose unusual psychological stresses. Perhaps both of these approaches contain truth, but neither has so far been very satisfactorily studied. In an able paper at p. 551 of this issue Dr. Nicolas Malleson isolates one of the best-recognized psychological stresses and describes its clinical manifestations. Fear of impending final examinations may affect as much as 10% of students in one of three ways. Most common is overt anxiety; second is continual daytime drowsiness, with insomnia at night; and third is a physical symptom like headache or dyspepsia. In his view depression leading to suicide does not come into this clinical picture. Suicide among students has other roots striking deeper than the approach of examinations. He gives an excellent picture of the supportive psychotherapy he offers to defeat the acute non-recurring stress of examination fear. Descriptive accounts of psychotherapy which teach the novice how to set about it are sadly few. Dr. Malleson's report deserves to be read by all who are interested in psychiatry, and not only by those who are interested in school and college health.

It would be interesting to have more information about suicide in British universities, to see whether it shows any special features. There is as yet no clear picture of the incidence of the different neurotic and psychotic syndromes among students as they present themselves for help, so that one cannot say whether they are influenced by possibly stressful features of

university life. For some students the university marks their first separation from home; for others it represents parental sacrifices to send them there. Analysis of mental ill-health in terms of social origin and faculty might give interesting facts. But any inquiry depends on its underlying philosophical assumptions. Dr. B. W. Davy, whose paper appears at p. 547, has given a set of questions to a group of Cambridge undergraduates (about one-twentieth of the total) and selected those men who said they were in some way disappointed with Cambridge as likely to contain among their number the maladjusted students, the unhappy who would benefit from medical help. He believes that there are a number of such students in any year who could be helped to find themselves, if only they could be tracked down. His initial criterion recalls the old debate whether it is better to be a pig satisfied or Socrates dissatisfied. But his contribution raises three questions of fundamental interest to mental health. What is meant by maladjustment? Should an attempt be made to seek out all the maladjusted, or to deal only with those who spontaneously seek help? How far can existing psychiatric techniques help them? Individuals differ among themselves in the range and depth of their intellectual and emotional capacities and in the speed with which they gain maturity in different aspects of their personality. Because of this normal curve of variation it is unlikely that any one form of institution or activity will suit everyone, any more than one cap will fit any head. People attend a university for different reasons, and most universities offer a variety of opportunities, but few men will take advantage of all of them. We do not know at present what groupings of intellectual and emotional qualities are advantageous for success in different adult occupations, nor whether an element of disappointment or dissatisfaction may not be a driving force which is socially useful. Many psychiatrists would therefore hold that maladjustment means a good deal more than personal unhappiness, or religious, sexual, or social difficulties, and would expect to find hampering symptoms of a severity to bring the sufferer spontaneously for help. Some would go so far as to draw a division between those who are constitutionally normal, but faced with environmental difficulties, and those who are constitutionally abnormal—the neurotic and the psychopath—and who must be the first claimants on medical aid. It is sad how little psychotherapy has certainly to offer these sufferers at present—perhaps some help in the crises, very occasionally some useful re-education. Psychiatrists should be wary of inviting the crowd in until they have more to offer them. Mental ill-health among students needs much more careful clinical study, of the kind Dr. Malleson is making, and much more careful thinking about fundamentals, before a rational health programme can be devised.

WORKING UNDER DIFFICULTIES

Scotland has long been a doctor-exporting country. As recently as 1947 more than one-third of all the medical students in Great Britain were trained in the Scottish schools, and even now the proportion is about one-

quarter. In the old days, when medicine was less scientific, there was little need to provide elaborate teaching equipment, and the students of those days were a hardy lot who demanded little in the way of amenity. Now things have changed. A committee of the Royal College of Physicians of Edinburgh¹ has found that facilities for medical education and provision for student amenity north of the Tweed leave much to be desired, comparing unfavourably with those in Scandinavia, Switzerland, and America. Aberdeen, with its new buildings, is something of an honourable exception: but the report finds much in the other three centres that is squalid, dreary, and discreditable. It is undoubtedly true that conditions in some of the Scottish schools, as in some south of the Border, fall far short of an acceptable level.

When the great teaching voluntary hospitals were built, little or no thought was given to the needs of teaching or of students. Nowadays the improvement of teaching facilities has to be approached against a political background. Under the National Health Service (Scotland) Act, 1947, "It shall be the duty of the Secretary of State, in providing hospital and specialized services, to make available such facilities for undergraduate and postgraduate clinical teaching and research as he considers necessary to meet all reasonable requirements." Not surprisingly, differences of opinion sometimes arise over the interpretation of "reasonable requirements." It was only in June of this year that the universities were notified of the administrative arrangements agreed between the Treasury, the University Grants Committee, and the Central Health Department for financing facilities required for teaching and research in hospitals. The teaching hospitals constituted such a major part of the country's hospital resources that when the Health Services Act was being framed it was deemed inexpedient to adopt in Scotland the type of administrative structure which gave the governors of English teaching hospitals the larger measure of autonomy which they enjoy; and to disarm criticism at that time provision was made in the Scottish Act for the establishment of medical education committees, on which universities and regional hospital boards had equal representation. These committees were charged with the task of advising the regional boards on the administration of hospital services so far as concerned facilities for clinical teaching and research; and the committees were given the right to make direct representation to the Secretary of State if dissatisfied with the course of events. But, as the Edinburgh report points out, the medical education committees have not worked well and have not achieved their object. In some Scottish teaching hospitals there is a feeling that uniformity of regional administration has brought for them a levelling-down in standards. Perhaps, despite the difficulties under which they have laboured, medical education committees might have been expected to press more effectively for the necessary improvements. The report makes some proposals

designed to increase the value of these bodies. Among other things it suggests, perhaps a little naively, that the Central Health Department might refer to all medical education committees such plans as are put forward in any one region, hoping thus to obtain helpful criticism and a measure of standardization; but uniformity often goes ill with the practice of medicine and with medical teaching.

THE STUDENT LOOKS AT THE CURRICULUM

Consumer surveys are much used these days to estimate popular taste, and the British Medical Students' Association has attempted something of the sort in a report¹ on undergraduate medical education in Great Britain and Northern Ireland. Medical teachers should welcome the opportunity to examine the views of those at the receiving end of the curriculum. In particular, any complaints ought to be studied with great care. D. C. Sinclair,² after remarking that the student's medical knowledge must be laid straight, even if it does involve him in some unpleasantly hard work, goes on to say: "He is, however, entitled to expect that his subjects should be clearly and logically arrayed, informative and stimulating, and as far as possible shorn of obsolete methods of thought and practice. His expectations are not always fulfilled."

Students are in general satisfied with the methods by which they are selected, variable though those methods are. They are greatly dissatisfied with the premedical course at some universities. In particular, they criticize the situation in those institutions where the examination standards for entry are set so high that nearly all the premedical work has been covered before the student reaches the university. "The repetitive nature of the course for these students makes it dull, wasteful of time and money, frustrating and conducive to laziness, whereas the first year in a university should be such as to promote the necessary adjustments to university life and proper habits of study." They also complain that about a third of the university medical schools do not run special science courses for medical students and therefore do not meet their particular needs. So far as medical training proper is concerned, the students have some decided views on the preclinical curriculum. The essence of their demand is "integration," a word much in fashion in education circles in America and now becoming popular here (though the General Medical Council in its recent "Recommendations as to the Curriculum" seems to favour "correlation"). Thus the B.M.S.A. asks for "integration of premedical and preclinical curricula," "integration of biology and anatomy," "integration of chemistry and biochemistry," and "integration of physics, biology, and physiology." Indeed, about the only other thing they ask for is a course on scientific method and medical statistics. They conclude that "the effect of this scheme would be to

¹ British Medical Students' Association: Report on Undergraduate Medical Education in Great Britain and Northern Ireland. First Report, October, 1956. Second Report, August, 1957.
² Sinclair, D. C., *Medical Students and Medical Sciences*, 1954, Oxford University Press, London.
³ Final Report of the Commission on Medical Education, 1932, New York.

reorganize the preclinical curriculum so that it formed a unified series of courses through which every medical student would have to pass regardless of previous education, the necessary grounding in basic science having been obtained at school or elsewhere."

These views are further expanded in the third part of the report. The students consider that all preclinical studies should be designed so that they impinge on what they consider to be the seven fields of medical discipline—geriatrics, general medicine, obstetrics and gynaecology, paediatrics, psychological medicine, social medicine, and general and special surgery. "All other studies, whether premedical, preclinical, or paraclinical, must be, and appear to be, so related to these great fields that the student is made ever aware of their bearing on, and importance for, medical practice generally. This is the fundamental problem of the organization and content of the curriculum."

What is striking about the report is its conservatism. An insistence that all preclinical studies should be directly aimed at improving medical practice has always been the basic tenet of British medical education. A quarter of a century ago an American Commission³ had this to say: "The deep-rooted traditions of British medicine have given certain characteristics to medical training in Great Britain. The training is primarily practical in character and the aim of the General Medical Council, the universities, and the examining corporations is to produce a safe, competent general practitioner. . . . Another characteristic of British training is the effort to correlate the various subjects of the curriculum to bring about greater cohesion and unity by the process of 'infiltration,' both downward and upward. By 'infiltration' is meant the clinical influence on the medical sciences and the carrying of instruction in those sciences into the clinical years, which has a tendency to correlate the various parts of the course and to break down the artificial subdivisions." The report from the B.M.S.A. certainly bears this out, and it will be interesting to read what the students have to say about the clinical part of the curriculum.

MEDICINE IN INDIA AND CANADA

The medical needs of the Commonwealth vary from country to country, and no one can yet tell what will finally emerge from the ferment of medical development that is going on, in Britain as well as overseas. In the opening pages of this issue Professor A. W. Woodruff describes how India is attempting to meet the medical needs of a population of over 400 million. With too little money and too few doctors—and with every medical advance bringing its own problems in the way of more mouths to feed—the task of those who are designing the Indian medical services of the future is an immense one. But as Professor Woodruff makes clear they are tackling it with boldness and enterprise. The main preoccupation at present is with expansion of the medical schools and with development of research. Ten years ago there were 17 medical colleges in India, and now there are 42, and it is hoped that within the

next five years about 12,500 newly qualified doctors will be added to the 70,000 already in India.

Professor Woodruff mentions that the medical legacy left by the British in India is much in evidence, and fortunately there are still many ways by which we can help our colleagues in India, by training their undergraduates and postgraduates at our medical schools, by facilitating the two-way traffic of medical teachers between India and Britain, and, as we recently stressed,¹ by making it possible for libraries, universities, and individuals to buy the British books and journals they want.

For young doctors in Britain there are many perplexities—the difficulty of entering general practice, the queue of registrars awaiting consultant posts, and grave doubts about the appearance of the N.H.S. in the political arena—and it is no surprise that the thoughts of many have turned to medical practice in the great underpopulated countries of Canada and Australia. Those with an eye on Canada will find the article by Professor A. Mair and Dr. G. H. M. Hatcher at p. 539 a useful source of practical information. Canada, unlike India, is not desperately in need of doctors (there is one doctor for every 948 persons, compared with a ratio of one in 980 in England and Wales), but industry is booming and the population is increasing quickly. Canada's medical resources are nearly enough to meet her own needs; a British doctor going out to practise in Canada must therefore expect to meet stiff competition and to serve a very discerning public. If he is likely to find it stimulating to practise in such conditions, then, as Professor Mair and Dr. Hatcher remark, there are great opportunities awaiting him.

One very notable difference between the organization of medicine in Canada and India is that in Canada the work of the medical officer of health is increasingly limited; he "does not enjoy the respect that his professional colleagues accord to clinical consultants and specialists." Professor Mair and Dr. Hatcher continue: "Either provincial governments will have to find and develop a more significant role for the local medical officer of health . . . or local and provincial public health work will cease to have much attraction for competent professional people." In India, on the other hand, the public health problems are more like those of the British medical officer of health one hundred years ago, and there is the widest scope for sanitarians, epidemiologists, nutritionists, and health educators. Professor Woodruff refers particularly to the efforts being made in India to promote mental health. This is something all the countries in the world are interested in: even Canada's mental hospitals are grossly overcrowded. When local authorities are satisfied with their services for promoting physical health, then perhaps the medical officer of health will be able to turn, as Lord Adrian² has suggested, to ensuring the mental welfare of the community which he serves. Thus even in the most advanced countries there is new territory for public health workers to explore.

¹ Report on Teaching Facilities and Students' Amenities in Scottish Hospitals, Royal College of Physicians, Edinburgh, 1957.

ENROLMENT IN MEDICINE

The total number of names in the *Medical Register* on January 1, 1957, was 87,203, an increase of 1,609 on the previous year and of 5,349 on the average for the last ten years. The number on the local *Register* for England was 42,201, or not quite 50% of the whole; for Scotland 21,379; and for Ireland 11,577. The Commonwealth and Foreign lists contributed 10,277 and 1,769 respectively.

During 1957 the number added by registration was 3,113, to which must also be added 116 names restored. The number removed for various causes, principally death, was 1,620. These figures do not include persons provisionally registered (under section 17 of the Medical Act, 1956). The number so provisionally registered in 1956 was 2,409, and the total number provisionally registered on January 1, including those registered in previous years who had not yet gone on to full registration, was 2,945. Of the new provisional registrations 106 were in the Commonwealth list.

Taking the period of the last twenty years, in 1937 the number on the *Register* was 60,163, so that during this period there has been an increase of more than 40%. Notwithstanding this great expansion of the *Register*, the number of names removed each year on evidence of death is very much the same as it was in the late 'thirties. Thus in the period 1937-43 the average annual number removed on evidence of death was 1,010, and in the period 1951-6, with the total *Register* in the 80,000's instead of in the 60,000's, the average was only 1,040—a fact which suggests increased longevity among doctors. The total number of penal erasures remains at a very low figure. During the second world war the annual average was eleven; since 1946 it has been between three and four.

The annual average of Commonwealth registrations in the years 1936-8 was 270, and in the years 1954-6 it was 715. Foreign registrations, which reached high figures during the war and immediate post-war years, have not reached more than 20 a year since 1951. Of the persons now on the *Register*, 11.80% have come in by way of the Commonwealth list and 2.02% by way of the Foreign list.

The following table gives the position on the *Register* at the end of each of the last ten years:

Year	Registration	Added by Restoration	Death or Removal	Total on Register
1946	2,237	14	1,092	76,292
1947	2,787	10	1,160	77,929
1948	3,968	16	5,621	76,292
1949	3,109	19	1,280	78,140
1950	3,160	45	1,123	80,222
1951	3,075	29	1,070	82,256
1952	4,493	46	2,881	83,914
1953	507	99	1,430	83,090
1954	2,222	152	1,565	83,899
1955	2,992	185	1,482	85,594
1956	3,113	116	1,620	87,203

The high figures for removal in 1948 were due to the shrinkage of the temporary list following the passage of the Medical Practitioners and Pharmacists Act, 1947.

The training of medical students is shared between the teaching hospitals and the universities. In London the twelve undergraduate teaching hospitals, and elsewhere in England and Wales the ten teaching-hospital centres in association with the universities, are designated as teaching centres. In Scotland hospitals are not designated as teaching hospitals; they all come under the jurisdiction of the five regional hospital boards, but provision is made for inclusion on the boards of management of nominees of the university on which the region is centred. In Northern Ireland the duty is laid upon the hospitals authority—a body corporate—to provide Queen's University, Belfast, with adequate facilities for medical teaching.

Primary and Additional Qualifications

All the universities offer the primary qualifications of Bachelor of Medicine and Bachelor of Surgery. Other primary qualifications are those of Licentiate of the Royal College of Physicians of London and Member of the Royal

College of Surgeons of England; Licentiate in Medicine, Surgery, and Midwifery of the Society of Apothecaries of London; Licentiate of the Royal College of Physicians of Edinburgh, the Royal College of Surgeons of Edinburgh and the Royal Faculty of Physicians and Surgeons of Glasgow; Licentiate and Licentiate in Midwifery of the Royal College of Physicians of Ireland and the Royal College of Surgeons in Ireland; and Licentiate of the Apothecaries' Hall of Dublin.

The additional registrable qualifications of Doctor of (or in) Medicine and Master of (or in) Surgery are offered by all the universities. Liverpool also offers the qualification of Master of Orthopaedic Surgery, Queen's University of Belfast that of Master of Obstetrics (M.A.O.), the University of Dublin that of Master in Obstetric Science, and the National University of Ireland that of Master of Obstetrics. The Royal Colleges of Physicians of London, of Edinburgh, and of Ireland offer the additional qualifications of Member and Fellow, and the Royal Colleges of Surgeons of England, of Edinburgh, and in Ireland, and the Royal Faculty of Physicians and Surgeons of Glasgow offer that of Fellow.

Diplomas in Public Health are obtainable in a number of the universities in the United Kingdom and the Republic of Ireland, also in the Corporations and, in the Commonwealth, in the University of Malaya.

For the diplomas granted in the British Commonwealth outside the United Kingdom which are recognized under the Medical Act, 1956, for the purpose of full or provisional registration in the Commonwealth list the *Medical Register* should be consulted.

Examination Results

The results of the final or qualifying examinations in 1956 show a percentage of passes in medicine ranging from 92 in the University of Liverpool to 49 in the Apothecaries Hall of Ireland; in surgery from 96 in the University of St. Andrews to 48 in the Apothecaries Hall of Ireland; and in midwifery from 96 in the University of St. Andrews to 58 in the Scottish Conjoint Board. In the final examination as a whole there were 1,979 passes and 934 rejections, the highest percentage of passes being 91 in the University of Aberdeen. The highest number of examinations were taken in the University of London, with 588 passes in medicine, 618 in surgery, and 619 in midwifery. The next highest were in the English Conjoint Board, with 517 passes in medicine, 528 in surgery, and 572 in midwifery.

The results of the examinations in anatomy and physiology held in 1956 showed the highest percentage of passes in anatomy (88) in the University of Birmingham, and in physiology (77) in both the University of Bristol and the University of Sheffield. The total number of students who were admitted to premedical studies (physics, chemistry, and biology) in 1956 was 1,676, the number exempted from premedical courses and examinations was 1,552, and the total number of students beginning the period of preclinical studies was 2,415. By far the largest number was in the University of London (779), the next largest being the University of Cambridge (203), the University of Edinburgh (170), and the University of Glasgow (166). A study of the results of examinations in 1956 arranged under individual subjects shows that in Glasgow more students were rejected than passed in both anatomy and physiology, also in the Society of Apothecaries of London and the Scottish Conjoint Board. Rejections also outnumbered passes in physiology in the English Conjoint Board; in both physics and chemistry in the University of Dublin; and in physics, chemistry, botany, and zoology in Dublin University College.

Fees for Registration

The fees payable to the General Medical Council (44, Hallam Street, London, W.1) for registration under the Medical Acts are five guineas on provisional registration, and six guineas on full registration in the case of a person already provisionally registered, or eleven guineas in the case of any other person.

UNDERGRADUATE EDUCATION

Below we give, by the courtesy of the respective deans, some account of the various undergraduate schools, and developments and events, past or prospective.

LONDON MEDICAL SCHOOLS

The *Royal Free Hospital School of Medicine* has done well this year with 62 students qualifying, one being awarded the university gold medal with honours in pathology, medicine, and obstetrics and gynaecology, and two gaining honours in one subject. Out of the nine students who passed the B.Sc. special examinations in anatomy and physiology one obtained first-class honours and five upper seconds. These results are noteworthy in a year of great student activity in other spheres, with several new events added to the normal programme. These have included a public performance of a full-length play by the dramatic society and an evening of one-act plays. The revival of interest in this society was heralded by a midsummer ball and cabaret held in the school quadrangle. A similar ball has been arranged for this year.

In November the school lost a great friend by the death of Professor Cullis, for many years head of the physiology department. A bequest of £1,000 under her will and some £850 contributed to a memorial fund are being reserved for a Winifred Cullis library at the Royal Free Hospital. A remarkable year in the school's history was crowned in February by the election of Dr. Lloyd-Williams as dean of the faculty of medicine in the university, the first occasion on which a woman has been appointed to this office.

At *Guy's Hospital Medical School* the first three years of preclinical studies are designed to prepare the student for the clinical work which will follow, and there is a close link between the departments of the school and the hospital. Oxford and Cambridge students are admitted for the three clinical years. The aim has always been to encourage responsibility from the moment the student enters on ward work. A three-monthly series of clerkships is arranged in the general wards and in special departments, so that students accept supervised responsibility for patients, and the emphasis is on bedside and out-patient teaching rather than on organized lectures. There are lectures and demonstrations organized which cover the whole field of medicine, surgery, obstetrics, paediatrics, anaesthetics, and other subjects. Pre-registration appointments are available for the newly qualified.

At *University College Hospital Medical School* a new method of noting a student's performance throughout his career has been devised; it is still hoped that such information may be used in assessing a candidate's suitability for being placed on the *Medical Register*. It is believed that too great an emphasis is placed upon marks obtained in final examinations, and that a student's record and behaviour throughout his undergraduate career should be taken into account.

U.C.H., together with its sector hospital at St. Pancras, now has a minimum of 1,000 beds, and the closely adjacent St. Pancras Hospital is being increasingly used for the clinical teaching of undergraduates. The new Rowland Hall is used a great deal for both clinical lectures and social activities such as concerts and dances. The hard tennis courts at St. Pancras are also proving a boon to students and the nurses. The sports ground with its new pavilion at Hendon is being used fully, and possible extensions are being considered.

The rebuilding of the dental hospital and school has not yet commenced, but there are indications that a start will be made before March, 1958. There is no lack of applicants for either medical or dental places in the school, and much time and thought is given to the selection of students. 103 students are now able to live on medical school premises.

Rebuilding at St. George's

At *St. George's Hospital Medical School* the rebuilding foreshadowed last year has begun. The phase of demolition

has been completed and work on reconstruction should be well advanced by the beginning of the next academic year. Academic units in medicine and surgery have started work under part-time directors and are already playing an important part in teaching. A certain amount of laboratory space is already available for research, although the major part will have to await the completion of rebuilding. A new and first-class Rugby football ground should be ready for use next year.

Guest lectures have been given during the last academic year by Professor J. Z. Young, F.R.S., Sir Sam Bedson, F.R.S., and Professor C. H. Best, F.R.S.

Additional research laboratories at *St. Mary's Hospital Medical School* for the departments of biochemistry, chemical pathology, and pathology were brought into use in October. At the beginning of the session Professor W. S. Peart took up his duties as head of the department of medicine in succession to Professor G. W. Pickering, now regius professor of medicine at Oxford University, who has accepted the invitation of the medical school council to become a vice-president of the medical school.

As a result of the second M.B. examination A. C. Buck was awarded the Sir William Dunn Scholarship, open to all students of the university, to take a course leading to an honours B.Sc. (Special) degree in physiology. The medical school gives a number of its own internal scholarships for students to take this course in either anatomy or physiology, and over the past years it has been found that the students doing this more advanced work, prior to clinical studies, have greatly benefited before and after qualification.

At *Westminster Medical School* the number of clinical students remains constant at about 200. This is the maximum desirable number having regard to the clinical facilities available in the Westminster teaching group. The applications for admission compared with recent years show a slight decline, but the standard of those accepted is at least as high as in the past. The Westminster teaching group comprises: Westminster Hospital of 430 beds, the Gordon Hospital of 100 beds, the Westminster Children's Hospital of 120 beds, and All Saints' Hospital of 50 beds. Instruction is also given at St. Stephen's Hospital, the Nelson Hospital, St. Teresa's Hospital, and the Western Hospital, Fulham. A scheme has been instituted on a voluntary basis by which students may reside for a fortnight with general practitioners in order to see the work of their practice. Special instruction in tuberculosis is provided by a fortnight's residence at the King Edward VII Sanatorium, Midhurst. Instruction in mental diseases is given at the Netherne Hospital. 40 vacancies a year in the Westminster Hospital teaching group have been recommended for pre-registration posts, and competition for these is keen.

The school was visited by the university grants committee during the year and capital projects were discussed with the committee, notably the proposed building of a new school on a site immediately adjoining the hospital. It has now been decided with the agreement of the university that the site shall provide for a clinical school only. It is hoped to accommodate in the new building professorial units in medicine and surgery. The improved facilities at the new sports ground at Cobham, Surrey, have been reflected in a higher standard of play and a large number of successes in all branches of outdoor sports.

"Tutors Scheme" at the Middlesex

The *Middlesex Hospital Medical School* provides a full medical education, including instruction in chemistry, physics, and biology for the London first M.B., but students who have obtained exemption from that examination at school are admitted direct to classes for the second M.B. Preclinical students enter in October; those from the universities of Oxford and Cambridge who join the school for their clinical course enter in April or October. The number of candidates at all stages remains high, and application should be made 18 months to two years in advance of the date at which entry is required.

The clinical facilities of the hospital are increased by an arrangement with the authorities of the Central Middlesex Hospital, whereby students may attend there for three months during their time as clerks and dressers in the wards. A number of house appointments are recognized for pre-registration purposes and are reserved for students on qualification.

During the last year a "Tutors Scheme" has been inaugurated. This is in no way connected with their work, but students are appointed to a senior member of the hospital or school staff; each "tutor" has six or eight students in whom he takes a particular individual interest, and the student, on his side, feels he always has someone to go to if he is in difficulty or needs help or advice. The scheme, which is not compulsory, has made a successful start, and, it is felt, will be a valuable addition to the life of the school.

The tutorial system in both the preclinical and clinical periods has been extended at the *London Hospital Medical College* during the past year, and continues to provide a useful method of linking the various parts of the curriculum. The departments of physiology and anatomy now regularly run B.Sc. (special) courses in physiology and anatomy, and scholarships are given as a result of the second M.B. examination to enable suitable candidates to take part in these courses. The number of applications at the London during the past year remained high. Application can be made at any time after the student has reached the age of 16 or has passed the general certificate of education at ordinary level, whichever is the earlier. Applicants are interviewed as soon as possible after they apply, and they are told of the result of the interview within a few days. This policy is still proving of value, as applicants are not left in uncertainty about their chances of obtaining a place. Applicants who are unable to obtain first M.B. exemption at school spend one year at Queen Mary College, but the number who need to do this steadily decreases. For entry to Queen Mary College for first M.B. work students must satisfy university entrance requirements, but applications to go there should be made through the London Hospital Medical College. In cases where the applicant from school is able to proceed to either Oxford or Cambridge the place offered for the whole course becomes automatically transferred for clinical work at a later date.

Research facilities at the London continue to expand in both the preclinical and the clinical field. New laboratories for clinical research under the direction of the medical and surgical units have been opened and are proving of great value. They have a close association with the newly established professorial departments of biochemistry and experimental biochemistry, ensuring that the highest standard of chemical advice will be available to workers in the clinical field. Junior research fellowships have been established by the college, the tenure of which normally is one year, so that graduates who have done their house appointments may gain experience in and have opportunities for original research under supervision. At the London there has been no difficulty in getting pre-registration appointments for all the newly qualified graduates, and the majority are able to hold at least their first appointment at the teaching hospital.

The athletic side of the college has been greatly helped by the opening of a new pavilion at the sports ground at Hale End.

Building Extension at King's

At *King's College Hospital Medical School* Stage I of the new extension will be ready for occupation at the beginning of the autumn term. It will contain on the top floor the new medical professorial unit; on the middle floor a large practical pathology laboratory, thus releasing the present laboratory for research; and on the ground floor additional rooms for student amenities, including offices for the clubs and societies union. Stage II has now been authorized and building will begin this summer. A readership in chemical pathology has been established in the school and the first reader appointed as from June 1, 1957. A new post of part-time

tutor in surgery has been established which provides for the equivalent of three sessions a week in the medical school.

The school admits clinical students for the London, Oxford, and Cambridge degrees. The dental school provides courses for the B.D.S. degree and the L.D.S. diploma. Each year 50 medical and 25 dental students are admitted. Students for the London degrees do their preclinical training at King's College, London, where they have the advantage of associating with students of all faculties. King's College Hospital has 550 beds (including Belgrave Hospital for Children). It is situated in the heart of a large residential area and it has one of the busiest out-patient departments in London, with an ample supply of clinical material. King's College Hall is within five minutes' walk, and it is still fairly easy to find comfortable lodgings in the vicinity. The school has the use and clinical control of 200 medical, surgical, and obstetric beds for undergraduate teaching at near-by Dulwich Hospital, where the instruction is undertaken by consultants from King's College Hospital and by some of the consultants of Dulwich Hospital who have been appointed associate teachers in the medical school. The arrangements whereby students gain first-hand experience of general practice have been extended. At their discretion individual students can now spend up to one week in residence with a general practitioner, the school bearing a part of the cost.

Alterations in the building at *Charing Cross Hospital Medical School* have been carried out to improve amenities for teaching and research. In the main building the photographic unit has been enlarged and modernized and additional accommodation has been acquired for the administrative department. The division of anaesthesia has acquired accommodation adjacent to the main school building. In the recent final M.B., B.S. examination all who submitted themselves for the examination in pathology were successful, and in each of the other clinical subjects pass rates not less than 93% were achieved.

The preclinical departments of *St. Bartholomew's Hospital Medical College* are situated in Charterhouse Square, with modern laboratories which provide full teaching and research facilities. There is also a resident hostel for 100 students. At the adjoining hospital adequate facilities are available for instruction in all subjects, including pathology and midwifery. Over one hundred resident appointments are made to the hospital staff each year from students who have passed their qualifying examination. Each quarter clinical appointments are available for undergraduates from the preclinical departments and from the universities of Oxford and Cambridge. Scholarships and prizes to the value of £2,000 are awarded annually.

St. Thomas's Hospital Medical School

St. Thomas's Hospital Medical School is to be totally rebuilt in the course of the next few years, as is also the entire hospital. To tide the school over this period and provide much-needed laboratory accommodation it is proposed to add an extension to the front of the existing buildings. In addition it is hoped to reconstruct the anatomy department in order to use its adequate cubic capacity to the best possible advantage. This has already been achieved in the department of biochemistry with marked success. During the past year the medical professorial unit has moved into its final quarters in a new wing of the hospital. Here it occupies two floors of spacious laboratories.

The ex-Service man is becoming a comparative rarity in the preclinical world and will soon disappear altogether. He will be much missed, for his maturity has given a certain stability to the main body of ex-schoolboys. One difficulty of a medical career at present is that the successfully marked candidate is for ever faced with finding his ultimate goal beyond his immediate reach, whether it be for general practice or consulting work. Prospects are being watched anxiously by future doctors.

The overseas applicants are for ever increasing in numbers; candidates from Nigeria and Hong Kong outnumber those from other countries. Many of the latter come over

here for their secondary education, whereas the Nigerians form an older age group and are absorbed by technical schools for their basic training in science.

THE SOCIETY OF APOTHECARIES

The Society of Apothecaries of London (Apothecaries Hall, Black Friars Lane, E.C.4) confers the diploma L.M.S.S.A.Lond., registrable under the Medical Act, 1886. Examinations for the final subjects are held monthly, except in September; and in anatomy, physiology, and pharmacology in January, April, July, and October.

OXFORD AND CAMBRIDGE ENTRY

Oxford

The number of preclinical students admitted to Oxford each year is 76 (65 men and 11 women). Preliminary acceptance by a college is essential for any prospective student. The medical course lasts six and a half years, of which three and a half are devoted to the study of the preclinical subjects. At the end of the second year the first B.M. examination in organic chemistry, anatomy, and physiology is completed so that the third year may be devoted to reading for the B.A. degree, usually in the honour school of animal physiology. All students who read medicine at Oxford, with the one exception outlined below, must qualify for the B.A. degree before proceeding to complete the examinations for the degree of B.M., B.Ch. The course for the honour school of animal physiology is followed by two terms spent in the study of general pathology, bacteriology, pharmacology, and principles of therapeutics. The remaining three years are devoted to the clinical subjects, either at Oxford or at one of the London teaching hospitals or elsewhere.

The university clinical school is situated in the United Oxford Hospitals (the Radcliffe Infirmary, the Churchill Hospital, the Oxford Eye Hospital, the Slade Hospital for Infectious Diseases, the Osler Hospital (for chest diseases), and the Cowley Road Hospital), which together make up the teaching hospital group and comprise a total of 1,263 beds. In addition the Nuffield Orthopaedic Centre (Wingfield-Morris Hospital) provides a further 234 beds and the mental hospitals under the regional board provide 1,137 beds. An extensive building programme is being carried out which will extend existing facilities for teaching and research and will provide new laboratories and wards for many of the professorial departments which were established following the generous benefactions of Lord Nuffield in 1936. In the Radcliffe Infirmary a new department for the Nuffield Professor of Clinical Medicine with 50 beds and adjacent laboratories should be completed in September, 1957. Twin theatres and laboratories are being built for the Nuffield Professor of Surgery, Professor P. R. Allison, and two wards in the Radcliffe Infirmary have been converted for his use. Professor G. W. Pickering, who succeeded Professor A. D. Gardner as Regius Professor of Medicine in October, 1956, has his own beds in the Radcliffe Infirmary, and new laboratories have been provided for him on the Radcliffe site. New departments of anaesthetics, biochemistry, and pathology are now being built, and plans are being drawn up for a new out-patient hall and for enlarging the x-ray department.

Even with the development of these new academic departments for teaching and research, and the provision of an increased number of teaching beds in the Radcliffe Infirmary, the university does not intend to increase the size of the clinical school, which will remain limited to an intake of 32 a year. The majority of the students are drawn from the preclinical departments of the university, but some are admitted from other universities. In the past all external students have read for the degree of their parent university. Most will continue to do so, but recently a university statute has made it possible for selected students from other universities to apply to take the Oxford B.M. degree without having taken the preclinical course at Oxford or the Oxford B.A. Students from other universities in the United Kingdom and overseas who apply to read clinical medicine

in Oxford and take the Oxford B.M. under the new regulations must have spent three years in the study of the preclinical sciences, have passed an examination equivalent to the first B.M. in anatomy and physiology, and have obtained an honours degree in the arts or sciences.

The aim of the university in limiting the number of clinical students is to ensure that each gets the maximum amount of personal instruction so that the scientific approach to the problems of medicine and the habit of independent thought, which is the hallmark of the honours course in physiology, can be fostered during the period of clinical study. The small size of the school makes it possible for each student to have a personal tutor and ensures that all have direct access to a large number of patients. Now that the pre-registration year has become part of the training of a medical student a further advantage that accrues from limiting the intake is that almost all who qualify from the United Oxford Hospitals can be sure of obtaining a pre-registration post in their own teaching hospital.

Cambridge

At the University of Cambridge the number of candidates wishing to study medicine continues to exceed the number of places available (about 220 per annum), and all college entries are subject to a university quota.

During the year two changes have been made in the regulations for the final M.B. examination. The first relates to the period of clinical instruction in midwifery and gynaecology. The regulations are amended so as to specify requirements of (a) six months' instead of three months' clinical training; (b) two months' instead of one month's residence in a maternity hospital; (c) instruction in antenatal and post-natal care. Students who began their clinical training before October 1, 1956, however, will be allowed to proceed to the final M.B. examination on producing evidence satisfying the midwifery and gynaecology requirements previously in force.

The second change is designed to permit undergraduates who by the end of their second year's residence have obtained honours in the Natural Sciences Tripos and have qualified in anatomy and physiology and who wish to undertake a course of non-medical study during the third year in Cambridge, to take the final M.B. examination at the same time as their contemporaries who devote three years to the Tripos and qualifying examinations. The requirement that a candidate for either part of the final M.B. examination shall produce evidence of having completed five years of medical study has been amended to restrict the requirement to Part II only of that examination. The Cambridge medical student normally completes three of these five years as an undergraduate in residence, and on October 1 following graduation begins clinical studies at a recognized hospital. If in the circumstances mentioned above the third year is devoted to non-medical study the student will begin hospital training with two years' medical study only to his credit, but will be allowed to count as part of his third year of medical study after graduation the period of three months during which he attends the long vacation course in elementary clinical methods. He will then be able to take Part I of the final M.B. (pathology and pharmacology) in the December of his third academical year at hospital and Part II (medicine, surgery, and midwifery and gynaecology) in the following June, if he begins hospital training in the July immediately following his qualification for the B.A. degree either in his clinical school or by taking the long vacation course in clinical methods in Cambridge.

TEACHING-HOSPITAL CENTRES IN ENGLAND AND WALES

Durham

At the *University of Durham* the extensions to the department of pathology in the teaching hospital were completed during the year, and it is now hoped that work on the extensions to the north block of the medical school, to provide more accommodation for the department of anatomy and to

the centre block to provide better facilities for animal house accommodation, will begin during the present summer.

A reflection of Newcastle's liveliness as a medical centre were two large medical gatherings which took place there recently: the B.M.A. annual meeting in July, and the annual meeting of the Association of Surgeons of Great Britain and Ireland in April. During the B.M.A. meeting college accommodation was used extensively.

At the beginning of the year the school was pleased to welcome Dr. R. C. M. Pearson, Medical Officer of Health for Newcastle, to the lectureship in public health. Dr. Pearson succeeds Dr. W. S. Walton, who resigned in order to take up the appointment of Professor of Public Health in the University of London. The Medical Students' Council has once again been most active in representing the interests of medical students both in the college and on the British Medical Students' Association. The University of Durham Medical Society has, as always, completed a full programme of lectures, visits, and social activities during the year.

Chair of Urology at Leeds

At the *University of Leeds* the beginning of session 1956-7 saw the establishment of the part-time chair of urology, Professor L. N. Pyrah taking up his appointment on October 1. This is the first chair in the subject in a British university. During the year the university received a generous grant from the Wellcome Trust to which the board of governors of the teaching hospital have added a substantial sum so that a new building can be erected to house laboratories for the medical research unit under the direction of Professor Pyrah and for the university department of medical physics. The building of the Martin Wing of the teaching hospital is well under way, and in this building will be housed the full-time professorial units of medicine and surgery. Each department is to have beds, laboratory, and research and tutorial rooms. This new accommodation will be of the greatest value both for teaching and for research. Also in the Martin Wing will be additional floors for purely hospital purposes and new laboratories for the clinical pathology and haematology services provided by the university department of pathology.

In the school itself the conversion of the men's and women's common rooms for library purposes is complete, and this has greatly improved the amenities, though it does not fully satisfy the needs for additional space of the library.

The university has suffered the loss of two Emeritus Professors in the last year—Emeritus Professor M. J. Stewart, Professor of Pathology from 1918 to 1950, and Emeritus Professor Watson, Professor of Clinical Medicine from 1925 to 1932 and Professor of Medicine from 1932 to 1937.

First M.B. Exemption at Bristol

The faculty of medicine of the *University of Bristol* has undertaken an extensive review of the medical curriculum and as an interim measure has made a substantial change in the requirements for exemption from the first M.B., Ch.B. Instead of passes at advanced level in physics, chemistry (including organic chemistry), and biology or botany and zoology, the university has now adopted the following minimum requirements: (a) The acceptance of a good pass at "O" level in physics in the G.C.E. or a pass at "O" level in physics on an "A" level paper. (b) The acceptance of "A" level chemistry in the G.C.E. without any special condition as to organic chemistry. (c) The acceptance of biology at "A" level in the G.C.E. or of a good pass in botany at "O" level (or a pass at "O" level on an "A" level paper) together with a pass at "A" level in zoology.

The course in forensic medicine has been reorganized with effect from August 1, 1957, and the separate examination in that subject has been abolished.

Numbers of applications for entry to all branches of the faculty—medicine, dentistry, and veterinary science—remain greatly in excess of the numbers of places available.

Manchester

In the *Faculty of Medicine at Manchester* a revised curriculum was introduced eighteen months ago involving some reduction in the content of the course, considerable rearrangement of the time-table, the introduction of more combined classes, and the provision of at least one relatively "free" long vacation during the clinical years. This new curriculum will be tried out over a period of years, and it is anticipated that further modifications and improvements will be made in the light of experience. The awkward period between the old and the new systems is being bridged by a rather complicated transitional scheme.

Final-year students have been attending the Darbshire House Health Centre for periods of a fortnight to gain experience in general practice, and, as this has already proved its value, the possibility of widening this experience by attaching students for additional short periods to other general practitioners is being investigated.

Building Programme at Birmingham

In the *University of Birmingham Medical School* it has been decided, at least for the time being, not to reduce the intake of medical students. To meet an urgent national need everything possible is being done to attract more students into the department of dentistry. To this end the building of a new dental hospital has been officially recognized as a major priority, both by the university and by the board of governors of the teaching hospitals.

The building of a new biological research block has been foreshadowed by the university grants committee for beginning in 1958 or 1959. This will house, amongst other scientific departments, medical biochemistry and pharmacology and chemical physiology. The Trustees of the Wellcome Foundation have offered to defray the cost of building a new Wellcome research block for clinical research. Other building projects which are scheduled for the near future include a new radiotherapeutic wing, the completion of the west wing, a blood bank and a paying patients' block at the Queen Elizabeth Hospital, and in addition a diagnostic x-ray department, new theatres, and a new casualty department at the General Hospital. The new operating wing at the Women's Hospital is already in course of construction. The Barnes Library at the medical school will soon be started, as will extensions to the department of medical biochemistry and pharmacology and the construction of a new animal house.

An innovation which is now beyond the experimental stage is a scheme of joint appointments by means of which hospital registrars do part-time research work in the medical school and medically qualified lecturers undertake some clinical work in the hospitals. This arrangement has worked extremely well and is forging even stronger links between the medical school and the teaching hospital.

Professor A. P. Thomson has been invited by the University Council to continue as Dean beyond the normal retiring age, and his successor in 1959 is to be Mr. A. L. d'Abreu, reader in thoracic surgery and consultant surgeon to the United Birmingham Hospitals.

Chair of Child Health at Liverpool

A full-time chair of child health has been established at *Liverpool University*, to replace the part-time professorship which has been held by Professor Capon since its foundation in 1944. Dr. John D. Hay has been appointed to the chair on the retirement of Professor Capon at the end of the session. Other members of faculty retiring at the same time are Professor Stones, Sir Arthur Gemmell, and Dr. C. E. Brunton. The board of governors of the United Liverpool Hospitals has been asked to provide facilities at the Royal Infirmary for a whole-time reader in the department of medicine to be appointed by the university.

The number of applications for admission to the medical school still exceeds the number of places, and a full com-

plement of students will commence their studies in October, 1957, but there are indications that the number of candidates for medicine is declining. No changes have occurred in the requirements for exemption from the first M.B. or in the medical curriculum proper, but a committee has been set up to consider the implications of the new "Recommendations" of the General Medical Council.

Before next session opens the new medical school building will be ready for occupation and will house the departments of pharmacology, pathology, bacteriology, medicine, obstetrics and gynaecology, radiodiagnosis, and the Dean's offices.

New Teaching Block at Sheffield

The new teaching block at *Sheffield Royal Infirmary* was formally opened in November, 1956, when an address was delivered by Professor George W. Pickering, F.R.S. regius professor of medicine at Oxford University. Further university building affecting the medical school is being planned. Co-operation is being maintained with the board of governors of the United Sheffield Hospitals in relation to the planning of a new teaching hospital. The hospitals sent a small deputation (including the Dean and representative clinical teachers) to inspect Swiss, German, and Swedish hospitals during the year, and a university team recently visited the new medical buildings in Belfast. Lack of new building has hampered planning for any increased numbers of medical students, but it has proved possible to increase the dental intake. Professor G. L. Roberts has been appointed the university's representative on the General Dental Council set up under the Dentists Act, 1956.

Reference was made last year (see this *Journal*, 1956, 2, 533) to the posthumous award of the Albert Medal to Dr. Mark Gregory Baker. The Ashby-de-la-Zouch Urban District Council has now endowed, as a memorial to Dr. Baker, a prize which will be awarded each year to the most distinguished student as judged by the combined results of the second, third, and final M.B., Ch.B. examinations. A group of dental practitioners has endowed an undergraduate prize to be awarded annually in the subject of orthodontics. Through the generosity of Mining and Chemical Products, Ltd., a research fellowship is at present being held in the department of pharmacology and therapeutics.

Active discussion among various groups has been going on for some time as to possible curriculum changes, and the policy revealed by the G.M.C.'s recently issued "Recommendations" is warmly welcomed.

Welsh National School of Medicine

The celebrations of the twenty-fifth anniversary of the school, which took place in October last (see this *Journal*, 1956, 2, 937), included the attendance of a very large number of old students.

The task of revising the schedules of accommodation for the new teaching centre in Cardiff has now taken a further step forward, for the observations of the Welsh Board of Health have been received and are being carefully studied. There are favourable indications that there will be "built . . . a centre fit to take its place among the great teaching and healing centres and worthy of its position as the teaching hospital of Wales." Alongside this project will be plans for the new preclinical departments, and it has been agreed that these shall be included in the building programme of the University College, Cardiff, so that they will be associated closely with the departments of physics, chemistry, and biological sciences in Cathays Park. Plans for accommodation for a new library, dining-hall, and reading-rooms for clinical students have been approved in principle by the council of the school and are now under consideration for grant assistance. The school has received several benefactions. The Sir Ewen Maclean Bequest has been increased as the result of a further legacy, and a research scholarship in pharmacology has been granted. Some revisions of the curriculum have been made, and much

thought has been given to this problem, which will now be facilitated by the new "Recommendations" of the General Medical Council. The school is also carrying out a review of the pre-registration appointments in hospitals in the region. A rearrangement of the time-tables of instruction in the preclinical years is being carried out, and the repeat examination in these subjects will be held in September instead of in June.

The number of students who entered the clinical courses at the school was 56, and in addition 16 premedical and 27 preclinical students started their courses at the University College of South Wales and Monmouthshire.

SCOTTISH SCHOOLS

University of Glasgow

The most important development within the medical school has been the institution of a chair in virology and the securing of a site immediately contiguous to the Western Infirmary and the university for a new building to house this new department. It is hoped that the new building will be available for occupation in two years' time. Until then temporary accommodation will be arranged for the tenant of the chair.

The number of applications for admission to the medical school is slightly, though not significantly, above that for last year, and is still in excess of the number of available places. The number of applications for entry to the dental school, which had shown a sudden and welcome increase last year, is this year well maintained. The veterinary school has also a satisfactory quota of applications.

The dental school has obtained an extensive site adjacent to the dental hospital which will provide additional accommodation, mainly for postgraduate activities. In the veterinary school the animal hospital and associated buildings for clinical instruction are now in full operation. The farm which was purchased three years ago is being developed as a field station with facilities for instruction in animal husbandry and preventive medicine, and with accommodation for experimental farm animals.

University of St. Andrews

In the *School of Medicine of the University of St. Andrews* instruction in the subjects of the clinical years of study is given in Dundee, while the premedical and preclinical subjects can be studied either at St. Andrews or at Dundee.

The annual intake of students to the Faculty of Medicine is limited to between 70 and 80 to ensure that the hospital facilities available are sufficient to allow of adequate clinical instruction being given to each undergraduate, as advised by the Goodenough Committee. The laboratory accommodation in both preclinical and clinical years has been recently extended and provides excellent facilities for students. There are at both centres excellent student residences which accommodate undergraduates from all or any of the faculties. Medical students in their early years are encouraged to reside in these, so that there is a width of contact among the undergraduates which is found to be of great educational value.

University of Edinburgh

At the *University of Edinburgh* the past year has been one of continuing activity. The number of applicants for admission to the M.B., Ch.B. course in October, 1957, remains high in relation to the number of places available. The procedure for the selection of medical students provides for the interview of a majority of applicants by a selection committee before admission to the faculty. Those applying for admission as students for the M.B., Ch.B. course beginning in October, 1958, should submit their applications to the dean of the faculty by December 31, 1957. It is proposed to operate in 1958 and thereafter a scheme whereby suitably selected applicants will be permitted to appear direct for the first professional examination

on the basis of work done and examinations passed at school or other pre-university institution. A limited number of undergraduate bursaries and scholarships are available to students in the faculty of medicine for advanced courses of study—for example, an honours course of instruction for the B.Sc. degree.

University of Aberdeen

At the University of Aberdeen the course for the degree of M.B., Ch.B. extends over six academic years. Courses in premedical and preclinical subjects are given in departments located in Marischal College and in Old Aberdeen, providing instruction to science as well as to medical students. The laboratory and lecture courses in the three clinical years are given in the university buildings on the Foresterhill site, where the main hospitals are, and clinical instruction is given in all the hospitals in Aberdeen.

Few changes have taken place during the past year, though a number of new projects are in course of completion or being planned. The new wing to the Royal Infirmary has been opened and provides accommodation among other things for an enlarged blood and fluids transfusion unit, which used to be housed in the department of bacteriology. The special research department in clinical midwifery, which will be staffed by the Medical Research Council and run under the honorary direction of the professor of midwifery, is in course of construction and should be opened in the autumn. In the course of preparation are plans for a new medical physics building and a new animal house, and it is hoped that a start will be made on this during the next academic year.

The number of students applying for admission tends to fall, but is still above the number of places available. During the year the four Scottish universities promoted an ordinance to permit certain candidates for admission to the medical faculty, under regulations to be made by each university, to sit the professional examination in physics, chemistry, and biology without attending university classes in these subjects. It is hoped that this ordinance will be approved and that the new regulation will come into force next year. The policy of attaching students to general practitioners in the region continues to be successful. Fears that the patients might object to such an arrangement have not been justified, and the relations between students and doctors have been friendly and helpful.

NORTHERN IRELAND

Queen's University of Belfast

During the current year Professor J. G. Gibson was appointed to the newly created chair of mental health. The hospital's authority has established a special psychiatric unit under his control in association with one of the general teaching hospitals. Professor O. L. Wade has been appointed to the chair of therapeutics and pharmacology and has been given clinical units in two of the teaching hospitals. A full-time lectureship in anaesthetics has been established.

MEDICAL EDUCATION IN EIRE

School of Physic, Trinity College, Dublin

The entry of students has been restricted so that the numbers in the clinical years will probably not exceed 50 in future. The chairs of medicine and surgery are now full-time appointments. Clinical tutors in medicine and surgery have been appointed in the hospitals attended by school of physics students, under the direction of the clinical professors. Special arrangements for the teaching of paediatrics and for clerking in this specialty have been made in the National Children's Hospital. A professorial unit with obstetrical and gynaecological beds has been established at the Rotunda Hospital, and additional staff has been appointed to assist the professor in the work of the unit. The course in pharmacology has been much extended, and includes additional practical work.

The laboratories of anatomy, physiology, biochemistry, and pathology have undergone extensive alteration and reconstruction, with new equipment and increased facilities for research. An extension of the chemistry building now nearly completed will provide greatly improved accommodation for premedical classes. Additional classes and demonstrations in pathology, bacteriology, and clinical biochemistry have been arranged in each of the hospitals; these are directed by the respective professors and will carry on the systematic teaching of these three subjects up to the final academic year.

The constituent colleges of the National University of Ireland are those of Dublin, Cork, and Galway. Between 200 and 300 students graduate in medicine from these colleges each year.

The Royal College of Surgeons in Ireland admits to the pre-registration classes approximately 100 students each year. The normal method of entrance is by competition in the preliminary examination, but a limited number of places are given to those with exceptional qualifications and to certain students selected by the Colonial Office.

The licentiate of the Apothecaries Hall of Dublin (95, Merrion Square) entitles to registration under the Medical Act, 1886. It enables the holder to practise pharmacy, as well as medicine, surgery, and midwifery, which means that he may, if he desires, open a medical hall. This, however, applies only to those who are qualifying to become doctors, not to pharmaceutical chemists. The Hall is an examining body only.

POSTGRADUATE EDUCATION

The universities and medical schools are responsible for most of the arrangements for postgraduate courses and other instruction facilities. Such courses will be found normally advertised in the medical press by the various organizations and authorities that provide them. Courses for general practitioners (ranking for Ministry grant) are arranged in London by the British Postgraduate Medical Federation (see below); in universities other than London by the deans of the faculties of medicine or directors of postgraduate studies, to whom application for further information should be made.

BRITISH POSTGRADUATE MEDICAL FEDERATION

The British Postgraduate Medical Federation (University of London) provides postgraduate education in the medical and dental specialties, supplementing the opportunities available at the undergraduate schools and teaching hospitals, and those provided by the three Royal Colleges. All postgraduates, including those from the Commonwealth and Colonial territories, and from foreign countries, may obtain the advice of the staff of the central office of the Federation (18, Guilford Street, London, W.C.1) on programmes of study. In addition to the Postgraduate Medical School of London at Hammersmith, with its university departments of general medicine, general surgery, and pathology, there are fourteen postgraduate institutes comprising the Federation. The provisions for study made by these are detailed below.

The Federation and its Institutes

Each of the institutes of the Federation is associated with a special postgraduate teaching hospital or with one of the Royal Colleges. The number of students who can be admitted to the clinical practice of these hospitals is limited. Resident clinical appointments are available to suitable students of the institutes and provide the most suitable form of postgraduate education. Selected graduates have opportunity for research. At all the institutes courses of instruction are given throughout the academic year; these are suitable for graduates in the early stages of their specialist education and also for those who have completed their

practical training. Two or more years of hospital work in general medicine and general surgery after graduation are normally advisable before beginning work in the special branches. The work at the institutes is of an advanced type and is comprehensive enough to enable graduates with suitable practical experience to prepare for higher degrees and diplomas. Emphasis is placed on clinical and laboratory teaching, supplemented by lectures and demonstrations. Each institute has a reference library and takes the current journals of its specialty.

Most of the institutes run short courses for consultants, and many of them have one-day courses for registrars. Short courses and other forms of continuing education for general medical and dental practitioners and local authority medical officers are arranged at hospitals throughout the four metropolitan regions, with the assistance of the advisers in postgraduate medical and dental education.

Travelling Fellowships

Postgraduate students from abroad are advised to make their arrangements well in advance. Those who desire the assistance of the central office of the Federation should get in touch with the director, Professor Sir Francis Fraser, at the address given above, as far in advance of their arrival in this country as possible. Those sponsored by their universities, Governments, or other official bodies receive first consideration in the allotment of vacancies. Established specialists from overseas who are here for a short time, and who wish to see something of the practice of the country, are always welcome; they are regarded as visiting colleagues, and the experts in their specialties are always ready to receive them and let them see the work and teaching being carried on. An information bureau of postgraduate activities in London and other university centres is maintained at the central office.

The Federation awards annually to graduates working in medical and dental schools or teaching hospitals of the University of London a number of travelling fellowships for the purpose of travelling abroad.

Postgraduate Medical School of London

The Postgraduate Medical School (Ducane Road, London, W.12) is associated with Hammersmith Hospital. The work in the departments of medicine and surgery is based on advanced clinical studies supplemented by lectures during three ten-week terms, starting in January, April, and October. A year's comprehensive training in anaesthetics is provided. The work of the department of pathology includes a year's course for the university diploma in clinical pathology for which sixteen students with some experience are selected. The hospital department of radiology trains doctors for the radiological diplomas. All these activities start in October.

The Specialist Institutes

The *Institute of Basic Medical Sciences* (Royal College of Surgeons of England, Lincoln's Inn Fields, London, W.C.2) comprises departments of anatomy, physiology, and pathology of the Royal College. It co-operates with other specialist institutes of the Federation in providing facilities for practical work and instruction in basic medical sciences, and provides opportunities for research for selected graduates. Full-time or part-time courses of fourteen weeks' duration, suitable for candidates for higher degrees and diplomas, begin in February and September.

The *Institute of Cancer Research* (Royal Marsden Hospital, Fulham Road, London, S.W.3) comprises the Chester Beatty Research Institute and parts of the departments of physics and radiotherapy at the Royal Marsden Hospital. The institute is concerned with all aspects of research into the causation and treatment of cancer, with the training of research-workers in this field, and with advanced teaching in biophysics, radiotherapy, and problems of atomic energy. There are laboratories for chemical, biochemical, and histological investigations into cancer and allied diseases. Facilities are afforded to those wishing to pursue research into the

clinical and pathological aspects of cancer or the physical and biological foundations of medical radiology, and who may be working for higher degrees such as the Ph.D. The department of radiotherapy gives a lecture and demonstration course of one week's duration in May and November annually, primarily for doctors from overseas, and accepts candidates to train for the diploma in medical radiotherapy. A course of lectures for students studying for the M.Sc. degree in biophysics commences in October.

The *Institute of Cardiology* (35, Wimpole Street, London, W.1) is associated with the National Heart Hospital. Six appointments in senior registrar and registrar grades are available in the hospital and the institute to provide specialized training for postgraduates who have already a sound grounding in general medicine. Full-time and part-time courses of instruction of about eleven weeks' duration are held three times annually, starting in January, April, and October, and two or three short intensive courses of lectures and demonstrations are held each year in February, June, and November; the June course is usually for general practitioners.

The *Institute of Child Health* (The Hospital for Sick Children, Great Ormond Street, London, W.C.1) is associated with that hospital and with the Postgraduate Medical School at Hammersmith; the Queen Elizabeth Hospital for Children, Hackney, also participates in the clinical teaching. The Province of Natal Model Welfare Centre offers facilities for the study and care of the healthy child. The institute provides tuition throughout the year in three terms of three months each; in addition a series of lectures by specialists is given each term. Clinical clerkships are available for selected students.

The *Institute of Dental Surgery* (Eastman Dental Hospital, Gray's Inn Road, London, W.C.1) trains dental practitioners in the special branches of preventive and therapeutic dentistry. For candidates preparing for the F.D.S. of the Royal College of Surgeons, courses lasting eight months are held twice yearly, beginning in October and April.

The *Institute of Dermatology* (St. John's Hospital for Diseases of the Skin, 5, Lisle Street, London, W.C.2) gives clinical teaching daily throughout the year in the out-patient department, and instruction is given twice weekly at the in-patient department at Homerton. Tutorials in clinical dermatology and histopathology of the skin are given twice weekly during term time. There are also facilities for study and tuition in pathology, including mycology, and in radiotherapy and physiotherapy. Advanced students can apply for clinical and research assistantships, the former of which are competitive. The year's lecture course continues from October until the end of June. During this period also there are weekly clinical demonstrations. In April special short courses in histopathology and in medical mycology are held. A discussion on cases of special interest, to which students attending the courses are invited, takes place once a week.

The *Institute of Diseases of the Chest* (Brompton Hospital, London, S.W.3) is associated with the Brompton and London Chest Hospitals. A comprehensive full-time course is conducted for a limited number of graduates who are specializing in chest disease, during the two terms beginning in October and January and a more selective one during the summer term. A larger number can be accepted for a part-time study, which is suitable for those reading for higher medical diplomas. Clinical instruction in thoracic surgery, including cardiac surgery, is also given during university terms. Part-time instruction in radiology of the chest is given, and lectures and demonstrations open to the medical profession are held each week.

The *Institute of Laryngology and Otolaryngology* (330-332, Gray's Inn Road, London, W.C.1) is associated with the Royal National Throat, Nose and Ear Hospital. There is daily clinical teaching throughout the year. Whole-time courses held twice yearly include: basic sciences (three months), intensive lecture course (six weeks), practical revision course (two weeks), and advanced revision course (two weeks). Short courses on endoscopy, audiology, pathology, aural surgery, and malignant conditions are held occasionally.

The *Institute of Neurology* (National Hospital for Nervous Diseases, Queen Square, London, W.C.1) is associated with the National Hospital and the Maida Vale Hospital for Nervous Diseases. Teaching is mainly by attendance on hospital practice, supplemented by lectures and demonstrations. Two courses in clinical neurology are held annually, beginning in January and October. Clinical instruction in neurosurgery is given throughout the year. A course in the technique and clinical application of electroencephalography is held jointly with the Institute of Psychiatry twice a year. Courses of clinical demonstrations (two-weekly) are held several times a year. Advanced students are appointed as clinical clerks in the wards or attached to the special departments and research laboratories.

The *Institute of Obstetrics and Gynaecology* (Chelsea Hospital for Women, Dovehouse Street, London, S.W.3) is associated with Queen Charlotte's, the Chelsea Hospital, and the department of obstetrics and gynaecology at the Postgraduate Medical School. Teaching is based on ward work, supplemented by lectures and demonstrations during two terms of thirteen weeks' duration which begin in March and September. For students preparing for higher qualifications, two intensive courses of a fortnight's duration are held in June and December. A week's course for general practitioners is held twice a year.

The *Institute of Ophthalmology* (Judd Street, London, W.C.1) is associated with the Moorfields Eye Hospital. In addition to teaching by means of attendance on the hospital practice, a routine lecture and tutorial course, normally covering two terms of approximately eighteen weeks each, is held twice a year, commencing in March and October; the first part of the course is devoted to anatomy, embryology, histology, physiology, optics, and elementary clinical instruction; the second part comprises bacteriology, pathology, operative surgery, medical ophthalmology, and all aspects of ophthalmic disease. Short courses are held in slit-lamp microscopy, orthoptics, and contact-lens practice. Clinical teaching and lectures are given for advanced students, and there are facilities for research for suitably qualified candidates.

The *Institute of Orthopaedics* is associated with the Royal National Orthopaedic Hospital (234, Great Portland Street, London, W.1). Training in orthopaedics to selected graduates who have already been trained in general surgery and the basic sciences is afforded by means of clinical appointments, with opportunities for research. Short advanced courses for graduates with practical experience are held at various times during the year. Twice a year, in the spring and the autumn, a short revision course of a week's duration in advanced clinical orthopaedics is held. Both the central hospital in Great Portland Street and the country hospital at Stanmore are attended by postgraduate students.

The *Institute of Psychiatry* (Maudsley Hospital, Denmark Hill, London, S.E.5) is associated with the Bethlem Royal and Maudsley Hospitals. Training normally covers three years, after experience elsewhere in general medicine, and is based on responsible hospital duties under supervision. Regular series of lectures and demonstrations are given throughout each of the university terms. Clinical training continues throughout the year and includes seminars and case discussions. Students who, because of previous experience, do not wish to take the comprehensive course are able to attend a limited series of lectures and clinical instruction. For those who wish to specialize in child psychiatry a six-months course is held twice-yearly. A year's course in abnormal psychology for the university postgraduate diploma in psychology is available to holders of an honours degree in psychology. There are facilities for original investigation under supervision in the clinical and other departments.

The *Institute of Urology* (10, Henrietta Street, London, W.C.2) is associated with St. Peter's, St. Paul's, and St. Philip's Hospitals. Comprehensive instruction is given in the wards, out-patient departments, operating theatres, and laboratories throughout the year. Week-end courses of

demonstrations and lectures are arranged for higher examination candidates. Occasional lectures on venereal diseases are arranged with the Medical Society for the Study for Venereal Diseases, and arrangements can be made for graduates to attend venereal diseases clinics. In the winter months lecture-discussions on urological subjects of interest to the whole profession are held on Wednesday evenings at 5 o'clock. Limited numbers of clinical assistants are appointed to individual surgeons for personal tuition, and there are also research assistantships.

Fellowship of Postgraduate Medicine

The Fellowship of Postgraduate Medicine (60, Portland Place, London, W.1) provides general information on postgraduate work available both in London and in provincial centres, and itself arranges a certain number of courses of instruction at hospitals in or near London. These courses are specially designed to be helpful to candidates for higher degrees and diplomas, though attendance at them is not restricted to such candidates. The courses include general medicine, general surgery, obstetrics and gynaecology, and children's diseases. Some are full-time, lasting for one or two weeks, but the majority are part-time and are intended particularly for postgraduates not free for full-time study.

The Fellowship also arranges week-end courses, occupying the whole of a Saturday and Sunday, in such subjects as general medicine, general surgery, orthopaedics, plastic surgery, rheumatic diseases, and infectious diseases. Although these are primarily intended for candidates for higher degrees, many of them are also suitable for, and attended by, general practitioners. The Fellowship is an independent body, and is not connected in any way with official arrangements for postgraduate instruction under the National Health Service.

COLLEGES IN LONDON

The Royal Colleges

The Royal Colleges arrange courses of lectures in the various aspects of their specialties, and provide expert advice on suitable hospital appointments and programmes of study for candidates for their higher qualifications. The Royal College of Surgeons is organizing the second of its full-time clinical surgery courses from August 26 to October 18 this year. Full details of their postgraduate courses can be obtained from the secretaries of the Royal Colleges.

College of General Practitioners

The College was founded in 1952 as an academic body, with broad educational aims, to be the headquarters of general practitioners in this country and in the Commonwealth, and to help and encourage them to maintain a high standard. It is organized for general practitioners, by general practitioners, to improve the efficiency and good name of the family doctor, and to raise his standing in the eyes of the medical profession, of students, and of the public. It has already 4,400 members and associates. Its aims are to supplement the work of the universities, of the three Royal Colleges, and of other educational institutions, and not to compete with them; its work is complementary to the scientific and educational functions of the British Medical Association.

The 35 regional faculties of the College (13 of them overseas) arrange courses, symposia, week-end courses, lecture-demonstrations, etc., for general practitioners in their district. They encourage schemes of student-attachment to family doctors, and lectures by general practitioners. The college *Teaching Register* shows the names of more than 1,200 family doctors in the British Isles who are willing to take students into their practices. A *Research Register* shows more than 500 general practitioners interested in research. Sixteen issues of a *Research Newsletter*, of more

than 1,200 pages, have been published. A records unit is being developed.

The college works closely with the British Medical Students' Association, the British Postgraduate Medical Federation, and the Edinburgh Postgraduate Board of Medicine. It has been given Public Welfare Foundation prizes for medical students interested in general practice, fifteen annual Upjohn travelling fellowships of £200 each, an annual James Mackenzie lecture, the Butterworth gold medal, and the Pfizer postgraduate grant. It has been invited to judge the entries for the Bengier prizes for original observations in general practice. A generous donor has offered to present this new college with a fine building of its own. Medical students may join the college as associates as soon as they qualify. Detailed information may be obtained from the secretary, College of General Practitioners, 54, Sloane Street, London, S.W.1.

UNIVERSITIES IN ENGLAND AND WALES

Postgraduate Facilities at Oxford

The university committee responsible for postgraduate medical studies at Oxford has recently been reconstituted and its duties have been made the subject of a new university statute. The first duties of this committee will be to meet the obligations imposed upon the university by Act of Parliament—namely, keeping general practitioners informed of the latest developments in professional knowledge, and approving hospitals and posts therein for pre-registration purposes.

Facilities for postgraduate medical studies are available in the Nuffield professorial departments of the university under the professors of medicine, surgery, obstetrics and gynaecology, anaesthetics, orthopaedic surgery, and plastic surgery. Certain clinical appointments on the staff of these departments are open to specialist trainees from the Commonwealth. In addition to the provision made in the above departments for the training of specialists there are approximately twenty trainee appointments in the teaching hospitals (the United Oxford Hospitals) and eleven in certain departments of selected non-teaching hospitals of the Oxford region. These appointments (senior registrars) are in the following branches of medicine: general medicine, paediatrics, psychological medicine, chest diseases, pathology, general surgery, orthopaedics and accident services, otolaryngology, ophthalmology, obstetrics and gynaecology, neurosurgery, plastic surgery, dental surgery, and radiology. Six of these are "paired" posts, the holders of which spend part of their period of training in a teaching hospital and part in a non-teaching hospital by mutual agreement.

Facilities for the continuing education of general practitioners are provided in hospitals at Oxford, Reading, Aylesbury, and Northampton. Most departments of the United Oxford Hospitals may be visited by general practitioners on certain days throughout the clinical year (September to July). Practitioners may follow either an intensive course of a week or a fortnight's duration (when programmes are arranged to suit individual requirements) or an extended course spread over a number of weeks or months. In addition, special short courses are arranged for general practitioners during the spring and autumn months.

All inquiries should be made of the Director of Postgraduate Medical Studies, Osler House, 43, Woodstock Road, Oxford, from whom further details of long and short courses may be obtained.

Cambridge Postgraduate Studies

The School of Postgraduate Teaching and Clinical Research includes the departments of experimental medicine, human ecology, medicine, and radiotherapeutics. In the John Bonnett clinical laboratories, pathological and biochemical services of the United Cambridge Hospitals are provided by university teaching officers under the direction

of the professors of pathology and biochemistry. Particulars of the research activities of the school are given in the departmental annual reports, which are published in the *Cambridge University Reporter* in February each year. From their inception, the medical school and its constituent departments have been closely linked with the United Cambridge Hospitals. Plans are now under discussion between the Board of Governors and the Ministry of Health for increasing the first stage of the development of the new hospital site in Hills Road by establishing a neurosurgical unit there. Extensions of the John Bonnett clinical laboratories are in progress, and it is hoped that the first stage, which includes extended post-mortem facilities, will be completed by the autumn. A small extension of the Doughty x-ray clinic has been completed during the year.

Between October and July in each academic year special sessions are devoted to teaching by members of the consultant staff of the United Cambridge Hospitals. A small number of undergraduate students are admitted to these teaching sessions. Other teaching activities include a clinicopathological conference held on the third Wednesday of each month, which gives an opportunity for general practitioners and others to meet the staffs of the teaching hospital and of the various departments of the medical school. One-day symposia on subjects of particular interest to general practitioners are held monthly on Saturdays throughout the academic year. These symposia usually take the form of lecture-discussions followed by case-demonstrations. Residential courses in midwifery are available for undergraduate and postgraduate students at the Maternity Hospital. All postgraduate courses and symposia are open, without fee, subject to the terms of the Ministry of Health scheme, to practitioners who are under contract with an executive council of the National Health Service, and who have not fewer than 500 (or in the case of a rural practice 250) persons on their N.H.S. lists. Practitioners who do not qualify for a grant under the Ministry of Health scheme are, in general, charged fees at rates corresponding with those which otherwise would have been payable by the Ministry. Further details of postgraduate facilities may be obtained from the Secretary of the Medical School, Tennis Court Road, Cambridge.

Postgraduate Facilities at Other Universities

The board of graduate studies at the *University of Birmingham* endeavours to provide courses of instruction for general practitioners on a scale adequate to satisfy fully the demands of doctors practising in Warwickshire, Worcestershire, Staffordshire, Shropshire, and Herefordshire. Practitioners from further afield, particularly Birmingham graduates, are welcomed. Extended courses in medicine and general surgery, dentistry, and midwifery are held at the teaching and at regional hospitals, and week-end courses in paediatrics are held at frequent intervals at the Children's Hospital, Birmingham, and in neurology, neurosurgery, psychiatry, and psychotherapy at the Queen Elizabeth Hospital, Birmingham, the Midland Centre for Neurosurgery, and Uffculme Clinic. In the arrangement of all postgraduate facilities for general practitioners the board of graduate studies works in close co-operation with the Midland Faculty of the College of General Practitioners.

The institute of accident surgery holds short intensive courses of instruction in traumatic surgery at the Birmingham Accident Hospital. Some courses cater for the needs of surgeons and surgical trainees, others are planned to help industrial medical officers and industrial nurses, and others are solely for general practitioners. Short intensive courses of instruction in industrial ophthalmology are held at the Birmingham and Midland Eye Hospital, usually in July. The university offers no diplomas, nor, with the exception of the M.R.C.P. and the diploma in psychological medicine, any courses of instruction for higher and specialist examinations. Courses of instruction for Part I and Part II of the D.P.M. are held in alternate academic years. M.R.C.P. courses are held every one or two years. Attachments are

arranged for increasingly large numbers of postgraduates from abroad who wish to come to Birmingham for long or short periods as observers or to work in the various departments of the medical school or teaching or regional hospitals. In conjunction with the university department of social medicine a number of research projects are in progress in which the field work is being done by general practitioners. The chairman of the board of graduate studies is Dr. A. G. W. Whitfield, The Medical School, Edgbaston, Birmingham, 15.

In the *University of Durham* a part-time course for the diploma in public health began in January of this year, eight candidates being accepted for the course, which extends over five academic terms. Courses for Part I and Part II of the diploma in psychological medicine began in October, 1956, six candidates being accepted for Part I and eight for Part II. Refresher courses for general practitioners were held during the year. These consisted of: (i) intensive week-end courses in paediatrics and obstetrics and (ii) extended courses consisting of nine Tuesday or Thursday afternoon sessions in various subjects. In addition several local practitioners have attended two-weeks resident courses in obstetrics. It is proposed to hold week-end courses in medicine, psychiatry, paediatrics, and obstetrics during the early autumn. Postgraduate instruction in anatomy, physiology, pathology, bacteriology, and other subjects of the medical curriculum is available by agreement with the professors of the departments concerned. Several postgraduate students from overseas have been provided with suitable courses and research facilities leading to higher degrees.

Full-time postgraduate courses at the *University of Liverpool* have continued as in previous years. Out of a total of 713 students in the medical school, 180 are postgraduates. 15 attended the course in general surgery, 17 in orthopaedic surgery, 17 in public health, 11 in anaesthesia, 18 in radio-diagnosis, 8 in radiotherapy, and 57 in tropical medicine and hygiene. 10 candidates have taken the course in psychological medicine; this is part-time and covers a period of two years, and is suitable for candidates for the Conjoint D.P.M. The course in general surgery is suitable for candidates who have already passed the primary examination for the F.R.C.S., but candidates for the course in orthopaedic surgery must already hold the F.R.C.S. to become eligible to take the examination for the degree of M.Ch.Orth. The courses leading to the D.M.R.D. and D.M.R.T. extend over two years; candidates are usually found registrar appointments during the second year. In the course in anaesthetics, students are found appointments in recognized general hospitals for the purpose of gaining practical experience. General-practitioner refresher courses have been held at Liverpool Maternity Hospital and Mill Road Maternity Hospital (62 doctors attended); at Walton Hospital (46 doctors attended); and at Broadgreen Hospital (50 doctors attended). A five-day intensive course in anaesthetics for general practitioners was arranged. Two more extended courses, at Sefton General Hospital and at St. Paul's Eye Hospital and the Ear, Nose, and Throat Infirmary, have been arranged for the latter part of the session. Further information regarding university postgraduate courses may be obtained from the Dean of the faculty of medicine.

At the *University of Bristol* the degrees of M.D., Ch.M., and Ph.D. are open to graduates of other universities, but only to those graduates who have pursued original research in the university for not less than two years, and in effect this regulation means that these higher degrees are open only to those graduates of other universities who hold appointments on the staff of Bristol University or one of the local hospitals. The university diploma in psychological medicine is in abeyance. The university offers a diploma in public health, and a course will be held in the session 1957-8. A few postgraduates are accepted for training for the D.M.R.D. and D.M.R.T. (Conjoint), and arrangements can sometimes be made for suitable candidates to hold a part-time post in the Bristol hospitals while doing the course. A course in child health lasting three months usually begins in October of each year. Refresher courses for general practitioners

consist of Sunday morning lecture-demonstrations in Bristol and occasional intensive week-end courses at hospitals in various parts of the south-west region.

At the *University of Leeds* extended refresher courses for general practitioners, comprising one half-day session a week for six weeks and week-end refresher courses on special topics, are arranged from time to time, both in the teaching hospitals and in regional hospitals. The university grants a diploma in public health, also a diploma in psychological medicine, the part-time course for which covers eight academic terms. The secretary of the Postgraduate Committee is Dr. T. A. Divine, School of Medicine, Thoresby Place, Leeds, 2.

In the postgraduate sphere, information is being collected about the duties undertaken by, and the education facilities available to, those holding pre-registration posts in the Sheffield region. The exchange, at intern level, with the Albany Medical School, N.Y., again operated with very satisfactory results during 1956-7. In 1957-8, though Sheffield will send an intern to Albany for his pre-registration year, various factors unfortunately prevent an actual "exchange" on this occasion. Discussion still continues on the value, in the training of senior registrars, of interchange between teaching hospital and regional hospital appointments. Well-established postgraduate teaching activities still continue (partly in liaison with the Sheffield Faculty of the College of General Practitioners)—regular ward visits or demonstrations during autumn or spring, an intensive refresher course in the late summer, and less formal arrangements for individual students desiring clinical experience in various spheres or working for specialist examinations. A part-time course in preparation for the university's diploma in public health was recommenced last October, and is proceeding satisfactorily. Though hopes for the development of a department of psychiatry at the *University of Sheffield* have been disappointed through present financial stringency, the advent of a professor has brought the university into the sphere of postgraduate work in this specialty.

At the *Welsh National School of Medicine* the arrangements under the new regulations for the D.P.H. course came into force this session, and a class of eleven part-time students is now pursuing this course, in conjunction with part-time public health appointments in the area. Two postgraduate courses for general practitioners are held each year, and are attracting an increasing number of practitioners from outside Wales. In addition four week-end postgraduate courses in dentistry are being held for dental practitioners.

EDINBURGH AND GLASGOW

Postgraduate Facilities at Edinburgh

The University of Edinburgh, through the medium of the Edinburgh Postgraduate Board of Medicine, on which the Royal Colleges of Physicians and Surgeons of Edinburgh are represented, has arranged a variety of courses. These are advertised at intervals in the medical press, and full particulars can be obtained from the Director of Postgraduate Studies, Surgeons' Hall, Edinburgh, 8. In addition the Board arranges library facilities and clinical work and helps the postgraduate students in a variety of ways. The courses of instruction are considered to be of value to those requiring a period of revision or those preparing for higher diplomas.

In the medical sciences a 12-weeks course begins at the end of June. This includes lectures and practical instruction in anatomy, physiology, pathology, biochemistry, and bacteriology. The instruction is of an advanced standard and students should already be well grounded in these subjects. In addition two 10-weeks courses are arranged to start in October and February. In surgery there are two 12-weeks courses each year, beginning in March and September. The numbers are limited and the instruction is primarily clinical in nature. In medicine there are two similar 12-weeks courses. The instruction is systematic, clinical, and by demonstrations. The fee for each of the 12-weeks

courses is 30 guineas; the fee for the 10-weeks course is 25 guineas.

At Edinburgh a two-weeks refresher course for general practitioners is held in May, giving a wide variety of instruction in medicine, surgery, and obstetrics (fee—10 guineas). There are also occasional one-day courses in selected subjects, and a series of clinical meetings arranged for the general practitioners of the South-east Region of Scotland. In addition, there are occasional courses specially arranged for dental surgeons and anaesthetists. The Edinburgh Postgraduate Board of Medicine is an advisory council to the university and provides courses of instruction leading to the higher qualifications granted by the Royal Colleges of Edinburgh. The Royal College of Surgeons of Edinburgh (18, Nicolson Street) has a two-part examination for its Fellowship.

Postgraduate Facilities at Glasgow

Glasgow University Postgraduate Medical Education Committee, representing the university and the Royal Faculty of Physicians and Surgeons of Glasgow, proposes to offer the following courses during the coming session. A nine-weeks part-time course of instruction in anatomy, physiology, biochemistry, pathology, and bacteriology will be held, as in previous years, from October to December. The course is suitable for candidates preparing for the primary examinations for the surgical fellowships, and will provide a total of approximately 180 hours of instruction. The course is organized primarily for the junior staff of hospitals in the Western Region of Scotland, but it is also open to other applicants. A modified form of the course is available for trainees in anaesthetics reading for the primary examination of the F.F.A. Clinical attachments of one to three months' duration can be arranged in general medicine, general surgery, and various specialties for those proceeding to higher qualifications.

The Glasgow medical school provides an annual course for the diploma in public health, and also a course for the diploma in industrial health in any year in which there are sufficient applicants. Short courses in other specialties are arranged from time to time when the demand arises, and are advertised in the medical journals. For the ensuing session a short course in chemotherapy and a course in mental deficiency have already been arranged. The department of psychological medicine will hold a course extending from January to June, 1958, for candidates reading for the D.P.M. Training in radiodiagnosis and radiotherapy, recognized for the D.M.R.D. and D.M.R.T., is available. Refresher courses for general practitioners are held from time to time; these consist largely of clinical demonstrations, but also include a few lectures on modern methods of treatment. A recent very successful addition to the range of postgraduate courses has been the institution of short intensive courses on the use of radioactive isotopes. These courses are organized by the staff of, and held in, the regional physics department, a department instituted by the regional hospital board to advise and assist their hospitals on matters concerned with the use of isotopes and electronic apparatus.

The Royal Faculty of Physicians and Surgeons of Glasgow grants, after examination, a fellowship *qua* physician and a fellowship *qua* surgeon. The examinations are clinical, written, and oral.

HYGIENE AND TROPICAL MEDICINE

The London School

The London School of Hygiene and Tropical Medicine (Keppel Street, Gower Street, W.C.1) is a postgraduate school of the University of London, devoting its attention to teaching and research in preventive medicine and occupational health, bacteriology, and the whole range of subjects concerned with tropical medicine and hygiene. The work of the school is organized in ten main departments: applied physiology, bacteriology and immunology, bio-

chemistry, clinical tropical medicine, entomology, human nutrition, medical statistics and epidemiology, parasitology, public health, and the Ross Institute of Tropical Hygiene.

The research work has many links with other institutions at home and abroad. On the teaching side the school prepares students for four academic postgraduate diplomas of London University: applied parasitology and entomology, bacteriology, public health, and tropical medicine and hygiene. These courses occupy a whole academic year. The school also provides a five-months course for the Conjoint Board's D.T.M.&H. Teaching for the University of London postgraduate D.P.H. is designed to develop the student's knowledge of principles of preventive medicine and to bring him in touch with practical issues of public health administration. Much of the work is in the form of practical instruction against the background of the British health services, and arrangements are made for the students to visit health areas in both urban and rural districts and to study central administration. The study of British health services is intended to illustrate the broad principles of public health in such a way as to render the course appropriate to students from both home and overseas. In addition to the subjects covered by the D.P.H. syllabus the students are entitled to take one of the following special subjects: child health, medical statistics and epidemiology, mental health, occupational health, and tropical hygiene. The special subjects in occupational health, together with the general teaching for the D.P.H., fulfil in part the requirements for entry to the examination for the D.I.H.

The course for the University of London postgraduate diploma in bacteriology provides advanced instruction for graduates in medicine, science, and pharmacy, and for non-graduates with suitable qualifications, who intend to follow a career in bacteriology. The course begins in October and lasts for nine months. The course for the Conjoint Board's D.T.M.&H. is of five months' duration and is held twice a year. The course for the University of London academic postgraduate C. and D.T.M.&H. is designed to give advanced training. There is a preliminary course of approximately four and a half months, commencing at about the beginning of October each year. The final course of not less than four months consists of advanced study in one of the following two fields—clinical tropical medicine and tropical hygiene.

The course for the University of London postgraduate certificate and diploma in applied parasitology and entomology, planned mainly for those wishing to take up research or laboratory appointments abroad, is held annually commencing in October. Graduates in medicine, veterinary medicine, veterinary science, and science, and those with approved non-graduate qualifications in medicine and veterinary medicine, are eligible. The full course lasts for nine months, the preliminary certificate part lasting for approximately four and a half months.

A course in statistical methods applied to medicine and epidemiology is held annually on two days a week from approximately the beginning of March to the end of June. Students without a medical qualification can be accepted. A ten-weeks course in environmental control is held twice a year, commencing at approximately the beginning of March and October. Although intended primarily for health inspectors from abroad, the course is so planned as to be of value to medical officers and others interested in the health aspects of environmental control both at home and abroad.

Royal Institute of Public Health and Hygiene

The Royal Institute of Public Health and Hygiene (28, Portland Place, London, W.1) conducts recognized courses of instruction for the Diploma in Public Health and for the Diploma in Industrial Health. The next courses will start on September 20, 1957. All tuition may be taken as whole-time or part-time study. Clinical tuition in general medicine at a postgraduate medical teaching hospital is available and may be undertaken optionally. The examinations are those of the Conjoint Board of the Royal College of Physicians of

London and the Royal College of Surgeons of England for both diplomas, and, in addition, of the Society of Apothecaries of London for the D.I.H.

Liverpool School of Tropical Medicine

Men and women students of any nationality who hold a medical qualification approved by the university are admitted at the Liverpool School of Tropical Medicine (Pembroke Place, Liverpool) to examination for the D.T.M.&H. (Liverpool). A complete course of instruction lasting about three months is given twice yearly. The examination is held in December and April, and consists of two papers on tropical medicine (including pathology and bacteriology), one on parasitology, one on entomology, two on tropical hygiene and related subjects; and practical and oral examinations in tropical medicine, parasitology and entomology, and tropical hygiene. The dates of the courses are September to December, 1957, and January to April, 1958. The School also gives courses in parasitology and entomology for students taking the D.P.H.

OTHER COURSES AND EXAMINATIONS

The Tavistock Clinic (2-4, Beaumont Street, London, W.1) is an out-patient clinic comprising two departments—the adult department for the treatment of patients with neurotic and personality disorders, and the department for children and parents in which difficulties in parent-child relationships and in the personality development of children are treated. Senior registrar and registrar appointments in both departments provide systematic training in adult psychotherapy and child psychiatry. The clinic also offers a two-year extramural course for psychiatric registrars and consultants in the principles of psychotherapy and psychopathology. Courses for general practitioners include an introductory weekly discussion group on principles of psychological medicine and the doctor-patient relationship, and a course, including case supervision, for those wishing to gain experience in the treatment of neurotic and psychosomatic disorders in their own practice. Rorschach courses (open to psychiatrists) are provided in conjunction with the Tavistock Institute of Human Relations, as well as general courses of training for clinical and educational psychologists, child psychotherapists, and social workers. The clinic welcomes visitors, and has some facilities for offering associate status to interested overseas psychiatrists, psychologists, and social workers who are in Great Britain for further training. Full particulars may be obtained from the Training Secretary at the above address.

The *National Association for Mental Health* (39, Queen Anne Street, London, W.1) organizes, with the extramural department of the University of London, courses on educationally subnormal children and mental defectives for school medical officers. The course includes lectures on normal child development, the pathology and causation of intellectual retardation and maladjustment, the psychology of educationally subnormal children, and educational and social implications of backwardness. A year's course is organized for men and women wishing to train for work in occupation centres and "school departments" of mental deficiency hospitals. Lectures and courses for social workers, health visitors, and teachers are also held.

The *Institute of Psycho-Analysis* (63, New Cavendish Street, London, W.1) furnishes a part-time course lasting about four years in psycho-analytic theory and technique. It includes personal analysis, attendance at lectures and seminars, and clinical work under supervision. General psychiatric experience must be obtained at other clinics or hospitals, since the teaching at the institute is confined to psycho-analysis.

The *Society of Analytical Psychology* (25, Park Crescent, London, W.1), founded in 1945, is the professional body representing Jungian psychology in this country, and is a training centre for analytical psychology with C. G. Jung as its President. For some years the society has operated

a part-time course of training in analysis. This consists of two parts. Candidates accepted for Part I undergo a personal training analysis for at least two years. Later, if accepted for Part II, candidates attend a two-year course of seminars on clinical practice, the theoretical aspects of analysis, and an introduction to mythological material in relation to medical psychology. In addition each candidate begins to treat cases under the supervision of a training analyst. Election to associated professional membership takes place when the candidates have fulfilled certain minimum requirements with regard to the length of their personal analysis and supervision period, and when they are considered competent to treat cases without supervision. For its own members the society gives the opportunity of participation in lectures, seminars, and research groups concerned with problems of adult and child analysis.

A course of instruction in homoeopathy for medical practitioners and senior students, arranged by the *Faculty of Homoeopathy*, begins at the Royal London Homoeopathic Hospital (Great Ormond Street, W.C.1) on October 10. It includes lectures on homoeopathic prescribing and on homoeopathy in theory and practice, also clinical tutorials for practical instruction in homoeopathic practice. The lectures deal with subjects required for examination for the Diploma of Membership of the Faculty.

CAREERS IN RESEARCH AND THE SERVICES

Medical Research Council

The Medical Research Council (38, Old Queen Street, London, S.W.1), originally established in 1913 as the Medical Research Committee, is appointed to administer the funds provided annually by Parliament for the promotion of research in medical science. The Council is under the general direction of the Committee of Privy Council for Medical Research, of which the Lord President is the chairman and the Minister responsible to Parliament. The Council is not constitutionally a Government department; it selects and appoints its own staff, who are not civil servants. The scientific staff of the Council work in some 60 establishments located mainly in hospitals and universities in Great Britain. The Council also maintains laboratories in Gambia, Jamaica, and Uganda. The total scientific staff of the Council numbers nearly 550, of whom over one-third are medically qualified. Its research establishments vary widely in size; the largest is the National Institute at Mill Hill, but the average research unit consists of from five to ten scientific workers with a number of technical and clerical assistants.

The aim of the Council is to provide the opportunity for careers which are equivalent to those offered in the universities to men and women of equal ability and experience; the Council's salary scales for scientific appointments are based on this principle. New appointments to the scientific staff, except in the case of senior posts, are normally made for definite periods, usually of three or five years at a time.

In addition to maintaining its own staff, the Council makes very large numbers of short-term grants in support of specific research projects carried out by independent workers in universities, hospitals, and elsewhere. The Council also awards clinical research fellowships, scholarships for training in research methods, and certain travelling fellowships; these last are awarded either on an agency basis for other bodies or from private benefactions entrusted to the Council.

Pamphlets dealing with the constitution and functions of the Council, and describing opportunities for service on its staff, are obtainable from the Council's headquarters office.

Public Health Laboratory Service

On behalf of the Ministry of Health the Medical Research Council administers the Public Health Laboratory Service, which was originally set up as an emergency service in 1939

and has since become permanent; there are over 50 separate laboratories in England and Wales.

In addition to their more routine duties, members of the staff of the service, whose salary scales are normally equated with those of the National Health Service, undertake research problems in bacteriology and epidemiology. Furthermore, the service maintains a number of special laboratories which act as reference centres for particular infections, and these engage largely in research.

Naval Medical Service

"Naval medicine" comprises a variety of subjects including aviation medicine, the physiology of diving, the physical aspects of service afloat and ashore, tropical diseases, and industrial hygiene. The naval medical officer is not concerned solely with the welfare of the sailor, but also with the families of Service men and of Admiralty personnel serving abroad. Officers on the permanent list are encouraged to specialize in all branches of medicine and are given full facilities to obtain higher qualifications. Courses of postgraduate study are carried out both in naval hospitals and at civilian teaching centres.

Service on the active list is up to the age of 55 for all officers, 57 for surgeon captains, and 60 for surgeon rear-admirals. Previous experience, both Service and professional, is counted in assessing seniority—previous commissioned service as a medical officer in one of the armed Forces counts in full, and non-medical commissioned service counts as to half. Civilian hospital experience and also some medical experience in private practice may be allowed to count up to a limit of seven years in all. Officers serving in the United Kingdom are granted 42 days' leave per annum on full pay and allowances, with three free travel warrants. If serving overseas local leave is given at the rate of 14 days a year, and foreign service leave at the rate of two days for each month is allowed on returning to the United Kingdom. Leave for officers serving in H.M. ships on general service is at the rate of three days for each month.

All entries at present are being made as short commissions in the first instance. Short service consists of either three or four years, during which period a medical officer becomes a surgeon lieutenant R.N., and is eligible to apply for transfers with full seniority to the permanent list. Officers who transfer to the permanent list after a minimum of one year's service will be paid a grant of £1,500 (taxable). The normal career of a medical officer enables him to be promoted to the full rank of surgeon lieutenant after one year's service and to surgeon lieutenant-commander after a further seven years' service. In the normal course surgeon lieutenant-commanders are promoted to surgeon commanders by selection at about their fifteenth year of total service, and surgeon commanders to surgeon captains at about their twenty-third year of total service.

Further information may be obtained from the Medical Department, Admiralty, Queen Anne's Mansions, St. James's Park, London, S.W.1.

A Career in the R.A.M.C.

Two-thirds of medical officers in the Royal Army Medical Corps are employed on general-practitioner duties. After attending the junior officers' course at the Royal Army Medical College, Millbank, they start their career as regimental medical officers and they become conversant with the soldier and his environment, the objects of the Army, and the requirements from its medical service in peace and war. They will later serve overseas, where, as regimental medical officers or in charge of a medical reception station or small hospital, they will be able to study the causation, prevention, and treatment of tropical diseases, the effects of climate, and the like. On return to the United Kingdom they attend the senior officers' course, the first two and a half months being spent in study at

Royal Army Medical College, Millbank, and the next three months undergoing a special postgraduate course at selected teaching hospitals. At this stage officers may opt to remain at general medical duties or take up field training or junior staff appointments. For the more senior appointments the requirements are a sound background of clinical and preventive medicine to meet their advanced responsibilities in the administration of the Army Medical Service in peace and war.

Specialists are, subject to professional proficiency, employed on specialist duties up to the rank of colonel. Thereafter they may serve in this rank up to the retiring age of 57 or may be selected for promotion to brigadier in either a specialist or non-specialist capacity. The process of selection for specialist training is carried out after the junior officers' course, those applicants who are most successful in the course examination being accepted. Those accepted are provided with excellent opportunities to obtain higher qualifications and specialist experience. At present ophthalmologists, otolaryngologists, and radiologists are especially required. There are liberal arrangements for specialists and non-specialists to undergo postgraduate training throughout their career.

All suitable medical officers, specialist or non-specialist, may be employed up to the age of 65 in appointments specially set aside for retired officers. Non-specialists are employed on general-practitioner or medical administrative duties and specialists on specialist duties.

Further information may be obtained from the Assistant Director General, War Office, A.M.D.2, London, S.W.1.

Medical Branch of the R.A.F.

The Royal Air Force offers an attractive career to both men and women medical practitioners who are British subjects or citizens of the Irish Republic. The normal upper age limit for applicants is 33, but older applicants may be considered. Appointment in the first instance is normally to short-service commissions for three, four, five, or six years, each of which may be extended to complete a maximum period of eight years. Exceptionally, suitable candidates may be appointed to permanent commissions direct from civil life. Short-service officers may apply for permanent commissions at any time during their service. Medical practice in the R.A.F. brings officers into contact with flying, and air evacuation of the sick and wounded as well as with the clinical specialties and the treatment of Service families. In addition, there are opportunities in aviation medicine, physiology, hygiene, and industrial health.

Officers serving on permanent commissions may be allowed study leave to take approved postgraduate courses, for which tuition fees on an approved scale may be granted. Officers having experience or aptitude in a specialty may be employed on specialist duties, if Service conditions permit, with the object of qualifying as senior trainee specialists and subsequently earning recognition as R.A.F. specialists. A full career is possible in the clinical specialties with time promotion to group captain and additional specialist pay. Non-specialist medical officers below the rank of group captain may be awarded additional pay on gaining a registrable D.P.H., D.I.H., or D.T.M.&H., provided the prescribed period of study occupied an academic year. Non-specialist medical officers can expect time promotion to wing commander, with promotion to higher ranks by selection. Antedate of seniority up to a maximum of seven years may be admissible for civil experience and will count towards pay, seniority, and promotion.

Further information can be obtained from the Under Secretary of State for Air, Air Ministry, M.A.1p, 2-8, Richmond Terrace, Whitehall, S.W.1.

Overseas Civil Service

In the medical department of the Governments of the territories overseas for which the Secretary of State of the

Colonies is responsible, openings occur in all parts of the world. Many future appointments are likely to be made on the bases of short-term contracts, usually renewable. Doctors in the N.H.S. may take temporary appointments overseas up to six years without loss of pension rights. In some territories permanent appointments are available; candidates selected for these appointments become members of the medical branch of Her Majesty's Overseas Civil Service. Candidates must normally be British subjects whose names appear on the *Medical Register*, and should not be over 45 years of age.

Full terms and conditions of service may be obtained from the Director of Recruitment, Colonial Office, Sanctuary Buildings, Great Smith Street, London, S.W.1.

Missionary Service

For doctors with a call to dedicated service, the mission field offers great opportunity for the exercise of medical knowledge and skill where the need is greatest. Though the financial rewards are small, a Christian doctor will find this work immensely satisfying. Any who have this service in view are advised to spend eighteen months or two years in resident appointments after qualification. Special missionary training is required by some of the societies. Although long service is preferred, short-term offers are considered by most societies. Application may be made to any of the missionary societies, or to the Secretary of the Medical Advisory Board, Edinburgh House, 2, Eaton Gate, London, S.W.1, or to the Secretary, Medical Missionary Association, 31, Bedford Place, London, W.C.1.

Medical Service of the L.C.C.

Just over 100 whole-time and nearly 500 part-time medical officers are employed by the London County Council in its Public Health Department. The duties of those holding whole-time appointments in the higher grades are mainly administrative. Senior officers have, generally speaking, graduated through the clinical field and have special knowledge of at least one branch of the service. The medical officers (recruitment grade) are mainly engaged in the school health and maternity and child welfare services. The D.P.H. is a suitable qualification. Arrangements are made for some of the officers to have clinical responsibilities at hospitals and to gain experience of environmental health services in the metropolitan boroughs. Part-time officers may be employed in residential nurseries, welfare institutions, staff examinations, sessional work at clinics, school medical inspection, etc. By arrangement with the London School of Hygiene, the Institute of Child Health, and several undergraduate schools, students have the opportunity of gaining experience in the Council's various services.

Salary scales of the Council's medical staff have recently been revised. The salary of the medical officer of health to the Council is £4,250. That of the deputy medical officer of health is £2,575 by £250 (biennially) to £3,075. For divisional medical officers the scale varies according to the population of the nine divisions in the London area. For populations up to 400,000 it is £1,780 to £2,215; for populations over 400,000 it is £1,885 to £2,320. A divisional medical officer who is also medical officer of health for two boroughs receives £2,795 to £3,060. A deputy divisional medical officer in a division with a population up to 400,000 receives £1,625 to £1,955, and in divisions above that limit, £1,675 to £2,005. The scales for other grades are: senior principal medical officer, £2,225 to £2,425; principal medical officers and psychiatrist (whole-time), £1,940 to £2,320; assistant principal medical officers, £1,530 to £1,790; and medical officers, £1,050 to £1,475. The remuneration of medical staff holding mixed appointments—that is, including some work for metropolitan borough councils—is determined in accordance with a Whitley Council formula.

PROFESSIONAL ORGANIZATIONS

British Medical Association

The British Medical Association, which was founded in 1832, now comprises a membership of almost 70,000, of whom about 16,000 are overseas. Its purpose is to promote the medical and allied sciences and to maintain the honour and interests of the medical profession. Membership is voluntary, and, as 80% of practising doctors in this country are members of the Association, it can justly claim to speak for the profession in its dealings with the Government and other authorities. The Association has important branches in Australia and New Zealand, and flourishing local units in many parts of the British Commonwealth. The Medical Associations of Canada, South Africa, India, and Ceylon are affiliated to the B.M.A. There are local units of the Association in every part of the United Kingdom; each member is automatically included in the membership of the local unit—the Division or Branch—in whose area he resides or practises. The local units hold regular meetings, and whether these are clinical, or social, or convened for business purposes, every member is entitled to take part.

Other privileges of membership of the Association include the weekly receipt of the *British Medical Journal* and its *Supplement*; the use of the Association's house and library at Tavistock Square, London, and elsewhere in Great Britain, and in certain Overseas Branches; and, not least important, the help of a highly skilled and experienced staff at Headquarters in the many difficulties and problems which arise in practice.

The policy of the Association is determined by the Representative Body, which is composed of representatives from all the Divisions. The Council is the Association's executive; its method of election has been recently revised to ensure as equal a representation as possible of all parts of the United Kingdom as well as to afford opportunity for the election of a certain number of members on a national basis, and to include representation of the medical branches of the fighting Services, the public health service, and the Overseas Branches. The principal work of the Association is carried out through a large number of standing and special committees. The Central Consultants and Specialists Committee (which also has a regional organization) acts with the Royal Colleges on all matters arising under the National Health Service Acts affecting consultants and specialists. The General Medical Services Committee acts as the executive of the Conference of Representatives of Local Medical Committees in all questions affecting practitioners rendering general medical service under the Acts and is the recognized mouthpiece of the profession in this field. The Public Health Committee, which has a working agreement with the Society of Medical Officers of Health, deals with all matters relating to the public health service. Other committees of the Association are concerned with private practice, ethical questions, and the encouragement of medical science and research, and there are joint committees with other bodies for the consideration of matters of mutual interest.

In addition to the *British Medical Journal* the Association publishes a number of specialist journals and abstracts. The library of the Association contains 70,000 volumes, and 1,600 periodicals are received regularly. The library has a large lending and circulating service and is available for reading and reference purposes to members calling at B.M.A. House.

Society of Medical Officers of Health

The Society of Medical Officers of Health (Tavistock House South, Tavistock Square, London, W.C.1.) is a body of medical officers engaged in public health work. It has branches and groups throughout Great Britain and Northern Ireland in New South Wales, and, since October, 1956, in Malaya, which meet regularly to discuss the medical and administrative aspects of preventive medicine. The

Council of the Society, representative of the branches and groups, is the governing body in respect of policy and finance. It examines all legislation concerned with the Ministries of Health, Housing and Local Government, and Education and the Department of Health for Scotland, and with public health, and maintains relations with the public health departments of the universities and local government authorities.

There is reciprocal representation on the Public Health Committee of the British Medical Association and the Council of the Society, and the Public Health Committee acts in conformity with an agreement with the Society of Medical Officers of Health under which medico-political activities are undertaken by the Association.

The Society is fully conscious of the need to keep members abreast of modern practice and developments in the field of public health. Accordingly the various groups of the Society arrange refresher courses for their members, which are well attended.

Apart from the new branch established in Malaya in 1956, two new functional groups were inaugurated in March 1957—namely, the Mental Health Group and the Teaching (Social and Preventive Medicine and Preventive Dentistry) Group. The membership of the former includes some twenty distinguished psychiatrists, and the Teaching Group has most of the professors of social and preventive medicine and preventive dentistry among its London members. The County Borough Group holds a week-end school every year, during the month of July. The County District Group also arranges a course. The Maternity and Child Welfare Group and the School Health Service Group also customarily hold courses. For senior school medical officers a course is held every few years in different centres. Some of these courses are residential in character, and in this way opportunity is given for those attending to discuss more easily and readily their common problems and the advances which are being made year by year.

Medical Women's Federation

The Medical Women's Federation (Tavistock House North, London, W.C.1.) works closely with the British Medical Association, and is represented by a woman member on the General Medical Services Committee. The Federation is the only professional organization consisting solely of medical women, and is thus in a position to represent the interests of women doctors and to deal with the problems affecting them as a minority in the profession. It also considers and investigates medical matters of special concern to women doctors. The Federation has active local associations all over the kingdom, including a large London association, and an association of its overseas members. These associations meet regularly, and the *Journal* of the Federation is published quarterly for private circulation among its members.

British Medical Students' Association

This association was founded in 1942, and its membership now includes over 90% of the medical students in the country. It is purely a professional organization, providing a means of communication between medical students in the different universities and hospitals, and also between British students and those in other countries. It presents the medical students' point of view to the medical profession, to Government departments, and to other interested bodies. The organization of the association depends on an annual general meeting at which an executive committee is elected, and on four regional councils. Both clinical and preclinical conferences and "schools" are arranged from time to time, and these are appreciated not only for their academic interest but also for the opportunities which they provide for meeting fellow students from other medical schools. Local activities of the con-

stituent organizations of the association include lectures, visits, discussions, and the showing of films from the B.M.A. and other film libraries. Amongst its publications are the *British Medical Students' Journal*, which appears once a term, and an annual list of vocation appointments for those members requiring work in hospitals during vacations.

The B.M.S.A. takes a keen interest in medical education and is in the process of compiling a report on the medical curriculum, bearing in mind the new G.M.C. "Recommendations" on medical curricula.

The association is represented on the Medical Students and Newly Qualified Practitioners Subcommittee of the B.M.A. and on the Undergraduate Education Committee of the College of General Practitioners. It maintains its close interest in the British Student Tuberculosis Foundation, of which it is a sponsoring body, and is a foundation member of the United Kingdom Committee of the World Health Organization.

In the field of sickness and other insurance the association has made arrangements with an insurance agency, set up by the medical profession for its own guidance, for the development of a special section to advise medical students.

The B.M.S.A. is a founder member of the International Federation of Medical Students Association, whose membership now embraces the associations of eighteen nations. I.F.M.S.A. continues to develop successfully and is recognized by the World Medical Association and Unesco. Under its auspices the annual students' international clinical conference has been held this year in Germany, while other courses both clinical and preclinical have been held in Yugoslavia and Denmark. Opportunities also exist for individual clerkships in hospitals abroad, and the B.M.S.A., through the offices of a student international secretary, does much to assist British students to take advantage of these and other opportunities to travel and see something of medicine in other countries. Similarly the B.M.S.A. makes arrangements for many foreign students to visit hospitals in this country, and the number of applications increases yearly, but unfortunately the number of places does not. To encourage and assist deserving British students to attend courses and hospitals abroad the B.M.S.A. established three years ago a travel fund. This year the administrators of the fund awarded nineteen scholarships of the total value of £150. It is hoped to improve on this figure in future years.

As its honorary president this year the B.M.S.A. has Professor J. Henry Biggart, professor of pathology in the Queen's University of Belfast. The address of the association is B.M.A. House, Tavistock Square, London, W.C.1.

ADVISORY BUREAUX

Medical Practices Advisory Bureau

About eight years ago the Association established the Medical Practices Advisory Bureau under the direction of a medical member of the secretariat.

The Bureau has two functions: it acts as an agency and source of information concerning openings in various fields of medical practice, introducing partners, assistants, and locumtenents. In addition, it is prepared to advise on individual problems associated with the entry into and the day-to-day conduct of practice. For example, the drawing-up of a partnership agreement is a matter for a lawyer, but there are many problems connected with contracts between doctors on which advice is needed from the medical rather than the legal angle. This advice is offered by the Bureau, and, as it is a department of the B.M.A., its services are free of charge to members of the Association. Non-members may be required to pay nominal charges for the agency service.

Inquiries should be addressed to the Medical Director either at the head office of the Association in London or at the branch offices: 33, Cross Street, Manchester; 7, Drumsheugh Gardens, Edinburgh, 3; or 234, St. Vincent Street, Glasgow, C.2.

Commonwealth Medical Advisory Bureau and the International Medical Visitors Bureau

The Council of the Association has set up at Headquarters, Tavistock Square, two organizations, one for welcoming and providing a personal advisory service for practitioners visiting this country from the Dominions and Colonies, and the other for performing a similar function for practitioners from countries outside the Commonwealth.

The Commonwealth Medical Advisory Bureau invites all medical visitors from Commonwealth countries to get in touch with it, if possible before arrival in this country, and to call at the Bureau as soon as possible after arrival and talk over with the medical director (Brigadier H. A. Sandiford) any points on which they may need advice or assistance. Last year nearly 1,300 inquirers made use of the Bureau and over 2,300 old and new visitors called there. A pleasing feature is the increasing number of inquirers year by year who get in touch with the Bureau before leaving their own countries and are thus enabled to make most satisfactory arrangements for their arrival. Personal contact is maintained with medical schools, postgraduate institutions, hospitals, and other bodies able to assist overseas visitors in the educational field. A register of suitable hotels and lodgings is maintained by the Bureau, and general information is afforded concerning travel, customs duties, facilities for sport, exhibitions, and the like.

The other organization is the International Medical Visitors Bureau, also located at B.M.A. House, under the directorship of Brigadier Sandiford. Here again information is obtainable on postgraduate education, visits to hospitals and clinics are arranged, and assistance is given to visitors in finding accommodation and in other respects. The Bureau also arranges "Holiday Exchanges" between the families of U.K. members and their Continental colleagues; last year nearly 200 exchanges were arranged.

Medical Insurance Agency

The Medical Insurance Agency (B.M.A. House, Tavistock Square, London, W.C.1.) is a recognized agent of all the leading insurance offices, and is thus able to obtain for members of the medical profession the best terms available in the insurance market. The agency, which this year celebrates its golden jubilee, is conducted on a non-profit basis, distributing all its surplus to medical charities. Total donations so far made by the agency to medical charities is £300,000. Special loan facilities are available for the purchase of houses, motor-cars, and equipment. Information can be obtained from the chief office of the agency or from its branches in Birmingham, Bristol, Cardiff, Dublin, Edinburgh, Glasgow, Leeds, Manchester, and Newcastle.

DEFENCE SOCIETIES

The *Medical Defence Union* (Tavistock House South, Tavistock Square, London, W.C.1.) has a membership in excess of 43,900. The Union accepts medical and dental practitioners as members, whether practising in the United Kingdom or in certain countries overseas. A particular appeal for early membership is addressed to the provisionally registered practitioners when they commence their hospital duties. Special arrangements exist with regard to the protection of temporarily registered medical practitioners who visit the United Kingdom to obtain further experience or a higher qualification.

All members elected since October, 1953, pay their second and subsequent subscriptions on the anniversary date of their application for membership; members previously elected pay their subscriptions on January 1 in each year. The Union provides advice and full financial indemnity for any member concerned with, or involved in, medical litigation raising a question of professional principle or an allegation of professional negligence. The subscription is

£1 for the first four years and £2 thereafter, with special rates for overseas practitioners. Since its foundation the Union has spent over £500,000 in the payment of damages and costs incurred in protecting its members.

The *Medical Protection Society* (Victory House, Leicester Square, London, W.C.2) has a membership of over 33,000. Membership is open to registered medical and dental practitioners, including those provisionally registered. Members are afforded advice and assistance in all matters of professional difficulty, with unlimited indemnity against legal expenses incurred in defending and conducting cases on their behalf, also against costs and damages in those cases in which adverse verdicts result. Legal expenses and amounts paid by way of adverse costs and damages greatly increased during the past year. Indemnity is secured by financial resources of £220,000 and reinsurance with Lloyd's underwriters. There are special provisions for members practising overseas: practitioners throughout the Commonwealth are joining the Society in increasing numbers.

The *Medical and Dental Defence Union of Scotland* (105, St. Vincent Street, Glasgow, C.2) has a membership of over 8,000. As with all other defence unions, there has been a considerable increase in the number of claims, although it has been possible in some of these to make a successful defence. The policy of the council has always been to give careful consideration to the interests of its members who have claims made against them for negligence, and to advise when requested regarding any business, legal, and professional matters arising from their practice.

NURSING AND MEDICAL AUXILIARIES

NURSING ORGANIZATIONS

The General Nursing Council for England and Wales is a statutory body established by Act of Parliament, while the Royal College of Nursing is a voluntary association of trained nurses. The differences between the respective constitutions and functions of these two bodies are not always appreciated even by doctors, all of whom at some time or another work with State-registered nurses, with nurses on special parts of the *Register of Nurses*, or with State-enrolled assistant nurses.

The following account of the General Nursing Council and of the Royal College of Nursing may be specially useful to those many physicians and surgeons who are closely connected with schools of nursing as members of management and education committees or of area nurse-training committees, or as lecturers or examiners for hospital or State examinations.

General Nursing Council for England and Wales

England was not the first country to introduce State registration, but with the passing of the Nurses' Registration Act of 1919 the General Nursing Council for England and Wales was constituted, its responsibilities being to set up and maintain a *Register of Nurses* and to lay down conditions of admission to such a register, including the conduct of examinations.

Similarly, in 1943, by Act of Parliament the Roll of Assistant Nurses was required to be formed and maintained by the General Nursing Council.

In both cases arrangements were made for existing nurses to apply for admission to the *Register* or to the Roll. If admitted they were designated State-registered nurses (S.R.N.) or R.S.C.N., R.F.N., R.M.N., R.N.M.D., according to the special parts of the *Register*, or State-enrolled assistant nurses (S.E.A.N.). After an appointed date admission was by examination for the State-registered nurse or by assessment for the State-enrolled assistant nurse.

Thus hospitals where nurses were in training were inspected and minimum standards formulated; syllabuses of

subjects for training and examinations were published. Boards of examiners were formed to prepare examination papers, and a panel of examiners was set up to carry out examinations and assessments throughout the country. Routine inspections of training schools are carried out by the Council's inspectors, and the education officer and inspectors are often able to help and advise the hospital authorities in implementing the Council's requirements in connexion with nurse training.

The length of training for a State-registered nurse is three years and there are two examinations, the preliminary, which may be taken after 12 months, and the final, taken after three years of practical and theoretical work. The pupil assistant nurse is eligible for assessment after 12 months but she must complete a total period of two years in an approved training school under supervision of State-registered nurses before enrolment. The course is mainly practical and is more limited than that for the general part of the *Register*. The assistant nurse has, however, had some experience in acute as well as chronic work and some experience in the care of children. In June of this year the number of training schools for the *Register* was 955 and for the Roll of Assistant Nurses 463. This shows a steady increase in the number of schools for assistant nurses in the country.

A new syllabus, at present experimental, is being used in some mental hospitals and certain experimental schemes of combined training have been approved by the General Nursing Council—namely, general and sick children; general and mental; general and health visiting.

Another responsibility of the Council is to examine the qualifications of nurses trained in other countries who wish to register here. Some may already be eligible for registration, others may be required to undergo further experience and possibly pass the Council's examinations before registration.

Of the members of Council some are elected and others appointed. According to the requirements of the Act elections take place every five years. Fourteen general trained nurses, one from each of the 14 regions of the country, are elected by nurses on the general part of the *Register* and on the part for fever nurses, two are elected by registered mental nurses, and one by registered sick children's nurses. Twelve members, six of whom must be registered nurses, are appointed by the Minister of Health, three by the Minister of Education, and two by the Privy Council. There are two statutory committees of the Council—the Mental Nurses and the Assistant Nurses Committees. Other committees are concerned with finance, registration, education and examination, and disciplinary and penal matters.

Since 1949 the Council has been concerned with the finances of nurse training, which are now separate from the finances of hospital administration. By Act of Parliament 14 area nurse-training committees were constituted, corresponding to the 14 regions, to act as advisory committees on nurse training in their particular areas. The General Nursing Council appoints five members to each area training committee. Estimates from the boards of governors and hospital management committees are submitted to area nurse-training committees. Grants are then made by the Ministry of Health to the General Nursing Council for distribution to the nurse-training committees according to the approved estimates.

Royal College of Nursing

The Royal College of Nursing was founded in 1916 by leaders of the nursing profession as an association to unite all trained nurses; to provide a uniform standard of training; to promote State registration; to improve the quality of the nursing service and the conditions under which nurses work; and to further in every possible way the advancement of the profession through post-certificate study, scholarships, and specialized training. Originally incorporated under the Companies Act, the College was in 1928 granted a Royal Charter and in 1940 the title "Royal" in recognition of its work. In 1945 the College achieved a Grant of Arms. The main provisions of the Royal Charter are to promote the

science and art of nursing, to advance nursing as a profession in all or any of its branches, and to assist nurses in adversity.

The College is administered by a Council of 36 nominated and elected by the members. The work of the College is carried out under the direction of the general secretary and the director in the Education Department supported by a specialist staff of nurse officers and experts in other fields. The interests of the members in Scotland and Northern Ireland are looked after by a Scottish Board with headquarters in Edinburgh and a Committee for Northern Ireland with headquarters in Belfast. The members are organized locally in 182 branches. Liaison between the Council and the membership is effected through the Branches Standing Committee. Area organizers advise and help branch secretaries and individual members in the areas.

The activities of the College, based on the terms of its Royal Charter, are carried out through two main divisions—the Professional Association Department and the Education Department.

The *Professional Association Department*, under the direction of the Council, plays a vital part in the shaping of national nursing policy by means of representation to Parliament in connexion with public measures affecting the profession and to Government departments on matters concerning the National Health Service, and by the appointment of representatives to serve on national and local committees. The College participates in international nursing affairs as a member body of the National Council of Nurses which is affiliated to the International Council of Nurses. The College strongly advocates nurse participation in all matters affecting the health and welfare of the community. This department also deals with a wide variety of professional problems and gives help and advice to individual members on professional matters. Within the College there are a number of sections which provide for special interests—namely, the sister tutor section, private nurses section, public health section, ward and departmental sisters section, and occupational health section.

The better selection of student nurses is one of the main objectives for which the College is at present working. This has not so far met with general approval, great pressure being sometimes exerted by the various authorities on matrons to sacrifice quality for quantity in the admission of students to the school of nursing. The result of this is only too often a high wastage rate and a poor standard of State-registered nurse who frequently is not able to meet the responsibility that State registration demands. The College further advocates a reduction in the number of training schools for the State *Register* and a corresponding increase in the number of training schools for assistant nurses, together with full recognition of student status. This, regrettably, is often opposed by the various authorities, since it is felt that status and prestige are diminished if the school prepares pupils for the Roll rather than students for the *Register*.

In view of the present need for planned economy in the nursing service, the College also recommends the adoption of the nursing team for the care of the patient, led by a State-registered nurse with the State-enrolled assistant nurse and nursing auxiliaries to assist her. The importance of the assistant nurse as the basic element in the nursing service has long been recognized by the College. Leadership by the State-registered nurse is essential if the growing demands on the National Health Service and the rapid advances in preventive and curative medicine are to be met.

The Royal College of Nursing, which is the largest and most representative professional organization for nurses, takes a leading part in obtaining good and equitable conditions for the profession. It takes a full part in negotiation on the Nurses and Midwives Whitley Council, having the largest number of seats on the Staff Side. The College supports the furtherance of joint negotiation and consultation and representation of the professional point of view to management wherever nurses are employed. It recommends a comprehensive salary policy based on the consideration of qualification, function, and responsibility, with satisfactory superannuation, for all nurses.

The Education Department.—The Royal College of Nursing is recognized by the Ministry of Education as a major establishment for further education. One of its purposes, as defined in the Charter, is to promote the science and art of nursing and the better education and training of nurses and their efficiency in the profession of nursing. The main function of the Education Department—to prepare State-registered nurses as administrators and teachers—is carried out through the provisions of post-certificate courses which enable nurses to qualify for service in special fields of nursing. These include a two-year course in preparation for the Sister Tutor Diploma of the University of London and a course for the Health Visitor Certificate of the Royal Society of Health. Courses for nurse administrators (hospital and public health), ward and departmental sisters, and occupational health nurses are offered in preparation for certificates awarded by the College. Refresher courses and study conferences are frequently arranged. The Scottish Board and the Committee for Northern Ireland organize comparable courses. The Birmingham Centre of Nursing Education extends the work of the Education Department.

An interesting development with which the College co-operated is the establishment of a Nursing Studies Unit within the University of Edinburgh.

The College recognizes the need for research into the many problems confronting the nursing profession and has resolved to establish an authoritative research body to examine these and to sponsor opportunities for research and to test the application of its findings.

The Library of Nursing is unique in that it is the only comprehensive library of professional nursing literature in the country. It is affiliated to the National Central Library and is much used for research.

The College has published many reports and documents on specialized subjects*; its official journal is the *Nursing Times*, and the *Journal for Industrial Nurses* is published in association with the occupational health section of the College.

It is hoped that this brief outline of the origin and function of the two organizations will help to emphasize their respective responsibilities.

MEDICAL AUXILIARIES

The *Board of Registration of Medical Auxiliaries* (B.M.A. House, Tavistock Square, London, W.C.1) exists to maintain and publish a register of properly qualified medical auxiliaries. The Board helps the medical auxiliary professions to attain or to consolidate and improve their professional status, and insists that each such profession shall, before registration, establish at least the basic principles for training and practice. In return it offers the registered persons protection in that they and they only are recommended to doctors as qualified to practise their particular specialty.

Separate or section registers of members of each branch of medical auxiliary work are printed, and are supplied free to medical officers of health, hospital management committees, hospitals, public libraries, medical practitioners, and others, the circulation lists varying according to the particular group of auxiliaries.

The register is composed of the following sections: audiology technicians, chiropodists, dispensing opticians, operating theatre technicians, orthoptists, radiographers, and venereal disease technicians. Copies of any or all of the current sections will be sent free to medical practitioners on application to the registrar.

The *Chartered Society of Physiotherapy* (Tavistock House South, Tavistock Square, London, W.C.1) approves 34 schools, connected with hospitals in London and the Provinces. These schools prepare students for the Society's examinations, which are recognized by the Ministry of Health under the National Health Service (Medical Auxiliaries) Regulations, 1954. Successful candidates may practise as Chartered Physiotherapists.

Correspondence

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

Hypopituitarism and Diabetes

SIR,—Drs. A. Grunberg and J. L. Blair, in their interesting paper (*Journal*, August 24, p. 439), point out how rare it is for diabetes mellitus to develop in patients suffering from a pre-existing hypopituitarism, and their paper reveals how much more complex therapy becomes when these two conditions coexist.

I previously reported such a case at the annual meeting of the Diabetic Association some five years ago, and the case history of this patient up to that time is detailed elsewhere.¹ Briefly, this patient, a married woman, was perfectly fit and well until the birth of her second child in 1943 at the age of 36. A classical caesarean section was performed as an emergency for excessive haemorrhage and labour from a central placenta praevia. Transfusion and resuscitation were necessary before operation could be performed. From this time forwards she was a classical case of Sheehan's syndrome (Simmonds's disease). Not until two years later, in 1945, did she develop symptoms of diabetes mellitus. At first stabilized on 15 units of soluble insulin twice daily, she later suffered from recurrent hypoglycaemic episodes, very sudden in onset and rapidly responding to glucose given orally or intravenously. In the face of any major stress, particularly infection, she would pass into spontaneous hypoglycaemic coma, even if no insulin had been received. On one such occasion, following a respiratory infection, having been returned to full consciousness by oral glucose, 4 units of soluble insulin resulted in full hypoglycaemic coma, for which intravenous glucose had to be given. She was subsequently given 4 units of insulin twice daily, and corticotrophin 10 mg. 6-hourly intramuscularly was started. Ten injections resulted in diabetic coma; her urine was heavily loaded with sugar and acetone; her blood sugar was over 600 mg.%. In the next 48 hours 280 units of soluble insulin was required to restore her balance. Subsequent dosage of insulin varied from none to 8 units, given on a sliding scale, with cortisone 12.5 mg. daily. At this time, 1951, her mental state necessitated her transfer to another hospital.

This case illustrates the extraordinary lability and the precarious balance of such patients so well shown in the case of Drs. Grunberg and Blair. It might be argued that the diabetic condition was itself a freak result of her ischaemic pituitary necrosis, but two years passed before the diabetic condition supervened.—I am, etc.,

London, S.W.1.

Autonomic Nervous System and Lung Disease

SIR,—Dr. Raymond Daley in the second of his Goulstonian Lectures (*Journal*, August 3, p. 249) reports the effects of single injections of certain drugs on the pulmonary arterial pressure of dogs. Adrenaline caused a rise in pressure with tachycardia. Noradrenaline caused a rise in pressure with bradycardia. 2 mg. of acetylcholine caused a fall in pressure with asystole. He makes the following comment: "These facts are interpreted as meaning that none of these drugs have any effect on the normal pulmonary circulation and that the effect is purely secondary and dependent upon their entry at least into the aortic root."

While I would agree that the results he describes in best be ascribed to factors other than an alteration in pulmonary vasomotor tone, I think that his experiments are so inadequately designed that he has no grounds to make any comment whatever on the state or response of the pulmonary vessels. Dr. Daley is aware that in this section

SEPT. 7, 1957

CORRESPONDENCE

Routine Ergometrine

SIR,—Mr. Terence Robinson (*Journal*, August 17, p. 408) refers once more to the routine use of ergometrine with the birth of the baby. We think that he misinterprets the idea in your leading article (*Journal*, August 3, p. 280) when he suggests that the implication is that its use should be enforced.

He states that it may be dangerous to mother and foetus if used by attendants who are not skilled, a far more misleading remark than that in your leading article. So far as the foetus is concerned, the only risk is that of giving ergometrine in a case of undiagnosed twins. That this danger has been exaggerated has been shown by Kurtz *et al.*,¹ who gave it in 64 such cases without ill effect. The only snag so far as the mother is concerned is a possible increased rate of manual removal of the placenta. In this connexion we agree with Mr. A. L. Deacon (*Journal*, August 24, p. 468) that many such operations can be avoided by traction on the cord, which is a perfectly safe manoeuvre if the placenta has separated. Against these can be put the real and undisputed advantages of a marked decrease in blood loss and a shortened third stage.

The important and, as yet, unanswered question is whether the routine use of ergometrine with the delivery of the baby reduces maternal mortality. It would be very interesting to know whether the authors of the *Report on Confidential Inquiries into Maternal Deaths*² can shed any light on this point.—We are, etc.,

J. G. DUMOULIN.

Acute Inversion of Uterus

SIR,—The case report by Drs. Bain and Ziolkowska under the above heading (*Journal*, May 11, p. 1102) is worthy of comment and criticism. The patient was a healthy young woman on her second pregnancy and was thrown into gross shock after the loss of only three pints (1.7 l.) of blood in the third stage of labour, which was "replaced" by a pint (0.6 l.) of dextran, two pints (1.1 l.) of blood after replacement of the inverted uterus (when her condition as a result of the manoeuvre was already dramatically improved and she was no longer in shock), and with an unstated amount of blood run in rapidly before the reduction.

I would refer the authors to the correspondence in the *Journal* of 1945 on this subject stimulated by a report by Dr. O'Sullivan¹ of a successful, though unexpected, reduction by hydrostatic pressure while washing the patient up with the old-fashioned vaginal douche routine, and especially the letter which closed the correspondence, by the late Dr. Gibbon FitzGibbon,² which completely sums up the rational approach to this problem.

The essential in the treatment of inversion of the uterus is to remove as early as possible the cause of the shock, which, in the complete case, is due to pressure of the uterine musculature upon the ovaries contained in the "inversion funnel." If replacement is attempted as soon as the condition occurs, then the cervix is still lax (as it is in early manual removal of the placenta even after the administration of oxytocic drugs) and the uterus turns right side out with surprising ease, as indeed the authors found in their case. Once the pressure on the ovaries is released the patient rapidly recovers from her state of shock, provided the process has not been too prolonged and there is no indication for replacement therapy, as shown in this case.

Where the inversion is incomplete the ovaries have not yet been trapped in the uterine pouch and shock does not occur, while with the passage of a few hours the cervix has closed down and thereafter halts the process, so that the inversion does not become complete. This was very

of the circulation the effects of intrinsic vaso-activity are very likely to be obscured by other haemodynamic phenomena. Yet he seems unaware that it is therefore a necessary requirement of any experiment, designed to inquire into the presence or absence of vaso-activity in the lungs, that all these other factors should so far as possible be controlled. He may also be unaware that investigations which largely meet this requirement have been carried out in man by Witham and Fleming¹ using adrenaline and Fowler *et al.*² using noradrenaline.

Dr. Daley does refer to studies on the influence of acetylcholine for which I was partly responsible.³ In these studies a continuous infusion of 0.5 mg. acetylcholine/min. into the main pulmonary artery of man caused a slight fall in pulmonary arterial pressure when the subject breathed ambient air. The fall in pressure was associated with a constant cardiac output, wedge pressure, heart rate, brachial arterial pressure, arterial saturation, and ventilation. The recordings of pressure were taken at 2 and 4 minutes after the start of the infusion and the cardiac output measured at 5 minutes. During this time the infusion was maintained. I would be interested to know how he would explain such results if he does not think that acetylcholine has caused a pulmonary vasodilatation. Dr. Daley also tries the effect of acetylcholine in dogs after pulmonary hypertension has been caused by the injection of lycopodium spores. This is with the purpose of seeing whether the injection of spores has caused any pulmonary vasoconstriction relivable by a vasodilating agent. As in his previous experiment, the occurrence of cardiac arrest renders naïve any attempt to interpret the effect of the drug on the pulmonary vessels.

In the studies referred to above,³ pulmonary arterial hypertension was produced by hypoxia, under which condition Dr. Daley agrees there is substantial evidence that pulmonary vasoconstriction occurs. The effect of an infusion of acetylcholine in lowering the pulmonary arterial pressure was then found to be increased. Under these circumstances the cardiac output was slightly increased during the infusion, while the central blood volume, wedge pressure, brachial arterial pressure, heart rate, and arterial saturation remained substantially unaltered. Dr. Daley finds this "a most difficult experiment to understand." Yet the idea of measuring the effect of acetylcholine under conditions of pulmonary hypertension is common to both his and our experiments. Unfortunately the results do not seem to fit his present theories.—I am, etc.,

Birmingham, 15.

Insufficiency of Internal Cervical Os

SIR,—The views of Hughesdon,¹ of Shaw,² and others, differing from those of Aschoff,³ and more recently of Danforth,⁴ serve to keep alive a stimulating controversy on the role of the cervix. Harvey bade us search out the secrets of nature by experiment; William Hunter told us to try rather than to think. The point we have laboured to make (*Journal*, July 20, p. 128) is that there is a hard core of abortion patients in whom certain clinical facts can be demonstrated, and for whom the management we suggest holds out a good chance of success. We ask others to confirm (or disprove) our findings. Up to date these are our results.

Is it only coincidence or good fortune?—We are, etc.,

London, S.W.3.

nicely illustrated by a case of Dr. Ninian Falkiner's (unpublished) which was seen in the Royal City of Dublin Hospital in 1938. The patient was admitted six days post-partum with the fundus inverted and appearing at the vulva; the cervix was in its usual position and firmly applied to the lower uterine segment. The patient had never been shocked and was in very good condition, the abnormality having been discovered accidentally. In this case the decision was to reduce by traction from above, and operation was delayed for ten days, during which the inversion reduced itself with the exception of the left cornu, where it was represented by a dimple in the peritoneum; the abdominal appearance of the uterus and adnexa was completely normal and there were no adhesions.

In their comment the authors state that the only factor which may have contributed to the inversion was traction on the foetal membranes, which was very gentle. I venture to suggest that this merely completed the inversion which had been initiated by the mother's expulsive efforts in expressing the placenta, for I doubt that the requirement of a firm contraction of the uterus, before using it as a piston, would be always fulfilled if the placenta is self-expressed in this manner. The mechanism suggested above is given by DeLee,³ who also mentions traction on the membranes as a cause.

To credit the exhibition of dextran as life-saving would appear far-fetched: if the attendant had replaced the uterus to its proper position as soon as the condition was recognized the recovery from the shocked state would have been just as dramatic, and it could then have been decided whether the patient required the further transfusion to replace the blood lost at the time when the uterus was congested, by interference with the venous return and while the maternal sinuses were still open in the atonic uterus. Whether or no the facilities of a well-equipped hospital are to hand at the hour of 3 a.m., it is well to remember that the first treatment of shock is to remove the cause where it is known, as it is in these cases, and to stop the bleeding in post-partum haemorrhage by simple measures while someone else worries about replacement therapy.

The prophylaxis of these cases lies in the careful conduct of the third stage of labour and knowledge of the mechanics of separation and expression of the placenta with restraint from interfering, either manually or by voluntary increased intra-abdominal pressure, with the uterus unless it is in a state of contraction.—I am, etc.,

Listerial Meningitis

SIR.—With reference to the article by my colleagues and myself (*Journal*, July 27, p. 188) and to the letter by Drs. C. S. Shaw and D. C. Turk (*Journal*, August 10, p. 351), may I add the following information?

I have tested a culture sent to me by Dr. Turk isolated from the case of "diphtheroid" meningitis reported in 1954¹ and can confirm his later conclusion that the organism is in fact *Listeria monocytogenes*. It gave a positive Anton's test (rabbit conjunctival test), was (poorly) motile, grew in 6.5% NaCl broth, grew in the refrigerator in one week, showed the usual Listerial morphology, and the sugar reactions conformed with the results already obtained by Turk, these being compatible with the diagnosis of *Listeria monocytogenes*. Furthermore, H and O antigens reacted to titre with factor-specific sera, giving the result type 1. The only discrepancy found was its failure to produce lesions in either of two guinea-pigs injected intraperitoneally with cultures of the organism. This could be due to the prolonged cultivation since isolation of the strain.

To modify our statement that no type 2 strain had been isolated from animals, may I add that information has since reached me from Dr. J. Donker-Voet, of Utrecht, that

she has isolated two such strains from chickens in the Netherlands? Dr. Donker-Voet has sent me these strains as well as a further strain C1878, isolated from a child dying of meningitis at Rotterdam, aged four months. All these were confirmed here as type 2.—I am, etc.,

Edinburgh.

Diet in Idiopathic Steatorrhoea

SIR.—Your readers may be interested in some further information on the patient (Case 1) to whom Dr. Alexander Brown referred in his recent paper (*Journal*, August 10, p. 337). She came under our care in 1956. For the previous eighteen months she had been eating an ordinary diet and her health had deteriorated. When first seen by us she was tired, unwell, and unable to work. She had had a series of painful ulcers in her mouth and had lost some 4 kg. in body weight during the previous year.

Investigation showed that she had steatorrhoea—mean value for daily faecal fat 8.1 g. (range 4.06–11.23). The stools were usually pale and semi-formed. The glucose absorption curve was flat (maximum increment 16 mg./100 ml.), xylose absorption depressed (8% excretion in 5 hours), although the chylomicrograph was relatively normal. Radiographic study of the small intestine showed a flocculation pattern and some dilatation. Examination of the blood revealed a moderately severe macrocytic anaemia (Hb 9.6 g.%; R.B.C. 2.55 million/c.mm.; W.B.C., 3,500 c.mm., with slight relative lymphocytosis; P.C.V. 29%; M.C.H.C. 33%; M.C.V. 113 cu. μ). These findings, together with Dr. Brown's previous studies, strongly indicated that she was suffering from gluten-induced enteropathy. This was confirmed by the results obtained with a gluten-free régime and also by a positive test on the effect of gluten.

On the gluten-free régime, with no other treatment, she rapidly improved. Reassessment six months later showed that she had regained her normal body weight, steatorrhoea was no longer present—faecal fat: mean 4.9 g. per day (range 4.19–5.96); the stools were normal in colour and consistency. Xylose absorption was normal (27.9% and 29.5% excreted in 5 hours). Blood examination showed marked improvement (Hb 12.2 g.%; R.B.C. 4.5 million/c.mm.; P.C.V. 40%; M.C.H.C. 30%; M.C.V. 88 cu. μ). There was now slight microcytosis and this was subsequently corrected by oral iron therapy. During this period of reassessment wheat gluten was introduced into her diet as an autoclaved peptide fraction that was known to be deleterious in patients with coeliac disease. The mean faecal fat value for the three three-day means prior to the administration of the gluten fraction was 4.8 g. per day, and for the three days following the introduction of gluten it was 11.2 g. per day.

It may therefore be concluded that this patient fulfils all the necessary criteria for a diagnosis of gluten-induced enteropathy. The condition appears to have been present since it was revealed in childhood, and there is every indication that she can only expect to maintain normal health so long as she adheres to a gluten-free régime.—We are, etc.,

Birmingham.

R. F. FLETCHER.

Examination of Tuberculosis Contacts

SIR.—There seems to exist on the part of a few chest clinics a curious reluctance to examine contacts of patients with pulmonary tuberculosis. Three examples that have recently come my way have served to point to this fact. A young man was found on routine x-ray in the Service to have extensive involvement of one lobe which was almost certainly of long standing; six months previously one of his sisters had developed a pleural effusion, but no attempt was made to x-ray the other members of the family. Another young man was admitted with gross disease involving the whole of one lung and sputum loaded with tubercle bacilli; his family were notified as contacts, but

after they had been visited by a health visitor from the local chest clinic they were told that it was not necessary for them to be x-rayed, as they had only seen their son for the few days that he was at home on leave shortly before coming into this hospital. The third young man has been courting a young lady with pulmonary tuberculosis off and on for four years, and has recently married her. At no time was any attempt made to x-ray his chest or test his tuberculin sensitivity. These are of course isolated examples, but, until the pursuit of contacts becomes much more whole-hearted, too many cases will escape detection.—I am, etc.,

Wroughton, Wilts.

PAUL MESTITZ.

Tuberculosis

SIR.—The remarkable results in the control of tuberculosis during the past forty years have been brought about by surgery, later by medicine (antibiotics), and during the whole time by recognition of the most important part played by immunization. Cow's milk is an important medium through which immunity against tuberculosis is acquired, and it is gratifying to know that most people are "tuberculinized" before adult life.

Great efforts have been made in some counties to establish clear areas where the dairy cattle are free from tuberculosis, and these have been successful in many cases; in other cases great difficulty is being experienced in acquiring and maintaining a T.T. herd. The difficulty seems to have been accentuated since myxomatosis brought about the disappearance of the rabbit, with the consequent upset of the balance of nature. As a result stoats have directed their attention for food to weasels—the lifelong enemy of voles. To those who believe that the vole plays a great part in the spreading of tuberculosis in cattle by contaminating the pasture, here is a ready explanation. In any case, since the milk supply has been raised to a high standard of purity, the numbers of young persons requiring B.C.G. immunizations is on the increase. It must be remembered that quite a large portion of the milk supply is pooled and pasteurized. Williams¹ observed that in the Isle of Lewis, where tuberculosis among cattle was extremely rare, tuberculosis of lymph glands was almost unknown, whereas tuberculosis of the lungs and of bones and joints was very prevalent. Perhaps more recent observations and research have disproved or modified this finding.

Those who are not immunized either by natural means or B.C.G. may be in real peril from the influx into our midst of large contingents from the West Indies and Hungary and other countries where the scourge of tuberculosis has not been so adequately tackled. The choice in the near future lies between natural immunity or active immunization with B.C.G. (the latter will have to be maintained, as it is too early to determine that a single B.C.G. injection will confer immunity for life). This must be decided upon by the Ministry of Health and the Ministry of Agriculture and Fisheries conjointly. An overall strategy is urgently required to decide on the line of action to be taken.—I am, etc.,

Sensitization to Tulle Gras Dressing

SIR.—The memorandum by Dr. C. M. Ridley from the London Hospital (*Journal*, May 25, p. 1224) described two cases of sensitization reactions to tulle gras dressing B.P.C. Both his patients were women with hypostatic eczema of the legs, and sensitization was caused by the constituent balsam of Peru. I have recently encountered a similar case in general practice. The patient was a man with an indolent ulcer of the leg over the mid shaft of the tibia, at the site of an injury sustained two years previously. He gave no history of allergy, and in the past had had tulle gras dressings without ill effect. The ulcer was treated with applications of eusol and tulle gras dressings with compression bandaging.

After six weeks, when the ulcer was healing well, the patient suddenly developed angioneurotic oedema of the face and neck, urticaria of the chest and arms, and eczematization of the skin around the leg ulcer. The whole attack rapidly subsided on antihistamine therapy and cessation of the tulle gras dressings. Subsequent patch tests with tulle gras and with 1% balsam of Peru were both strongly positive, while the yellow soft paraffin control patch was negative.

The cardinal maxim in treatment of skin disorders is *primum non nocere*, and the bland nature of tulle gras is its chief virtue. From my experience I would support Dr. Ridley's plea that the potentially noxious balsam of Peru be removed from the formula of tulle gras dressing B.P.C.—I am, etc.,

Heartburn of Pregnancy

SIR.—I was most interested in the letter from Dr. Frank McLoughlin (*Journal*, August 10, p. 356). I agree with Dr. McLoughlin that the standard methods of treatment for heartburn during pregnancy meet with little or no improvement, and we must look for a precipitating factor brought about by the pregnancy itself, be it hormonal or mechanical. My own impression is that it is often a mechanical cause, due to the presence of a hiatus hernia. More than 50% of my patients with this complaint develop it in the second half of pregnancy, find that it is aggravated by lying down, and get considerable relief by raising the head of the bed on blocks 6–9 in. (15.2–22.8 cm.). Owing to the difference in pressure between the abdominal cavity and the thorax it is clear that pregnancy itself may cause a temporary herniation of the stomach through the oesophageal hiatus and is the cause of the heartburn. Unfortunately I can offer no radiological proof of this.—I am, etc.,

Leven, Fife.

A. WILSON ROBERTSON.

X-rays and Bronchial Carcinoma

SIR.—Your correspondent Dr. J. F. Burdon (*Journal*, June 1, p. 1305) states that "X-rays are known to encourage neoplastic developments. Therefore there should be a connexion between the incidence of bronchial carcinoma and radiography of the chest." In the mass x-ray survey for tuberculosis in the Sydney metropolitan area 891,560 x-rays were taken. Among these 90 proved bronchogenic carcinomas were found. It is interesting in view of Dr. Burdon's comment that 41 of these 90 cases had never had a previous chest x-ray.

However, an interesting feature requiring further elucidation is the relatively high percentage of patients found in our mass surveys who were born in the United Kingdom. Of the 90 proved carcinomas, 61 were born in Australia, 23 in the United Kingdom, and only 6 were from other countries. The proportion of United-Kingdom-born residents in this area is approximately 10%.—I am, etc.,

Sydney, Australia.

C. RUBINSTEIN.

Foreign Body in Stensen's Duct

SIR.—An infant developed acute parotitis, which proved penicillin-resistant; suppuration followed, and on incising the abscess M. G. Pascoe¹ saw and withdrew a large (hen) feather from the interior of the abscess cavity.

At the height of secretion, intraglandular pressure of saliva rises to above that of the blood pressure, and the gland increases in size. When the stimulus is removed the gland collapses, possibly with reflux along Stensen's duct. Intraglandular negative pressure following sudden removal of salivary stimulus appears to me to be the most likely explanation of the occasional entry of a foreign body into the duct.—I am, etc.,

Sholden, Kent.

Stove-in Chest Injury

SIR,—Mr. L. Henry (*Journal*, August 10, p. 339) treats a stove-in chest by plating the sternum. Mr. J. A. Rhind (*Journal*, August 24, p. 470) accuses him of tempting providence and advises tracheotomy in all cases. It is gratifying to note the interest in the treatment of this hitherto neglected injury, but it is to be hoped that rival schools of "stabilizers" and "tracheotomists" will not arise. Clearly there is a place for both approaches to the treatment of this grave disorder. The two lines of treatment are complementary; stabilization provides specific treatment and tracheotomy symptomatic treatment.

If the instability of the chest wall is diagnosed early, then stabilization of the flapping segment will save the patient from wet lung and the necessity for tracheotomy. It must be emphasized, however, that the method of stabilization should be simple. Rigid fixation is unnecessary. Fixing the sternal fracture with a plate is unnecessarily complicated, because adequate stabilization can be obtained by

screw traction. I have designed a guarded sternal screw (manufactured by Zimmer Orthopaedic Ltd., Bridgend) which can be inserted blindly under local anaesthesia. Wiring of multiple rib fractures by open operation is also unnecessary. A few strong nylon sutures inserted blindly around the ribs at the centre of the flapping segment will provide effective stabilization (see Fig.). The sternal screw or rib sutures should be attached to a weight passing over a pulley rather than springs, because this enables the patient to move freely without altering the degree of traction.

Where the patient has already a wet lung, or where stabilization is not possible, then tracheotomy is a life-saving procedure. But it is surely irrational to apply this as a first line of treatment. Tracheotomy with repeated suction is not without its discomforts and dangers, as emphasized recently by F. Plumb and M. F. Dunning.¹ A reasonable approach to the stove-in chest can be summarized by advising stabilization if possible and tracheotomy if necessary.—I am, etc.,

Bridgend, Glam.

A. W. FOWLER.

REFERENCE

- ¹ Plumb, F., and Dunning, M. F., *New Engl. J. Med.*, 1956, 254, 193.

SIR,—In his criticism of the effective operation performed by Mr. L. Henry (*Journal*, August 10, p. 339), Mr. J. A. Rhind (*Journal*, August 24, p. 470) asserts that the performance of a tracheotomy is the only measure needed in the management of these injuries. I, too, have had occasion to note the effectiveness of tracheotomy as an adjunct to treatment in stove-in chest. But it is most important that treat-

ment should primarily be directed towards the restoration of normal cardio-respiratory function. The elimination of paradox, which Mr. Henry achieved, is of prime importance; in his case it rendered tracheotomy unnecessary.

When I read the article by Dr. Hulman¹ to which Mr. Rhind refers, I was surprised to note that the presence of a large haemo-pneumothorax was not considered of sufficient moment to warrant its immediate and active removal. It is only by effective correction of all of the factors which combine to produce anoxia resulting from a stove-in chest that the distressingly high mortality will be reduced.—I am, etc.,

London, E.2.

Centipede Bites

SIR,—Occasionally mention is made about centipede bites (*Journal*, December 31, 1955, p. 1619; April 28, 1956, p. 986). However, the occurrence of bites by the giant tropical centipedes is widespread, and many a practitioner in hot countries is well aware of the painful bites and after-effects inflicted by these vicious arthropods. All authors confirm unanimously the immediate and excruciating pain at the site of the bite and the subsequent infection and lymphangitis. Even paralysis and contractures of the extremities and heart irregularities are described. After two or three days the symptoms generally subside.

As far as I could trace in the literature on the subject, a recurrence of symptoms has never been mentioned. Only from the far east came a legend of recurrent oedema at the site of the bite when the moon was full.¹ In a series of twelve cases of centipede bites in Dutch New Guinea, however, I noted recurrence of pain and swelling in seven separate cases.² After a week's interval the local inflammation returned for a short period of one to three days. In one case there was a swelling of the interdigital joints of the bitten finger. Similar after-effects due to animal bites were observed in the case of a spider bite³ and probably also after rat bites. The local symptoms of rat-bite fever caused by *Spirillum minus* infections are supposed to be a cyclic allergic reaction of the skin to the bacterial antigen. In my opinion the recurrence of the symptoms after centipede bites is also due to an allergic reaction of the superficial layers of the skin, for it seems probable that the centipede does not inject only venom with its poison-fangs but also bacteria. If this hypothesis of a combination of immediate tissue destruction by venom and a later sensitization by inoculated bacteria should be correct, the cortisone treatment as advocated by Ariff (*Journal*, July 16, 1955, p. 204; April 28, 1956, p. 986) seems to be the most excellent therapy. Other readers may be able to confirm my observations regarding the rather frequent recurrence of symptoms after centipede bites.—I am, etc.,

G. T. HANEVELD.

Corrections.—The name of Professor W. W. Mushin was omitted from the list of members of the Medical Research Council's Committee on Non-explosive Anaesthetic Agents given in our issue of August 31 (p. 479). One of the co-authors of the report on "Some Pharmacological Actions of Fluothane" was Dr. G. A. Feigen. We regret that his name was wrongly spelt on p. 479.

The figure "400 g. and over" qualifying the column heading "Perinatal Mortality" in the table in Professor F. J. Browne's letter, "Stillbirth Rates in 'Non-White' Women" (*Journal*, August 17, p. 412), should have been placed so that it related only to the third percentage perinatal mortality rate listed in the column, that for "Hospital Z" (2.7%). Professor Browne was using the table, which compared "the results of interference and non-interference in cases of so-called post-maturity," to answer points raised in a letter by Drs. D. N. Menzies and J. S. Scott (*Journal*, July 6, p. 46) which followed an earlier letter by Professor Browne on foetal post-maturity (*Journal*, June 22, p. 1472).

Obituary

CUTHBERT LOCKYER, M.D., F.R.C.P., F.R.C.S.
F.R.C.O.G.

Mr. Cuthbert Lockyer, vice-president and consulting gynaecologist to Charing Cross Hospital, died at his home in Penzance on August 28 after a long illness. He was 90 years of age. For many years he was one of the leading gynaecological surgeons in London.

Cuthbert Henry Jones Lockyer was born at Evercreech, Somerset, on April 13, 1867, and was educated at King's School, Bruton, and at the University of London, receiving his clinical training at Charing Cross Hospital, where he won the Golding Scholarship. He also studied abroad at Bonn and Vienna. Mr. Lockyer qualified M.R.C.S., L.R.C.P. in 1894, and two years later he received the diploma of Fellow of the Royal College of Surgeons of England. In 1897 he took the degree of B.S. of the University of London, and in the following year he proceeded to the M.D. and was elected a Member of the Royal College of Physicians of London, becoming a Fellow in 1914. He was elected F.R.C.O.G. in 1929, being a Foundation Fellow of the College.

After qualification Mr. Lockyer held the posts of house-surgeon and obstetric house-physician, demonstrator of surgery, surgical registrar and tutor at Charing Cross Hospital, and later became honorary gynaecologist to St. Mary's Hospital, Plaistow, and surgeon to in-patients at the Samaritan Hospital for Women. He was for many years obstetric physician to Charing Cross Hospital, and was lecturer in his subject in the Medical School. Other appointments he held were those of gynaecologist to the National Hospital in Queen Square and consulting gynaecologist to the Royal Northern and St. Mary's, Plaistow, Hospitals. A great lover of music, and possessed himself of a fine tenor voice, he gave his services to the Royal College of Music as consulting physician. He was examiner in midwifery and diseases of women for the universities of Cambridge, London, Birmingham, Leeds, and Sheffield and for the Conjoint Board in London. He was a member of the council of the Royal College of Physicians of London in 1929-30 and at one time president of the Section of Obstetrics and Gynaecology of the Royal Society of Medicine, of which he was a vice-president. When the British Medical Association held its Annual Meeting at Toronto in 1906 Mr. Lockyer acted as one of the honorary secretaries of the Section of Obstetrics and Gynaecology, and at the Annual Meeting held at Birmingham in 1911 he served as a vice-president of the same Section.

Mr. Lockyer will long be remembered at Charing Cross Hospital for his collection of obstetric and gynaecological specimens, which he formally presented to the hospital in October, 1930. The collection, housed in the museum of the Medical School, was the result of over 30 years' work and included 2,000 mounted specimens and an equal number of microscopic slides, contained in a special cabinet. He wrote and published at his own expense a detailed catalogue of the exhibits, and provided a sum of money the interest on which is spent on the upkeep and repair of the collection. Mr. Lockyer also presented to the library of the hospital a number of books, including his own famous monograph *Fibroids and Allied Tumours*, published in 1918, many of the illustrations of which he drew himself. He was also the co-author, with Mr. T. Watts Eden, of *Gynaecology, a Textbook for Students and Practitioners*. He was a most able writer, and only four years ago contributed an informative and amusing letter to this *Journal* about the reporting of a case of primary ovarian pregnancy in 1900.

Mr. Lockyer was twice married. By his first wife, who died in 1924, he had two sons and one daughter, who was

killed in an air raid in 1940 while on duty as a physiotherapist at St. Thomas's Hospital. He is survived by his second wife.

We are indebted to Mr. CLIFFORD WHITE for the following appreciation: The Lockyers come from the west of England, and Cuthbert Lockyer's family had been yeomen farmers in Somerset for generations. He was one of the elder children in a large family, and so, when he had taken the London matriculation examination, he did not immediately become a medical student but had to take a salaried post for a few years while some of the younger children were being educated. Most of this time he spent as a schoolmaster, and this hiatus before taking up medicine accounts for his always being a few years older than his colleagues throughout his professional life. As soon as the other children had finished their education he went to Charing Cross, where his brilliant brain had no difficulty in passing examinations. After house appointments his thoughts began to turn towards gynaecology, when Stanley Boyd, who had noticed his extremely active mind, offered to support him if he would apply for the post of surgical registrar. This attracted him financially, and he held the post for a year or two and thus became competent to perform operations outside the scope of the average gynaecologist. His desertion to the general surgeons annoyed the gynaecological staff at Charing Cross, but they forgave him later and he became obstetric registrar—a post he held for many years after he was on the staff of other hospitals. His first staff appointment was to St. Mary's, Plaistow, followed by the Samaritan. At the Royal Northern he was successful against Bonney and worked there with Blacker as his senior for many years.

In 1905 Wertheim read a paper at the Annual Meeting of the B.M.A. at Leicester on the operative treatment of carcinoma of the cervix. He broke his journey in London, and Herbert Spencer asked Wertheim and Lockyer to dinner. Lockyer offered a suitable patient for Wertheim to operate on at St. Mary's, Plaistow. A few days later Spencer, Meredith, Targett, Lockyer, and Wertheim drove there in a carriage and pair. Lockyer wore gloves, Wertheim did not and refused to permit the use of a metal retractor; he seized a house-surgeon who was washing his hands in the theatre to retract the abdominal wall. The operation was successfully completed, but the patient died on the third day. It appeared the house-surgeon had been dressing a very septic case and had not finished washing his hands when Wertheim took his partially washed hands and put them on the abdominal wall. Lockyer's next three dissections for carcinoma were fatal, but as he learned not to attempt grossly inoperable cases his results improved and he soon had 115 cases with a mortality of 18%. At the Annual Meeting of the B.M.A. at Exeter in 1907 he showed 12 specimens removed by operation, and then Comyns Berkeley came to him for tips and details and—with Bonney—started the Middlesex Hospital series. Thus there is no doubt that Lockyer introduced the Wertheim operation into Britain.

He was an outstanding operator. By accident while I was R.M.O. at Queen Charlotte's in 1907 I was asked to go to the Samaritan to act as house-surgeon, as they were short-handed. Lockyer's exhibition of incredible speed and skill astounded me, as I was used to the more plodding methods of Spencer and Blacker, but it was great fun trying to keep pace with him and a joy when he asked me to come and help him again. I subsequently became registrar at the Samaritan and attached myself to him as his assistant, to my great advantage. His speed in operating was entirely due to manual dexterity—he did not use any special aids. As he got older he became somewhat slower.

He combined with Eden to produce the Eden and Lockyer *Gynaecology* in two volumes. His personal article was to be on fibroids. His fantastic energy and interest in the literature soon produced a manuscript far too large for any general textbook, so he enlarged the manuscript by writing very extensively on what was then called adenomyomata and published a book under the title of *Fibroids and Allied Tumours*. Most unfortunately before it was

published uterine endometriosis had been recognized and put on a sound basis, and his book with its chapters of incorrect pathology was out of date before it reached the public. His personal knowledge of pathology was very large, as he followed Targett as reporter on microscopical slides to Eastes's Laboratories, and at the meetings of the pathological subcommittee of the Obstetrical Section his opinion carried great weight. The younger members of the subcommittee looked joyfully forward to a clash between Lockyer and T. G. Stevens (who reported for Watergate House), but one did not often occur, as they both knew their work too well. He was an honorary fellow of several foreign societies and a foundation member of the Gynaecological Visiting Society. He took little interest in obstetrics and was not an outstanding obstetrician. His interest was gynaecology and pathology. He often operated by the vaginal route, and came back from St. Petersburg with an amazing collection of vaginal instruments fitted with electric lights to illuminate the interior of the pelvis, but they were hardly ever used.

Lockyer played golf and liked coarse fishing, but otherwise took little interest in sport. He was a keen Mason and a natural artist. His oil paintings were regularly shown at the exhibition at the R.S.M. When he retired to Penzance he turned the rooms above the garage into a studio and with his wife spent a lot of time painting and etching. They regularly exhibited their pictures at the local art exhibitions. He was also interested in gardening, and, as his grounds were sheltered, he grew semi-tropics with great success and pleasure. For the last few years his heart and eyesight had worried him and he had to rely increasingly on the ministrations of Violet Lockyer, his very devoted wife. He was popular with his colleagues, and on his 90th birthday he received a mass of congratulations from the numerous young people whom he had helped and befriended.

A memorial service to Mr. Cuthbert Lockyer will be held at All Hallows by the Tower, Byward Street, E.C.3, on September 9 at 12 noon.

C. I. GRAHAM, F.R.C.S.

Mr. C. I. Graham, consulting ear, nose, and throat surgeon to St. Mary's Hospital, died at Golant, Par, Cornwall, on August 8, at the age of 80.

Cecil Irving Graham was born in Western Australia on April 11, 1877, and entered the medical school at St. Mary's Hospital in 1895, qualifying M.R.C.S., L.R.C.P. in 1901. After holding resident posts at St. Mary's and the Hospital for Sick Children, Great Ormond Street, he obtained the Fellowship of the Royal College of Surgeons of England in 1905, and was appointed surgical registrar to St. Mary's. Later he became senior clinical assistant to the Ear, Nose, and Throat Hospital, Golden Square. In 1908 the throat and ear departments of St. Mary's amalgamated under the charge of Dr. William Hill, and Graham was elected as honorary assistant surgeon to the department. In 1919 Dr. Hill retired, and Graham took charge of the department until 1937, when he retired and was then appointed consulting ear, nose, and throat surgeon to the hospital. After joining the staff of St. Mary's he acquired appointments as ear, nose, and throat surgeon to King Edward VII Memorial Hospital at Ealing and to the North Herts and South Beds Hospital at Hitchin, and he carried on a successful private practice from Wimpole Street.

J. F. S. writes: Graham's fine physique and athletic ability made him an outstanding figure at the hospital in his student days. In 1900 it was he who captained the team and led the forwards when St. Mary's won the Inter-hospitals Rugby Cup for the first time. In the same year St. Mary's won the United Hospitals sports; in these Graham won two events—putting the shot and throwing the hammer with a record throw.

Graham was very dexterous as an ear, nose, and throat surgeon, as will be well remembered by any who saw him use the tonsil guillotine on adult patients. Although he did not contribute very much to the literature, he was among the earliest in this country, if not the first, to essay decompression of the sella turcica for a pituitary tumour via the nasal septum. He and Dr. Wilfred Harris published an account of this in 1913. In the early nineteen-thirties he practised an approach to the mastoid through the concha and external auditory meatus. This approach, although not precisely the same as that popularized by Lempert, preceded the latter's publications by some years.

Throughout his association with St. Mary's Graham interested himself with the activities of the students and was for many years president of the Rugby Football Club and other athletic clubs. "C. I.," as he was affectionately known, was a popular figure at the hospital, and until the end of his time he retained his particular brand of puckish humour and was always ready to take part in a practical joke.

On retirement he went to live quietly in the little Cornish village of Golant, on the Fowey river. Here he indulged in boating, fishing, and prawning, to which he was passionately attached. However, increasing arthritis rendered this more difficult as time went by, until eventually his motor-boat became his only form of transportation. As expected, he carried on his lonely battle against this disability with extreme courage and resolution: in fact, it was this resolve not to surrender which ultimately caused his death, when last July he slipped and fell while getting out of his boat and eventually succumbed to the injuries he sustained. Many old St. Mary's men will be deeply grieved to hear of his passing.

W. S. SHEARER, M.B., F.R.C.S.Ed., D.R.

Dr. W. S. Shearer, director of the radiodiagnostic department, Edinburgh Royal Infirmary, died suddenly on August 20 while on holiday in Orkney. He was 53 years of age.

William Stewart Shearer was born in Edinburgh and was educated at Boroughmuir and at Edinburgh University, where he graduated M.B., Ch.B. in 1926. After resident surgical appointments in the Midlands he returned to Edinburgh, where he worked in the department of anatomy of the university. While there he carried out postgraduate studies and was elected a Fellow of the Royal College of Surgeons of Edinburgh in 1929. He returned to the Midlands for a short spell, but was soon to realize that his main interest lay in the sphere of radiology. He studied and obtained his Diploma in Radiology from Edinburgh University in 1931.

His next eight years were spent in Manchester, helping to build a radiological practice and at the same time serving on the staff of the Royal Albert Edward Infirmary, Wigan. Being a Territorial officer, he was mobilized at the outbreak of war in 1939, serving in the United Kingdom and subsequently in the Middle East, where he spent most of his Service career as a specialist radiologist with the rank of major. During the "blitz" his home and consulting-rooms in Manchester were destroyed, and on his release from the Army in 1945 he returned to his parents' home in Edinburgh. Soon he joined the staff of the Royal Infirmary in Edinburgh, and in 1946 was appointed director of the radiodiagnostic department and senior lecturer in radiodiagnosis in the university. His interests extended to all branches of his specialty, and his opinions were highly valued by all his colleagues. His clarity of thought was outstanding, enabling him to reduce a problem to its essentials. His professional knowledge was extensive, and problems of diagnosis were referred to him from all parts of the world. Latterly he made a special study of the radiology of the acute abdomen, of bone disease in general, and of bone dysplasias in particular. During his tenure of office a considerable expansion in radiodiagnostic services took place, and, ever mindful of the needs of the patient, he adopted a policy of decentraliza-

tion to bring these services to him. He was responsible for the development of several self-contained specialized radiodiagnostic units throughout the Royal Infirmary. As director of the radiodiagnostic department he was responsible for the administration of the school of radiography and recently became the Scottish representative on the education committee of the Society of Radiographers.

An active member of the Scottish Radiological Society, he was president from 1951 to 1953. His wise counsel was often in demand, and his influence did much to advance the society to its present authoritative status. He was a member of the Faculty of Radiologists, the British Institute of Radiology, and the British Medical Association. For a time he was a Scottish representative on the Radiologists Group Committee of the B.M.A., and this year was a vice-president of the Section of Radiology at the Newcastle Meeting.

As a teacher he will be affectionately remembered by his many former students now scattered in all corners of the Commonwealth. Those fortunate enough to remain with him as junior colleagues will be the poorer, for they have lost not only a respected teacher and chief but also a personal friend. Seldom does one meet a man with such a capacity for endearing himself to others. Respect rapidly grew to affection, affection for the man and respect for his ability. Sympathetic by nature, a leader and an example to all who knew him, he had the capacity for getting the best out of those with whom he worked. He is survived by his sister and brother, to whom we extend our sincere sympathy.

—D. W. L.

A. E. W. McLACHLAN, M.B., D.P.H.

Dr. A. E. W. McLachlan, consulting venereologist to the South-western Regional Hospital Board, died at Bristol on August 15. He was 58 years of age.

Angus Elrick William McLachlan was born on October 15, 1898, and was educated at George Heriot's School, Edinburgh. After serving as a lieutenant in the Royal Scots from 1917 to 1919, he entered Edinburgh University, where he graduated M.B., Ch.B. in 1924. Three years later he obtained the D.P.H. of the Scottish Conjoint Board. He was interested in venereal diseases from the outset of his career, and his early appointments at Edinburgh were in this specialty. Leaving Edinburgh in 1927, he obtained appointments in Birmingham which gave him wide practical knowledge of medicine and surgery, after which he returned to the field of venereology and held posts at the West London Hospital and St. Paul's Hospital for Genito-urinary Diseases until 1936. In 1932 he was invited to join the medical advisory board of the British Social Hygiene Council.

The extensive training and practical experience which McLachlan had now obtained enabled him to take charge of the large venereal diseases clinic at Newcastle upon Tyne in 1937. He was also appointed lecturer in venereal diseases in the medical school of King's College, where he undertook the routine instruction of undergraduates, postgraduates, and D.P.H. candidates. At Newcastle he built up a highly efficient service.

In 1944 McLachlan was appointed consultant in venereal diseases to the city and county of Bristol, and it was during the first year of his appointment there that he produced his *Handbook of Diagnosis and Treatment of Venereal Diseases*, which went through four editions within six years. During his early days at Bristol McLachlan was a member of the editorial committee of the *British Journal of Venereal Diseases*.

E. H. J. writes: Though McLachlan had been concentrating on his work for so many years in a highly specialized field of medicine, he retained a wholesome perspective towards the general medical and social implications of the venereal diseases. He was a practised speaker on these subjects and willingly gave his services in any direction which would promote the enlightenment of public opinion. Almoners, social workers, and contact tracers one and all paid tribute to his readiness to give them every assistance

and encouragement in their activities. His specialty brought him into contact with large numbers of patients, rich and poor, and invariably he extended to them a kindness and sympathy which were as sincere as they were spontaneous. A wide and avid reader, he could be scintillating in discussion on diverse subjects. Kindly and sincere, he was upright in everything he did, and disliked intensely humbug and subterfuge. His death came as a great shock to all who knew him, but it was fitting that a man who was truly great and who had achieved such eminence in his profession should pass on while still enjoying life to the full. His close colleagues will miss him dearly; he was a wonderful chief and friend, and for those who loved him there are no words to describe adequately how great is their loss. He leaves a widow, to whom our deepest sympathy is extended.

B. S. writes: It was a most unexpected and incredible shock to learn of the death of Eric McLachlan. His attitude to patients, like all good venereologists, was most striking in its humanism, and made those who hesitatingly attended his clinics feel that their coldness towards venereology had been completely misconceived. The trust and confidence that patients had in his skill and optimism were also invigorating and inspiring to those of us who went to him to listen and to learn. Remembering his personal life, sometimes the façade of Scotch dourness was most evident; but his sense of humour, erudition, love of the English language, his generous hospitality, and his charming wife who is bereft are the principal features which frame the moments of memory.

E. A. SCOTT, F.F.A.R.C.S.

Dr. E. A. Scott, consulting anaesthetist emeritus to Guy's Hospital and physician-superintendent and anaesthetist to Orpington Hospital, died on August 11. He was 66 years of age.

Eric Arnold Scott was born on October 3, 1890, and studied medicine at University College Hospital, qualifying in 1915. After holding the posts of house-physician and house-surgeon at University College Hospital, he served in the R.A.M.C. for the remainder of the first world war. In 1920 he was appointed anaesthetist to Guy's Hospital Dental School, a little later becoming honorary anaesthetist to Guy's Hospital itself. He obtained the D.A. of the English Royal Colleges in 1939, and was elected a Fellow of the Faculty of Anaesthetists of the Royal College of Surgeons of England in 1948, the year in which he was granted the title of consulting anaesthetist emeritus to Guy's Hospital. He was also consulting anaesthetist to the Putney and Surbiton hospitals.

During the second world war Scott served as an anaesthetist in the Emergency Medical Service, and in 1941 became deputy medical superintendent of the Orpington E.M.S. Hospital. In 1946 he was appointed medical superintendent of the hospital and occupied the post until 1955, when he was due to retire on reaching the age limit. But the Orpington and Sevenoaks Hospital Management Committee recommended to the South-east Metropolitan Regional Hospital Board that his services should be retained. Accordingly he was appointed as part-time medical superintendent, at first for a year, the appointment being made personal to himself.

J. D. B. writes: Few men can have deserved a reputation for kindness to and thoughtfulness for junior medical staff as did Dr. Eric Scott. His amazing memory for past members of hospital medical staff, his unerring recollection of a man's particular idiosyncrasies, or his measure of a man's ability made him an eminently reliable source of information much sought after by his colleagues. Those of us who knew him will remember the phrases which he turned with so much wit to describe a junior or senior member of the staff. Never do I recall Dr. Scott having recourse to sarcasm; even the rare administrative correction which he found necessary to apply was tempered with such kindness that the most rebellious nature could hardly take exception. Needless to say, a man so mindful of his colleagues was a

kindly doctor, and despite the work thrust upon his shoulders as physician-superintendent he maintained the perfect relationship of the great doctor with his patient. Dr. Scott had, as we say, "a way with him," and he made every patient feel that he or she was his only patient.

G. P. C. CLARIDGE, M.B., B.S.

Dr. G. P. C. Claridge, honorary pathologist and bacteriologist to the Norfolk and Norwich Hospital, died on July 13 at the home of his daughter at Cambridge. He was 77 years of age.

George Percival Charles Claridge was born in 1880 at Southsea, where his father was a curate. The greater part of his life was spent in Norwich, to which city his family moved on his father's acceptance of the living of St. Thomas's. He was educated at King Edward VI School, Norwich, and later went to St. Mary's Hospital as a medical student, graduating M.B., B.S. from London University in 1906. In 1910 he was appointed the first and, as it transpired, the only honorary pathologist and bacteriologist to the Norfolk and Norwich Hospital, with which he combined the posts of honorary pathologist to the Jenny Lind Hospital for Children and the Norfolk and Norwich Eye Infirmary. He was also curator of the museum of the Norfolk and Norwich Hospital, which, dating from 1843, was the first museum to be founded in a voluntary non-teaching hospital.

A member of the British Medical Association for nearly 50 years, he was honorary secretary of the Norwich Division from 1911 to 1920 and of the Norfolk Branch from 1928 to 1938. He also served as chairman of the Division in 1922. He was an original member of the Norwich Rotary Club and served on a number of its committees.

B. B. M. writes: Claridge was a kindly, quiet, and unassuming man and a diligent worker. With his colleagues he was completely free from jealousy and selfishness, and was always ready to give of his time for discussion and advice in their problems. It is difficult in these times to realize that the laboratory services in his day were efficiently carried out with the sole but staunch assistance of two technicians, formerly members of the sanitary squad of a Regular battalion of the Royal Norfolk Regiment. His later years were clouded by ill-health, during which he was comforted and supported by the devotion of his wife, to whom and to his son and daughter the sympathy of all his colleagues and friends is extended.

M. M. St. G. JOHNSTONE, M.R.C.S., L.R.C.P.

Dr. M. M. St. G. Johnstone, a general practitioner of Staunton, in Gloucestershire, and formerly honorary anaesthetist to the Gloucestershire Royal Infirmary, was drowned while bathing in the sea at Tintagel, Cornwall, on August 21. The probable cause of his death was the breaking of the glass of his mask when swimming under water. He was 51 years of age.

Maxwell Maughan St. George Johnstone was born on April 28, 1906, the son of an Irishman, Dr. J. E. St. G. Johnstone, who is in general practice near Gloucester. "Peter," as his family called him, or "Johnnie" Johnstone, as he was known to his contemporaries, was captain of the shooting eight and a prefect at Malvern. He went up to Trinity College, Cambridge, and then on to St. Thomas's Hospital, where he qualified in 1930.

F. M. S. writes: It is a tribute to Johnnie Johnstone's great personality and clinical ability that although he was not a prize-man, and achieved no particular academic success, he held no fewer than five resident posts at his teaching hospital. During his junior residencies he developed an interest in the then infant science of anaesthetics, and became senior resident anaesthetist and later R.M.O. at St. Thomas's Home—an arduous and responsible post calling not only for skill and stamina as an anaesthetist but also for an infinite supply of tact, good humour, and clinical

cal imperturbability. Ultimately in 1936 he decided to join his father in the family practice, which duties he was able to combine with an appointment as the honorary anaesthetist at the Gloucestershire Royal Infirmary.

Medically he was a perfectionist, which led to his breakdown in health, for when war came pressure of work in his practice caused him to resign his anaesthetic appointment at the Infirmary. The imperfections of the National Health Service, particularly inimical to the rural practitioners, did nothing to help him. In committee—and he served on many—he was reasonable but fearless. He was a much-loved man, of whom no one ever said an unkind word—a direct result of his own philosophy that you could do what you pleased in this world provided you hurt no one. His gentleness, generosity, and consideration were paramount, and, added to his uproarious sense of humour, made him a perfect companion. It is particularly bitter that this tragic accident should snatch him from his wife and their six children when, after a long period of unpleasant treatment, patiently tolerated, he had at last recovered his health and happiness.

Vital Statistics

Poliomyelitis

Poliomyelitis notifications (uncorrected) in England and Wales in the week ending August 24 were as follows, with the figures for the previous week in parentheses: paralytic 188 (176), non-paralytic 175 (191), total 363 (367). Total cases in Scotland were 3 (3), Northern Ireland 24 (22), and Eire 3 (9).

The main incidence of the disease continued to be in the Midlands and southern England and in Northern Ireland. In Kent 36 cases were reported (Cranbrook 7, Dartford 7, Malling 4, Maidstone 4). The 7 notifications from Lincs (Lindsey) were fewer than for some weeks, with only 4 from Lincoln C.B. In Warwickshire 52 cases were notified (Coventry C.B. 17, Birmingham C.B. 14, Nuneaton M.B. 10). The 29 cases in London were spread over 15 metropolitan boroughs (Wandsworth 8). Of the 11 cases in Middlesex, 4 were notified from Hendon M.B. In Somerset 14 cases were reported (Long Ashton R.D. 4), and in Devon 15 (Barnstaple R.D. 4). The disease continued to be prevalent in Essex, with 34 cases (Colchester M.B. 5, Harlow U.D. 5, Southend-on-Sea C.B. 4). In West Sussex 12 cases were notified (Chichester R.D. 5, Crawley U.D. 4).

Of the 24 cases reported in Northern Ireland, 9 were from Belfast C.B., 8 from County Antrim, and 6 from County Down.

Influenza

Since the end of July the Asian type of virus strain has been isolated and confirmed in Great Britain in about a dozen instances, according to a statement issued last week by the Ministry of Health. These cases were of travellers entering the country at seaports and airports. The distribution of the virus in this country is at present unknown, though it is suspected of causing some recent outbreaks of influenza.

Week Ending August 24

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 255, whooping-cough 1,107, diphtheria 6, measles 4,267, acute pneumonia 176, dysentery 287, paratyphoid fever 12, typhoid fever 4.

Infectious Diseases

The largest variations in the notifications of infectious diseases in England and Wales during the week ending August 17 were decreases of 1,309 for measles, from 7,929 to 6,620, and 36 for dysentery, from 274 to 238, and rises of 155 for whooping-cough, from 1,050 to 1,205, 43 for food-poisoning, from 344 to 387, and 39 for acute poliomyelitis, from 328 to 367.

The largest falls in the incidence of measles were 167 in Warwickshire, from 375 to 208, 111 in Kent, from 444 to 333,

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending August 17 (No. 33) and corresponding week 1956.

Figures of *cases* are for the countries shown and London administrative county. Figures of *deaths* and *births* are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available.

The table is based on information supplied by the Registrar-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES in Countries and London	1957					1956

Whooping-cough ..	1,205	55	55	2	29	2,497	180	226	11	83

The graphs below show the uncorrected numbers of cases (deaths for influenza) of certain diseases notified weekly in England and Wales (great towns for influenza). Highest and lowest figures reported in each week during the years 1948-56 (influenza, 1952-6) are shown thus - - - -, the figures for 1957 are shown as a solid line. Except for the curves showing notifications in 1957, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

§ Includes puerperal pyrexia.

Medical News

Central Council for Health Education.—The Council's annual summer school, held at the University College of North Wales last month, was attended by 117 participants, a third from overseas. The inaugural address and lecture were given by Dr. J. N. MORRIS, director of the Medical Research Council's social medicine research unit, on "Health Hazards in the General Population." A new feature this year was six teaching and learning sessions in the form of a symposium, at which the various methods and media used in health education were demonstrated and discussed. Guest lectures were given by Dr. WILFRED BARLOW on "Posture and Health," and by Dr. C. O. CARTER, general secretary of the Eugenics Society, on "Genetics and Health." There was also an international forum and a public "arena" meeting in Bangor, arranged by Dr. D. E. PARRY PRITCHARD, the M.O.H. for Caernarvonshire, to discuss cancer education. Dr. JOHN BURTON, the Council's medical director, spoke on the Wiesbaden Health Education Conference. Practical work included the making of a film and film strips on health topics and the preparation of leaflets, posters, flannelgraphs, plastigraphs, and display models.

Peaceful Uses of Atomic Energy.—The British Government has accepted an invitation from the Secretary-General of the United Nations to participate in a second international conference on "The Peaceful Uses of Atomic Energy." The first conference was in 1955. The second conference will be held in Geneva next year from September 1 to 13. There will be twelve plenary sessions for papers of a general survey type, and four parallel series of technical sessions. One of the latter series will deal with the production and uses of isotopes and ionizing radiations in research, medicine, agriculture, and industry; dosimetry; biological effects of radiation; radiological protection; reactor safety and location; and meteorological and oceanographical aspects of the large-scale use of atomic energy. Arrangements for United Kingdom participation are being organized through an executive committee under the chairmanship of Sir JOHN COCKCROFT, F.R.S. Information about the submission of papers or other aspects of the conference may be obtained, respectively, from the "papers secretary" or the secretary of the executive committee, at the Atomic Energy Research Establishment, Harwell, Berks. Titles and 500-word abstracts of papers must be in the hands of the Secretary-General of the United Nations by March 1, 1958, and final texts by June 1, 1958.

Chemotherapy of Cancer.—The subcommittee for Great Britain and Ireland of the chemotherapy committee of the International Union against Cancer met in Cambridge on July 26 and 27 under Professor J. S. MITCHELL's chairmanship. Besides the reading of scientific papers there were informal discussions on future work in this field and on the design and testing of new chemotherapeutic agents and plans were made for a symposium on the chemotherapy of cancer to be held at Cambridge, probably immediately following the seventh International Cancer Congress next July. During the meeting demonstrations were given in the university department of radiotherapeutics and at the radiotherapeutic centre, Addenbrooke's Hospital. The technical papers included contributions on the treatment of leukaemia and polycythaemia vera, the use of the newer nitrogen mustards for testicular tumours, the treatment of neuroblastoma by vitamin B₁₂, and radiosensitizers.

Pasteur Institute's Offer.—Last week the Member of Parliament for Coventry North, Mr. MAURICE EDELMAN, told the press that the Pasteur Institute in Paris had offered to supply enough of its poliomyelitis vaccine for about 20,000 British children. Some details about the Pasteur vaccine were given at the Fourth International Poliomyelitis Congress in Geneva in July. It is understood to be a trivalent killed vaccine, Type 2 virus being represented by the M.E.F. 1 strain,

as in the Salk and British vaccines, but Types 1 and 3 being chosen from a series of strains recovered from poliomyelitis patients in France. The relationship of the latter strains to those used in the American and British vaccines is not clear. So far the Pasteur vaccine has not been submitted to any large-scale field trial apparently, though some 100,000 doses have been issued commercially in France. It is understood also that the Institute's method of safety-testing differs from that used here. On behalf of the Ministry of Health Sir SAMUEL BEDSON, F.R.S., and Dr. L. H. MURRAY visited Paris last week-end to discover more about the vaccine.

Army Medical Advisory Board.—Lord MORAN has been appointed chairman of the Army Medical Advisory Board in succession to Lord WEBB-JOHNSON.

COMING EVENTS

Medical Defence Union.—Annual meeting of the Medical Defence Union, September 17, at 3.15 p.m., at Tavistock House South, Tavistock Square, London, W.C.1.

King's College Hospital Medical School.—Sir GORDON GORDON-TAYLOR will give the inaugural address at 3 p.m. on September 27 at the School.

University College Hospital Medical School.—Dame JANET VAUGHAN will give the inaugural address at 2.50 p.m. on October 1 at the School.

Charing Cross Hospital Medical School.—Dr. J. F. LOCKWOOD will give the inaugural address at 3 p.m. on October 3 at the Royal College of Physicians, Pall Mall, London, S.W.1.

Middlesex Hospital Medical School.—Annual dinner, October 4, 7 for 7.30 p.m. at the Savoy Hotel. Details from the Secretary of the Medical School.

Gastroenterological Convention.—Twenty-second annual convention of the American College of Gastroenterology, October 21–23, at Boston, Mass., followed by the annual course in postgraduate gastroenterology. Details from the American College of Gastroenterology, 33, West 60th Street, New York 23, New York.

Induced Hypotension.—A fortnight's course on induced hypotension in anaesthesia will be held at the Royal Infirmary, Edinburgh, on January 13 to 24, 1958. For details see advertisement page 64.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Wednesday, September 11

ROYAL MEDICO-PSYCHOLOGICAL ASSOCIATION: PSYCHOTHERAPY AND SOCIAL PSYCHIATRY SECTION.—At 11, Chandos Street, London, W., 8 p.m. Miss Gillian Elles: The Post-hospital Phase of Family Treatment. (Open to members and their guests.)

Thursday, September 12

SURREY INTER-HOSPITAL PSYCHIATRIC ASSOCIATION.—At Cane Hill Hospital, Coudsdon, Surrey, 8 p.m., clinical meeting. Dr. A. Sainz (New York): A film showing the Comparative Action of the Various Tranquillizing Drugs; Dr. N. H. Rathod: Tranquillizing without Tranquillizers.

Friday, September 13

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. J. G. Scadding: clinical demonstration.

LONDON UNIVERSITY.—At Charing Cross Hospital Medical School, 5 p.m., special university lecture in human anatomy and morphology by Professor M. L. Barr (Western Ontario): Some New Concepts of Sex Anomalies.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Whittaker.—On August 1, 1957, at the Princess Elizabeth Hospital, Nairobi, Kenya, to Elizabeth, wife of Dr. Leslie R. Whittaker, a sister for Clive and Neil.

MARRIAGES

Tweedie-Watkin.—On August 24, 1957, at the Friends Meeting House, Liverpool, Maurice Charles Kenneth Tweedie, M.Sc., A.Inst.P., of Reading, to Joyce Kathleen Watkin, M.B., Ch.B., D.P.H., of Liverpool.

DEATHS

Scott.—On August 11, 1957, Eric Arnold Scott, F.F.A. R.C.S., M.R.C.S., L.R.C.P.

Umpherston.—On August 14, 1957, at 6, Eildon Street, Edinburgh, Alice Marion Umpherston, L.R.C.P. & S.Ed.

Whiting.—On August 3, 1957, Walter Smurthwaite Whiting, M.B., B.S., of 2, Kelvin Grove, South Shields, Co. Durham.

SARCOIDOSIS IN IDENTICAL TWINS

WITH TORULOSIS AS A COMPLICATION IN ONE CASE*

BY

N. S. PLUMMER, M.D., F.R.C.P.

W. St. C. SYMMERS, M.D.

AND

H. I. WINNER, M.D.

Charing Cross Hospital and Medical School, London

[WITH SPECIAL PLATE]

The identical twins whose histories are recorded in this paper were found to have sarcoidosis. While under observation because of sarcoidosis one of them developed torulosis (cryptococcal infection). The presenting manifestation of this infection was osteitis of one scapula, and as this resolved there was at first some hope that the infection might run a benign course—recovery from localized torulosis has been recorded several times (see Gendel *et al.*, 1950); eventually, however, the patient died of cryptococcal meningitis.

CASE REPORTS

The twins were born in 1921. They had no brothers or sisters. Their father died of asthma and pneumonia at the age of 36, their mother of coronary thrombosis when 62. Except during the war, and from 1948 to 1952, the twins lived together in Kent. Both served in North Africa during the war, and the first twin also spent some time in India.

First Twin—Sarcoidosis Complicated by Torulosis

This man, who was employed in an estate agency, married in 1946. In January, 1952, his wife had a small haemoptysis: radiography showed small, partly calcified lesions in the apical part of each lung; tubercle bacilli were found in films of one specimen of sputum, and once subsequently in gastric washings. She was treated conservatively in a sanatorium, made a good recovery, and remains in good health. A radiograph of her husband's chest in February, 1952, showed some mottling of both lung fields. He was advised to come into hospital for investigation; as he had no symptoms he delayed doing so until January, 1954.

First Admission (January 7 to February 13, 1954)

The only clinical abnormalities were two small, soft, mobile lymph nodes in the right supraclavicular fossa and one in the right axilla, very large but clean tonsils, and a nodule, about 0.5 cm. in diameter, in the skin over the fifth left costochondral junction. The scar of an inguinal herniorrhaphy, which had been performed in childhood, was healthy.

Investigations.—Chest radiograph (Special Plate, Fig. 1): extensive infiltration in lungs, predominantly in middle and lower zones; no obvious hilar enlargement. Mantoux reaction negative (0.2 ml. of 1:10 old tuberculin). Serum albumin 5.5 g., globulin 3.7 g. per 100 ml. Hb 14.9 g.

*These patients were mentioned briefly by Littman and Zimmerman (1956) on p. 37 of their monograph on torulosis.

per 100 ml. Leucocytes 7,000 per c.mm. (neutrophils 4,865, eosinophils 35, lymphocytes 700, monocytes 1,400). Erythrocyte sedimentation rate 11 mm. in one hour (Westergren). Wassermann reaction negative. Biopsy of a cervical lymph node (January 13) showed histological changes which were consistent with the clinical diagnosis of sarcoidosis (plate, Fig. 2).

Treatment.—A course of cortisone (100 mg. by mouth daily), streptomycin (1.0 g. intramuscularly three times a week), and sodium *p*-aminosalicylate (12 g. by mouth daily) was started on January 15. On February 2 the dose of cortisone was raised to 150 mg. daily.

Progress.—During the first week in hospital he had occasional slight fever in the evening; subsequently he was afebrile. After he left hospital the dose of cortisone was reduced—on February 26 to 100 mg. a day, and on March 5 to 75 mg. a day. His tonsils had become appreciably smaller by this time; there was no radiological change in his chest. On March 8 he had a rigor (temperature 101° F.=38.3° C.); he therefore stopped taking cortisone (total dose 6,400 mg. over 53 days). Rigors occurred again on the next two days and his left shoulder became swollen and painful. Examination on March 12 showed an ill-defined, fluctuant swelling, about 6 cm. across, over the left acromion; the nodule on the chest wall was also noticed to have become larger and fluctuant. The patient said that the tip of the left shoulder had become sore during his first week in hospital, a few days before starting the course of cortisone, and that the soreness had passed off after two or three days; later it recurred periodically until the sudden onset of the painful swelling at the same site. The swelling was aspirated (March 12), yielding about 50 ml. of pink fluid which was noted to be remarkably mucoid. No organisms were seen in films of the fluid, some of which was therefore inoculated into a guinea-pig; aerobic and anaerobic cultures on blood-agar were sterile after 72 hours' incubation at 37° C. A Löwenstein medium was also inoculated.

Second Admission (March 15 to May 21, 1954)

Radiological examination on admission showed irregular areas of destruction in the acromion and neck of the left scapula (Special Plate, Fig. 3). The findings in chest radiographs were unchanged. Between March 16 and 30 he received 40,500,000 units of penicillin by intramuscular injection. The swelling on the shoulder was aspirated several times at intervals of a few days, yielding mucoid, bloody fluid in amounts ranging from 10 to 50 ml.; 5 ml. of 10% sodium *p*-aminosalicylate was instilled through the needle after each aspiration. At first the fluid

reaccumulated rapidly, but by April 23 the swelling was getting smaller. The swelling on the chest wall was aspirated once (March 27), yielding 2 ml. of fluid like that from the shoulder; it then gradually disappeared. The patient's temperature was usually normal during this stay in hospital, and it never exceeded 99.6° F. (37.6° C.). Early in May the guinea-pig which on March 12 had been inoculated with fluid from the shoulder lesion was killed: the only noteworthy finding at necropsy was enlargement of a lymph node draining the inoculation site, and histological examination of this node showed suppurative lymphadenitis with morphologically typical cryptococci in the abscesses (Special Plate, Fig. 4).

Further Investigations.—May 6: Re-examination of fluid which had been kept in a refrigerator at 4° C. since it was aspirated from the shoulder on March 22 showed cryptococci in wet films. *Cryptococcus neoformans* was isolated in cultures from this stored specimen, and also from a freshly aspirated specimen and from the Löwenstein culture inoculated on March 12. No fungi or tubercle bacilli were found in gastric washings (films, cultures, and guinea-pig inoculation). Cryptococci were not isolated from sternal marrow or from 24-hour specimens of urine. The cytology of the sternal marrow was normal. The erythrocyte sedimentation rate fell from 58 mm. (March 16) to 18 mm. (May 4) in one hour (Westergren). Serum albumin 4.3 g., globulin 2.2 g. per 100 ml. Electroencephalography normal. The patient went home on May 21.*

Third Admission (July 7 to August 19, 1954)

The patient's general condition was good. The swelling on his shoulder had gradually disappeared while he was at home. His skin was healthy, and there was no trace of the lesion in the skin of the chest. Three soft, mobile lymph nodes were felt above the clavicles, and four in the right axilla. His tonsils had enlarged again. On July 21 tonsillectomy, bronchoscopy (normal), and excision of an axillary lymph node were performed; the operation wounds healed uneventfully. Cultures of both tonsils and of bronchial washings yielded *Streptococcus viridans*, *Neisseria catarrhalis*, and an unencapsulated yeast-like organism which was not studied further; cultures of the lymph node were sterile. The specimens yielded no growth on Löwenstein's medium; material from each of them was injected into mice, which remained healthy and showed no abnormality when killed 138 days later. Histological examination of the tonsils and lymph node showed sarcoid lesions identical with those in the lymph-node biopsy of January 13; no organisms were found in the sections.

Further Investigations.—Radiographs of the chest and left shoulder showed no material change since the previous admission. Radiographs of the spine were normal; calcified mesenteric lymph nodes were present. Hb 14.8 g. per 100 ml. Leucocytes 5,500 per c.mm. (neutrophils 4,345, eosinophils 165, lymphocytes 770, monocytes 220). Erythrocyte sedimentation rate ranged between 17 and 10 mm. in one hour (Westergren). As is usual in torulosis, no agglutinins to cryptococci could be demonstrated, and a cryptococcal complement-fixation test was negative.

Treatment.—Although the swelling over the shoulder had already subsided, a course of 2.575 g. of 2-hydroxystilbamidine was given by injection (July 26 to August 19). Thrombophlebitis developed in the veins used for the injections; there were no other reactions.

Progress.—The patient returned to work in September, 1954. In October he mentioned a feeling of tightness in both parietal regions; clinically there was no other change. In February, 1955, he felt well, apart from a feeling of tightness across the forehead; the only clinical abnormality was a single palpable lymph node in the right axilla; radiographs of the skull were normal, those of the chest showed

no change, and the scapular lesion had regressed considerably. By November the scapular lesion had regressed still further; the patient felt well and had no fever. In April, 1956, he began to complain of losing energy and weight. Although he looked well his temperature was 99.8° F. (37.7° C.), the tip of his spleen was palpable, and the erythrocyte sedimentation rate was 31 mm. in one hour (Westergren). He stayed at home under observation; slight fever persisted. After a month he was admitted to hospital with two weeks' history of pain above and between the eyes, stiffness of the neck and slight photophobia, with occasional vomiting. Up to this time cerebrospinal-fluid examination had always been avoided so that there might be no possibility of precipitating cryptococcal meningitis by needling the theca.

Fourth Admission (May 25, 1956)

On admission he looked ill; his temperature was 99.4° F. (37.4° C.) and his spleen reached half-way to the umbilicus. Radiography showed considerable diminution in the extent of the osteolytic lesion in the left acromion, with some restoration of the normal structure; the appearances in the chest were unchanged, and the skull and cranial air sinuses were radiologically normal. Lumbar tap: cerebrospinal fluid under normal pressure; 12 leucocytes per c.mm.; protein 50 mg. per 100 ml.; *Cryptococcus neoformans* isolated on cultivation. His temperature ranged between normal and 102° F. (38.9° C.) during the fortnight after admission.

Treatment and Progress.—"Nystatin" ("mycostatin")† was given in doses of 200,000 units in 2 ml. of 2% procaine solution twice daily by intramuscular injection between June 8 and 21 (total 4,800,000 units), and in doses of 1,000,000 units three times a day by mouth between June 8 and July 12 (total 101,000,000 units by mouth). Although the cryptococcus from the C.S.F. was sensitive *in vitro* to nystatin, the antibiotic had no clinical effect. The patient's temperature ranged between 97° and 103.8° F. (36.1° and 39.9° C.), and was seldom less than 100° F. (37.8° C.); he was troubled by frontal or occipital headache on some days, but otherwise felt well, apart from a rigor (temperature 104.6° F.=40.3° C.) on June 20. A course of 2-hydroxystilbamidine, to which the cryptococcus was sensitive *in vitro*, was started on June 20; an intravenous injection of 250 mg. was given on alternate days until July 19 (total 3,375 g.). During July the fever continued and his general condition gradually worsened; nausea and vomiting were troublesome at times and were not lessened by chlorpromazine. Mild papilloedema developed and he had periods of drowsiness and coma. Sulphadiazine was given in doses of 1.0 g. four times a day between July 7 and August 3 (total 61 g.). A second course of 2-hydroxystilbamidine was begun on August 2, 250 mg. being given intravenously every second day until August 20 (total 2 g.). There was no local or systemic reaction of any sort to this treatment. Lumbar tap on July 31: pressure 180 mm. of C.S.F., with no sign of obstruction; fluid slightly yellow; 40 leucocytes per c.mm.; protein 380 mg. per 100 ml.; chloride (as NaCl) 575 mg. per 100 ml.; large numbers of cryptococci in centrifugate; *C. neoformans* grown on culture. Lumbar tap on August 14: pressure 180 mm., with little rise with Queckenstedt's test; 20 leucocytes per c.mm.; protein 500 mg. per 100 ml.; *C. neoformans* isolated. Paper-strip electrophoresis of C.S.F. showed that most of the protein was albumin; the total globulin content was so small that it was impossible to get well-defined staining of the separate fractions; mucopolysaccharides could not be demonstrated by the method of applying toluidin blue to the paper.

The patient's condition deteriorated more rapidly after the first week in August; his temperature became subnormal and coma deepened. He died quietly on August 21, 1956, about 32 months after the first symptom of cryptococcal infection and 15 weeks after the onset of meningitic symptoms.

†We are indebted to Messrs. E. R. Squibb and Sons for supplies of this antibiotic.

Biopsy Histology

The lesions in the cervical lymph node (January 13, 1954, before treatment with cortisone) and in the axillary lymph node and tonsils (July 21, 1954) were identical (Special Plate, Fig. 2). Rounded aggregates of epithelioid histiocytes had replaced most of the lymphoid tissue. Some of the aggregates were confluent, but their individuality was readily appreciated, particularly in preparations silvered to show reticulin. Giant cells were rare. No organisms were found on examination of over 200 serial sections of each specimen (among the staining methods used were Ziehl-Neelsen, Gram, Gridley, periodic-acid-Schiff, mucicarmine, and silver impregnation), including examination by fluorescence microscopy (auramine-O preparations), dark field illumination, phase-contrast microscopy, and polarized light—all methods which may from time to time prove valuable in searching for fungi when these are scanty. There was no caseation; a few of the larger aggregates showed central fibrinoid necrosis. There was a little hyaline sclerosis around some aggregates. No Schaumann bodies or asteroids were found. The appearances were fully consistent with sarcoidosis.

Necropsy

The main findings *post mortem* were: cachectic emaciation; cryptococcal meningitis, affecting particularly the base of the brain and the cauda equina; an ill-defined pseudocyst in the acromion of the left scapula, with no detectable abnormality in the overlying soft tissues; sclerotic sarcoidosis affecting all groups of lymph nodes, the lungs, and the spleen; and heavily calcified, caseous lymph nodes in the mediastinum and in the mesentery of the small intestine. Cryptococci were demonstrated microscopically in the meningeal exudate (Special Plate, Fig. 5), and *C. neoformans* was cultivated from this exudate and from the liver, but not from the spleen, lymph nodes, lungs, or left scapula. Histological study showed that the tissue reaction in the cryptococcal meningeal lesions was predominantly of the granulomatous type, although the picture was obscured by extensive necrosis of the granulomatous tissue, particularly in the cerebral sulci and the adjacent part of the cortex; in places the picture was merely that of widespread colonization of the meninges by cryptococci, with little or no reaction to their presence. No cryptococci were demonstrated in sections of any other part of the body, although over 100 blocks of tissue were examined. The acromial lesion showed old necrosis of adipose marrow, with patchy fibrosis but no specific features; apart from a little fibrosis no abnormality was found in the soft tissues around the scapula or at the site of the former fluctuant lesion of the skin of the chest wall. The lesions of sarcoidosis were histologically typical of that condition, although predominantly in an advanced stage of sclerosis; active lesions were present in association with the sclerotic ones wherever the latter were found. The calcified, fibrocaseous mediastinal and mesenteric lymph nodes were devoid of features diagnostic of their nature, although their appearances were quite consistent with effete tuberculosis; no micro-organisms of any sort were found in them.

Mycology

The organism isolated from the patient's shoulder in 1954 showed the characteristics of a *Cryptococcus neoformans* of moderate virulence as defined by Benham (1956). On primary isolation it possessed a well-defined capsule; it grew well on peptone-maltose agar and blood agar at 37° C., but not at room temperature: it fermented glucose, saccharose, and maltose, but not lactose. The guinea-pig which was inoculated on March 12, 1954, with the first aspirate was killed 41 days later when still apparently well; cryptococci were found only in the lymph node draining the inoculation site, and sections of the spleen, liver, lungs, heart, and kidneys were normal. The findings were similar in a guinea-pig which was killed 41 days after inoculation with aspirate on May 6.

Cultures of the cryptococcus which was isolated from the aspirate of May 6 were inoculated into the peritoneal cavity of three mice on May 17. Torulosis was subsequently confirmed in two of these mice, with typical cerebral involvement in one. In subsequent experiments the organism gave rise to a variant form which caused rapidly fatal disseminated torulosis in mice.

The cryptococcus isolated from the cerebrospinal fluid during the final stages of the patient's illness, and from the tissues at necropsy, showed the same features as the original strain in this case. An india-ink preparation of the cerebrospinal fluid, showing *C. neoformans* with typical halo-like capsules, is illustrated in Fig. 5 of the Special Plate.

Unencapsulated yeasts which were isolated from a 24-hour specimen of urine on May 21, 1954, and from the tonsils and bronchoscopic washings on July 21, 1954, were thought to be commensals, of no pathological significance.

Blood-agar plates which had been planted with fluid aspirated on March 27, 1954, from the lesion on the chest wall yielded a very scanty growth of yeasts. As no yeasts were seen in films of this specimen the organisms which were grown were considered to be contaminants; they were not investigated further.

The cryptococcus isolated from the scapular lesion in 1954 was sensitive *in vitro* (plate test) to 2-hydroxystilbamidine isethionate, bis-(2-hydroxy-3,5-dichlorophenyl) methane, methyl *p*-hydroxybenzoate, undecylenic acid, chlorphenesin, diamidinodiphenylamine dihydrochloride, mersalyl, anemonin, and mercaptomerin. It was resistant to sulphadimidine, penicillin, streptomycin, chloramphenicol, chlortetracycline, oxytetracycline, sodium propionate, and *p*-aminosalicylic acid.

The cryptococcus isolated from the C.S.F. in 1956 was sensitive *in vitro* to nystatin, 2-hydroxystilbamidine isethionate, and "novex"; it was resistant to sulphadiazine and *p*-aminosalicylic acid. There was no evidence of synergism or of antagonism between nystatin and the stilbamidine preparation.

Second Twin—Sarcoidosis

This patient, who is a clerk, was the identical twin of the first patient. When his sister-in-law was found to have tuberculosis he was advised to have his chest radiographed. He delayed taking this advice until February, 1954. The picture showed mottled shadowing in both lungs, mainly in the middle zones, with collapse of the basal part of the right upper lobe; there was no evident enlargement of the hilar lymph nodes. He was admitted to hospital for investigation.

First Admission (April 20 to May 18, 1954)

He had no symptoms other than mild, vague "indigestion." His health had always been good; he broke a rib at games in 1951, and radiography at that time showed no evidence of lung disease. The only clinical abnormalities on admission were a large mobile lymph node above each clavicle, a smaller node behind the left sternomastoid and one in the right axilla, and a few rales high in each axilla. His tonsils were normal. There was a healthy scar where a meibomian cyst had been excised some years earlier. He had no fever.

Investigations.—Mantoux reaction negative (0.2 ml. of 1:10 old tuberculin). Hb 16.3 g. per 100 ml. Leucocytes 5,200 per c.mm. (neutrophils 3,925, eosinophils 25, basophils 50, lymphocytes 700, monocytes 500). Erythrocyte sedimentation rate 6 mm. in one hour (Westergren). Serum albumin 5.1 g., globulin 2.2 g. per 100 ml. Biopsy of a supraclavicular lymph node (April 23) showed a picture of sarcoidosis, indistinguishable from that in the biopsy specimens from his brother; no organisms could be demonstrated in sections examined by the methods used in the case of the brother's biopsies; no specimen was available for culture. Gastric washings: no tubercle bacilli or yeasts found (films, cultures, and guinea-pig inoculation). No organisms in films or cultures of bone marrow and of 24-hour specimens of

*Studies of the blood groups of both brothers by Dr. S. Shaw gave identical results: Group A₁; rhesus phenotype CcDde, probable genotype CDe/cde; NsNs; P+, Lu+, K-, Lea-, Leb+, Fya+.

urine. Cytology of sternal marrow normal. Wassermann reaction negative. Radiographs of shoulders, spine, and pelvis normal.

Treatment.—Streptomycin (1 g. intramuscularly daily, April 29 to May 14; thereafter, thrice weekly until June 14) and sodium *p*-aminosalicylate (18 g. daily, April 29 to June 14) were given.

Progress.—He was seen regularly as an out-patient after leaving hospital. At the end of 1954 he had a short neuritic episode, with pain in the left shoulder on moving his head, "pins-and-needles" and numbness in the left thumb, and loss of sensation to pin-prick on the medial aspect of the back of the left hand and forearm. Radiographs showed no abnormality of the cervical spine and shoulders. His general condition remained good, although there was no change in the radiological findings in the lungs; lymph nodes in the neck, axillae, and groins were transiently enlarged, and in June, 1955, the spleen was just palpable. Throughout these months he had periodic bouts of aching in the right iliac fossa after meals.

Second Admission (November 4 to December 3, 1955)

He was readmitted because of the persisting complaint of abdominal pain, which culminated in a severe attack than usual a fortnight before admission. This attack was associated with malaise and shivering, and he took to bed. For some days he vomited often, and was able to keep only fluids down. He had no fever while in hospital; there was slight tenderness in the lower part of the abdomen, particularly in the right iliac fossa, and slight enlargement of the seminal vesicles. Moderately enlarged, mobile lymph nodes were present in the neck and axillae.

Investigations.—Radiological examination after a barium meal showed that the terminal loop of the ileum, while mobile, had a fixed S-shape, which suggested the possibility of adhesions to a mass of lymph nodes or to the mesentery. Chest radiographs showed no definite change since April, 1954. Hb 14.7 g. per 100 ml. Leucocytes 8,200 per c.mm. (neutrophils 6,070, eosinophils 165, lymphocytes 1,640, monocytes 325). Erythrocyte sedimentation rate ranged between 13 and 18 mm. in one hour (Westergren). Repeated examination of vomitus, faeces, and urine (including mid-stream specimens of urine obtained after massage of the seminal vesicles and prostate) showed no tubercle bacilli, fungi, or other pathogens (films and cultures). Intravenous pyelography revealed no abnormality of the renal outlines or of the calices and pelves. Urine normal.

Progress.—His symptoms gradually subsided without special treatment. It was thought that they were due to sarcoidosis affecting the abdominal lymph nodes. He felt well and had no symptoms when he left hospital. In March, 1956, the spleen was palpable, but the superficial lymph nodes were considerably smaller than on any previous examination; the wall of the caecum was readily felt and was thought to be thickened; the chest radiographs were unchanged, and he felt well. In April, 1957, his condition was reported as unchanged.

Comment on the Cases

These identical twins were found to have sarcoidosis at about the same time. It is conjectural whether the tuberculous infection from which the wife of the married twin suffered was related to their illness. It is interesting that calcified lymph nodes, suggestive of past tuberculous lymphadenitis, were found radiologically and at necropsy in the first case. Sarcoidosis has been observed in at least three other pairs of identical twins (Sherer and Kelley, 1949; Gilg, 1952; Rogers and Netherton, 1954); sarcoidosis in other siblings has been reported by several authors, whose cases are referred to by van Zwanenberg and Barry (1955) and by Swirsky and Lowman (1955).

The original diagnosis of cryptococcal osteitis in the first case was established, in our view, beyond any reasonable doubt, although at necropsy no specific evidence of infection

of the bone remained demonstrable. The radiological findings were remarkably similar to those of cryptococcal acromial osteitis illustrated by Collins (1950). Cryptococcal osteitis is not uncommon in cases of torulosis (see Gosling and Gilmer, 1956). No other evidence of torulosis was found in our case at first, with the possible exception of the lesion on the chest wall, the nature of which was unproved. The clinical history suggested that the cryptococcal bone infection was already manifest before the course of cortisone was started. It is debatable whether cortisone in any way affected the progress of the infection, although the liability of infective conditions to advance rapidly in patients taking cortisone makes it possible that resistance to the cryptococcal infection was lessened in this case. Israel *et al.* (1954) drew attention to the risk of aggravating fungal infections by giving cortisone, and their observations have been repeated by others. The hormone was given to our patient with the hope that the sarcoidosis might be favourably influenced and the risk of pulmonary fibrosis reduced. There have been many reports indicating that treatment with corticotrophin or cortisone may be beneficial, particularly in cases of extrapulmonary sarcoidosis with symptoms of short duration (Israel *et al.*, 1954). Substantial improvement in certain cases of pulmonary sarcoidosis treated with streptomycin, *p*-aminosalicylic acid, and cortisone was observed by Hoyle *et al.* (1955). The only evidence that treatment influenced the lesions of sarcoidosis in either of our twin patients was the temporary, but striking, shrinkage of the tonsils in the one who received cortisone. In view of the manifestation of cryptococcal infection during treatment of his brother with cortisone this drug has not been given to the second twin.

There is no evidence that any of the antibiotics or other drugs affected our patient's cryptococcal infection in any way. The organism was resistant *in vitro* to *p*-aminosalicylic acid, streptomycin, and penicillin, of each of which the patient had received full courses before the cryptococcal infection was recognized; it was sensitive *in vitro* to 2-hydroxystilbamidine, but clinical manifestations of the bone infection had already subsided before this drug was first given, and neither it nor nystatin had any effect on the meningitis. The ineffectiveness of treatment conforms with the published experience of others (see Littman and Zimmerman, 1956), although Leithold *et al.* (1957) have suggested that 2-hydroxystilbamidine was responsible for the "apparent cure" (15½ months' observation without evidence of recurrence) of the cryptococcal infection in their patient with sarcoidosis.

This is the nineteenth case of torulosis in this country. References to the first ten cases have been given elsewhere (Symmers, 1953); one of these cases (Galton and Whittick, 1950) has now been described in detail (Lumb, 1954). Eight further cases are on record (Cruickshank and Harrison, 1952; Pierce, 1953; Spencer, 1954; Caldwell and Raphael, 1955; Beck *et al.*—2 cases; Levene and Michaels, 1955; Misch, 1955), and several unpublished cases are known to us.

As is usual with torulosis, the source and portal of entry of the infection are unknown in our case. The natural environment of *C. neoformans* is not known; pathogenic strains have been isolated from soil (Emmons, 1951) and from pigeon nests and droppings (Emmons, 1955). Spontaneous infections occur in animals, but seem to be uncommon (literature: Skulski and Symmers, 1954); the only animal infection so far reported in Britain was in a pet ferret (Skulski and Symmers, 1954), although Carter and Young (1950) isolated pathogenic cryptococci from cow's milk in Scotland.

DISCUSSION

The occurrence of cryptococcal infection in a patient with sarcoidosis is of particular interest in view of the occasional association between other diseases of the lymphoreticular system and torulosis. Torulosis and sarcoidosis have been associated in only a small number of published cases—a case mentioned briefly by both Collins (1950, Case 3) and

T. J. MILLS: FRACTURES OF RADIUS

FIG. 1a.—Smith's fracture of radius.

FIG. 2a.—Anterior marginal fracture of radius.

FIG. 1b.—End-result of treatment of Smith's fracture.

FIG. 2b.—End-result in anterior marginal fracture.

FIG. A.—Deformity in Smith's fracture. (From R. W. Smith's *Fractures and Dislocations*.)

In the anterior marginal fracture a wedge-shaped fragment of bone, of varying dimensions, is split off from the front of the lower end of the radius, the base of the wedge being articular surface. The lower fragment is displaced, with the carpus, forward and upwards (Special Plate, Fig. 2). The mechanism of injury is a longitudinal compression strain directed slightly forwards, as is sustained by a fall on the hand with the wrist fully dorsiflexed. The deformity is similar to that of Smith's fracture, but less marked. It is important that this fracture be fully reduced and the reduction maintained so as to minimize the severe articular damage.

Treatment

Traction on the hand with replacement of the lower fragment by compression, followed by fixation in a below-elbow plaster with the wrist dorsiflexed, is advocated by Böhler (1935), Speed (1935), Judet and Judet (1948), Watson-Jones (1955), and Stimson (1956). Key and Cornwell (1951) modify this method by fixing the arm in an above-elbow plaster ("sugar-tongs" plaster slab) with the forearm in mid-rotation and the wrist in neutral position with some ulnar deviation. Although either fracture may be reduced by the above method, there is a great tendency for the displacement to recur. I believe that redisplacement is contributed to by (a) gravity, especially when the plaster becomes loose owing to the subsidence of oedema and wasting of the forearm muscles; and (b) the patient's continual attempts to supinate the radius from its position of pronation in plaster.

I have found the following procedure to give an accurate reduction without fear of redisplacement in both the Smith's and anterior marginal fractures.

Technique.—To reduce a fracture of the left radius, the patient having been anaesthetized, the surgeon grasps the lower fragment in his right hand, between his thenar eminence on the volar surface of the fragment and his fingers around the radial side and back of the wrist. The forearm is held at the junction of the middle and lower thirds by the surgeon's left hand, which exerts such counter-pressure as is required (Fig. B). The right hand now applies traction with the patient's wrist slightly flexed, and the reduction is completed by a twisting movement which supinates and pushes backwards the lower fragment on the supinated radius. The fracture is stable while the wrist is held fully supinated. A carefully moulded above-elbow plaster is applied over a layer of plaster wool, this cast being changed to an unpadded one at the end of 10–14 days. The plaster should extend from just below the axillary folds to the metacarpal heads, with the elbow flexed to a right-angle, the forearm fully supinated, and the wrist in neutral position (Fig. C), and it should be retained for five weeks. The arm may be supported by a calico bandage passing a plaster loop just below the elbow (Patrick, 1946). Finger and shoulder exercises are encouraged throughout the period of immobilization.

Summary

Smith's fracture and the anterior marginal fracture of the radius are described together with a method of treatment which has been found to be successful.

My thanks are due to Mr. H. Osmond-Clarke for his helpful criticism, and to Mr. R. F. Ruddick, of the Photographic Department of the London Hospital, for the illustrations.

[WITH SPECIAL PLATE]

The clinical and pathological findings in this case have already been reported (Armstrong, 1955; Case 1). The right gonad was predominantly a testis in which the seminiferous tubules were mostly represented by hyaline ghosts, only the outlines of the cells being recognizable; Sertoli cells were present in some tubules and there were numerous large masses of interstitial (Leydig) cells (Special Plate, Fig. 1). There was at least one atretic follicle in the right gonad (Plate, Fig. 2). The left gonad was an ovary and contained numerous atretic follicles, corpora albicantia, small atrophic cystic follicles (Plate, Figs. 3 and 4), and at the hilum a conspicuous number of interstitial cells.

The present report describes the sex chromatin of skin, oral mucosa, and internal genitalia, identified by the methods of Moore, Graham, and Barr (1953) and Moore and Barr (1954, 1955). The neutrophil morphology, following the criteria of Davidson and Smith (1954), is also described, and a full account is given of the very unusual blood-group findings because they may be related to the hermaphroditism and are interesting in themselves.

Examination for Sex Chromatin

Skin.—Over half the epidermal nuclei were chromatin-positive. Chromatin-positive nuclei were not found in an area about 1 mm. wide extending through the specimen.

Oral Mucosa.—Scrapings from both cheeks were chromatin-positive; 25% of suitable nuclei showed the typical planoconvex mass at the nuclear membrane.

Internal Genitalia.—Sex chromatin was identified in the interstitial cells of ovo-testis (Plate, Fig. 5), theca cells of ovo-testis (Fig. 6) and of ovary (Fig. 7), mucosa and muscle of uterus, uterine tube, and vas deferens. It was, however, present with less than the usual frequency, and often smaller in amount than in the normal female. Sex chro-

matin was not found in the Sertoli cells of the ovo-testis (Plate, Fig. 8), nor in the lining cells of the ovarian follicles, (Fig. 9); these cells did not display the clear chromatin pattern found in nuclei in which diagnosis is technically possible. Professor Barr (Barr, 1956) has examined these sections and the skin biopsy and agrees with the description above; he believes that the unusual appearances are due to technical causes and that the internal genitalia should be regarded as chromatin-positive.

Blood Films.—Neutrophils of typical female morphology were found in only two to three per 500 neutrophils examined. A further two to three neutrophils displayed a "drumstick" closely resembling the typical morphology, but were rejected because they were not quite solid, presenting a relative paleness at the centre or the periphery. It has not been our experience that these rejected neutrophils are found so frequently in the male. Fig. 10 on the Special Plate shows the five neutrophils most nearly fulfilling Davidson's criteria of female morphology in a count of 500; the first (a) is typical, the second (b) is very slightly pale in the centre, the third (c) and the fourth (d) show a more definite pale portion towards the periphery, and the fifth (e) is flattened on one side. Fig. 11 shows three neutrophils from the same count of 500; these were rejected as (a) a definite racket, (b) a minor lobe, and (c) a sessile knob. The exposure given during development of the prints has been varied so as to give the best reproduction of the microscopical appearances; all parts of the same print had identical exposures.

The Blood Groups

The ABO group of the patient is unusual. Her red cells are not agglutinated by anti-A or by anti-B sera, therefore they appear to be Group O; but her serum, though it contains the anti-A, lacks the anti-B expected of a Group-O person. She is a secretor and her saliva contains the H substance expected of a Group-O person, but it also contains B substance. The urine also contains B substance.

We can find nothing like this reported in the literature. The B₃ of Moullec *et al.* (1955) can clearly be distinguished, and so can the B_w of Levine *et al.* (1956). The peculiar B mentioned by Dunsford *et al.* (1956) was incompletely investigated and no comparison is possible.

Examples of an analogous condition in which the cells are apparently Group O though the serum lacks anti-A and the saliva contains A substance were described in 1942 by Gammelgaard and in 1956 by Wiener and Gordon. In 1957 Weiner *et al.* described two more examples; they were able to study the genetic basis of the phenotype and found it to be due to normal A genes and normal secretor genes acted upon by a rare and independent modifying gene, y, recessive in its effect. The genotype yy interferes with that function of A genes which normally would result in the presence of the antigen A on the red cells. The genotype yy has no effect on the B or H antigen. Had the patient been a normal subject we would have guessed that her blood and saliva adumbrated the existence of a complementary modifying gene, but as it is the blood-group abnormality seems more likely to be connected in some way with the hermaphroditism.

Serological Details.—It is only in the ABO system that the patient is outstanding; her groups in the other systems are normal.

Absence of B from Red Cells.—Agglutination tests on saline suspensions of the cells with many anti-B and anti-A+B sera were negative. Suspending the cells in albumin had no effect. The indirect antiglobulin test using anti-B serum was negative. The absence of B substance was, however, shown most convincingly by the sensitive tests of absorption and of elution: the red cells failed to absorb anti-B, and failed to give up anti-B on being heated after exposure to the antibody. The strength of the H-antigen of the patient's red cells appeared to be between that of an average Group O and an average Group B.

in 10% salt cooked-meat broth (Maitland and Martyn, 1948). The results of these investigations are summarized in the Table.

Virological Investigations

Virus Isolation

For isolation of virus the medium into which the swabs had been collected was inoculated in 0.1-ml. amounts into the amniotic sac of six 11-day fertile hens' eggs, and in 0.5-ml. amounts into two tubes of monolayer tissue cultures of human epidermal carcinoma cells (strain HeLa). After the eggs had been incubated for three days at 36° C. the amniotic fluids were harvested, tested for haemagglutinating activity against human and fowl red cells, and re-inoculated into a further six eggs. Three such passages in eggs were made for each specimen. No haemagglutinating activity was found, except in the second- and third-passages eggs inoculated with the patient's throat swab collected in milk-saline. None of the tissue cultures showed any cytopathic effect after incubation at 37° C. for seven days on either the first or second passage, nor was any haemagglutinin detected in the tissue-culture fluids.

Further tests on the positive amniotic fluid showed that the haemagglutination was due to a strain of influenza virus C. The characteristic property of agglutinating red cells to higher titre at 4° C. than at room temperature, and of agglutinating fowl cells to higher titre than human cells, was observed. Feeble agglutination of guinea-pig red cells was also noticed with the early passage material, as described by Taylor (1951) for the strain 1233, but this property was lost on subsequent passages. Specific complement-fixation was shown to occur between dilutions of the amniotic fluids and sera known to contain antibody against influenza virus C. No complement-fixation could be demonstrated in tests with known positive influenza A and influenza B sera, nor was any observed with a serum known to fix complement strongly with "influenza D" (Sendai virus (Kuroya *et al.*, 1953; Jensen *et al.*, 1955).

The identification of the virus as influenza virus C was kindly confirmed by Dr. L. A. Hatch, of the Virus Reference Laboratory, Colindale, by whom its international reference designation, C/Eng/293/56, was allocated.

Serological Examinations

Two kinds of serological examinations were made, complement-fixation (C.F.) tests and haemagglutination-inhibition (H.I.) tests. The C.F. tests were performed on "perspex" sheets by a method based on the technique described by Fulton and Dumbell (1949), in which overnight fixation at 4° C. is used. A five-volume test, using 0.02 ml. as the unit volume and 2 units of complement, was employed. Sera inactivated at 56° C. for 30 minutes were tested by this means against the following antigens issued by the Standards Laboratory for Serological Reagents, Colindale: influenza A (soluble), influenza B (soluble), influenza C, adenovirus group, psittacosis—L.G.V., and *Rickettsia burneti*. The sera were also tested against the patient's strain of influenza virus C, using undiluted amniotic fluid as antigen, and against a strain of "influenza D" (Sendai virus) kindly supplied by Dr. D. A. J. Tyrrell, of the Virus Research Laboratory, Lodge Moor Hospital, Sheffield, using high-titred allantoic fluid as antigen.

H.I. tests were performed at 4° C., using plastic haemagglutination plates (W.H.O., 1953), with, as antigens, amniotic fluid from eggs inoculated with influenza virus C strain 1233, kindly supplied by Dr. B. E. Andrews, of the Virus Reference Laboratory, Colindale, and similar material from eggs inoculated with the patient's strain of virus. Four 50% agglutinating doses of virus were used and sera were inactivated for 30 minutes at 50° C. before testing. Prior treatment with *Vibrio cholerae* filtrate was not undertaken, since it has been shown by Hilleman and Werner (1953) that human sera do not possess heat-stable inhibitors against influenza virus C. The results of these tests are shown in the Table.

Discussion

From the clinical aspect, the interest of this case lies in the fact that, although it occurred out of season, the condition was recognized on admission to hospital and appropriate treatment was begun immediately to combat the extensive pneumonia and profound toxæmia. Previous experience of infections due to influenza virus A complicated by staphylococcal pneumonia had shown the urgency of parenteral antibiotic therapy and the need to alleviate as far as possible the circulatory collapse. Despite such measures the response was only temporary. Removal of the bronchial secretions by the patient's own efforts was clearly impossible owing to the stuporous state, and mechanical cleansing by aspiration could hardly have proved effective. Oxygen relieved the state of hypoxia but did nothing to relieve the intense toxæmia. Although staphylococcal antitoxin was given intravenously its apparently favourable effect proved to be transitory and it failed to prevent a fatal outcome. It would appear that a stage is quickly reached when such measures are of no avail.

Culture of the sputum or a throat swab from these cases usually yields *Staph. aureus* in abundance. The negative result in the above case may be accounted for by the marked prostration, "bubbling" respiration, and ineffective cough which were such prominent features. Nevertheless, *Staph. aureus* was isolated in heavy, almost pure culture from the lungs and bronchial secretions after death, and was shown to be fully sensitive to the antibiotics administered. The strain isolated in the present case reacted with a bacteriophage of group II. This reaction was given by only 14% of the strains of *Staph. aureus* isolated from cases of influenza pneumonia in the series reported by Williams *et al.* (1953), in which most of the strains were found to react with phages of group I.

Whether there is a particular phage group association with influenza virus C infections, as apparently occurs with influenza virus A and B, is not known. Although influenza virus C does not possess the marked ability to spread in epidemic form which is characteristic of influenza viruses A and B, the surveys of antibodies which have been made in this country (Andrews and McDonald, 1955; Grist, 1955; Balducci *et al.*, 1956) indicate that many persons have been infected in childhood or early adult life. In the contacts studied, the sera from four persons showed raised H.I. titres and none showed a raised C.F. titre. These findings indicate that these individuals had been infected by influenza virus C at some time, but, since no raised C.F. titres were found and no virus was isolated from the two contacts with respiratory symptoms, there was nothing to show that these infections had been acquired recently.

This report serves to emphasize the problem of fulminating staphylococcal pneumonia, which is a well-recognized complication of infection by influenza viruses A and B, and which may, as in the present case, complicate the usually milder infections by influenza virus C. In any case of pneumonia rapid deterioration leading to a state of shock should raise immediate suspicion that the patient belongs to this group and every available resource should be employed as a matter of urgency.

Summary

A case of fulminating pneumonia in a middle-aged woman due to a penicillin-sensitive strain of *Staph. aureus* is described in which death occurred despite intensive antibiotic and antitoxin therapy. In four of six household contacts serological evidence of past infection by influenza virus C was obtained, but no evidence was found to show that the infections had been acquired recently. None of the contacts harboured the same phage type of staphylococcus as the patient. The importance of prompt recognition of the condition and the urgency of instituting adequate therapeutic measures are stressed.

We are indebted to Dr. A. J. N. Warrack for his report on the post-mortem examination, and to Dr. E. H. Gillespie for phage-typing the staphylococci. We thank Dr. L. A. Hatch, of the Virus Reference Laboratory, Colindale, for confirming the identity of the strain of virus isolated; Dr. G. S. Wilson for his helpful criticism; and Mr. P. M. Hinchliffe, Mr. M. W. Scruton, and Mrs. B. Newton for technical assistance.

PROTOVERATRINE A IN TREATMENT OF HYPERTENSION

BY

IAN R. GRAY, M.D., M.R.C.P.

Consultant Physician, Coventry Group Hospitals; Late Senior Registrar, National Heart Hospital, London

AND

NEIL A. J. HAMER, M.B., M.R.C.P.

Registrar, National Heart Hospital, London

Extracts of the *Veratrum* plants cause a fall in blood pressure and bradycardia through the vagal reflex described by von Bezold and Hirt (1867) and by Jarisch and Richter (1939). Their use for the treatment of hypertension has been limited by the frequent occurrence of nausea and vomiting. Trials have suggested that certain of the pure veratrum alkaloids might lower the blood pressure with less emetic effect (Hoobler *et al.*, 1952a). A study of protoveratrine, the principal alkaloid of *Veratrum album*, was therefore undertaken. This has been shown to be a mixture of two closely related ester-alkaloids, protoveratrine A and protoveratrine B (Stoll and Seebeck, 1953; Nash and Brooker, 1953).

Parenteral administration of protoveratrine to patients with hypertension causes a fall in blood pressure with bradycardia (Meilman and Krayer, 1949). This is accompanied by vasodilatation in the limbs, and the cardiac output is not consistently altered (Hoobler and Corley, 1950). Renal blood flow remains constant or is increased, but with considerable falls in blood pressure the glomerular filtration rate is diminished (Hoobler *et al.*, 1952b).

Methods

The effect of protoveratrine preparations was studied in patients with hypertension admitted to hospital for assessment. All blood pressures were taken by one or other of us and the value recorded was the lowest of three successive readings. Oral test doses were given daily after the patient

had been resting for an hour, the blood pressure being observed during that time. Pulse and blood pressure were taken every 30 minutes for the next four hours and hourly thereafter.

The initial amount given was 0.25 or 0.5 mg. of protoveratrine A, and successive doses were increased by 0.25 mg. until a satisfactory response was obtained. With intravenous administration, blood-pressure readings were taken each minute for 15 minutes and at longer intervals thereafter, or, alternatively, a continuous record was made from an indwelling arterial needle. Blood-pressure readings after resting in bed for 10 minutes were taken at 9 a.m. each day throughout the patient's stay in hospital. The average of the first three daily readings before treatment was taken as a baseline for subsequent out-patient assessment.

Out-patients on treatment with protoveratrine A were seen every two weeks at first and later every four or six weeks. The blood pressure recorded was the lowest of three measurements made after resting on a couch for 5, 10, and 15 minutes.

Activity of Protoveratrine A and B

The response to intravenous injection of protoveratrine was studied in nine patients with hypertension. In several of these patients a continuous pressure record was obtained with an indwelling arterial needle. After an injection of 0.15 to 0.21 mg. of protoveratrine the blood-pressure and pulse rate gradually fell, reaching their lowest levels in about 10 minutes. A substantial fall in blood pressure occurred in every case. Blood pressure and pulse rate returned to their original levels in two to three hours (Fig. 1).

FIG. 1.—Effect of intravenous protoveratrine A (0.18 mg.) on blood pressure and pulse rate in a man aged 55 and weighing 75 kg. (Case 1).

Patients were usually aware of a feeling of warmth in the chest and arms as the blood pressure fell, and occasionally hiccup occurred, but there was no nausea or vomiting. A further fall in blood pressure sometimes took place if the patient stood up while the hypotensive effect was at its greatest. The response of the blood pressure and pulse to Valsalva's manœuvre was, however, preserved. The response to intravenous protoveratrine was the same using protoveratrine A, protoveratrine B, or a mixture of the two alkaloids (Table I).

The amount of protoveratrine taken orally which caused a fall in blood pressure varied widely from patient to patient.

TABLE I.—Response to Intravenous Protoveratrine

Proto-veratrine	No. of Tests	Average Dose in μ g./kg. Body Weight	Average Initial B.P.	Average B.P. Fall
Mixture	3	3.2	193/102	81/42
A	5	2.3	197/126	64/44
B	4	2.3	231/128	65/24

In earlier trials a mixture of protoveratrine A and B in the ratio of two parts to one was used ("puroverine," Sandoz). Pure protoveratrine A then became available. The minimum effective oral dose of both these preparations was between 0.3 and 1.75 mg. of protoveratrine A.

Protoveratrine B was given to six patients in doses up to 4 mg. In only one was there any hypotensive effect. In this patient the blood pressure fell after 2 mg. by mouth, and 3 mg. caused toxic effects. Since protoveratrine B seemed ineffective by mouth in most patients (Fig. 2) subsequent trials were confined to protoveratrine A.

FIG. 2.—Comparison of oral protoveratrine A (1 mg.) and B (2 mg.) in man aged 40 and weighing 81 kg.

Protoveratrine A

The effect of single doses of protoveratrine A was examined in 20 patients with hypertension, a total of 65 administrations being made. A significant fall in blood pressure took place in 48 of these trials, the average fall being from 204/126 to 145/92 mm. Hg. A substantial fall in blood pressure could be obtained with a single oral dose in nearly every case. The blood pressure began to fall about one and a half hours after giving the drug and reached a minimum in about three hours. The hypotension lasted for at least two hours after this and often for much longer (Fig. 3). These findings suggested that effective control of blood pressure throughout much of the day might be expected with oral administration every six or eight hours.

FIG. 3.—Effect of single oral dose of protoveratrine A (mean of 10 patients). Average dose 0.7 mg. P.V.A.

Prolongation of Action.—In an attempt to prolong the effect of protoveratrine A taken orally, tablets were prepared by the manufacturers in which some of the drug was in the form of strongly compressed granules which would not dissolve for about two hours. A comparison of these tablets with those not so treated showed no difference in hypotensive action and no prolongation of effect. Tablets were subsequently prepared ("retard" form) in which one-third of the drug content was untreated and the other

two-thirds mixed with substances each of which delays absorption to a different degree. No attempt was made to measure the duration of action of these tablets by single oral dose, but they were employed in the therapeutic trial. It was found that somewhat larger doses of the "retard" tablets were needed to produce comparable effects, suggesting that the protoveratrine A in the "retard" tablet might be more slowly or possibly less efficiently absorbed.

Side-Effects.—These resembled those described using mixtures of veratrum alkaloids (Hoobler and Dontas, 1953). A feeling of warmth in the front of the chest and throat occurred most frequently, often with paraesthesiae of the fingers or mouth. Larger doses caused nausea, and sometimes vomiting. This was often sudden in onset with little discomfort. Hiccup was also frequent. Bradycardia was a constant feature. Two subjects with atrial fibrillation changed temporarily to a regular, possibly nodal, rhythm after 0.18 mg. of protoveratrine intravenously, and one patient in sinus rhythm periodically exhibited nodal rhythm over long periods on oral therapy. In the therapeutic trial the dosage was such that side-effects occurred in most subjects, but were not such as to interfere with their normal life. Severe hypotensive episodes occurred on two occasions with vomiting and loss of vision for several minutes but no permanent ill effects followed.

Therapeutic Trial of Protoveratrine A

Prolonged reduction of blood pressure with protoveratrine A given by mouth three or four times daily was attempted in 21 patients (11 males, 10 females) aged 24-69 with hypertension. The hypertension was severe as judged from the fundus oculi, the cardiac and cerebral complications, and the levels of blood pressure.

Evaluation before Therapy.—Left ventricular failure was present in 7 and triple rhythm in 13. Fundus oculi (Keith, Wagener, and Barker, 1939): grade 4 (papilloedema), 5 subjects; grade 3 (exudates and haemorrhages), 6 subjects; grade 2 (arterial changes only), 10 subjects. Radiographs of the chest showed varying degrees of left ventricular enlargement (cardiothoracic ratio, 42–64%—mean 53%). Renal function was investigated in all cases. Blood urea exceeded 50 mg./100 ml. in five patients. Intravenous pyelography was performed in most and was abnormal in three, but in none of these was surgical treatment thought advisable. The electrocardiogram showed evidence of left ventricular hypertrophy in 17 subjects. Complete right bundle-branch block obscured the picture in one subject, but this was lost while the patient was under observation, revealing the typical pattern of left ventricular hypertrophy. Cerebral vascular accidents had occurred in 12 of the 21 subjects and varying degrees of disability persisted. The reasons for attempting reduction of the blood pressure were as follows: retinopathy grade 4 or 3 in 10 subjects; cerebral vascular accidents in 12; left ventricular failure in 7; high blood-pressure readings alone in 2.

In-patient Treatment with Protoveratrine A

Hypotensive therapy was undertaken after an initial period of 5-20 days' rest in hospital. An appreciable fall in blood pressure commonly occurred during this time. After assessment of their response to single doses of protoveratrine A a group of 12 patients were observed in hospital for varying periods so that the effect of regular administration could be judged. The drug was given three to five times daily, the dosage being increased until satisfactory control of the blood pressure was obtained throughout the day or unpleasant side-effects appeared. In these circumstances it was possible to achieve a satisfactory control of the blood pressure in all cases for periods of up to two months. The average fall in blood pressure was from 201/124 to 173/106 mm. Hg, and in seven subjects the diastolic pressure was maintained below 100 mm. Hg. The effective dosage varied widely, from 0.9 to 4.3 mg. daily. In no case did side-effects occur more often than on alternate days.

Protoveratrine was given intramuscularly to two patients, using a mixed preparation of A and B alkaloids in a dose of 0.3 to 0.4 mg. three times a day with an adequate blood-pressure fall in both subjects. Transfer to oral therapy was carried out later without increase in the frequency of side-effects.

Out-patient Treatment with Protoveratrine A

Following the in-patient observations of the hypotensive effect of protoveratrine A, 8 of the 12 patients studied were followed as out-patients taking three to four doses daily for long periods. To this group were added nine subjects who had shorter periods of in-patient treatment or had been started on protoveratrine A as out-patients. These patients were encouraged, and were indeed able, to lead normal active lives. Periods of treatment alternated with periods either without therapy or on placebos in six of the patients. Since patients were very soon aware of the absence of side-effects with the inert tablets the use of placebos was thought unhelpful. The duration of treatment has been from one month to as long as two years (mean nine months). The total treatment months were 155. The dosage employed varied from 0.5 to 3.6 mg. daily. The drug was taken three times daily after meals and an additional dose often on retiring. It was sometimes possible to give a larger dose after breakfast than later in the day. The aim was to give as large an amount of protoveratrine A as could be tolerated. This generally led to the occasional occurrence of unpleasant side-effects such as nausea or vomiting, but the patient was encouraged to adjust the dosage so that these did not occur more than once a week. Where the dosage had been determined during a period in hospital it was commonly found that alteration was necessary after the patient returned to normal life; the amount tolerated was generally less than while in hospital.

Of the 17 patients in this group, treatment is being maintained in seven. The results as judged by blood-pressure levels and objective improvement may be regarded as good

TABLE II.—Long-term Treatment with Oral Protoveratrine A

Case No.	Sex and Age	Duration of Treatment	Initial B.P.	Average B.P. During Treatment	Daily Dosage (mg.)	Remarks
1	M 40	11 months	225/145	175/105	1.8-3.6	Malignant hypertension. Good result (see text)
2	M 56	8 "	255/150	210/115	3-6	Good result
3	M 42	16 "	200/145	195/105	1.5-3.0	Good result. Diabetic
4	F 41	8 "	170/120	140/100	1.4-2.7	Fair result
5	M 39	9 "	240/135	200/120	3-0	Malignant hypertension. Fair result. Papilloedema lost
6	F 46	5 "	265/150	240/125	1-8	Fair result
7	M 45	19 "	185/125	185/120	0.5-1.4	Poor result. Paroxysmal A.F. disappeared

in three and fair in three others (Table II). The case of one patient with an excellent response is described in more detail below.

Case 1.—A man aged 40 had had pulmonary tuberculosis successfully treated by a left thoracoplasty in 1936. He attended hospital because of increasing dyspnoea, and the casual blood pressure was 250/160. Pulsus alternans and a pre-systolic triple rhythm were noted. There was papilloedema with many exudates and haemorrhages, and the electrocardiogram showed left ventricular hypertrophy. In hospital the blood pressure fell from 225/145 to 190/120 mm. Hg over a period of 17 days. Treatment with protoveratrine A for 14 days reduced the blood pressure to 155/105 without any side-effects, and improvement in the papilloedema was noted. Out-patient therapy for 14 months with protoveratrine A 1.8 to 3.6 mg. daily has maintained the blood pressure at 175/107 with nausea only two or three times a month. The papilloedema, retinal haemorrhages, and exudates disappeared in five months, and there was marked improvement in the electrocardiogram (Fig. 4).

Treatment was regarded as unsatisfactory in 10 patients. In five of these the drug was stopped because the therapeutic

response was inadequate, high blood pressures continuing while the maximum tolerated dose was being given. Two patients who exhibited a fair response over several months' treatment developed complications of their hypertension—one cardiac failure after nine months and the other a cerebral thrombosis after 12 months. Treatment must be judged to have failed in these cases.

Three patients died. One had a fair response to protoveratrine initially, but control of the hypertension became

progressively more difficult and he died from cardiac failure and uraemia. One man with malignant hypertension from chronic nephritis responded satisfactorily at first but renal failure supervened. The third was treated for three months with satisfactory control of blood pressure but died from cardiac infarction during a control period without treatment.

The effective dosage of protoveratrine A in any single patient was not found to alter greatly either in the first few days or after months of treatment. No evidence was obtained of the development of tolerance to the drug. In two patients subject to paroxysmal atrial fibrillation the frequency of attacks was much diminished during treatment with protoveratrine A. In five subjects reserpine 0.5-1.5 mg. daily was added to the treatment when the full effect of protoveratrine A had been obtained. No further fall in blood pressure occurred, and no change was seen in the effective dose of protoveratrine A or in the frequency of side-effects.

Discussion

The intravenous administration of protoveratrine A and protoveratrine B demonstrated that they were equally effective hypotensive agents by this route. Oral administration of the two substances revealed a marked difference in their activity. While protoveratrine A could be relied upon to cause a fall in blood pressure provided a sufficient amount was given, protoveratrine B was clearly much less potent by this route, and the activity of a mixture of the two seemed to depend solely upon its content of protoveratrine A.

Trials of protoveratrine A given in divided doses to in-patients suffering from hypertension showed that it was possible to lower the blood pressure significantly in the majority of patients without serious side-effects. The prolonged administration of protoveratrine A to a group of out-patients with severe hypertension proved rather

FIG. 4.—Effect of treatment on the electrocardiogram in Case 1. Left, August 19, 1955; right, February 1, 1956.

disappointing. The drug had to be given to the limit of tolerance, so that side-effects occurred at some time in all patients, but these in fact were not such as to interfere with their normal lives. In 3 of 17 patients the treatment was regarded as thoroughly satisfactory. Objective improvement and a reduction in blood pressure were obtained over long periods. Another three patients were thought to be improved, but the fall in blood pressure was less impressive. In the remaining 11, although there was sometimes a fall in pressure the overall effect was judged to be unsatisfactory.

As with the other less purified veratrum preparations, the amount of protoveratrine A which can be given is limited by the occurrence of unpleasant side-effects. No direct comparison has been made with the preparations of veratrum viride, but it is clear that only a minority of patients are able to tolerate therapeutically effective amounts of protoveratrine A.

The effect of protoveratrine on the heart has occasionally been demonstrated. Atrial fibrillation temporarily reverted to a regular, apparently nodal rhythm in two patients, and one patient in sinus rhythm periodically exhibited nodal rhythm while on treatment.

In the somewhat limited group of patients who can tolerate an effective dose over long periods protoveratrine A has distinct advantages over other hypotensive agents. It should be considered for the treatment of patients with severe hypertension where oral therapy is preferred, especially those in which treatment with ganglion-blocking drugs is not thought desirable. The risks inherent in the abrupt fluctuations of blood pressure found with effective doses of these drugs are avoided and paralysis of the bowel and bladder does not occur.

Conclusions and Summary

Protoveratrine is a mixture of two closely related ester-alkaloids, protoveratrine A and protoveratrine B. These substances have been shown to be equally potent hypotensive agents when administered intravenously. Hypotensive activity when given by mouth seems to be practically confined to the protoveratrine A fraction.

The response to oral administration of protoveratrine A has been studied in a group of hypertensive patients. A trial of long-term therapy in 17 patients is described. The effectiveness of the drug was limited by side-effects. The results of treatment were judged to be good in three, fair in three, and unsatisfactory in 11 patients. The place of protoveratrine A in the treatment of hypertension is discussed.

We thank Dr. D. Evan Bedford for his encouragement in this work and Dr. H. Holgate, of Sandoz Ltd., for much assistance and generous supplies of protoveratrine. We are grateful to Mrs. Connolly, of the photographic department of the Institute of Cardiology, for her help in preparing the illustrations.

SUPERFICIAL GLANDULAR TUBERCULOSIS

TREATMENT WITH CHEMOTHERAPY

BY

G. S. KILPATRICK, M.D., M.R.C.P.Ed.

AND

A. C. DOUGLAS, M.B., M.R.C.P.Ed.

From Southfield Hospital and the City Hospital, Edinburgh,
and the Department of Tuberculosis and Diseases of
the Respiratory System, University of Edinburgh

Much has been written for many centuries about superficial glandular tuberculosis. Several theories regarding its pathogenesis have been suggested and many treatments have been tried, but, in general, glandular tuberculosis is a notoriously chronic relapsing disease which is unsatisfactory to treat. While the number of cases is now probably falling, it can still be a serious and often disfiguring condition.

Interest has been aroused in antituberculous drugs for the treatment of glandular tuberculosis by the satisfactory results which can be achieved by their use in the treatment of other forms of tuberculosis, and this paper is a report of our experience of 52 cases of superficial glandular tuberculosis treated by antituberculous chemotherapy.

Material and Methods

The 52 cases comprise a heterogeneous collection derived principally from two Edinburgh hospitals. They were seen between 1952 and June, 1955, and have been followed up to June, 1956: all have therefore been observed for at least one year. The age extremes of the 52 patients (37 females, 15 males) were 4 and 67 years, 13 (8 females, 5 males) being 15 or less. The cervical region was affected in 50 and the axillary in two. In six of those with cervical adenitis the glands were bilaterally involved. Of the 44 with unilateral disease the right side was affected in 30 and the left in 14. The proneness of tuberculous glands to relapse is shown by the history obtained from 46% of our patients (24 out of 52) of at least one previous glandular episode. Radiological evidence of either active or inactive pulmonary tuberculosis was found in 26 cases (50%). A persistently negative Mantoux test was recorded in two patients; one, a girl aged 17, had histologically proved tuberculous granulation tissue in a neck gland removed surgically, while the other, a girl aged 8, was one of a series of cases which comprised a small epidemic of tuberculosis traced to an infected cow.

Only two patients had had previous antituberculous chemotherapy before coming under our observation and in each case it was for a short period of time. In all but three of the cases the glandular disease was present when the patients were first seen. The exceptions were three females aged 18, 26, and 37 with miliary tuberculosis in whom tuberculous cervical adenitis developed while they were under observation in hospital and after they had had five, six, and five months' good chemotherapy.

In most cases the diagnosis of tuberculous adenitis was originally made on clinical grounds, but in 23 it was confirmed either bacteriologically or pathologically. The assessment of progress in patients with tuberculous adenitis is not easy, and, though we have personally seen most of the patients at regular intervals, the recorded happenings can only be clinical impressions. In general, fluctuation, discharge, the persistence of large gland masses, or sinus formation has been regarded as an unsatisfactory result. Satisfactory treatment, in addition to causing a retrogression of the glands, must reduce the relapse rate, and to show this a long-

term follow-up of cases is essential. Of our 52 cases, 26 have been observed for 12 to 23 months, 21 for 24 to 35 months, four for 36 to 47 months, and one for 51 months. This paper should be regarded as an interim report.

All the patients had antituberculous drugs, but these were given for varying lengths of time. A few of the earlier cases did not have what we would now regard as entirely satisfactory chemotherapy; some, for instance, had courses of less than six months, while others had what we now believe to be unsuitable combinations of drugs, such as intermittent streptomycin and P.A.S. Details of the chemotherapeutic regimes are given below.

Results

For the purpose of analysis the results are considered under four headings.

Wholly Satisfactory

This group of 31 patients (21 females, 10 males) comprises those in whom there has been a satisfactory retrogression of the condition. Twenty of them were treated as in-patients. Twenty-two had chemotherapy only, while nine had surgery in addition. In 15 there was a history of at least one previous glandular episode. The chemotherapy was, in general, daily streptomycin and isoniazid followed by daily P.A.S. and isoniazid, while the duration of chemotherapy ranged from 2 to 21 months, with a mean of 9.3 months. Of these 31 patients, 29 have completed chemotherapeutic treatment and two are still having the drugs.

Unsatisfactory Course—Satisfactory End-result

This group of 13 patients (10 females, 3 males) comprises those in whom the end-result was satisfactory but in whom the course of the disease was unsatisfactory because fluctuation or sinus formation occurred before an eventual satisfactory result was obtained. Twelve were treated as in-patients. Five required surgical intervention and five gave histories of previous episodes. The chemotherapy was, in general, daily streptomycin and isoniazid followed by P.A.S. and isoniazid. In two patients, while it is strictly true to say that the end-result was satisfactory so far as the adenitis was concerned, there was considerable neck scarring. In each case previous glandular episodes had occurred and the scarring was present before the patients came under our observation. Both of them may eventually require plastic surgery.

Pending

In two female patients the treatment has so far failed. It is hardly surprising that one of them, aged 63, did not respond to treatment as she was a diabetic, with a history of a previous gland episode, who had been given unsatisfactory chemotherapy. She also had pulmonary tuberculosis and this deteriorated at the same time as the adenitis. Tubercle bacilli in the sputum were eventually found to be resistant to streptomycin, P.A.S., and isoniazid. On the other hand, it was disappointing that a girl, aged 16, with cervical adenitis and pulmonary tuberculosis who had had what we believed to be satisfactory treatment should not have done well. She had been in hospital for 11 months having daily streptomycin and isoniazid (her pre-treatment organisms being sensitive to these drugs) and had just completed a convalescent period following a segmental pulmonary resection when her adenitis recurred while she was still on chemotherapy. The old sinus broke down to discharge pus in which acid- and alcohol-fast bacilli were found; these did not grow on culture.

Relapses

The six patients (four females, two males) in this group were regarded as having a satisfactory end-result following chemotherapy, but their adenitis recurred after the chemotherapy had been discontinued. A relapse is defined as an exacerbation of the condition (gland enlargement, fluctuation, or sinus formation) that necessitated further treatment.

The mean duration of chemotherapy in this group was 8.5 months. It may be useful to consider these patients in more detail.

Case 1.—A girl aged 6 with cervical adenitis but no history of previous episodes was treated as an out-patient by daily P.A.S. and isoniazid for 10 months. One month after the cessation of chemotherapy the glands increased in size suddenly to become fluctuant, but no sinus formation occurred.

Case 2.—A girl aged 18 with cervical adenitis of recent onset was treated by daily streptomycin and P.A.S. as an in-patient for three months and for a further three months as an out-patient. Seven months after treatment had been stopped the adenitis recurred and fluctuation became apparent.

Case 3.—A girl aged 18, who had had three previous glandular episodes, was treated, apparently successfully, by means of daily streptomycin and isoniazid as an out-patient for six months. For 13 months after this she had no trouble, but the adenitis then recurred and fluctuation became obvious.

Case 4.—A woman aged 23 who had had two previous cervical glandular episodes, was treated as an out-patient by daily streptomycin and P.A.S. for three months followed by daily P.A.S. and isoniazid for seven months. Later, however, on close questioning it became apparent that latterly the drugs were taken very irregularly, if at all. Despite this a discharging sinus became dry after six months' treatment and she had no further trouble for seven months after her treatment was officially stopped, when the sinus broke down once more, this coinciding with early pregnancy.

Case 5.—A boy aged 12 with cervical adenitis and no history of previous episodes was treated with P.A.S. and isoniazid as an out-patient for 15 months. There was a satisfactory reduction in the size of the gland mass, but two weeks after stopping chemotherapy the glands again became markedly enlarged.

Case 6.—A man aged 36, with cervical adenitis and a previous history of this condition, was treated as an out-patient with streptomycin thrice weekly and P.A.S. daily for three months. The condition recurred 10 months later.

While it is inadvisable to attempt to draw many conclusions from this small number of patients, three factors may well be of importance: duration of chemotherapy, type of chemotherapy, and out-patient treatment. Cases 2, 3, and 6 had courses of chemotherapy which we would now consider too short, while Cases 1 and 5 did not have streptomycin. The type of chemotherapy given may be of importance, as a certain proportion, probably now a small proportion, of cases of tuberculous adenitis are caused by the bovine type of bacillus. Some strains of bovine bacilli are known to be primarily P.A.S. resistant (Wallace and Webber, 1956), so that it is possible that resistance also developed to the second drug, streptomycin or isoniazid. We have been unable to test this theory, as in none of these relapses have we been able to culture tubercle bacilli.

With the exception of one patient (Case 2), who was treated in hospital for three months, all those who have relapsed had out-patient treatment only. This may well be of importance, as it is known that a proportion of patients having ambulatory chemotherapy do not take the drugs prescribed (Simpson, 1956); Case 3 is an example of this.

Five of the six patients in this series who relapsed have been re-treated with chemotherapy, so far with satisfactory results. The remaining patient had an isolated residual gland removed surgically.

Surgery

The place of surgery in tuberculous adenitis is difficult to assess, but its employment must be considered in relation to neck scarring. The considerations are largely aesthetic ones and different workers may have different views. For example, is it better to have a tidy surgical scar rather than risk the inevitable scarring subsequent upon sinus formation? On the other hand, a satisfactory medical treatment should remove the possibility of either. No fewer than 40 (77%) of the 52 patients had a neck scar, or scars, at the end of the period of observation. These patients may be subdivided as follows:

1. Neck Scars from Any Cause Present Before Coming Under Our Observation (24 patients: 15 females, 9 males).—The reasons for scarring were as follows: biopsy 6, sinus formation 7, incision 8, excision 3.

2. *Scar of a Simple Incision* (7 patients: 6 females, 1 male).—This type of scar is usually the least obvious. In each instance a simple incision was made when fluctuation became apparent or when aspiration failed. All seven cases responded well and none developed a sinus.

3. *Scar Resulting from a Formal Gland Excision* (8 patients: 6 females, 2 males).—In each of these cases elective surgery was done because of a persisting large gland mass or because of a chronic sinus.

4. *Scar Resulting from Sinus Formation* (8 patients: 6 females, 2 males).—The scarring that follows sinus formation can be very disfiguring, and it is of interest to review the cases in which a sinus developed while they were under observation. In four instances the adenitis had been recurrent and a scar which was already present broke down after one week, one week, six weeks, and five months of chemotherapy. In the remaining four cases sinus formation developed after two weeks, two months, six months, and eight months of chemotherapy. It is possible that in patients who developed a sinus within one to two weeks the condition was so far advanced toward sinus formation that treatment could not be expected to prevent it. In the remaining cases it is possible that earlier incision rather than repeated aspirations might have prevented sinus formation.

Discussion

No controlled trial of the treatment of glandular tuberculosis has ever been made, and, while various methods of treatment have been recommended, case selection has inevitably affected the published results. For example, the method of treatment chosen will almost certainly depend on whether the patients are seen by a general surgeon, general physician, paediatrician, or tuberculosis physician. Our own series of cases is no exception.

As we are not reporting the results of a controlled trial, and because of the dangers of extrapolation from previous experience for comparison purposes, it is impossible to say with certainty whether chemotherapy has hastened the healing process in our patients, although we believe that it probably has done so. Comparison with other authors' series is also difficult because of the different age groups of patients treated, the different drugs used, and different duration of treatment. Bailey (1945, 1948), Evans (1952), and Ross (1953) consider that surgical intervention will be required in most cases, while antituberculous chemotherapy, with or without surgical treatment, has been recommended by several authors (Lester, 1951; Morris and Prosser-Evans, 1951; Hasche-Klinder, 1953; Gale, 1953; American Trudeau Society, 1954; Sen, 1955; Lester and Jones, 1956; Butler, 1956).

Successful results have been claimed for other methods of treatment, such as radiotherapy of the affected glands (Lampe *et al.*, 1949; Aceto *et al.*, 1953) and the systemic administration of nitrogen mustards (Bovo and D'Agnolo, 1953). Many authors have recommended tonsillectomy in children with cervical tuberculous adenitis (Swenson and Small, 1952; Kendig and Wiley, 1955). This has been done only once in our series, admittedly with a satisfactory result, as the adenitis immediately subsided. We have not been impressed by the amount of tonsillar disease present in our patients, but they were mainly in the older age groups. We have occasionally used calciferol (Gauvain, 1948) and tuberculin, but we have insufficient experience of these drugs to comment on their usefulness.

The predominance of females in this and in other series (Thompson, 1940; Sen, 1955) makes the cosmetic result a very important criterion of success, and, while we have confirmed the findings of others that no immediately dramatic results may be expected from the chemotherapeutic treatment of tuberculous adenitis, it is our impression that the results achieved to-day are better than those obtained previously.

Plan of Treatment

As a result of our experience the following plan of treatment is suggested. A patient presenting for the first time with adenitis of any extent is admitted to hospital to ensure adequate rest, supervision of chemotherapy, and minor

surgery at the optimum time if it is required. Chemotherapy is given in the form of 1 g. of streptomycin sulphate daily and 100 mg. of isoniazid twice daily to patients under 40 years. To prevent the onset of giddiness caused by streptomycin, older patients are given 1 g. of streptomycin thrice weekly together with 5 g. of sodium P.A.S. and 100 mg. of isoniazid twice daily. These regimes have been shown to prevent the emergence of drug-resistant organisms in pulmonary tuberculosis. While we believe that streptomycin and isoniazid daily is the best and safest form of therapy, because of the possible risk of encountering primarily P.A.S.-resistant organisms, it may be justifiable to use isoniazid together with P.A.S. in the doses already indicated when the patient is discharged from hospital after a satisfactory initial course of treatment. In either case it is considered that the chemotherapy should be prolonged, at least 12 to 18 months' treatment being required.

When there is obvious fluctuation the pus is either aspirated as necessary or a small incision is made. If aspiration is undertaken streptomycin is sometimes inserted into the cavity, but care must be taken not to maintain too much tension as the overlying skin is often in a precarious state. If a sinus forms it is allowed to drain in the usual way, but it is felt that an early small incision to achieve dependent drainage may do much to prevent excessive scarring.

It is thought that elective surgical intervention may be less frequently required now, but it has been our practice to remove isolated large gland masses when these have failed to respond to four to six weeks' chemotherapy and occasionally to operate on patients thought, or known, to be unreliable in the taking of chemotherapy.

Summary

Antituberculous chemotherapy was given to 52 patients with superficial glandular tuberculosis. All were followed up for at least one year. Of the 52 patients, 44 (85%) may be regarded as having a satisfactory end-result. In two the result is still pending but treatment has so far failed, and in six the adenitis recurred after cessation of chemotherapy. These cases are discussed in detail. From our experience we believe that the best results are likely to be achieved by means of initial hospital treatment, which ensures adequate bed rest, supervision of antituberculous chemotherapy, and provision for minor surgery, if it is required, at the optimum time. It is further recommended that the chemotherapy should be given for at least 12 to 18 months.

We thank Professor John Crofton and Dr. N. W. Horne for their advice and encouragement during the preparation of this paper.

MALIGNANT CHANGE FOLLOWING HERPES SIMPLEX

BY

R. WYBURN-MASON, M.D.

Late Gordon Jacob Research Fellow, Royal Marsden Hospital, London

In 1955 I described a series of cases in which herpes zoster of the skin or breast was followed after a variable period by malignant change in the affected tissues (Wyburn-Mason, 1955). During the investigations at the Royal Marsden Hospital there were also observed a number of cases of malignant change in the skin of the lip which were preceded by herpes simplex. No mention of herpes simplex as a premalignant condition has been found in an exhaustive search of the literature. A brief account of six of these cases follows.

Case Reports

Case 1.—Man aged 65. For five years he had been subject to recurrent herpes at the right angle of the mouth. After the last attack three months prior to hospital attendance a lesion had persisted, gradually increased in size, and bled from time to time. On examination a circular raised ulcer with everted edge was present, measuring 1.5 cm. in diameter (Fig. 1). Biopsy showed the lesion to be a squamous carcinoma.

Case 2.—Man aged 72. Three years previous to hospital attendance he developed herpes of the left upper lip. This was followed by the formation of a wart and by recurrent

herpetic attacks in the same area. After the last attack, four months previous to examination, a growth had appeared (Fig. 2) and biopsy showed the presence of a squamous carcinoma.

Case 3.—Man aged 62. Eight weeks prior to attendance he developed herpes of the right upper lip, which almost healed within a

fortnight, but then broke down again and ulcerated, gradually increasing in size and bleeding at intervals. The appearance is shown in Fig. 3. Biopsy showed the lesion to be a squamous carcinoma.

Case 4.—Woman aged 67. Seven weeks prior to attendance she developed a severe coryza, during which there appeared extensive herpes of the lower lip and the right angle of the mouth spreading on to the cheek. The lesion healed within a fortnight, except for a small area near the angle of the mouth, and during the next four weeks this rapidly increased in size and began to bleed. Biopsy showed the presence of a squamous carcinoma.

Case 5.—Woman aged 65. Eighteen months prior to hospital attendance she developed herpes of the left lower lip, which continually healed and broke down, particularly after exposure to sunlight. After such an exposure some three months prior to hospital attendance the lesion appeared, failed to heal, and then rapidly increased in size and began to bleed. It was found on biopsy to be a squamous carcinoma. She was treated with x rays with complete healing. Eighteen months later, after a further exposure to sunlight, she developed a fresh herpes in the same area.

Case 6.—Man aged 65. A year previous to attendance he pulled a piece off the lower lip with a cigarette. Next day herpes appeared in the denuded area and spread to involve the entire mucocutaneous margin of the lower lip. This was followed by crusting and bleeding after mild trauma, but never by complete healing (Fig. 4). Biopsy a year after the onset showed the presence of a squamous carcinoma. He was treated by x rays with complete healing. A year later, after exposure to sunlight, he developed a further herpetic lesion in the original area.

Discussion

The six patients were aged between 60 and 70 years at the time of onset of the herpetic lesion. One (Case 2) developed a wart, and two (Cases 5 and 6) showed recurrence of the herpes when exposed to sunlight. Such an abnormal sensitivity to sunlight is also observed in the skin of tar-workers, those exposed to x rays and arsenic, and in cases of xeroderma pigmentosa, in all of which malignant change may also occur in the affected skin. The cases described are of more than academic interest, as they might serve as evidence of the virus theory of cancer causation. It is important to consider certain observations about herpes simplex (see Van Rooyen and Rhodes, 1948; Stoker, 1957).

The pathological changes of herpes simplex or zoster and herpetiform lesions are those of an inflammation with oedema between the epidermal cells, and there is nothing specific about the changes. Herpes simplex and herpetiform lesions may be produced by many different factors, which include general infections or intoxications; respiratory infections; the administration of drugs, such as arsenic, antigenic substances, or antisera; the local application of irritant (blistering) agents; or chronic exposure to tar, x rays, etc. They may also occur on skin which is the site of causalgic

FIG. 2.—Case 2.

FIG. 3.—Case 3.

FIG. 4.—Case 6.

pain. In cases of herpes zoster the same type of lesion is produced as a result of disturbance of the innervation of the affected part. The virus of herpes simplex is the causative agent not only of herpes on the lips or nostrils, but also of herpes genitalis and cornealis, herpetic (aphthous, Vincent's, or ulcerative) stomatitis, eczema herpeticum (a type of Kaposi's varicelliform eruption), and meningo-encephalitis. The last three conditions do not recur, but many individuals are subject throughout life to recurrent attacks of herpes around the lips and nose, of the genitalia, or of the cornea, and these develop in response to non-specific stimuli, such as sunburn, fever, or trauma and not through exposure to another source of herpes virus. In women, recurrence is often associated with the menstrual periods.

The vesicle fluid from herpes simplex lesions affecting the face, genitalia, or cornea may produce herpetic vesicles when inoculated into the skin or keratitis when applied to the conjunctiva of the rabbit, and it is therefore usually considered that all simple herpetic lesions are due to the same virus. There is, however, some doubt whether a virus can be demonstrated in all herpetic simplex lesions. According to Stoker, "there is no doubt that the virus is present during each of these recurrent attacks, because it can invariably be isolated in the early stages." It has been suggested (Burnet and Williams, 1939) that in recurrent cases herpetic infection occurs in childhood and persists throughout life. This is based on serological and skin tests, the sera of most adults containing antibodies against the virus. It is supposed that the virus remains within the epidermal cells, dividing with them, and normally causing no damage. A number of non-specific stimuli which lead to cell breakdown may release the virus particles.

Stalder and Zurukzoglu (1936) showed, however, that areas of facial skin subject to recurrent herpes no longer developed the disease if transplanted to another part of the body. Yet a recurrent attack usually occurs in roughly the same site. Because of this some favour the central nervous system, dorsal root ganglia, or cutaneous nerve endings as the permanent home of the virus. In this respect it will be recalled that the lesions of herpes zoster, which are due to infection with the herpetic zoster virus, are identical pathologically with those of herpes simplex, but the causative lesion for the skin change is found in the posterior nerve root ganglia (Lewis, 1927). It is thus by no means certain that the lesions of herpes simplex are always due to, or contain, a virus affecting the skin. It seems possible that this type of tissue reaction in the skin may result from various forms of irritation, of which the herpes simplex virus is one example; that even in recurrent cases of herpes simplex local irritation plays a part in causing the recurrence, and that, as in cases of herpes zoster, disturbance of local nerve fibres may be a factor in causing this.

Whatever the explanation of recurrent herpes simplex, it seems that the appearance of the original lesion may predispose to malignant change in elderly subjects. Malignant change following herpes simplex may simply be an example of what may occur, especially in elderly subjects, at the site of any chronic irritation or inflammation, such as eczema or psoriasis, and not the specific result of virus infection. On the other hand, if all, and particularly recurrent, cases of herpes simplex are due to local infection with herpes simplex virus, and since the subjects may exhibit abnormal sensitivity to sunlight as do tar-workers and those subject to x rays or arsenical dermatitis and xeroderma pigmentosa, it may be that infection by the virus, which is widespread, is an important cause of malignant change. Since the buccal mucosa and the skin of the genitalia and other tissues may also be infected by herpes simplex there is a possibility that in some cases in these tissues, too, the infection may be related to the later appearance of malignancy.

Summary

Six cases of herpes simplex of the lips in old people followed by the development of squamous carcinoma

six weeks to five years afterwards are described. The significance of the observation in relation to the virus theory of cancer causation is briefly considered.

The above observations were made while holding a Gordon Jacob Research Fellowship at the Royal Marsden Hospital. I should like to express my thanks to the Medical Committee of the hospital for permission to publish the brief case histories.

MOTOR COMPLICATIONS OF HERPES ZOSTER

BY

DAVID KENDALL, D.M., M.R.C.P.

Neurologist, South-west Metropolitan Regional Hospital Board

The occasional appearance of muscular weakness in association with herpes zoster has been recorded in numerous papers since Broadbent (1866) described a patient with extensive weakness of an arm preceded by a herpetic eruption. Head (1899) quotes as examples an eruption in the territory of the first dorsal root with severe hand weakness, ophthalmic herpes with oculomotor palsy, and facial palsy with an eruption in the second and third cervical area. Taylor (1896) drew attention to the occasional presence of weakness of the abdominal muscles with herpes of the trunk, and Ford (1944) has suggested that localized weakness of intercostal or abdominal muscles may be quite common, but may often pass unnoticed in the absence of disability. Other cases of lower motor neurone paralysis have been described by Joffroy (1882), Waller (1885), Buzzard (1902), and more recently by Cornil (1930), Barham-Carter and Dunlop (1941), Taterka and O'Sullivan (1943), Parkinson (1948), Scobey (1949), and McIntyre (1951).

Evidence of direct involvement of the central nervous system was first observed by Brissaud (1896) and has since been described by Lhermitte and Nicolas (1924), Lhermitte and Vermes (1930), Worster-Drought and McMenemey (1933-4), and Whitty and Cooke (1949). Following the observations of Lhermitte and Nicolas of segmental changes in the spinal cord at the affected level, it has been suggested that the root entry zone of the cord is often if not always affected, and that many of the anomalous clinical findings in herpes zoster can best be explained by regarding the condition as a disease of the central nervous system in addition to the posterior root ganglion.

Denny-Brown, Adams, and Fitzgerald (1944) examined at necropsy the nervous system of a patient who had had the "Ramsey Hunt syndrome" and found no significant change in the geniculate ganglion. It has become well known since Ramsey Hunt's (1907) original description that wide discrepancies occur from patient to patient in the distribution of the eruption in relation to the facial palsy. Denny-Brown *et al.* postulated that herpes zoster may therefore be primarily a unilateral segmental polio-

myelitis in which the brunt of damage falls upon the dorsal part of the spinal cord, a view previously put forward by Wohlwill (1924) and since supported by most other writers.

The cases described below show the considerable variation that occurs in the site and type of paralysis and the anatomical discrepancies between the cutaneous and nervous manifestations of the disease.

Herpes Involving Cranial Nerves

Case 1.—A man aged 60 began to have severe pain in the left side of the forehead on December 1, 1951. Two days later an extensive herpetic eruption appeared in the territory of the first and second divisions of the left trigeminal nerve. Twenty-four hours later he awoke to find the left eye closed, and was subsequently found to have a complete paralysis of the left third nerve. During the next three months he recovered from the ocular palsy with the exception of a mild degree of ptosis. The area of the skin supplied by the ophthalmic division of the left fifth nerve was anaesthetic and has remained so.

Case 2.—A woman aged 65 developed severe pain on the left side of the face on November 5, 1954, and a vesicular rash appeared in the territory of the second and third divisions of the left trigeminal nerve, on the left side of the tongue, and on the left side of the neck from C2 to C4. Two weeks later a complete left facial palsy appeared, with loss of sense of taste on the left side of the tongue. Recovery was complete in six months, without residual neuralgia.

Case 3.—In November, 1954, a man aged 62 developed a very severe left-sided ophthalmic herpes with corneal ulceration. Two weeks later a complete left facial palsy appeared and was associated with a generalized herpetic eruption on the trunk and limbs. Taste was lost on the affected side. (See Fig.) Complete motor recovery took place within two months.

Case 4.—A 70-year-old man experienced pain in the left mastoid region for 10 days. This was followed by a herpetic rash on the left pinna and by vesicles on the left faucial pillar. Almost simultaneously a complete left facial palsy appeared and was associated with a moderately severe left-sided nerve deafness. The latter remained permanently, but the facial palsy had recovered within three months.

Case 5.—A woman aged 81 developed a very extensive vesicular eruption extending from the left side of the vertex over the trigeminal area, the left side of the neck, and the left shoulder. A week later a complete left facial paralysis occurred with loss of taste. This was still present four months later, when she also had severe and diffuse neuralgic pain.

Case 6.—A man aged 45 developed chicken-pox on May 15, 1955. Three weeks later, when the last crust had almost disappeared, he developed a complete left facial palsy without impairment of sense of taste. Recovery was complete in three weeks.

Case 3. Photograph showing complete left facial palsy and extensive herpetic eruption.

Herpes with Flaccid Limb Paralysis

Case 7.—A woman aged 55 was first seen in August, 1954, three weeks after the onset of a severe herpetic eruption extending from the region of the right deltoid muscle, along the outer side of the arm to the radial side of the forearm. Simultaneous with the appearance of the rash, severe weakness of the hand and forearm was noticed. Examination showed complete paralysis of all the intrinsic muscles of the right hand, with severe weakness of the wrist and finger flexors. There was no weakness of the extensor muscles or of any muscles acting on the elbow or shoulder. Moderate recovery took place in about 18 months, leaving quite severe residual weakness and wasting of the interosseous muscles.

Case 8.—In September, 1951, a woman aged 57 had an extensive eruption in the distribution of C7-8 and T1 on the left side. At the same time the right trapezius, deltoid, pectoral, spinatus, and serratus muscles became completely paralysed. All the tendon reflexes in the right arm were abolished. There was complete cutaneous anaesthesia in the C6-7 area. Recovery was complete in five months.

Case 9.—In July, 1951, a 76-year-old woman had a moderately severe herpetic rash in the left C6 area, with moderate pain. This healed, with some scarring, in about six weeks. Two weeks later severe lancinating pain was experienced throughout the affected arm and was rapidly followed by complete paralysis of the whole arm. Examination showed a flicker of contraction in the triceps and extensor digitorum communis only; all other muscles acting on the left upper limb were paralysed; the tendon reflexes were absent; and there were severe impairment of cutaneous sensation corresponding to C8-T1 and loss of postural sensibility in the fingers. Recovery was very slow, but within nine months was complete in the shoulder muscles, biceps, and triceps. Weak grip returned in one year, but the hand remained very weak, with severe wasting of intrinsic muscles. Normal sensation returned within six months.

Case 10.—Two weeks after being exposed to chicken-pox a woman aged 23 developed a very severe and extensive herpetic eruption extending from C2 to D2 on the left side. Simultaneously she developed moderate weakness of the left deltoid, biceps, and triceps muscles. The biceps and triceps reflexes were lost. The next day a generalized herpetic eruption appeared and was associated with headache, fever, confusion, and slight nuchal rigidity. Recovery was uneventful and was complete within two months.

Case 11.—In October, 1954, a woman aged 60 developed severe pain in the right shoulder followed after four days by an eruption in the area C2-6 on the right side. Ten days later complete paralysis of all muscles acting on the right shoulder and elbow developed, together with moderate weakness of the right hand. When examined four weeks from the onset there was minimal herpetic scarring over the neck and shoulder. Good grip was present, but she had severe wrist-drop and all other muscles in the right upper limb were paralysed. All the tendon reflexes in the arm were lost and there was dulling to perception of pin-prick over C5-6. Recovery was progressive over 18 months, and after two years there was only minimal weakness in abduction of the shoulder.

Herpes with Involvement of Spinal Tracts

Case 12.—A married woman aged 38 noted the sudden onset in May, 1956, of pain in the right side of the chest associated with a weakness of the right lower limb. At that time a rash appeared in the painful area, at first petechial, later vesicular. About 24 hours later she complained of numbness of the left leg and left side of the abdomen. When examined three weeks from the onset there was evidence of a healing and quite slight herpetic rash corresponding to D6-7 on the right side. She had a mild spastic

weakness of the right lower limb with an extensor plantar response, and impairment of superficial sensation on the left side below D 7. Three months later full motor recovery had taken place, but there was still some subjective alteration of sensation in the left lower limb.

Case 13.—A married woman aged 35 experienced the sudden onset of severe pain between her shoulders, radiating to the right breast. Twenty-four hours later a rash of moderate severity appeared in the distribution of D 5 on the right. During the following week she noticed an increasing weakness of the right leg, which subsequently started to improve. When examined two weeks from the onset a fairly extensive eruption, more marked posteriorly, was seen. The right abdominal reflexes were absent and there was a moderate spastic weakness of the right lower limb. Sensation was unaffected. Recovery was complete within two months.

Case 14.—A man aged 63 was first seen in March, 1950, with a history of a very severe attack of herpes affecting D 3-4 on the right side six weeks previously. Four weeks from the onset he complained of sudden pain on the inner border of the right arm, radiating to the fifth finger. This was followed rapidly by weakness of the right hand and of both lower limbs. Objectively there was severe weakness of the intrinsic muscles of the right hand, together with spastic weakness of the legs, more marked on the right side. Superficial sensation was impaired in the D 1 area on the right. Two weeks later definite wasting was present in the affected hand. Two months later the lower limbs were normal, there was still a minor degree of wasting and weakness in the right hand, and sensation was normal.

Discussion

During the period 1950-6 I have seen, in addition to the cases described above, nine other instances of facial palsy associated with herpetic eruption on the pinna, face, or palate, and in the same period 76 patients with "Bell's palsy" have been examined. It is perhaps justifiable to speculate whether some of the latter may have been instances of herpes sine herpette. Aitken and Brain (1933) carried out complement-fixation tests for herpes and obtained positive results in 9 out of 9 instances of the Ramsey Hunt syndrome and in 4 out of 22 instances of Bell's palsy. It would therefore seem at least possible that a small proportion of the cases of Bell's palsy may be due to herpes zoster, and in this

connexion the occasional occurrence of very severe pain in the mastoid and upper cervical region prior to the paralysis may be a significant pointer.

On the same basis it is of interest to compare the clinical manifestations of paralytic zoster in the limbs with the findings in neuralgic amyotrophy (Turner and Parsonage, 1948). The clinical findings in seven patients suffering from this condition are set out in the Table. It will be seen that in each instance the pattern of the history and findings follows very closely that of herpetic paralysis in the upper limbs, differing clinically only in the absence of the rash. It would seem likely that neuralgic amyotrophy may, in some cases at least, bear a similar relationship to herpes as facial palsy. In general, it may be said that motor weakness or paralysis is a not uncommon accompaniment of herpes zoster and that the prognosis is as a rule quite good, with complete or almost complete return of muscle function.

The anatomical relationships of the eruption and the paralysis are by no means constant, and frequently do not coincide—a feature which supports very strongly the contention that herpes is essentially a disease of the spinal cord or brain stem and not a radicular disorder as was originally supposed. Case 6 is unusual in that facial palsy appeared to be related to chicken-pox.

Summary

Fourteen cases are described in which the patients suffered paralysis as a result of herpes zoster infection.

The distribution of the paralysis varies greatly but corresponds approximately to the distribution of the rash.

It is now generally accepted that herpes is essentially an affection of the central nervous system rather than of the dorsal root ganglia, thus making the not infrequent appearance of motor symptoms more logical.

It is suggested that a certain number of patients with "Bell's palsy" may, in fact, be suffering from the Ramsey Hunt syndrome, and the points of similarity between zoster paralysis in the upper limbs and the clinical condition described as neuralgic amyotrophy are such that there may be grounds for considering the two conditions as aetiologically similar.

The prognosis in zoster paralysis is on the whole good, but the incidence of recovery of facial paralysis due to this cause is not so satisfactory as in true Bell's palsy. Recovery of paralysed limbs is usually nearly complete.

A METHOD OF TABULATING DATA FOR EASY REFERENCE AND APPRECIATION OF SIGNIFICANT RELATIONSHIPS

AN OBSTETRIC EXAMPLE

BY

C. N. SMYTH, B.M., B.Sc., M.I.E.E.

AND

M. N. BAINBRIDGE, M.A.

Nuffield Research Assistants, Obstetric Unit, University College Hospital, London

It is common practice to-day for information collected from patient's notes to be indexed or collated on punched-card systems with the object of ascertaining the aetiology of disease and the efficacy of treatments. The usefulness of this procedure depends primarily upon the collection of all possible relevant information and on the choice, wherever possible, of facts which can be measured accurately. Thus, at the very outset the most careful thought must be given to systematic note-making; otherwise conclusions drawn after years of patient record-keeping may be criticized on the grounds of unreliability of data, or made useless by an absence of information caused entirely by lack of forethought. For this reason it is desirable to inspect the collected information frequently and critically to ensure its accuracy and completeness, quite apart from any wish to draw conclusions from the work.

However, the effort involved in studying say 40 factors and their interrelationship is very considerable and few people would be able to hold the various findings sufficiently in mind to be sure of making the best use of the information collected. We therefore present a chart (Fig. 1),* which we believe to be new, for the purpose of reducing the amount of mental effort required to a very reasonable level. It not only provides a simple method of listing the incidence of factors singly or in pairs but is a diagram from which the answers to relevant questions can be found by instant reference, and their reliability is expressed in statistical terms.

Basically the chart is an arrangement of totals and percentages; each line of percentages should consist of a series of similar numbers if the numbers are due to chance; if they are not, positive or negative correlations are to be suspected.

The chart resembles the mileage chart in the *A.A. Handbook*, and the ease with which that is understood encouraged us to develop and apply the method to obstetrics.

***Explanation.**—The principal cells on the main diagonal show the numerical incidence (upper figure) and percentage (lower figure) of 36 factors. The cells in the bottom left-hand half show the numerical incidence of patients having the two factors named in the intersecting row and column. The cells in the top right-hand half contain two percentages—that is, the number of patients having both of the appropriate row and column factors expressed as a percentage of the total incidence of (1) the column factor (upper figure) and (2) the row factor (lower figure).

To See If These Percentages Differ Significantly From the Mean.—Taking the lower percentage only, subtract it from the percentage in the principal cell on the same row (or vice versa); compare the answer with the figures in columns B to E on the same row; observe how many patients are needed for this difference to be significant; lastly, examine the principal cell in the same column to see if that number of patients required in the column principal cell for the test to be applicable to that row.

Explanation of Chart.—Suppose K factors (36 on this chart) are selected for recording—for example, foetal distress, relative disproportion, breech deliveries, etc. The factors are noted down on the left of the chart, one horizontal row to each. They are also written, in the same order, along the top of the chart with one vertical column to each, giving K² squares or "cells" formed by the intersection of row and column. It will be noticed that some of the factors are mutually exclusive. For example, a patient cannot have more than one length of labour, she cannot have both breech and occipito-posterior vertex presentation. The cells for combinations of such factors are left unfilled.

Incidence of Factors

Consider first that part of the chart below the diagonal cells—that is, the bottom left-hand half of the chart. In each of these cells is a single figure which records the incidence, out of 2,324 deliveries, of the combination of two factors—row and column. Thus in the "stillbirths" row and "forceps" column the figure 2 shows an incidence of two cases of forceps delivery in which the baby was still-born.

The diagonal cells, having the same factor for both row and column, show the total incidence of this factor. This is the upper of the two figures in the cell, the lower figure expressing the incidence as a percentage of the total deliveries. These diagonal cells are referred to as *principal cells*. Thus the principal cell for forceps shows there were 213 cases out of 2,324 deliveries, a percentage of 9.16.

Percentages

The actual incidence of every pair of factors is therefore tabulated, but it is probably more informative if they are expressed as percentages. As percentages of what? The two cases of forceps delivery with stillbirths may be expressed as a percentage of (1) all forceps deliveries—that is, the percentage of forceps deliveries resulting in stillbirths; (2) all stillbirths—that is, the percentage of stillbirths which were delivered by forceps; (3) all births. In fact the first two of these percentages are recorded on the chart. In the top right-hand half of the chart (above the main diagonal) each cell contains an upper and a lower figure.

The *upper figure* is the incidence of the combination of row and column factors as a percentage of the incidence of the *column factor*. The *lower figure* is the incidence of the combination as a percentage of the incidence of the *row factor*.

Thus the forceps row, stillbirths column, has an upper figure of 0.9 showing that 0.9% of forceps deliveries were stillbirths. The lower figure is 6 showing that 6% of stillbirths were delivered by forceps (2/213 = 0.9%, and 2/33 = 6%).

To demonstrate one way in which the chart may be used we take a particular example. If we wish to see what factors are related to stillbirth we examine the *lower figure* in the stillbirth row. We see that 0.2% of post-mature babies were stillbirths, 0.64% of term babies were stillbirths, 23% of premature babies were stillbirths, and so on. However, after "age of mother" we come to the edge of the chart and must now examine the *upper figure* in the stillbirths column.

Thus 4.2% of babies born after a first labour stage of 40-60 hours were stillborn, 3.1% of babies born after a first labour stage of 30-40 hours were stillborn, 1.3% of babies born after a first labour stage of 20-30 hours were stillborn, and so on. If we compare these figures with the incidence of stillbirths, 1.42% of all births (lower figure of stillbirth principal cell), we see that post-mature and term deliveries had a smaller proportion of stillbirths than average, while premature deliveries had a much higher

proportion than average. Thus by a comparison with the total incidence of the factor being considered we may determine which factors are related to it.

Comparisons

It is apparent therefore that if two factors are unrelated the lower percentage figure in their intersecting cell should be about the same as the percentage figure in the principal cell of that row (total percentage incidence of one factor). The upper percentage figure in the intersecting cell should be similar to the figure in the principal cell of the column (total percentage incidence of the other factor).

The percentages will not, of course, be exactly the same, and if we wish to decide whether two factors are related we must apply some test of statistical significance.

Statistical Test

As the chart is really a multiple form of 2×2 table, the statistical methods which have been evolved for this type of comparison may therefore be applied to it.

Consider the symbols portrayed in the miniature diagram of the chart (Fig. 2). The symbol N denotes the numerical incidence, the symbol P the percentage incidence, and the suffixes denote the factors considered. Na is the incidence of factor a, Pbd/d is the incidence of the combination bd as a percentage of the incidence of d.

	a	b	c	d	e
a	Na Pa				
b		Nb Pb		Pbd, b Pbd/d	
c			Nc Pc		
d		Nbd		Nd Pd	
e					Ne Pe

FIG. 2

Data for factors b and d could be extracted and put into the familiar 2×2 table thus:

	d	Not d	Total
b	Nbd		Nb
Not b			
Total	Nd		N

The usual 2×2 table tests are now applicable.

For our purposes, however, we can apply such tests directly to the chart by writing the test criterion in the following form:

$$U = \frac{N_{bd} - N_{a,b}}{N} \left(1 - \frac{N_{bd}}{N} \right) \left(\frac{1}{N_a} - \frac{1}{N} \right)$$

In this expression, the denominator is the standard deviation of the difference in proportions. If U is greater than 2 or less than -2 the difference is significant at the 5% level.

To apply this to an actual example from the chart consider stillbirths and forceps delivery in a 2×2 table:

	Forceps	Not Forceps	Total
Stillbirths	2	31	33
Not stillbirths	211	2,080	2,291
Total	213	2,111	2,324

The bold figures are obtained by subtraction.

Then, to test whether the percentage of forceps resulting in stillbirth ($2/213 = 0.9\%$) is significantly different from the total percentage of deliveries resulting in stillbirths ($33/2,324 = 1.42\%$), we calculate:

$$U = \frac{2}{213} - \frac{33}{2324} \left(1 - \frac{33}{2324} \right) \left(\frac{1}{213} - \frac{1}{2324} \right)$$

As the chart already shows many of these fractions as percentages we can simplify the arithmetic by writing

$$U = \frac{0.9 - 1.42}{1.42(100 - 1.42)} \left(\frac{1}{213} - \frac{1}{2324} \right)$$

Now the factor $\sqrt{1.42(100 - 1.42)}$ is the same for all cells in the stillbirth row of the chart (and similarly $\sqrt{Pd(1 - Pd)}$ for other rows) and the factor $\sqrt{\frac{1}{213} - \frac{1}{2324}}$ is the same for all cells in the forceps column (and similarly $\sqrt{\frac{1}{Na} - \frac{1}{N}}$ for all other columns). There is therefore no need to enter each comparison it is desired to study into a 2×2 table, since representative values for different numbers of patients in the column can be calculated for each row—for example, for 10, 100, 500, 1,000 patients. This in fact has been done in the chart columns labelled B, C, D, and E, where, by a further simplification of arithmetic, the minimum difference between Pb and Pbd for significance at the 5% level has been expressed directly. The actual

number given is $2\sqrt{Pd(1 - Pd)} \times \sqrt{\frac{1}{Nb} - \frac{1}{N}}$. For more exact interpolations the value of U should be calculated for the particular cell under consideration.

The number given in the columns B, C, D, and E—that is, the significant difference—is therefore twice the standard deviation. If these differences are exceeded the probability of a significant relationship rises steeply, thus:

1.0 × significant difference (5%) = 2 × Std. Dev.	Probability	5% = 20:1
1.3 × " " " = 2.6 × Std. Dev.	Probability	1% = 100:1
1.5 × " " " = 3.0 × Std. Dev.	Probability	0.2% = 500:1
2.0 × " " " = 4.0 × Std. Dev.	Probability	0.01% = 10,000:1

This test criterion is applicable if $\frac{Nb, Nd}{N}$ is equal to or greater than 5. If this is not so, the exact test for a 2×2 table (see, for instance, *Statistical Tables* by Fisher and Yates) could be applied. The number of patients required in each column to make a row satisfy this criterion

$\frac{Nb, Nd}{N} \geq 5$ is written in column A. If the test is not significant it does not mean that the two factors are necessarily unrelated. It means that there is no evidence that they are related. Also, 5% of comparisons where no real difference exists will appear significant, purely by chance.

Examples from the Chart

The first example taken is "first stage of 40-60 hours," which occurs in row 3; the second, foetal distress, in row and column 22.

In rows 1, 2, 3, and 22, and in column 22, all the percentages where $\frac{Na, Nb}{N}$ is less than 5 are in italics; these figures can be indicative only because the samples are too small. All the other percentages in these rows and columns have been compared with the principal cell percentages respectively, and where the difference is significant the figures are in bold type.

Figures which are neither in italics nor in bold type need further consideration; they may be so near the mean as to rule out the possibility of any correlation at all; or they

may differ noticeably from the mean but at a level of significance lower than the 5% which is considered necessary for medical purposes; or, despite a large number of patients, they may remain persistently near to, but not equalling, the significant difference, in which case the possibility must be borne in mind that the condition tabulated may represent a combination of two factors. For example, foetal distress is not significantly related to post-maturity, but the figures may approach a significant difference, and on further study it is discovered that when toxæmia supervenes in post-maturity there is a correlation.

Where the number of patients is too small but the percentage difference is otherwise highly suggestive there is a real case for collecting information from a further group of patients.

It can be seen that in rows 1 and 2 there are insufficient patients to allow us to reach any definite conclusions. In row 3, two factors (columns 9 and 36) are highly significant, with more than twice the significant difference—namely, the occurrence of a long second stage and the absence of any occurrence of a long second stage and the absence of any occurrence of a long second stage. For several other factors the mother under 20 years of age. For several other factors the difference exceeds significance—namely, presence of second stage over 2 hours (column 9), absence of short second stage ($\frac{1}{4}$ to $\frac{1}{2}$ hour) (column 11), high incidence of forceps delivery (column 13), occurrence of post-maturity (column 28), rarity of patients at full term (column 29), rarity of very young patients (column 36).

The study of the foetal distress column and row shows a positive correlation with long labour and a negative correlation with short labour, a positive correlation with forceps delivery, relative disproportion, and prematurity, and no significant correlation with post-maturity.

It will be noticed, in following these examples, that if the top percentage in a cell fails because there are too few patients, the lower one fails for the same reason. Similarly, if one percentage in a cell is significant, the other is significant also and to the same degree. The double percentages can thus form a check on the arithmetic, besides being useful when referring simply to the incidence of various paired factors.

The possibilities of the chart have been demonstrated. To discuss every relationship could be the subject of many separate publications, but enough has been said to enable readers to extend and adapt the chart to their own needs.

Summary

A chart is presented upon which the substance of some hundreds of studies can be tabulated; the interrelations of factors can be discovered rapidly and the statistical reliability of the data verified at a glance. It will be useful particularly to those who have access to numerical data from punched-card filing systems.

An obstetric example is given.

We are grateful to the Nuffield Foundation and the Medical School Council for their support of a programme of obstetric research of which this article forms a part; to Professor W. C. W. Nixon for his continued encouragement; and to Mr. W. N. Please, of the Department of Statistics, University College, London, for his advice on statistical methods. We thank Miss K. Billing, Miss Julia Lewis, Mrs. E. Johnston, and Miss Ann Hart, who over the years have helped with record-keeping and analysis.

The Department of Scientific and Industrial Research has issued a report on the Fire Research Station's work entitled *Fire Research 1956*. The report discusses fire detection, injuries from burning clothing, fires in industry, the fighting of aircraft fires, chimney fires, and fires caused by children of smokers. The results of investigations carried out at the Station were used by the British Standards Institution in devising a test for the grading of flammable fabrics. *Fire Research 1956* is obtainable from Her Majesty's Stationery Office, price 4s. net.

CHRONIC EAR INFECTIONS

LOCAL TREATMENT WITH HYDROCORTISONE, NEOMYCIN, AND POLYMYXIN COMBINED

BY

JULIAN BIHARI, M.B., F.R.C.S.

Senior Registrar, E.N.T. Department, University College Hospital, London

The purpose of this paper is to report the results of a therapeutic trial with a new compound preparation, containing hydrocortisone, neomycin, and polymyxin, used locally in a series of recalcitrant cases of otitis externa, chronic otitis media, and infected mastoid cavities.

The use of local antibiotic preparations in the treatment of chronic ear infections has become popular in recent years. Although initial results were encouraging, follow-up studies have shown that many of these have not been of lasting value. There are probably several reasons for their long-term failure.

1. A mixed flora is commonly responsible for chronic infections of the external and middle ear. The use of a single antibiotic agent even with a "broad-spectrum" action would control only such organisms as are highly sensitive. Other organisms less sensitive or resistant, of which *Pseudomonas pyocyanea*, fungi, and yeasts are the most notorious in ear infections, will soon predominate and maintain the infection.

2. The local application of the antibiotic agent may fail to reach the whole infected area. Where there is evidence of bony involvement or inadequate drainage of the middle ear, local medication must give place to surgical measures. However, in non-surgical ear infections the presence of oedematous inflamed tissues with granulations and adhesions encourages small smouldering pockets of infection, and makes it difficult for topical antibiotic substances to get into intimate contact with the infective organisms.

3. Failure to treat underlying causative factors inevitably leads to relapses. Surgical drainage or ablation must be employed wherever there is mastoid or attic disease in chronic middle-ear infections. In otitis externa the main aetiological factor and most distressing symptom is irritation of the external auditory canal. Unless this is adequately controlled the persistent scratching leads to repeated secondary infection, often from the ano-genital region (Keogh and Russell, 1956).

4. Certain substances, when applied locally, may induce sensitization of the skin and possibly systemic manifestations. Also there is grave danger of increasing the number of resistant organisms by the initial failure of complete bacteriological control of the infection. This applies particularly to local preparations of penicillin and chloramphenicol.

The Combination

With these potential faults of local antibiotic therapy in mind, it was decided to try a combination of neomycin ($\frac{1}{4}\%$), polymyxin B (10,000 units per ml.), and hydrocortisone ($\frac{1}{4}\%$) in an aqueous solution.

Neomycin is a broad-spectrum antibacterial substance produced by the naturally occurring soil organism *Streptococcus fradiae*. It has a marked bacteriostatic and bactericidal action on Gram-positive and Gram-negative organisms, being particularly effective against *Escherichia coli* and *Proteus vulgaris*. It is inactive against fungi and viruses.

Bacterial resistance to the drug develops slowly, and, although potentially a nephrotoxic and ototoxic substance when given parenterally, it appears to be free of any toxic or sensitizing effects on local application on account of its poor absorption (Jawetz, 1956). In the local treatment of a variety of infective dermatoses neomycin has been found superior to most other antibiotics (Kile *et al.*, 1950, 1953).

Polymyxin B is also derived from a naturally occurring soil organism *Bacillus polymyxa*. Like neomycin it is potentially nephrotoxic when administered parenterally. There is minimal absorption from topical application, and because of its intense bactericidal action there is very little likelihood of organisms becoming resistant. In the relatively high local concentration achieved by topical application it is highly active against *Ps. pyocyanea* and moderately active against fungi, yeasts (*Candida albicans*), and coliform organisms (Jawetz, 1956).

Topical *hydrocortisone* has been used with success in a variety of dermatological conditions. Its exact mode of action is not known, but there is little doubt that its anti-inflammatory and antipruritic effects are primarily responsible for the symptomatic relief it gives (Dunlop, 1955). It is reasonable to believe that the anti-inflammatory action, with its inhibitory effect on the fibroblastic reaction of repair and formation of granulation tissue, allows more intimate contact to occur between the antibiotics and the infective organisms. The antipruritic effect is of considerable value in controlling the irritation the persistence of which is responsible for recurrence after treatment of otitis externa.

Studies of the bacterial flora in chronic ear infections have shown that in most cases the predominant infective organisms are *Ps. pyocyanea*, coliform organisms, *Pr. vulgaris*, and pyogenic cocci (Ballantyne and Rutter, 1952; Senturia and Alford, 1954; Keogh and Russell, 1956). The antibacterial spectrum of a combination of neomycin and polymyxin B covers these infective organisms and also yeasts and fungi. The risk of drug resistance is reduced to a minimum with such a combination of antibiotics, particularly as their toxicity makes them unsuitable for general use and thus unlikely to produce resistant strains in the community (E. J. Stokes, 1957, personal communication). This is of considerable importance when antibiotics are employed as local applications. The use of neomycin with hydrocortisone has already been described by Senturia and Alford (1954) and that of polymyxin B alone in a solution of propylene glycol by Farrar (1954). With both forms of treatment there were a large number of successes, though no prolonged follow-up data are available.

Investigation and Results

Thirty-four patients with intractable chronic otorrhoea were treated with the compound otic solution. Their previous treatment had ranged from simple aural toilet to powders and drops containing single antibiotics, including polymyxin and neomycin. The patients were instructed to clean their ears by dry mopping and then to instil three drops of the solution at least thrice daily.

The incidence and distribution of the infective organisms are shown in Table I. This agrees with the findings of previous bacteriological studies, which stress the mixed nature of the flora with predominance of Gram-positive cocci, *Ps. pyocyanea*, and other coliform organisms (Senturia and Alford, 1954; Keogh and Russell, 1956).

TABLE I.—Incidence of Infective Organisms

	Otitis Externa (16 Patients)	Chronic Suppurative Otitis Media (6 Patients)	Infected Mastoid Cavity (12 Patients)	Total
Pyogenic Gram-positive cocci	13	2	10	25
<i>Ps. pyocyanea</i>	3	4	5	12
<i>E. coli</i>	3	1	1	5
<i>Pr. vulgaris</i>	6	1	2	9
<i>C. albicans</i>	3	—	—	3
Others	4	2	4	10

The clinical response to treatment is correlated with the bacteriological findings in Table II. The response to treatment in the various clinical conditions is shown in Table III.

All but two patients improved considerably after one week's treatment. Thirteen became completely symptom-free and remained so for a follow-up period of nine months or more. The remaining 19 still complained of some irritation with occasional slight discharge after discontinuing treatment. These symptoms were controlled by further

TABLE II.—Effect of Compound Solution on Bacterial Flora

	Clinically Cured or Considerably Improved (19 Patients)	Improved but Needing Further Treatment (12 Patients)	No Effect	Total
Pyogenic Gram-positive cocci	13	11	1	25
<i>Ps. pyocyanea</i>	9	2	1	12
<i>E. coli</i>	2	2	1	5
<i>Pr. vulgaris</i>	6	2	1	9
<i>C. albicans</i>	1	2	—	3
Others	5	4	1	10

TABLE III.—Results of Treatment

	No. of Cases	Symptom-free for at Least Nine Months "Cured"	Improved but Residual Irritation and/or Slight Discharge			No Effect
			No Further Treatment Required	Controlled with Further Treatment	Not Controlled	
Infective otitis externa	16	9	1	6	—	—
Chronic suppurative otitis media (tympano-tubal infection)	6	1	2	2	—	1
Infected mastoid cavity	12	3	3	4	1	1
Total	34	13 (39%)	6 (18%)	12 (34%)	1 (3%)	2 (6%)
		57% Considerable improvement	34% Improved	9% Little or no improvement		

medication with the compound solution or with 1% hydrocortisone ointment. Twelve patients required maintenance therapy for periods of up to three months. One patient relapsed despite continued treatment. The three who ultimately failed to respond had bony disease and one has since required operation. No toxic or allergic side-effects were observed in any of the patients.

Discussion

Farrar (1954) reported that ear-drops containing polymyxin alone were highly active in the treatment of *Ps. pyocyanea* infections (90% cure), partially active in *E. coli* infections (65% cure), and ineffective against *Pr. vulgaris*. The response in coccal infections was not stated and there was no prolonged follow-up. His results are compared with those of the present trial in Table IV. Cases which were improved but required further treatment are excluded from this table.

TABLE IV

Organism	Polymyxin Only (Farrar, 1954)	Compound Solution (Present Trial)
<i>Ps. pyocyanea</i>	90% cure	75% cure
<i>E. coli</i>	65% "	50% "
<i>Pr. vulgaris</i>	10% "	66% "
Pyogenic Gram-positive cocci	Not stated	52% "

The results obtained in the present trial are compared in Table V with those of Senturia and Alford (1954), who used a combination of neomycin and hydrocortisone. These authors classified the response to treatment as "excellent," "good," "fair," and "poor," but the criteria of clinical improvement were not defined and the length of the follow-up period was not stated.

TABLE V

Clinical Response	Neomycin and Hydrocortisone (Senturia and Alford, 1954) (90 Patients)	Compound Solution (Present Trial) (34 Patients)
Considerable improvement*	38%	57%
Improved†	48%	34%
No improvement‡	14%	9%

*According to Senturia and Alford's classification, * = excellent response, † = good and fair response, and ‡ = poor response.

The results reported confirm the usefulness of a combination of neomycin, polymyxin, and hydrocortisone. The combined antibacterial spectrum of these two antibiotics is shown to be particularly effective against the mixed flora of chronic ear infections. The addition of hydrocortisone, by virtue of its antipruritic action alone, plays an effective part in breaking the vicious circle of irritation-scratching-infection-irritation. Those who have relapsed after discontinuing the treatment inevitably complain of the return of the irritation, a symptom that is often impossible to cure but is readily controlled with periodic local application of hydrocortisone.

The usual methods of careful aural toilet and instillation of oily antiseptic drops—namely, aurist, hydrarg. nit. dil.—often suffice in the treatment of chronic ear infections. When this is unsuccessful and culture of the aural swab indicates the presence of *Ps. pyocyanea*, *Pr. vulgaris*, or *E. coli*, the use of this compound otic solution appears justified. It should not be regarded as a panacea, but it is without doubt valuable in cases refractory to other treatment.

Summary

Thirty-four patients with chronic ear infections were treated with a compound otic solution containing neomycin, polymyxin, and hydrocortisone in an aqueous base. A cure was effected in 13, 19 were improved, and there was no effect in two. The most satisfactory response occurred in cases of otitis externa. No toxic or sensitizing reactions were encountered.

I am grateful to Mr. Myles L. Formby, Miss W. J. Wadge, Mr. P. F. Milling, and Mr. L. G. Kingdom for allowing me to treat their patients in this trial. I am indebted to Dr. E. J. Stokes for help and advice with the bacteriology. My thanks are due to Dr. P. O. Jones for his encouragement and help in the preparation of this paper. The compound otic solution was supplied by the Wellcome Foundation Ltd.

Malaria and its Control for Planters and Miners, Bulletin No. 7 in the series issued by the Industrial Advisory Committee of the Ross Institute, has recently been rewritten. In the foreword Professor G. MACDONALD explains that the continued improvements in the control of malaria in different parts of the world necessitate the frequent revision of such a handbook. The bulletin has sections on the different epidemiological types of malaria; conditions and carriers in some selected areas; principles of malaria control; residual insecticides, including resistance to insecticides; control of mosquito breeding; and drug prophylaxis. The section on insecticides includes photographs of pumps and sprays suitable for antimalarial use. The life cycles of the malaria parasite and the anopheline mosquito are also described. Copies of publications of the Ross Institute are available from the secretary of the Institute, London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1.

PRETIBIAL LESIONS

BY

C. G. CLARK, M.B., Ch.B.

Registrar in Surgery, Aberdeen Royal Infirmary

AND

G. E. MAVOR, M.D., Ch.M., F.R.C.S.Ed.

Senior Registrar in Surgery, Aberdeen Royal Infirmary

The pretibial region is frequently the site of minor injury. It is poorly protected by clothing, especially in women, and even in obese subjects there is little subcutaneous fat. The deep fascia fuses with the anterior and medial borders of the tibia, further increasing the susceptibility to trauma. Swellings occurring after injury are usually lightly dismissed as haematomas. Though clinically resembling acute or chronic haematomas, such lesions, as the following case reports show, may be of more serious import.

Case 1

A housewife aged 30 complained of a painful swelling of eight months' duration over the anterior aspect of the right lower tibia. She stated that during the third trimester of her second pregnancy she sustained an injury to the right leg during the course of her housework. The injured area became swollen and discoloured, and these features persisted. Increasing pain a month before examination made her seek medical advice.

On examination a firm mass 1 cm. in diameter was found overlying the medial border of the tibia, just above the malleolus. It appeared to be attached to skin but not to underlying fascia, and the skin itself showed an erythrocyanotic colour. A few centimetres higher was a firm pea-sized nodule lying in the subcutaneous fat, independent of skin or deep fascia, and in the upper pretibial area a similar nodule was palpable. The regional lymph nodes were not abnormal.

The swelling was at first regarded as an organizing haematoma. An unsuccessful attempt was made to aspirate it. The mass was therefore excised, and it revealed soft greyish material. Histologically the specimen showed the features of an anaplastic tumour, the cellular type and distribution suggesting a non-pigmented naevocarcinoma (Fig. 1). Supracondylar amputation was carried out with block dissection of the inguinal nodes. The pathological report was as follows. The leg showed a subcutaneous haemor-

FIG. 1.—Case 1. Section showing anaplastic non-pigmented naevocarcinoma. (×60.)

rhagic mass about 1 cm. across, situated in the lower pretibial area. It was adherent to skin but not to underlying fascia, and the biopsy wound was well healed. A few centimetres higher there was an opaque white nodule a few millimetres in diameter, not adherent to skin or deep fascia, and in the upper pretibial area was a similar nodule. Histologically the lowermost nodule, previously reported as an anaplastic tumour, consisted of haemorrhagic granulation tissue. No recognizable tumour tissue was seen in the section examined. The middle nodule from the leg was a small well-localized cellular tumour which, although non-pigmented, showed the features of naevocarcinoma. The uppermost tumour was smaller, but proved to be of a similar nature.

Case 2

A housewife aged 32 was admitted to hospital because of a six-months-old swelling below the right knee following slight trauma. This had appeared almost overnight during her confinement with her second child. The tumour was at first painless, but a month later it became hot and tender, simulating an inflammatory lesion. It was incised, with the escape of some thick non-purulent debris, and healing rapidly occurred. However, the swelling recurred and she was referred for further treatment.

On examination a firm mass about 4 cm. in diameter was noted in the subcutaneous tissue of the upper pretibial area.

FIG. 2.—Case 2. Section showing fibrosarcoma possibly of neurogenic origin. ($\times 60$.)

It was not attached to skin. The surface was smooth, the edge ill-defined, and the overlying skin showed a bluish discoloration. Wide excision of the tumour was carried out. The pathological report showed that the tumour was highly cellular and composed of fasciculated spindle cells (Fig. 2). Much iron pigment was present in some areas. Mitoses were seen, but were not unduly abundant. The appearances were those of a fibrosarcoma possibly of neurogenic origin. The tumour extended locally down to sub-jacent fascia, but the muscle was not invaded.

Case 3

A girl aged 16 sustained an injury to the right leg in the lower pretibial region as a result of a motor-car accident. Bruising and swelling occurred, and as these subsided a painless swelling was noted beneath the skin. Persistence of the swelling for three months made her seek surgical treatment.

On examination a firm mass 2 cm. in diameter was found over the anterior surface of the tibia at the junction of the middle and lower thirds. It was not attached to skin or deep fascia, and the skin was of normal texture. The tumour was excised. The pathological report indicated that

FIG. 3.—Case 3. Section showing capsule of cyst and gelatinous contents. ($\times 40$.)

the tumour was cystic and contained pale yellow gelatinous material. The wall consisted of dense fibrous tissue without epithelial lining and contained no glandular elements. The lesion was not identifiable as a haematoma having regard to the small amount of iron demonstrated. Indeed, its precise histogenesis remained in doubt (Fig. 3).

Five months later another tumour appeared at the site of the scar and this was also excised, with the following histological characteristics. The specimen had a pseudocystic appearance, having a wall of dense fibrous tissue and containing much fibrin, some red blood corpuscles, and cells which were mainly mononuclear in type. The diagnosis seemed to rest between an organizing haematoma and a varix, and, as special stains have failed to reveal any evidence of muscle in the wall, the diagnosis of haematoma seems more likely.

Comment

The role of trauma in the aetiology of cancer has been the subject of much debate. Although chronic irritation of skin or mucous membrane is sometimes followed by neoplastic change, the general opinion is that a single traumatic episode will not promote neoplasia in normal tissue (Stewart, 1947, 1954; Kotin and Kahler, 1953; Pedden, 1953).

In the above cases trauma was definite in two and doubtful in one. In Case 3 no satisfactory interpretation of the histology was forthcoming, but the fact that the tumour recurred after adequate excision may be of some significance. In the other two cases the lesions were malignant. None of the patients suffered from chronic irritation, and because of pregnancy two had been medically examined a few weeks prior to the appearance of the tumour. It is of interest that in all three cases the lesions resembled haematomas clinically, and were diagnosed initially as such.

Conclusion

Three cases with pretibial lesions are described. Tumours appearing and persisting after trauma should not be lightly dismissed as organizing haematomas, for they are occasionally of a more serious nature.

We are grateful to Mr. G. Gordon Bruce for permission to publish these case reports.

Medical Memoranda

Torula Meningitis in Malaya

Cerebrospinal blastomycosis has been recognized for over 50 years, but is still a rare occurrence. Only one case has previously been reported in Malaya (Institute of Medical Research, 1953). The following case shows several well-known features of the disease, but is unusual in that it ran a rapid course, death occurring within four weeks of the onset. In addition the presenting symptoms—sudden and complete blindness and deafness—are impressive.

CASE REPORT

A 44-year-old Chinese newspaper-seller was admitted to Taiping Hospital on December 27, 1955, complaining of headache, deafness, and blindness. He had been perfectly fit until three weeks previously, when he began to suffer from severe early-morning headaches associated with vomiting and accompanied by numbness and weakness in all limbs. These gradually became more disabling, and after seven days he was too weak to leave his bed. Loss of vision came on suddenly at this time and progressed to complete blindness in 48 hours. Shortly afterwards he was noticed to become increasingly deaf, and by the day of admission he was semi-conscious. There was no vertigo or tinnitus and he had taken no quinine or other drug. His past health had been good and his family history had nothing of note. He had never suffered a severe head or spinal injury.

Examination revealed an emaciated semiconscious patient, completely deaf and blind, who responded in an agitated fashion to tactile stimuli. He complained continually of severe frontal headache. His speech was normal. Investigation of the nervous system showed definite neck rigidity, with a positive Kernig sign; fundi normal, apart from a small white area near the left disk resembling a choroidal tubercle; pupils dilated, equal, and unreactive to light, but ocular movements apparently normal; and complete nerve deafness. The remaining cranial nerves were normal. The limbs were flaccid, with gross reduction in power and some wasting. Tendon reflexes were absent and plantar responses extensor. There were no skin lesions, and other systems showed nothing of note; the blood pressure was 140/90; the urine was normal; no malarial parasites were found on routine blood film, haemoglobin was 60%, and the blood Kahn reaction was negative.

On lumbar puncture the C.S.F. pressure was 250 mm. of water. The fluid was clear; cells, 10 per c.mm.; protein, 35 mg. per 100 ml. Chloride and sugar contents were normal, and culture on blood agar was sterile. A few yeast cells were seen, but were thought to be contaminants.

During the first 48 hours in hospital his condition remained unchanged, he had no fever, and his headache was relieved by the lumbar puncture. Although drowsy he was easily rousable and able to feed himself. He retained sphincter control and issued loud commands at intervals to the nursing staff for the urine bottle. On the third day in hospital he became more drowsy, and was found to have a complete internal and external ophthalmoplegia.

Lumbar puncture was repeated, showing 10 lymphocytes per c.mm. and 90 mg. protein per 100 ml. Large numbers of budding yeast organisms were seen on direct film. Culture and mouse-inoculation tests showed these organisms to be identical with those of *Cryptococcus neoformans* (see below).

The patient became more and more deeply unconscious, with paralysis of all limbs and incontinence of urine, and he eventually died of respiratory failure after one week in hospital.

Treatment.—Streptomycin sulphate, 1 g. intramuscularly and 100 mg. intrathecally, was given for the last four days of life, but appeared to have no effect.

PATHOLOGICAL RECORD

At necropsy the main features were found in the central nervous and respiratory systems. Both lungs were haemorrhagic and sodden with oedema affecting both lower lobes and the right middle lobe.

The meninges appeared normal, but were exceptionally dry and tough, and were tightly bound down to the cortical tissue over the vault. The underlying white matter in this region presented a "sandy" appearance and imparted a gritty sensation to the touch. The ventricular system was normal and there was no apparent obstruction to the flow of C.S.F., which had a slightly opalescent appearance. Serial sectioning of the brain showed no abnormality apart from a general hyperaemia and congestion.

On microscopical examination cryptococci were found in large numbers in the meninges over the vault and around the base of the brain. There was relatively little inflammatory reaction and no evidence of suppuration or granulomatous change. Sections of the brain in the region of the frontal cortex showed organisms in the Virchow-Robin spaces. Unfortunately the cranial nerves were not examined microscopically. Scanty organisms were also seen in the liver and spleen.

Initial wet nigrosine preparations of centrifuged cerebrospinal fluid deposit and macerated brain showed the presence of the organism in large numbers. These took the form of round yeast cells varying considerably in size from 3 to 8 μ . Many budding forms were present, and a large number were surrounded by thick, clear, highly refractile capsules. A striking characteristic was the complete absence of mycelia.

The organism was cultured on blood agar and Sabouraud's dextrose-agar medium at 37° C. and 28° C., and a free pure growth on both media occurred after 72 hours' incubation at 37° C. and rather longer at 28° C. This consisted of small dome-shaped semi-transparent mucoid colonies, prepared films of which showed the original capsulated Gram-positive yeast form, proliferating by blastospores only, with no mycelia.

Fermentation tests showed that the organism grew readily in glucose, lactose, mannitol, dulcitol, and maltose peptone waters, slowly forming acid in glucose and maltose only, and without producing gas in any.

Antibiotic-sensitivity tests, using a blood-agar plate and impregnated paper disk technique, proved the strain to be completely resistant to 10 μ g. of penicillin, chlortetracycline, chloromycetin, and oxytetracycline per ml., and to 20 μ g. of streptomycin per ml.

Three adult male white mice were subsequently inoculated intraperitoneally as follows: (A) 0.1 ml. of the original C.S.F.; (B) 0.1 ml. of a suspension in sterile normal saline; and (C) 0.1 ml. of a preparation from the colonies of the blood-agar culture. B died on the 11th day, C on the 17th, and A on the 43rd. Necropsy and wet nigrosine preparations from all three animals showed the yeast cells to be widely disseminated in the peritoneum, spleen, lungs, and brain, whilst the original organism was recoverable from the brain on culture.

Thus it was conclusively shown that an organism resembling *Cryptococcus neoformans* was recovered from the brain and C.S.F., subsequently cultured, and proved to be highly pathogenic to mice.

We are indebted to the S.M.&H.O., Perak, Malaya, for permission to publish this case.

to continue the study of muscular physiology when he left for London to organize and inspire medical research on the grand scale. Lady Fletcher essayed a daunting duty, but she has achieved a gracious and valuable record of her distinguished husband.

D. V. HUBBLE.

THE AMERICAN BOARD OF SURGERY

History of the American Board of Surgery, 1937-1952. By J. Stewart Rodman, M.D. (Pp. 104+x; illustrated. 24s.) Philadelphia and Montreal: J. B. Lippincott Company. London: Pitman Medical Publishing Co. Ltd. 1957.

Upon the knowledge, judgment, and skill of the surgeon depend the well-being and lives of many thousands of persons annually. It is of the utmost importance that the character and training of surgeons should be the best possible. At the beginning of this century the standard of surgical qualifications was very unequal, and disquietude over this caused a desire for improvement. In 1935 that distinguished surgeon Dr. E. W. Archibald, of Montreal, gave it as his opinion that the Australian system of training surgeons was the best, in that aspirants had to possess a sound knowledge of the basic sciences and were required to serve a long surgical apprenticeship under the supervision of a surgeon of unquestioned authority. Stimulated by this suggestion, representatives of various American surgical associations consulted together and formed the American Board of Surgery, whose main object was to set up an examining and qualifying body in general surgery which would maintain a high standard of training and achievement. This book gives an account of the first 15 years of the work of the Board. It consists largely of the dry bones of committee meetings, lists of members of the Board, and the results of examinations, but a little imagination makes the dry bones live. The Board has achieved a distinct success in raising the standard of surgical training in America. It has also helped to stop the practice of fee-splitting, which they term "pernicious, leading as it does to a traffic in human life." Reading between the lines one would conclude that the Board still has many improvements which it would like to introduce. It is a worthy aim.

ZACHARY COPE.

RADIOLOGY OF HEAD AND NECK

The Head and Neck in Roentgen Diagnosis. By Eugene P. Pendergrass, M.D., J. Parsons Schaeffer, M.D., Ph.D., and Philip J. Hodes, M.D. Second edition. (Volume I, pp. 878 +iv+index of lxvi pages. Volume II, pp. 879 to 1,759 +xli+index of lxvi pages. Illustrated. £14 the two volumes.) Oxford: Blackwell Scientific Publications. 1957.

The title of these immense volumes can give no idea of the extent or value of their contents, for in them there has been gathered a mass of information of the greatest practical value, much of it original or from sources difficult of access, but all fully assimilated and set out with the utmost clarity. Although radiology remains throughout as the chief means of investigation, the authors provide the radiologist with all the detailed information that may be obtained from other sources in order that he may appreciate the findings of his own special craft. As a result we are presented with the anatomy of the head and neck from a new and most original point of view, a revelation equally to the anatomist and the clinician.

No review could do justice to the contents of this great work and we can only mention a few outstanding points. The first volume is devoted to the skull and the many variations which may occur from development, injuries, and tumours. Here will be found a superb description of the temporal bone, illustrated by the exquisite drawings of Max Brödel, the greatest of all anatomical draughtsmen. There follows a description of the orbit and a full account of the complex procedures involved in the localization of foreign bodies in the eye.

The second volume is largely devoted to the diagnosis of cerebral tumours, but space is found for a very clear

account of the mechanism of vision and of the anatomy of all the cranial nerves. Cerebral pneumography is described in full detail, but the climax of this section is the superb account of cerebral angiography, with illustrations from actual cases which are real triumphs of radiography. The whole work is a very great achievement and deserves the gratitude of our whole profession.

HENRY SOUTTAR.

JUNG'S WORKS

The Collected Works of C. G. Jung. Edited by Sir Herbert Read, Michael Fordham, M.D., M.R.C.P., and Gerhard Adler, Ph.D. Volume I—*Psychiatric Studies*. Translated from the German by R. F. C. Hull. (Pp. 269+xiii; 25s.) London: Routledge and Kegan Paul. 1957.

Jung spent the first eight years of his professional life on Eugen Bleuler's staff at the Burghölzli Mental Hospital in Zurich. It is therefore fitting that Volume I of his *Collected Works* should be devoted to his early observations on patients seen in hospital. The book contains many case-histories, briefly recorded, but with a full discussion on aetiology and treatment.

Jung published his *Psychology of Dementia Praecox* separately, and the present book concentrates on other clinical conditions such as twilight states, stupor, hysterical cryptomnesia, manic mood disorders, and the complications of simulated insanity. He does not agree with those who claim that the detection of malingering is a simple problem. Malingering is comparatively rare, but it does occur, particularly amongst psychopaths, some of whom are highly intelligent and show unexpected resource and resolution in the simulation of disease. The paper "On the Psychology and Pathology of so-called Occult Phenomena," translated by the late Dr. M. D. Eder in 1916, is now retranslated. The other papers, till now available only in various European medical journals, appear in English for the first time. A few terms are old-fashioned (for instance, "dementia praecox" for "schizophrenia"); but apart from such details these studies, far from being "dated," might have been written yesterday. Those familiar only with Jung's later work should note that it rests on the foundation of a sound training in general medicine and clinical psychiatry. In addition he had done research and teaching in physiology. The book will be of interest and value to any clinician, be he physician, surgeon, or psychiatrist. Mr. Hull's translation is first-rate.

E. A. BENNET.

HOME DOCTOR

Illustrated Medical and Health Encyclopedia. Edited by Morris Fishbein, M.D., with the collaboration of leading specialists in medicine and surgery. Published in eight volumes. No price given. New York: H. S. Stuttman Co. 1957.

This is a "home doctor" on a very generous scale, and among its class of publication it scores high. One must, however, bear in mind inevitable limitations of a publication which is likely to lie on the shelves for many years in such a rapidly expanding subject as medicine. Without going into the ethics of producing books which contain information on medical terms for the general public, this particular encyclopaedia manages to give a clear, very readable description of the items with which it deals. These are listed in alphabetical order—abdomen, allergy, birth, etc.—and to a subject such as allergy several pages of up-to-date information are given. The reading level is approximately that of *Family Doctor*, and one presumes that it is aimed, therefore, at the intelligent general reader, but it would certainly not insult the intelligence of medically qualified people. Inevitably, however, with such a compilation, some sections appear disappointing; that on birth, for instance, is both pedestrian and incomplete, since it ignores recent views on natural childbirth which would undoubtedly be of great interest to the majority of parents. The illustrations are excellent and copious throughout.

HOMOSEXUALITY IN SOCIETY

The report of the Departmental Committee on Homosexual Offences and Prostitution, medical features of which are summarized at p. 639, contains much of interest to the medical profession. Prostitution was recently discussed at length in these columns,¹ so that comment will now be restricted to those parts of the report concerned with homosexuality. This variety of deviant behaviour has, like others, been affected by the present general tendency by which "the concept of illness expands continually at the expense of the concept of moral failure."²

The Wolfenden Committee, doubtless guided by its medical members, kept clear of any too narrow and old-fashioned a concept of disease, and adopted the dictionary definition of homosexuality—"a sexual propensity for members of one's own sex." This leaves open the questions whether such a propensity results in overt behaviour that alone makes it of legal importance, and whether the propensity is to be detected in some people only, or, as the psycho-analyst asserts, in everybody. The committee agreed with the idea of a rating scale for sexuality as proposed by Kinsey, which ranges from complete heterosexuality to complete homosexuality. According to Kinsey about 4% of American men are exclusively homosexual; Desmond Curran and D. Parr³ found 5% homosexuals (most of whom had had overt experience) in a consecutive series of private patients. The proportion and certain other figures are close to these. The propensity is known to occur in association with a wide variety of psychiatric conditions as well as in people who are apparently normal, being stable, free of symptoms, and socially adjusted. This point is brought out particularly in a note by the medical members of the committee—Drs. D. Curran and J. Whitby—which agrees with the data of F. H. Taylor,⁴ T. C. N. Gibbens,⁵ and Curran and Parr.³ These psychological complexities are of special relevance to the difficult problem of the disposal and medical treatment of offenders.

The most far-reaching of the committee's recommendations (with one dissentient) is that homosexual

⁶ *Homosexuality and Prostitution*, 1955, British Medical Association (2s. 6d.).

acts between consenting adults in private be no longer a criminal offence. This opinion derives from the committee's proposition that "it is not, in our view, the function of the law to intervene in the private lives of citizens, or to seek to enforce any particular pattern of behaviour, further than is necessary to carry out its purposes," which are "to preserve public order and decency, to protect the citizen from what is offensive or injurious, and to provide sufficient safeguards against exploitation and corruption of others." Most doctors will probably agree with the opinion expressed by the B.M.A. Committee in its evidence that, if the legal prohibition on homosexual acts between consenting adults is removed, then the age of consent should be not less than 21, and the consent must amount to complete concurrence of view. The undesirability and immorality of such acts are not in question. What is questionable is whether the present law is the best way of diminishing them, or whether more success would come from better education and the strengthening of individual responsibility. Medical opinion is probably divided on the issue, but psychiatrists have usually lent support to the majority view recorded by the Wolfenden Committee.

The medical treatment of offenders suffers from the familiar difficulties common to the treatment of all mental disorders—not enough doctors, not enough knowledge of the aetiology and treatment, unsatisfactory conditions under which doctor and offender must work, and factors in the patients' personalities that make treatment unrewarding. Psychiatrists usually consider that a prison sentence may do more harm than good, by providing opportunities for homosexuality inside and new partners to meet outside. An interesting corrective to this view comes from a survey, referred to in the report, by the Cambridge University Department of Criminal Science, which found that the same proportion—nearly one-third—of men relapse after being placed on probation as after a prison sentence. In a further note Drs. Curran and Whitby considered the committee had unduly stressed the difficulties rather than the constructive opportunities. But it must be admitted that the most likely and valuable effects of treatment will be helping the young man whose homosexuality is transient but who requires psychotherapy to help him past it. For the patient who is adjusted to being homosexual much less is possible; no doctor could produce for the committee a "cured" case of complete homosexuality. The committee stresses the need for planned research into all aspects of this problem, a view that every doctor will endorse.

The report of this committee, following hard on the report of the Royal Commission on Capital Punishment, prompts the question whether these complex subjects of medical, legal, and social interest

are best dealt with by committees of that kind. A changed attitude to suicide has taken place without the need for a committee to explore its legal and medical aspects. A somewhat similar problem now coming to the fore is the causes and effects of accidents, for in these days of comprehensive insurance and the welfare State hardly anything is an "accident" whose effects cannot be blamed on someone else, nor be spread over persons besides the victim. It is debatable whether the appointment of Government committees to consider such questions—usually not until much heat has developed round them—is the best way to ensure that the law, public opinion, and scientific knowledge remain in harmony with each other, particularly since the effectiveness of the committees' recommendations may be, and often is, defeated by the inactivity of a Government.

HAZARDS OF DIAGNOSTIC RADIOLOGY

Early in 1955 the Medical Research Council at the request of the Prime Minister appointed a committee under the chairmanship of Sir Harold Himsworth to report on the medical aspects of nuclear radiation, including the genetic effects. In a comprehensive report,¹ published in June, 1956, the committee estimated the levels of exposure to radiation from all sources, including diagnostic and therapeutic x rays, occupational exposure, and exposure due to nuclear explosions, and sought to assess the hazards resulting from these sources. An unexpected finding was that in the population as a whole the gonadal exposure from diagnostic x rays probably amounted to no less than 22% of the total normal background radiation and might well be considerably above this figure. It was estimated that the gonadal exposure attributable to fall-out from the testing of nuclear weapons was less than 1% of the background. Hard upon the publication of the M.R.C. report came the communication by Dr. Alice Stewart and her colleagues² which suggested the possibility that leukaemia in childhood might result from intrauterine exposure to x-radiation for diagnostic purposes in pregnancy, and this added to the disquiet already occasioned by the finding of the M.R.C. report. It seems likely that the developing foetus is more sensitive to radiation damage than the mature organism, and this may be true too of the early years of infancy.³

Little is known about the true magnitude of the genetic and leukaemogenic (and possibly carcinogenic) risks from diagnostic exposure, and in view of the urgent need of further information on these matters the Minister of Health and the Secretary of State for Scotland have with commendable promptitude set up a committee under the chairmanship of Lord Adrian to review the present practice in diagnostic radiology and the radiotherapy of non-malignant conditions with the object of determining its hazards. Meanwhile it is necessary to retain a sense of proportion when considering the magnitude of these hazards. Professor L. J. Witte,⁴ in a recent article in this *Journal*, wrote: "The possible 50 cases of leukaemia a year from x-radiation *in utero* must be set against 439 deaths of mothers in childbirth, 15,829 stillbirths, and 9,750 deaths in the first week of life in 1955. Obstetricians and radiologists believe that the mortality of mother and child may be significantly reduced by appropriate x-ray examination in pregnancy, and that they can save more lives than are likely to be lost from leukaemia, appreciating as they now do the hazards of x-radiation."

The leukaemogenic and carcinogenic risks affect only the individuals exposed to the radiations. Of another order is the genetic or racial hazard due to the increase of gene mutations in the population. It is believed that new mutation induced by radiation is probably directly proportional to the additional radiation.^{1,5} Most geneticists agree that the radiation dose which would double the natural mutation rate might have serious ultimate effects on the race. Even if it were assumed for the purpose of argument that all the present mutation rate is due to natural radiation (which is not the case), then the increase due to the cumulative effect of diagnostic radiology would be of the order of 22% of the present rate. In fact, however, only a proportion of the natural mutation rate is due to radiation (estimated at from 2–20% in the M.R.C. report). Accordingly, even at the worst, the maintenance of the use of diagnostic x rays at current level would not increase the present burden of mutational disease and disability by more than a fraction, although, of course, because of the great increase in man-made radiation for all purposes, it is obviously desirable that exposure to radiation should be kept to a minimum. Attempts have been made to calculate the cumulated dose which would be required over the average reproductive lifetime (say 30 years) to double the mutation rate. The reports of both the Medical Research Council and of the American National Academy of Sciences⁵ agree that this dose may lie between 30 and 80 r—that is to say, an average dose of perhaps 1–3 r per year during the reproductive period. If the contribution of diagnostic radiology in Britain is taken to be 22% of the normal background of approximately 0.1 r per annum, it will be

seen that the contribution of diagnostic radiation to the doubling dose is indeed fractional.

The Medical Research Council's committee recognized that almost the whole of the gonad dose from the use of diagnostic x rays was accounted for by a relatively few sites of examination—the pelvis, hip-joints, lumbar spine, and lower abdomen—and that the far more frequent examinations of chest, head, and limbs make relatively unimportant contributions. That radiologists themselves have become well aware of the radiation hazard from diagnostic exposure of these sites is evident from the frequency of discussions and articles on this subject in recent months. In a recent issue of the *British Journal of Radiology* there is a leading article⁶ on radiation hazards in diagnostic radiology, and an announcement of the future publication of a series of papers by radiologists and physicists of special experience, the purpose of which is to review the literature and to state briefly and clearly the steps which may be taken in any x-ray department to minimize both skin and gonad dosage. In the same issue are three short papers on this subject. D. K. Bewley, J. W. Laws, and C. J. Myddleton⁷ have estimated the dose to various parts of the foetus and to the maternal ovaries during obstetric radiography at from 100 to 120 kVp. They find that the higher kilovoltage techniques result in a substantial reduction in dosage sustained by maternal ovaries and foetus. C. G. Clayton, F. T. Farmer, and C. K. Warrick⁸ have also carried out an investigation on the same subject with particular reference to the dosage sustained in the various standard radiographic views. These papers are valuable in that they provide an indication of which views incur the greatest exposure—and in this they are in substantial agreement. The third paper is by G. M. Ardran and H. E. Crooks⁹: working at the Medical Division of the A.E.R.E., Harwell, these authors measured the dose of radiation to the gonads from various diagnostic procedures. They found that in many cases the exposures were lower than those hitherto accepted, and they attributed the reduced exposure to special attention to technique—in covering the testes with lead, the use of fast screens for barium work, and the use of filters. Other factors to which they paid attention were the reduction of air scatter and the checking of radiation leaks in tubes and accessories. In the latest issue of the same journal G. M. Ardran contributes the first of the promised special papers, his subject being dose reduction in diagnostic radiology.¹⁰ W. G. Clarke has recently shown that in chest radiography care is needed to prevent the radiation from reaching areas beyond the chest.¹¹

Taken all together, there is no doubt that much can be done by the methods already referred to, and also by the reduction of screening times to the minimum and the use of limiting diaphragms, to reduce the

exposure from diagnostic radiology. Radiologists in charge of most departments in this country doubtless already have these improvements in technique well in hand, and all would agree with the conclusion of a W.H.O. study group, whose report¹² was published last week, that "those in charge of sources of ionizing radiations should always ensure that there is adequate justification for exposing individuals to doses however small."

HEADACHE MECHANISMS

The work of Dr. Harold Wolff and his colleagues in New York has cleared up many common misconceptions about the mechanism of headache, and a useful summary of their investigations has been published.¹ Observations on conscious human beings show that the bones of the skull and healthy brain tissue are quite insensitive, but the vascular structures connected with both are sensitive in varying degrees. There is no doubt that the stretching or displacement of these vascular structures is the mechanism accounting for most headaches of organic origin arising inside the skull. Increased intracranial pressure *per se* does not cause headache, and it is even possible to find patients with brain tumours in whom headache is relieved by raising intracranial pressure and precipitated by lowering it. Headache may, of course, accompany increased pressure, but there is no relationship between the height of the pressure and the severity of the pain; and whether or not headache occurs seems to depend on whether vascular structures are stretched or displaced.

Five main structural mechanisms are suggested for headaches caused by changes inside the skull; first, traction on the veins that pass to the venous sinuses from the surface of the brain and displacement of the great venous sinuses; second, traction on the middle meningeal arteries; third, traction on the large arteries at the base of the brain and the main branches; fourth, direct pressure by tumours upon the fifth, ninth, and tenth cranial nerves and the upper three cervical nerves; and fifth, inflammation in or about any of these structures as well as of the pia and the brain itself. The part played by disease of the nose and sinuses in the production of headache has undoubtedly been much exaggerated, and E.N.T. surgeons are now well aware that few headaches are cured by nasal operations. But the part played by functional disturbance has perhaps not received as much attention as it deserves. Hyperaemia of the nasal mucous membrane, swelling of the turbinates and so on—which may sometimes be allergic but are much more often part of an emotional disturbance—may well be the explanation of many obscure pains and neuralgias in the face and head.

There is as yet no good evidence that "histamine" headaches occur naturally, but they have been much used experimentally to study the nature of certain vascular headaches. An injection of histamine produces an ache, throbbing in character, all over the top of the head. The ache begins when the temporary rise of blood pressure following the injection has subsided, and there is evidence to show that it is due to an increased distension of the intracranial vessels with each cardiac systole. This headache can be abolished by raising the pressure of fluid in the subarachnoid space (or by spinning the patient head outwards in a human centrifuge). Distension of intracranial arteries is probably the mechanism of headaches due to nitrites, polycythaemia, atmospheric pressure changes, and, rather more commonly, to hunger, "hangover," fever, and infections. That migrainous headaches are also of this type is now well known. Attribution of headaches directly to constipation and to referred pain from structures below the level of the neck cannot, according to Wolff, stand critical examination. It may be good news to a few that vascular headaches, including some cases of migraine, can sometimes be abolished by standing on the head.

One other common type of headache—usually non-pulsatile and often lasting unchanged for long periods—has been shown by means of records of action potentials to be associated with abnormal contraction of the skeletal muscles of the head and neck. Patients so affected may complain of a "tight band around the head," a fixed neck, and sore shoulders. The pain is apparently partly due to sustained muscle contraction and partly to vasoconstriction, reduced blood flow, and ischaemia of muscle. Such headaches are particularly apt to be associated with a tense emotional state.

Wolff's long interest in headaches and his great experience must lend weight to his general conclusions about their management. "More than 90% of people with headache have their headache as a result of vascular disturbances, sustained skeletal muscle contraction about the head, and vasomotor disturbances within the nose . . . Two people out of three with this vascular-muscle-tension headache combination can be greatly helped by any physician who is interested in human problems, and willing to spend a minimum of time with his patients in reviewing them with him." It is notable that one who has spent so much time on the study of headache by experimental methods should arrive at such very human conclusions. Perhaps a strictly scientific outlook and a human approach to clinical problems are not as incompatible as they are sometimes made to appear; and we may hope that more clinical investigators will be attracted to this kind of combined investigation.

SYNDROME OF SARCOIDOSIS

The general reliability of the tuberculin skin test as an index of active tuberculosis is not in question. With the exception of a few well-recognized conditions—late pregnancy and the puerperium, intercurrent infections, hypothyroidism, and cachectic states—failure to react to dilutions of 1 in 100 or 1 in 10 of old tuberculin excludes clinical tuberculosis with an error of about 2%.¹⁻³ However, persistently negative reactions⁴ have been recorded in undoubted cases of active tuberculosis in which positive reactions were to be expected. It is probable that such anomalies occur only once or twice in every 1,000 tuberculous subjects tested, and for epidemiological and statistical purposes they can safely be ignored. But for the clinician they may offer an important and far-reaching lesson.

There are certain clinical similarities between the cases so far recorded. They have all been of an indolent and slowly progressive nature, and closely resemble sarcoidosis, a disease in which the tuberculin test is usually negative. A further four proved cases are now reported by J. G. Scadding.⁵ They have been selected from 107 cases of pulmonary tuberculosis seen since 1951, and have been shown to have tubercle bacilli in their sputa but not to react to 100 tuberculin units (T.U.) of P.P.D. A further seven patients were seen who reacted to 100 T.U. but not to 10 T.U., and in whom the clinical and radiological picture was similar. The high figure of 11 anomalous reactions in 107 cases is perhaps to be explained by the author's known interest in the subject. Once tubercle bacilli have been demonstrated in the sputum, no reason remains to doubt the clinical diagnosis of active pulmonary tuberculosis. If negative tuberculin reactions occur in such cases, then clearly the anomaly lies in the infecting organism, in the host's reaction, or in a combination of the two. Great interest therefore attaches to Scadding's investigation of the tubercle bacilli isolated from one such case, and also from five cases of sarcoidosis which eventually became sputum-positive. In all six the bacilli were shown to be of the human type, and of normal virulence for the guinea-pig. This is strong negative evidence that the abnormality is of the host's response, and it is further supported by Scadding and Citron's study⁶ of the effects of cortisone on tuberculin reactions in tuberculosis and sarcoidosis.

Thus it seems that certain people, if infected with human tubercle bacilli of normal virulence, will develop an illness clinically resembling sarcoidosis, and will remain tuberculin-negative. In some others an illness indistinguishable from sarcoidosis may occur and yet at a later stage of the disease tubercle bacilli may be found in the sputum, and in some the tuberculin reaction may become positive. At this stage we may reasonably ask, What is sarcoidosis? And apparently the answer

should be that it is not a disease, but a syndrome, a response of the body that may be provoked in some people by the tubercle bacillus, in others by beryllium dust,⁷ and probably also by a number of other as yet unidentified agents, exogenous and endogenous. Sometimes there may be a hereditary basis to it, for several cases of its occurrence in identical twins have been reported, though this would naturally be expected occasionally by chance. Drs. N. S. Plummer, W. St. C. Symmers, and H. I. Winner describe in the opening pages of the *Journal* this week its onset at about the same time in identical twins. A connexion with a tuberculous relative remained problematical. Clinically the disease seems to extend from the mildest forms such as erythema nodosum, hilar lymphadenopathy, and negative tuberculin reaction, occurring in young people and having a good prognosis,⁸ through relatively benign "fixed" forms, such as pulmonary sarcoidosis and Crohn's disease, to the malignant, progressive, widely disseminated lesions affecting such vital structures as the heart, kidney, and nervous system, and leading to the patient's death.

A possible clue to the nature of the morbid process may lie in the frequent occurrence of hyperglobulinaemia in sarcoidosis, a feature shared with systemic lupus erythematosus. May not both conditions represent abnormalities of antigen-antibody reactions? The subject might be clarified by further studies of the globulins present, and by applying the technique of fluorescence-labelled antibody⁹ to investigate the histology of the affected tissues. Meanwhile it is clear that in cortisone and its derivatives we have beneficial treatment, but, in view of the intimate relationship that has been shown to exist with tuberculosis, one that needs giving with care. Probably no cases of at least pulmonary sarcoidosis should receive steroids without adequate antibiotic protection.

OBSTETRICS IN NIGERIA

A high standard of professional skill and care is not the only prerequisite to good results in surgery and obstetrics: satisfactory socio-economic conditions, an educated public, and adequate facilities are also required. After discussing some of the difficulties of surgery in backward countries in an address that was published in the *Journal* last week, Professor F. A. R. Stammers¹ concluded with the words: "Keen students and housemen tend to think that what they see in their own teaching hospitals is the complete and last word in everything, practised in the only possible way: they will find that this is not so." A timely reminder of this is offered by the 1956 annual report of the Government Maternity Hospital in Lagos, Nigeria. This institution, the only maternity hospital for a population of about 400,000 persons, is staffed by five doctors and by fewer than 80 midwives, of whom a little less than half are fully trained.

During 1956, 10,635 patients were admitted to the 78 beds, a turnover made possible only by discharging all cases of normal labour within twelve hours of delivery. Patients were admitted even when there were no empty

beds, because there was no alternative. The strain on the staff has been tremendous, but it has produced two outstanding and encouraging results. The first is a steady decline in maternal and foetal mortality. The second, and probably consequent, result is the apparent increasing confidence of the population in modern medicine and the extra safety which they have come to associate with delivery in the hospital. Of the 66 maternal deaths in 1956, seven were due to causes unrelated to pregnancy and a further seven resulted from abortion or ectopic gestation. Of the remaining 52, 13 were due to post-partum haemorrhage and obstetric shock and 7 to rupture of the uterus. Almost two-thirds of the deaths were emergency cases who died within 48 hours of admission. The 57 cases of eclampsia were treated by the intravenous thiopentone technique advocated by the late O'Donel Browne, of Dublin. There were five maternal deaths, but the foetal salvage rate was as high as 75%.

Some of the rewards of such unceasing endeavour are shown in the fall in maternal mortality rate from 95 per 1,000 total births in 1955 to 78 in 1956 and in the perinatal mortality rate from 84 to 79. In the circumstances of long distances, grossly inadequate accommodation, chronic shortage of staff (especially for the administration of anaesthetics), and the lack of a blood bank in a country where anaemia is common and often due to multiple deficiencies, the valiant efforts of all the members of the hospital staff, professional and lay, deserve high commendation.

CHLORPROMAZINE JAUNDICE

The continued widespread use of chlorpromazine has led to the steady accumulation of cases of jaundice attributed to it. These have now reached such a number that it is possible to draw a fairly reliable picture of both the clinical and the pathological manifestations and to speculate upon the pathogenesis.

According to R. B. Doughty¹ the incidence of jaundice in patients treated for more than one week varies between 0.8 and 1.4%. It is not surprising, therefore, that as many as 22 cases were recognized at the Mount Sinai Hospital in New York in a period of 14 months.² A study of these patients and of a further 27 from other centres shows that "chlorpromazine jaundice represents a distinct syndrome." A prodromal period lasting about a week usually precedes the appearance of jaundice and begins about a fortnight after starting the drug. This period is usually marked by chills, fever, pruritus, abdominal pain, and nausea. Apart from the pruritus, these symptoms usually subside by the time the jaundice appears. This is obstructive in type, with dark urine, pale stools, a high serum phosphatase, and generally unimpaired parenchymal function as judged by the usual laboratory tests.

The clinical findings are largely supported by the pathological picture revealed on biopsy. The most conspicuous histological features are a moderate cellularity

of the portal tracts, bile stasis in the intralobular bile capillaries, and some evidence of regeneration of parenchymal cells. The infiltrating cells in the portal tracts include many eosinophils during the first week of jaundice, but these become few in number in later weeks, when lymphocytes predominate. Resolution is ultimately complete, and no evidence has yet been obtained of any permanent hepatic damage.

The liver lesions found in these patients could result either from injury brought about by a direct toxic effect of the drug or from an acquired hypersensitivity to it. The evidence available favours the second hypothesis. The majority of "direct" hepatotoxic agents—for example, carbon tetrachloride—produce conspicuous injury to the parenchymal cells, whereas in patients on chlorpromazine the parenchymal injury is trivial and the usual correlation between dose and severity of the lesion is absent. Moreover, in favour of the allergic hypothesis are the time interval between first taking the drug and the onset of symptoms, and the appearance of eosinophils in the early lesions. The reappearance of symptoms within a few hours of restarting treatment with chlorpromazine after an interval of several months further supports this contention. The primary site of the damage is still obscure, though an excessive permeability of the cholangioles, as postulated by C. J. Watson and F. W. Hoffbauer³ for certain types of infective hepatitis, could explain both the clinical and pathological findings.

CRASH HELMETS ON TRIAL

During the six years 1950–5 more than a thousand deaths of motor-cycle riders or passengers were reported every year in England and Wales. Death was due to head injury in about 80% of these cases, a figure that did not vary much from year to year. Yet the wearing of crash helmets would have been expected to reduce this percentage, if not indeed the total number of deaths, as each year more motor-cyclists wore them. Commenting on these statistics last week,¹ the Registrar-General suggested the following possible reasons why the proportion of deaths in motor-cycle accidents due to head injuries has remained constant. First, the type of motor-cyclist most likely to have a crash helmet is least likely to have an accident. Secondly, some crash helmets of bad quality give little or no protection. Thirdly, too few crash helmets are being worn. A fourth possibility suggests itself—namely, that more vehicles of all kinds on the road, and higher speeds everywhere, may increase the severity of accidents, thus offsetting some of the benefit given by crash helmets.

When these deaths from head injury are related to the numbers of licensed motor-cycles, a rather different, if no more encouraging, picture emerges. During 1950–5 the numbers of motor-cycles licensed each year were, in millions, 0.69, 0.78, 0.88, 0.96, 1.06, and 1.17. In the same years the death rate from head injury among motor-cyclists per 100,000 licences varied as follows: 124, 122, 99, 90, 87, and 88. The fall in the rate is notable, but it is apparently not due to the wearing of crash helmets. Estimates obtained by various surveys

of the proportion of motor-cyclists wearing crash helmets have been given by Walpole Lewin and W. F. C. Kennedy.² They reported that before 1953 the figure was only 2%. By the end of 1953 it was 16%; in 1954 it was 19–22%, and in 1955 about 30%. Thus the main increase in the wearing of crash helmets took place in 1953–5, but the main decrease in the death rate from head injury took place before 1953.

Another Government publication³ issued last week throws some light on these deaths. It analyses, for 1956, the number of motor-cyclists killed per 1,000 injured. For riders with crash helmets, on roads with a speed limit, the rate was 12.9, as compared with 14.8 for riders without crash helmets. On roads without a speed limit the corresponding figures were 35.5 and 39.9. The benefit conferred by a crash helmet, as thus measured, is therefore surprisingly small. For pillion passengers, however, the benefit was much greater, being something over two times. The figures point clearly to the danger of speed as a cause of fatal accidents.

Whether sufficient protection is given by the ordinary general-purpose helmets seems worth investigating. The British Standard was revised last year,⁴ so that time may show some improvement in the death rate from motor-cycle injuries. Any helmet necessitates a compromise between the discomfort its wearer will put up with and the protection he gains from it. But if civilians are to get anything like the benefit that the armed Forces did from the investigations of Cairns and his colleagues and successors further careful study would seem to be necessary, for the problem is not solved.

THE MEDICAL JOURNAL OF AUSTRALIA

A week after his retirement, at the age of 73, from the editorial chair of the *Medical Journal of Australia*, Dr. Mervyn Archdall died, having been in ill-health for a long time. His career is described in a memoir at p. 646 of this issue. Dr. Archdall joined the staff of his journal in 1922 and succeeded Dr. H. W. Armit as editor in 1930. During the 27 years of his editorship the *Medical Journal of Australia* has grown steadily in stature and has exercised a great and beneficial influence on the Australian medical profession. Just before his death the Australasian Medical Publishing Company had appointed Dr. Archdall consulting editor, and Dr. Ronald Winton editor, of the journal it owns. Dr. Winton is a graduate of the University of Sydney, and after distinguished wartime service in the Royal Australian Army Medical Corps joined Dr. Archdall's small staff as assistant editor in 1947, and was appointed deputy editor in 1953. Dr. Winton went round the world last year, and spent some time visiting the offices of medical journals in Britain and elsewhere. Those fortunate enough to have met him will know that the standard and tradition Dr. Archdall established will be secure in the able hands of his successor.

INFLUENZA VACCINE TRIALS STATEMENT ON BEHALF OF THE MEDICAL RESEARCH COUNCIL'S COMMITTEE ON CLINICAL TRIALS OF INFLUENZA VACCINE

Field and serological trials of different virus A influenza vaccines developed and prepared by Dr. F. Himmelweit, of the virus department of the Wright-Fleming Institute of Microbiology, have been carried out in the past few years under the aegis of the above committee. It has throughout been the committee's object to improve the degree of effectiveness and the duration of immunity afforded by the vaccines. It was therefore disappointing that in the most recent trial in 1955–6 the effectiveness of the vaccine in preventing absences due to clinical influenza in inoculated persons was only of the order of 30–40%.

It is possible that inactivated influenza virus vaccines may in fact be unable to prevent influenza to any greater extent, but it is also likely that the low attack rate experienced during recent epidemics vitiated clinical assessment. The latter view is supported by the excellent results obtained by the use of a suitable virus A vaccine in a sharp outbreak in a boarding school reported by Hawkins *et al.* (1956); also by the fact that the difference in clinical influenza attack rates between the various inoculated persons and the controls month by month was greatest during the period in 1956 when virus A influenza was proved to be prevalent by laboratory tests (M.R.C. Committee on Clinical Trials of Influenza Vaccine, 1957).

Asian Virus

A new situation has now arisen because of the occurrence of large outbreaks in many parts of the world of influenza due to a strain of virus designated Asian influenza A. Although clinically the disease is mild and differs little from the recent outbreaks of Virus A influenza in this country, the attack rate in many of the outbreaks in the Far East and in semi-closed communities elsewhere has been high (10–30%). The virus antigen differs from those of all previously encountered influenza A viruses. Antibodies against the virus have been found only in the serum of aged persons (Mulder, 1957).

A vaccine made from Asian virus has been prepared by methods similar to those employed with other influenza vaccines in the past at the Wright-Fleming Institute. Serological trials have shown that antibody formation is stimulated by this vaccine. It is urgently necessary to test the vaccine in different dose concentrations and in comparison with influenza vaccines prepared from combinations of various strains.

Field Trials this Autumn and Winter

As the possibility of Asian influenza becoming widespread cannot be ruled out, it is desirable to begin trials now, and inoculation of the first batches of volunteers is due to begin in the week ending September 14. The others will be inoculated at intervals throughout the remainder of the month, and all inoculations will, it is hoped, be completed by the second week in October. Volunteers taking part number about 8,000, and they are in four main groups, with the volunteer centres in each group distributed throughout the United Kingdom.

Group A.—A special group of miscellaneous centres, including two ministries, a county council, three universities, a naval dockyard, an industrial firm, a branch of the London transport services, and a London school.

Group B.—Teachers' training colleges, some 20 in number.

Group C.—Public schools, 12 in number.

Group D.—Volunteers among patients with chronic bronchitis drawn from about 40 chest clinics. The trial in this group is in association with the British Tuberculosis Association.

Volunteers in each centre in the four groups will as in previous trials be divided into three approximately equal parties on a random basis, each party receiving one of the

various vaccines under test. The period of observation of volunteers must depend upon the epidemiological developments, but will normally be for some five months. In view, however, of the early dates of inoculation, and again depending upon developments, it is expected to obtain additional volunteers in certain of the groups who will not enter the trial until early December and will be inoculated then. At the end of the trial the results will be analysed to ascertain the incidence of influenza in those inoculated with the different vaccines.

Doctors' Co-operation Requested

Under the arrangements made it will be known to any general practitioner or other medical officer attending a volunteer that that person is in fact a volunteer. It is hoped that all general practitioners seeing such volunteers will co-operate in the investigations by filling in the simple record form with which they will be provided and will bear in mind the great importance of as accurate a diagnosis as possible between true influenza and other respiratory infections with a winter prevalence. The medical officers of health in the areas in which the trials are being carried out can help, and will in particular be able to keep those concerned in the volunteer centres informed on the occurrence of influenza and the progress of any outbreak which attacks the area. For this purpose medical officers of health in those areas in which there are volunteer centres will be given the details of these.

Laboratories of the Public Health Laboratory Service are ready to give any assistance they can and have been informed of the location of volunteer centres in their areas. At the same time those concerned in the volunteer centres will, it is hoped, keep in touch with the local public health laboratories, and, in the event of an outbreak of influenza-like illness within the centre occurring, will provide the laboratory with material from a few cases to allow of the diagnosis being confirmed.

These trials can succeed only if there is the fullest co-operation between all concerned, and the committee has every hope that this will be forthcoming. More detailed information may be had from the secretary of the M.R.C. Committee on Clinical Trials of Influenza Vaccine at the Ministry of Health, 23, Savile Row, London, W.1 (Tel. Regent 8411 Ext. 91).

INTERNATIONAL CONGRESS ON CLINICAL CHEMISTRY

STOCKHOLM, AUGUST 19–23

[FROM A SPECIAL CORRESPONDENT]

A five-day international congress on clinical chemistry was held in Stockholm last month, under the presidency of Professor JÖRGEN LEHMANN, of Göteborg. The congress was sponsored by the Scandinavian Society for Clinical Chemistry and Clinical Physiology and organized by the Swedish Society for Clinical Chemistry. The main subjects discussed were the influence of hormones on electrolyte metabolism, the clinical applications of chromatography, polysaccharides of medical interest, and the use of enzymes in micro-analysis and diagnosis.

Hormones and Electrolytes

Dr. J. F. TAIT (London) considered the relative potencies of some of the adrenal cortical hormones and their likely daily production in man. The main physiological hormones were aldosterone and hydrocortisone. Other hormones, however, might be the main compounds responsible for certain diseases. In hypophysectomized patients aldosterone was

Dr. R. NORDMANN (France) described paper chromatography of plasma organic acids. He had shown by this

Many papers dealt with developments in plasma protein electrophoresis. Dr. T. ARONSSON (Sweden) described a new buffer which enabled separation on paper into nine fractions. Dr. O. P. FOSS (Norway) used labelling with radioactive iodine to improve the sensitivity to traces of

BRITISH MEDICAL JOURNAL 639

*The members of the committee were Sir John Wolfenden (Chairman), Mr. James Adair, Mrs. Mary G. Cohen, Dr. Desmond Curran, Canon V. A. Demant, Mr. Justice Diplock, Sir Hugh Linstead, M.P., the Marquess of Lothian, Mrs. Kathleen Lovibond, J.P., Mr. Victor Mishcon, Mr. Goronwy Rees (resigned, April, 1956), the Rev. R. F. V. Scott (resigned March, 1956), Lady Stopford, Mr. William T. Wells, Q.C., M.P., Dr. Joseph Whitby. *Secretary:* Mr. W. C. Roberts (Home Office); *assistant secretary:* Mr. E. J. Freeman (Scottish Home Department).

Before reaching its recommendation to legalize homosexual behaviour between consenting adults in private, the committee studied, among other things, the possibility of this leading to an increase in paedophilia. Expert witnesses, however, states the committee, were in no doubt whatever that

†In England and Wales, 622 in 1931, and 6,644 in 1955.

paedophiliacs are recognizably distinct from other types of homosexuals, and that homosexuals accustomed to adult partners seldom turn to boys. The committee therefore discounts this consequence of its proposal. In choosing 21 as the age at which a person should be regarded as adult, the committee was guided by four considerations: the need to protect the young and immature; the age at which the pattern of a man's sexual development can be said to be fixed; the age at which a person should be held responsible for his actions; and the consequences of selecting any particular age.

One of the committee's recommendations is that buggery should be reclassified as a misdemeanour. At present buggery is a felony, carrying a liability to life imprisonment; it is singled out for more severe punishment than other forms of homosexual behaviour even when committed in similar circumstances. The committee accepts medical and prison evidence as suggesting that the nature of the deed has no special clinical or penological significance, and that most practising homosexuals indulge at some time in all types of homosexual behaviour; and further that the physical, emotional, or moral harm to a victim of homosexual attention depends more on the surrounding circumstances than on the nature of the act. In spite of this, the committee (with four members dissenting) believes there is some case for retaining buggery as a separate offence. The committee does, however, recommend its reclassification as a misdemeanour. The reason for this is to protect the doctor-patient relationship, for in English law a person who fails to disclose a felony known to him himself commits a criminal offence—misprision of felony. There should be no bar, the committee holds, tending to discourage homosexuals from seeking medical advice.

Medical Treatment in Prison

After reviewing the possible alternatives to prison open to the courts in dealing with homosexual offenders, and noting the difficulty in choosing the most appropriate for a particular case, the committee strongly criticizes a practice of some courts in delivering sentence. It appears that the offender is sometimes told from the bench that he will receive medical treatment for his condition, or even that he is being sent to prison for this purpose. "We are strongly of the opinion that such statements ought not to be made," states the committee. If such treatment does not materialize—and only a very small proportion of these offenders receive it—the prisoner is likely to be left with an unwholesome sense of grievance. Nor, says the committee, in a case with a hopeful prognosis, should the duration of sentence be fixed by reference to any estimate of the time which treatment is likely to take.

One factor that naturally limits the possibilities of treatment in prison, apart from clinical prognosis, is the strength of the prison service. On this the committee says: "The prison medical service is understaffed and incompletely integrated with the National Health Service." While testifying to the valuable and devoted work done by members of the prison medical service, the committee notes particularly the shortage of psychiatrists and recommends a two-way flow of them between the prison medical service and the regional boards. The committee also recommends an urgent review of the "organization, establishment, and conditions of service" of the prison medical service.

The committee is content to leave to the court's discretion the question of medical reports on homosexual offenders of 21 or over, but for those under 21 the committee recommends that before sentence a psychiatric report should be obligatory.

Therapeutic Measures

Treatment is looked at in its broadest context. While it is concluded that total reorientation from complete homosexuality to complete heterosexuality is "very unlikely indeed," the committee recognizes the success that may be achieved in giving a better adjustment to life and in reducing the intensity of the homosexual impulse.

There are many obstacles to successful psychotherapy. Many homosexual offenders are either unwilling to co-operate or of too low intelligence. Out of 1,065 such prisoners in 1955 only 15% were rated by prison medical officers as suitable for psychotherapy, and ultimately only 6% were accepted for treatment at the psychiatric units at Wakefield and Wormwood Scrubs. The therapeutic roles of probation and of prison itself are discussed, and evidence is adduced to support a more extensive use of probation with medical treatment as a condition. Although a prison sentence can, in many cases, states the committee, detrimentally affect any prospect of successful treatment, to some men it acts as a salutary shock and for others it is necessary for the protection of the public. The committee is against the establishment of a special institution, part prison and part mental hospital, as a solution for offenders who are dullards but not certifiable under the present laws.

Oestrogens, in some homosexuals, will reduce the strength of the sexual urge although not altering its direction. But in prisons in England and Wales (not, apparently, in Scotland) their use is forbidden even if requested by the prisoner. The committee therefore recommends that if a prisoner wishes to have oestrogen treatment, and the prison medical officer agrees it might help, this treatment should be allowed. On the other hand the committee is against castration.

This part of the report is supplemented by a note written by two medical members of the committee, Dr. Curran and Dr. Whitby. The note describes in more detail the clinical varieties of homosexuality and their treatment, and aims to redress what its authors consider an "appearance of unjustified pessimism" about prognosis.

Medical Witnesses

Among the professional bodies which gave written and oral evidence before the Wolfenden Committee were the B.M.A.,* the Institute of Psychiatry, the Institute of Psycho-Analysis, the British Psychological Society, the Institute for the Study and Treatment of Delinquency, the Royal Medico-Psychological Association, the Tavistock Clinic, and the Davidson Clinic, Edinburgh. The Royal College of Physicians submitted a written memorandum.

A memorandum on the organization of Scottish cancer services, recently circulated to regional boards by the Department of Health, advises the establishment of regional cancer committees. Their purpose would be "to ensure, throughout Scotland, the promotion of early diagnosis and the efficient treatment and aftercare of patients," according to a press statement from St. Andrew's House. The memorandum was prepared by the Scottish Health Services Council's standing committee on cancer, whose chairman is Professor J. S. YOUNG, Regius professor of pathology at Aberdeen. It is important, states the memorandum, that cancer should not be regarded as a specialty in itself and that special cancer hospitals should not be established. Cancer clinics should be set up at suitable local hospitals to obviate lengthy and sometimes unnecessary journeys by patients to major centres, and also to make effective follow-up examination easier. In the main centres also there should be, as at present, a headquarters hospital or hospital group where surgery for every form of cancer is available and where radiotherapy of all types is provided. This would extend in the two largest regions to the most complicated and expensive apparatus. "For the most specialized treatment—whether by surgery, radiotherapy, or other means—patients from any part of Scotland should be transferred to the appropriate hospital." On research, the memorandum recommends that close relations should be established with research departments and the appropriate university departments.

*Those giving evidence on behalf of the B.M.A. were Dr. Dennis Carroll, Dr. T. C. N. Gibbins, Dr. Ronald Gibson, Dr. Ambrose King, Dr. Doris Odum, Dr. Leonard Simpson, and Dr. E. E. Claxton (Assistant Secretary).

Correspondence

Erasure from the Register

SIR,—I am instructed by the Executive Committee of the General Medical Council to say that they are concerned at the number of medical practitioners who, as further explained below, have not replied to letters sent to them in recent months under section 41 of the Medical Act of 1956. Under the Act and the Council's Standing Orders these practitioners are rendering themselves liable to removal from the Register.

Section 41 requires the Registrar and the three Branch Registrars of the Council to keep the Register correct, to erase the names of persons who have died, and to make the necessary alterations in the addresses of registered persons. For these purposes it is necessary for the Registrars from time to time (roughly at intervals of five years) to send to every registered medical practitioner, at his address on the Register, a letter inquiring whether he has ceased to practise or has changed his address; and if no answer is returned within six months it then becomes lawful to erase the name of the practitioner from the Register.

In February, 1957, letters were sent for these purposes to all fully registered practitioners whose surnames begin with the letters from Sm to Z, inclusive, apart from those practitioners who (1) first became fully registered on or after January 1, 1956, or (2) qualified outside these islands. Unfortunately, nearly 2,000 practitioners sent no reply to these letters. Except in cases where the letter had been returned through the dead letter post, further letters were sent by registered post in May to those practitioners from whom no reply had been received. With the co-operation of Messrs. Churchill (*The Medical Directory*), the British Medical Association, the Medical Defence Societies, the Ministry of Health, and other bodies, efforts are being made to establish communication with the practitioners concerned. Nevertheless, as matters stand it will become necessary to remove from the Register in November of this year the names of upwards of 500 persons. While many of these practitioners have no doubt died or gone overseas, previous experience suggests that some are still in practice and would desire to remain on the Register.

In these circumstances the Executive Committee appeal to any practitioner in the group concerned who has not received or has not yet answered such a letter to communicate with the Council as soon as possible. Persons in other groups are urged to ensure that the Council are always in possession of a registered address which will afford a trustworthy means of communication with the practitioner.—I am, etc.,

W. K. PYKE-LEES,
Registrar, General Medical Council.
London, W.1.

Placentography in Management of Placenta Praevia

SIR,—Mr. H. B. Watson and his colleagues (*Journal*, August 31, p. 490) have undoubtedly helped the progress of modern obstetrics by their timely reminder of the assistance to be gained from radiological placentography. They have also demonstrated that the conservative treatment of placenta praevia may largely abolish the danger of prematurity to the baby, for with an average birth weight of 7 lb. 2 oz. (3.2 kg.) and no mortality in 25 cases they set a very high standard.

It is therefore unfortunate that they make use of these results of fine obstetric judgment to decry the value of traditional examination under anaesthesia of cases of placenta praevia prior to caesarean section. It is admitted, albeit grudgingly, that palpation of the placental edge may have a place in assessing those cases of minor degrees of placenta in which the radiologist has reported an anterior placenta and the foetal head has failed to engage. Attention is paid to irregularities of the foetal heart following

pressure on the head in an attempt to effect engagement, regardless of the fact that this is constant whatever the placental site. Undue reliance also appears to be placed upon the radiological localization of the lower limit of the placental edge, although it is not suggested that its essential relationship to the internal os of the cervix may be thus established.

It is probable that, with good surgical technique and modern methods of resuscitation, a few unnecessary caesarean sections will make little difference to foetal and maternal statistics, but it is surely wrong to perform these operations without the exactitude of diagnosis that can only be achieved by the delicate palpation of the placental edge. The decision as to the proper method of delivery may be balanced so nicely that radiology alone cannot hope to give an answer of sufficient accuracy, especially when it is realized that the portion of placenta overlying the internal os may be infarcted and incapable of bleeding.

There are other dangers. It is easy to suspect placenta praevia in all cases with a free presenting part and only too easy to find some excuse for an elective section in such patients when the placentography has given indeterminate results. It is also possible to mistake the diagnosis in those less common cases with associated pelvic neoplasms. Recently two such have occurred. There was antepartum bleeding associated with oblique lie of the foetus in a woman of such vast proportions that placentography was indeterminate and vaginal specula proved inadequate to reach the cervix; fortunately she was examined under anaesthesia, when an unexpected carcinoma of cervix was discovered and the subsequent section combined with a Wertheim operation. On the other occasion a multipara had had repeated haemorrhage in the last month of pregnancy and the foetal head would not engage; the vaginal examination was made as a matter of principle, but its value was demonstrated when a large submucous fibroid was removed from the lower uterine segment and an easy normal delivery followed rupture of the membranes. For these various reasons it is felt that the examination under anaesthesia should remain a routine practice in the standard treatment of cases of suspected placenta praevia prior to caesarean section.—I am, etc.,

Birmingham.

W. G. MILLS.

SIR,—With my limited experience I consider it would be extremely dangerous to discharge patients from hospital with a history of vaginal bleeding late in pregnancy even though placentography has excluded placenta praevia, as has been suggested by Dr. H. B. Watson and his colleagues in the concluding paragraph of their article (*Journal*, August 31, p. 490). Human errors in the interpretation of radiographic appearances do occur, and it is the false negative reports of placenta praevia that are dangerous. One instance is reported in this article (Case 2), and I have had personal experience of another instance, the report being made by a radiologist experienced in this work; the error was of interpretation. And can a radiologist always exclude a succenturiate lobe sited near the internal os?

As Dr. Watson and others have shown, placentography is an extremely valuable aid in the practice of obstetrics, but the final exclusion of placenta praevia can only be made by examination under anaesthesia in a theatre fully prepared for caesarean section. To discharge from hospital those patients who have a history of vaginal bleeding late in pregnancy without this precaution is courting disaster, and the obstetrician risks being contributory to an avoidable maternal death.—I am, etc.,

St. Clears, Carmarthenshire.

P. J. OLNEY.

Fluothane

SIR,—There are several points in the Medical Research Council's report on fluothane (*Journal*, August 31, p. 479) which I find rather confusing. The views expressed on its effects on cardiac output and on autonomic activity are at variance with accepted concepts concerning the maintenance of cardiac output during inhalational anaesthesia. It is known

that ether, chloroform, and cyclopropane cause a diminished and possibly fatal myocardial depression in the presence of sympathetic ganglion block.¹ During anaesthesia with these agents the cardiac output is maintained by an increased production of adrenaline and noradrenaline brought about by the stimulation of the central autonomic centres.¹ The sympathomimetic effects of these anaesthetic agents are manifested clinically by increasing peripheral vasoconstriction with a rising pulse rate, and, after prolonged and deep anaesthesia, by the appearance of a condition indistinguishable from adrenaline shock.² The authors admit that fluothane paralyses the sympathetic reactions. The mechanism of the diminished cardiac output under fluothane anaesthesia must therefore be of considerably less serious significance than that associated with other inhalational agents. It is most probably analogous to the diminished output caused by ganglionic blockade with hexamethonium bromide.³

I cannot accept the suggestion that fluothane depresses the central autonomic centres. The vasoconstrictive reaction to carbon dioxide retention during fluothane anaesthesia is immediate and brisk, indicating that the vasomotor centre is functionally intact. This reaction is consistent with a block at ganglionic level.⁴ A peripheral adrenergic or a direct depressant effect on the blood vessels can be excluded as the response of the vessels to direct trauma and to peripherally acting vasopressors is unimpaired.

In the assessment of recovery times and post-operative vomiting the clinical report does not make adequately clear whether the figures related to fluothane anaesthesia or to opiate-fluothane anaesthesia. I can assure the authors that fluothane has no significant effect on the incidence of post-operative nausea and vomiting caused by the pre-operative administration of an opiate. I find it very difficult to see how a clinical report based on 245 cases dealt with over a period of 18 months by the anaesthetists of four large teaching hospitals provides grounds for comment other than the obvious "Only when several thousand patients have been anaesthetized will it become possible to estimate its advantages and disadvantages."—I am, etc.,

Manchester.

British Medicine Abroad

SIR,—When considering the question of the reputation and influence of British medicine abroad and the important work of the British Council, it is well not to forget that large numbers of foreign doctors and medical students visit London and other centres of medical education and research in Britain. We are not, I think, doing all we could to make these visits as fruitful as they might be, and I would like to mention one particular source of annoyance and irritation. The Library of the British Medical Association is open to foreign medical visitors on presentation of a letter of introduction by a B.M.A. member. However, the member is requested to write a new letter each time the same foreign visitor wishes to renew his attendance at the Library. This rule can be circumvented by means of cyclostyled letters, but surely it is absurd and should be dropped.

I may say that in the post-war years I have gained ample proof that the reputation of British medicine is steadily gaining in Italy, and I am glad that friendly exchanges between the Italian and the British medical profession are increasing.—I am, etc.,

London, W.C.1.

E. MONTUSCHI.

Phenylbutazone

SIR,—Since the introduction of phenylbutazone there have been frequent reports of serious complications from its use, and your own pages have been used to report nine deaths thought to be caused by this drug. Deaths have most commonly been from agranulocytosis, aplastic anaemia, or

haemorrhage from peptic ulcers. Though serious complications may be less common with the doses now recommended than with the higher doses recommended when this drug was introduced in 1952, fatalities will continue to recur while it is used extensively. Though a case can be made for using such a drug in severe rheumatoid arthritis, I feel that there can be no justification for using this drug, which can kill, in trivial conditions. I have been disappointed to see that a manufacturer has recently been extensively advertising its use for such conditions as "fibrositis" and superficial thrombophlebitis. The only way to combat this advertising is to keep on reminding the medical profession of the dangers of the drug. I hope, if sufficient reports of its adverse effects appear in the medical journals, that it will fall into disuse, and I therefore report two further cases with serious complications which have been seen at the King George Hospital within the last three months.

(1) A female, aged 66, without any dyspeptic history, was given phenylbutazone ("butazolidin"), 100 mg. twice a day, because of aching in her knees without objective evidence of arthritis. After six days she had a haematemesis and was admitted to hospital next day. Bleeding continued, and at operation she was found to have an acute high lesser-curve gastric ulcer. Bleeding continued after a high gastrectomy, but she eventually recovered after she had had 34 pints (19.5 l.) of blood. X-ray later showed a small para-oesophageal pouch with probable ulceration. (2) A female, aged 50, without any dyspeptic history, was given phenylbutazone for thrombophlebitis in superficial varicose veins of the right calf. She had 600 mg. daily for two days, then 400 mg. a day. On the fifth day the drug was stopped because she developed a generalized papular eruption with fever and enlargement of cervical lymph glands. Over the next few days her rash developed a purpuric element and she passed two melaena stools. On admission five days after her rash had appeared she had a temperature of 103° F. (39.4° C.) and was slightly jaundiced, with an enlarged liver. She had a generalized papular urticarial rash with purpura in places. The platelet count and bleeding time were normal. The fever persisted for a further week, but she seemed completely well on discharge ten days after admission.

Perhaps this letter may stimulate others who feel as I do to report serious complications from this drug.—I am, etc.,
Ilford, Essex.

T. B. DUNN.

Premedication with Methypentynol

SIR,—Dr. A. Fry in his letter (*Journal*, August 17, p. 411) replied to Dr. G. Kagan (*Journal*, July 20, p. 161) that hypnosis will help and cure enuresis, and is preferable to the use of drugs. In selected cases I agree with Dr. Fry, but would suggest that his remarks comparing methypentynol carbamate ("oblivon-C") with alcohol are not in accordance with practice nor with the research of P. Trotter¹ (3,000 cases), who states that methypentynol speeds reaction and has a negligible deleterious effect on behaviour.

My own recent satisfactory use of methypentynol has prompted me to write affirming my approval of its use and particularly with regard to dental anaesthesia. I also refer here to Dr. F. R. Gusterson's letter (*Journal*, May 4, p. 1062), with which I agree. At the beginning of the last war I was a dental anaesthetist in large London clinics, and later, after my return from the Far East, where I was continuously employed as an anaesthetist, I again gave anaesthetics in local government dental clinics. Normally, in previous years with the help of an expert team, I was accustomed to smooth induction aided by reassuring conversation and followed by satisfied patients in the recovery room. During the last three years, however, with the habitual use of methypentynol, the pre-anaesthetic phase and subsequent stages of induction and recovery have been rendered even easier for the anaesthetist and pleasanter for the patient, either child or adult.

Detailed research by Dr. R. Goulding and his colleagues (*Journal*, April 13, p. 855) concludes that dental premedication with methypentynol in order to produce sedation "scarcely provides the answer." I cannot agree with this statement and feel (in all fairness to them) that they did not employ high enough dosage: one and a half or twice their dosage would be effective and safe. I obtain excellent

sedation with methypentynol elixir, using 1½ teaspoonfuls for children 3–5 years; 2 teaspoonfuls for children 5–10 years; and 2 to 4 teaspoonfuls for adults (according to individual case). One teaspoonful = 250 mg. methypentynol.

In young children up to the age of 7 methypentynol relieves the work of the dental team—they do not have to create assurance or dispel apprehension; the patient, on the contrary, reassures the team; he "feels fine," is "sleepy," "doesn't care." In older children and adults there are those who do not appear to need sedation, but in others, more nervous, methypentynol provides the answer. I am also persuaded by my observations in the surgery and in the home afterwards that even in the outwardly calm patient methypentynol in the beginning shortens the distance to the dentist's chair and leads to a happier recovery in the end.—I am, etc.,

Drug Addiction

SIR,—Dr. J. Tudor-Hart (*Journal*, August 24, p. 468) has drawn attention to the discrepancy that exists between the officially admitted figures for drug addiction and those available from his own practice. There must be many doctors whose experience is similar to his. Your annotation (*Journal*, July 27, p. 210) indicates that drug addiction is an occupational hazard among doctors, and this is particularly true of anaesthetists. In a relatively short professional career I have had sufficient experience of drug addiction among colleagues in the specialty to appreciate that its extent is far greater than is officially recognized. What is particularly disturbing is its occurrence among young doctors in training posts. It is, of course, difficult if not impossible to establish the full extent of this problem. How many victims will admit to addiction even to themselves? The penalties are too great; social ostracism, loss of livelihood, and, not least, loss of supplies make it unlikely that the addict will seek treatment.

The problem is especially important in anaesthesia, not only because of the particular type of responsibility required of anaesthetists but also because of the easy access to a large variety of drugs of addiction. Moreover, if addiction is suspected or even proved, sympathetic but misguided colleagues may shield the sufferer so that he continues to work in an environment which can only further his addiction. The ethical and medico-legal questions raised by a matter of this sort are considerable, and there is perhaps a case for an examination of the whole problem of drug addiction in anaesthesia by one of the professional associations. In the meantime, anaesthetists with administrative responsibility might consider whether their supervision of dangerous drugs in the operating theatre is as careful as it should be.—I am, etc.,

London, W.12.

J. P. PAYNE.

A Lapinarian Uprising

SIR,—The rabbit has little enough opportunity to hit back at his ruthless persecutors bent on his eventual destruction, but recently a large domesticated buck rabbit, quick to size up the situation, struck boldly, if a trifle ungratefully.

A certain kindly family in Kent devotedly tended a large hutch of tame grey rabbits. The youngest member, a precocious infant of 18 months, was placed in the hutch to study their ways. Summoned by cries of distress, the family were disconcerted to find that a large rabbit had neatly bitten off the distal two-thirds of the terminal phalanx of the child's right index finger. The injury healed without incident, and animal lovers will be relieved to know that no swift reprisals were taken; indeed, that same hutch continues to be carefully tended. What the eventual outcome may have been if the neighbours' rabbit, dog, or child had caused the injury is worth conjecture.—I am, etc.,

Farnborough, Kent.

E. C. WATSON.

Proteus Infection of Urinary Tract

SIR,—Most pathologists would probably agree with Dr. J. E. Middleton's main conclusion (*Journal*, August 31, p. 497) that nitrofurantoin is the most useful of the drugs commonly tested against *Proteus* strains, but few would expect to find them all sensitive. Using the same tablets for the test we have found 7 strains out of 32 to be resistant. Of more practical interest is the date and origin of the resistant strains. We analyse the results of all sensitivity tests twice yearly and break them down into in-patient, out-patient, and general-practice strains. This inevitably results in small groups, but the trends of changes they show over a period may still be significant. Thus, while in the first year the drug was used here only 1 strain of 13 was resistant, in the second there were 6 out of 19. Furthermore, 5 of these 6 came from patients in the wards.

These results are so like those that have followed the introduction of other antibacterial substances to therapeutics that they point to the same conclusions. In particular I would emphasize the importance of stating the time over which results are obtained and would agree that much larger series are desirable. In general these will only be obtainable, within set periods, by pooling results such as these. I should be most interested to hear from any of your readers who have similar data and would be interested in such a scheme.—I am, etc.,

London, E.7.

J. B. ENTICKNAP.

Hygiene in Public Lavatories

SIR,—In all medical journals and newspapers there has been a considerable amount of publicity given to fly-borne diseases. Recently I have returned from a touring holiday in England and I had on several occasions to make use of public lavatories in villages. The majority of these were absolutely filthy—some had no water—and these places were the finest breeding-grounds for flies that one could imagine. My wife tells me that the ladies' public lavatories were also in a disgraceful condition. We pride ourselves upon our standard of hygiene in this country, and I would suggest that the medical officers of health should co-operate with the local councils to ensure that the public lavatories are kept in a hygienic condition, thus eliminating one very definite source of danger. I would also like to see provision made for the washing of hands after use of the toilet.—I am, etc.,

London, S.E.6.

R. G. WIGODER.

Churches' Council of Healing

SIR,—Sympathetic though I am to the views of Dr. Jane H. Thompson (*Journal*, July 27, p. 238) on the importance of the spiritual factor in healing, I confess I am not attracted by her suggestion that the B.M.A. should have "a section devoted to spiritual considerations in healing and keeping whole, and be able to present studies which demonstrate the interaction of body, mind, and spirit in health and disease—in short, a section on spirito-psycho-somatic medicine, misnamed at present psychosomatic."

Other correspondents suggest other terms for much the same thing. My objection is not that there is here any terminological inexactitude, but that it is a fundamental mistake to confuse the scientific and the spiritual, which belong to different planes of thought and experience. The scientific deals with what is general and uniform, and as such is open to observation and analysis; the spiritual, being essentially of an individual and personal character, cannot be estimated and described in this way. One can have a science and a technique when dealing with any part of a man, but not when dealing with man's nature as a whole, precisely because that includes a spiritual factor, which takes one completely beyond the bounds of scientific study.

One may of course observe and estimate the results of spiritual happenings, but these happenings in themselves, being spiritual, can only be spiritually discerned and valued.

We must not, as G. K. Chesterton once said, "try to be more natural than it is natural to be."

In my opinion it would be a mistake to have a special department in our medical schools or hospitals which would convey the impression that the spiritual factor can be relegated or confined to any one aspect of medical science.

I am sure that this is far from Dr. Thompson's thought, but I fear her letter might easily give this impression to any less well-informed in these matters. We cannot remind ourselves too often that religion, as John Caird once said, is not so much a duty as something that has to do with all duties: "To spiritualize what is material, to Christianize what is secular—that is the noble achievement of Christian principle."—I am, etc.,

Rubella in a Young Baby

SIR,—As it is not generally known that rubella can occur in infancy I wish to record a case that recently came under my care. The baby was born at home in an isolated village on July 1, and she developed a typical rash with adenitis of the neck and groins on July 21. The rash gradually faded and had disappeared by the third day. The only rubella contact that this baby could possibly have had was her brother, aged 8, whom I diagnosed on June 17, a fortnight before her birth. Moreover on July 2 this boy was sent away to his boarding-school, so the baby must have been infected on the day of her birth. This case confirms that the incubation period of rubella can be as long as 21 days, but it also shows that the textbook isolation period of 7 days from the appearance of the rash is not long enough to protect susceptible contacts.—I am, etc.,

Bungay, Suffolk.

HUGH CANE.

Hospital Confinement

SIR,—In reply to Dr. M. G. Smith (*Journal*, August 17, p. 414), the incidence of episiotomy in primiparae, or perineal tear if the former is not performed, is in the region of 50% of cases. Surely no doctor is going to condone the practice of episiotomy, and subsequent suture, in the home if it can be avoided. Therefore this reason alone, apart from the many others, should make us urge the delivery of primiparae in hospital.—I am, etc.,

Ely.

JOHN FRAMPTON.

Smoking and Lung Cancer

SIR,—It may be worth reviving the suggestion that the causal relationship between smoking and lung cancer could be one in which the carcinogenic effect of tobacco smoke is simply to determine the site of the primary tumour in the lungs of congenitally cancer-prone smokers, rather than elsewhere in their bodies, and that these cancer-prone individuals were destined to develop the disease sooner or later in any event, whether or not they had indulged in smoking.

The idea that there is a congenital hereditary factor in at least some forms of cancer is an old one that is now widely accepted, and I have pointed out¹ that the hypothesis that external carcinogenic agents may determine the form, site, and time of onset of cancer, rather than its origin, can explain several puzzling problems in the incidence of the disease. In particular, where one form of cancer is prevalent in a group of people there is often a lower incidence of other forms, so that total cancer incidence varies less than would have been expected if it were caused by a number of quite independent external agents. For example, the relatively low lung cancer rate in women, that cannot be wholly explained by differences in smoking habits, is offset by much higher mortality from mammary and genital cancers compared with men.

This hypothesis has been considered by Doll and Bradford Hill,² who rejected it on the grounds that, in the latest figures from their forward inquiry into the smoking habits and mortality of British doctors, the smokers showed a higher standardized death rate from all forms of cancer than the non-smokers, and the excess corresponded approximately with the difference in death rates from lung cancer alone. This argument, however, may not be entirely conclusive, for, if smoking really does induce cancer only in a cancer-prone person, it will still act earlier than would another agent due to produce a tumour elsewhere in his body had he been a non-smoker and so avoided the risk of cancer in his lungs. Furthermore, since lung cancer is a particularly lethal and rapid form of the disease, its victims will, on average, survive for a shorter time than will patients suffering from other forms of cancer. Consequently smokers who develop lung cancer must expect to have their deaths advanced, compared with non-smokers, whether or not they were congenitally cancer-prone, and this will have the effect of raising their standardized death rates; but that does not disprove the hypothesis of cancer proneness.

If this is what happens it is important to know by how much a congenitally cancer-prone smoker can expect that his death will be advanced if he develops lung cancer. It is clearly most relevant to know whether the statement that a man who is a heavy cigarette-smoker has one chance in eight of dying of lung cancer could equally well be expressed by saying that he has one chance in eight of shortening his life by, say, for the sake of argument, a couple of years.

The full data of the M.R.C. inquiry are now, no doubt, too extensive to be published in any but summary form, and no proper estimate of this effect can be derived from the figures given for standardized death rates in the different classes of smokers. But a precise question can be asked, which is, "By how many years, on the average, would it be necessary to assume that the dates of death of the lung cancer victims in this inquiry had been advanced in order to bring the total cancer incidence and mortality of the smokers down to that of the non-smokers?" Due allowance would have to be made for the risk of mortality from other causes during this period. A straightforward numerical answer to this question should be obtainable from the original data of the M.R.C. inquiry, and if the answer is of the order of 10 years any effect of cancer-proneness in the causal relationship between smoking and lung cancer may be considered of negligible practical importance. If the answer turns out to be a couple of years or so, then a heavy smoker would still be well advised to give up smoking, for one chance in eight of losing two years of life is not a negligible risk, but he would at least have a better idea of the true risk that he runs than is available to him at present.—I am, etc.,

Cambridge.

Radiation Hazards

SIR,—Dr. G. M. Ardran,¹ writing from the Nuffield Institute, states: "It is obvious that no x-ray should be taken or no patient fluoroscoped unless the information required cannot easily be obtained by other means. This will require education on the part of the medical and legal professions and the general public." I do feel that this problem merits serious consideration by the medical defence bodies and by teachers at our medical schools. Many young residents in our hospitals now arrive with the idea that any patient with the most trivial injury who arrives at the casualty department, at any time of the day or night, must be x-rayed at once. Medico-legal risks are covered by the term "reasonable care and attention."

I was present at the Annual B.M.A. Meeting at Bournemouth in 1934 when, in a discussion on the value of radiology as an aid to the general practitioner, which took place at a meeting of the section of radiology and electrotherapeutics, the President of the Association stated that in the

case of the simple sprain or injury he never asked for an x-ray examination unless the patient's progress at any stage was not consistent with a simple injury. He added that in the course of thirty years' experience, which included attendance at a number of fashionable girls' schools, he could only recall one case in which he regretted not having called for radiography at an earlier stage. I do think that some clear guidance should be given to the profession regarding the radiation hazards involved.—I am, etc.,

Ipswich.

Operative Treatment of Cardiac Failure in Early Infancy

SIR,—Dr. J. J. Kempton and Mr. D. J. Waterston in their article (*Journal*, August 24, p. 442) draw attention to the opportunity for surgical salvage of newborn and young infants in otherwise lethal cardiac failure, when this is due to coarctation of the aorta. They are to be congratulated on their excellent results. Experience in Glasgow of infants in cardiac failure suggests that relatively few have congenital lesions amenable to operative correction, and we feel that Dr. Kempton is fortunate that four of his ten patients had technically correctable anomalies.

During the past year, amongst the infants with coarctation of the aorta in cardiac failure referred for thoracotomy by Dr. J. H. Hutchison, only one had the lesion uncomplicated by intracardiac anomalies. This infant survived a resection of the coarcted aorta with direct anastomosis under general hypothermia on the thirteenth day of life, making an uncomplicated recovery.—We are, etc.,

Glasgow, C.3.

R. S. BARCLAY.

J. F. R. BENTLEY.

Benign Myalgic Encephalitis

SIR,—Your valuable leading article (*Journal*, August 31, p. 513) on the diagnosis of poliomyelitis states that "benign myalgic encephalitis, the so-called 'Royal Free disease,' is unlikely to be diagnosed without much observation and investigation." On the other hand, if familiar with its characteristics, it seems unnecessary to refrain from making at least an early provisional diagnosis of this condition when confronted with cases that clinically suggest it. Seven such cases were seen in this infectious disease unit last year,¹ mostly admitted as poliomyelitis in a season when there was little of that disease in Coventry. This year, under opposite conditions, four cases clinically allied to the Royal Free syndrome have been admitted up to the present.

The most typical of them was a woman of 29 who had backache, general aches, and very marked lassitude for four days followed by a feeling of instability and aching in her legs, worse after exertion. Her doctor found marked general weakness in her left leg with normal reflexes, her temperature being 99° F. (37.2° C.). In hospital her left hamstrings were found to be painful on stretching and there was diffuse tenderness in the muscles of the left leg. The left heel could be lifted clear of the bed only after a pause for effort and concentration. All voluntary movements of the left foot were weak and restricted and the left ankle jerk appeared slightly reduced. Blunting of sensation was found to touch and pain and to vibration and position in the left ankle and foot. The patient said she had seen evanescent flickers in the muscles of her leg, but these were not confirmed on examination. There was slight weakness and aching on exertion in the left upper arm. The cerebrospinal fluid was normal. The patient improved steadily, being discharged home after 2½ weeks in hospital. At that time sensation was normal and she walked fairly well, although dragging her left leg if she attempted to hurry.

A milder type of case, seen at home because of weakness in her right leg observed by her doctor, was not admitted

to hospital. This patient had headaches, slight sore throat, and stiffness of the neck for a week before she noticed that her right leg felt unsure, heavy, and tended to ache and to tire rapidly. Examination showed no more than discomfort on neck flexion; there was slight loss of power in the right leg with jerkiness and a reduced ability for sustained effort. The tendon reflexes appeared normal. There was a numb feeling in the leg but no loss of sensation.

The resemblance of these cases to descriptions of benign myalgic encephalomyelitis was recognizable on first examination at the bedside.—I am, etc.,

Coventry.

Anthropology and Menstruation

SIR,—Recently I have come across two instances of the attitude, under different religions, towards menstruation which would seem to show the extreme limits of indifference and of abhorrence.

(1) Bernard Lelong and Jean-Luc Javal, in the translation from the French of their book *The Stars Weep*,¹ describing studies of social organization in Bolivia and Peru, say:

It was on the subject of menstruation that we had our first little difficulties with our interpreter. When we asked what the women did about it, Aramayo answered at once without passing our question on. As a matter of fact, what he told us was perfectly true, but we wanted our information to come as far as possible from the Indians themselves. It took us quite a little time to explain this to him, the trouble being that we had touched on a subject that offended his delicacy. In the end, however, we persuaded him reluctantly to ask. The Indian women do nothing about it at all. They simply allow the blood to run down their legs, which they wipe with their skirts. They are subject to no prohibitions at this period and work exactly as at other times.

(2) The orthodox Jewish woman is directed to cut her nails before the ritual bath (Mikveh) after menstruation so that there may be no obstruction to the penetration of the purifying water to every part of the body's surface. "... It has long been the established custom to pare the nails of their hands and feet before taking the bath of immersion. She should be careful to burn her nails, for it is dangerous for her husband or some other man to tread thereon."² Thus the impurity of the woman before immersion is such that it can render another person impure through the medium of nail-parings.—I am, etc.,

Compulsory Powers over Mental Patients

SIR,—With reference to the Report of the Royal Commission on the Law Relating to Mental Illness, and discussing the recommendation of compulsory admission of mental patients by the psychiatrist, Dr. C. R. Birnie has written (*Journal*, July 27, p. 234): "In cases where the psychiatrist is attached to the receiving hospital (and this is recommended) the doctor-patient relationship is poisoned from the outset." On the same subject Dr. Alexander Walk wrote (*Journal*, August 24, p. 467): "Even now, mental hospital doctors very often take part in the certification of patients whom they are to receive; for, as consultants to observation units (which may actually be within their own hospitals) or in the course of domiciliary visiting, it falls to them to recommend compulsory admission, even if the statutory certificate is written by another hand. Our patients are not deceived and know where the responsibility lies. But there is no 'odium,' no 'poisoning of the doctor-patient relationship'; on the contrary, the patient is pleased to know that the initiative was taken by the doctor in whom his subsequent treatment has led him to have confidence."

It so happens that, as specialist-psychiatrist to the Government of Kenya Colony, I had to work for many years within

the terms of an ancient law—the Indian Lunacy Act of 1858. Under this Act patients whose condition called for compulsory admission were so admitted on a magistrate's order supported by one doctor's certificate. Since the psychiatrist attached to the mental hospital was not, in this Act, debarred from being the person who made out the medical certificate, and since that psychiatrist—myself—was for most of that time the only medical man in the colony with much psychiatric experience, it usually fell to me to make out that certificate. I am therefore in a position to know exactly how this sort of procedure does affect the doctor-patient relationship. It often poisons it. I have no reason to believe (to misquote Dr. Walk) that my subsequent treatment of these patients led them to have less confidence in me than they would have had in most psychiatrists in similar circumstances, but, for the first few days at least, they were usually very far from pleased to know that the initiative for their compulsory admission had been taken by myself.

Admittedly one could usually break down the resulting hostility fairly quickly, but the interlude was often an unhappy one and quite prejudicial to the type of cordial doctor-patient relationship which is of such especial value in psychiatry. The documentary aspect is important, and I can well recall my great relief and the sustained improvement in these relationships when, in 1949, a new Mental Treatment Ordinance was introduced, incorporating the principle that no person attached to the admitting mental hospital could play this documentary part in the case of compulsory admissions. Furthermore, I do not believe that, for the patient, this rose would smell one whit sweeter for the change of name from "certify" to "recommend."—I am, etc.,

Havant, Hants.

J. C. CAROTHERS.

The Forgotten Thomas Splint

SIR,—How delighted I was to see the letter from Colonel A. G. D. Whyte with the above title (*Journal*, August 17, p. 414). Having had the misfortune to fracture my left femur high up, in January, 1956, I was kept three months in bed, and when allowed up was repeatedly told "not to put any weight on the left leg." No Thomas splint was ever provided, and when I ventured to mention it I was told it was not used any more. Now, 17 months later, I still walk with a limp, and the surgeon says I should throw away my stick crutch, without which I can do nothing. On looking up the subject in my *Orthopaedics for Practitioners*,¹ I find this statement: "The ideal treatment is undoubtedly the splint, in which they can get about with crutches, swinging the leg and wearing a patten beneath the other foot." I hope Colonel Whyte's letter will receive the attention it deserves.—I am, etc.,

Worthing.

London Medical Orchestral Society

SIR,—Many members of the medical profession will be interested to know that the London Medical Orchestral Society, under the presidency of Mr. Dickson Wright, is now in its fifth year. It is the aim of this orchestra to raise money for medical charities. At a recent concert the sum of £190 was handed over to a medical charity after paying all concert expenses.

In order to maintain and expand this charitable work, it is essential that the number of playing members should be augmented, particularly in the 'cello and bass sections. It is hoped that as a result of this letter to the *Journal* members of a good standard of musicianship will apply to me for full particulars of how to join the orchestra.—I am, etc.,

6, Oxford Court,
London, W.3.

E. V. SLAUGHTER,
Hon. Secretary, London Medical
Orchestral Society.

Obituary

MERVYN ARCHDALL, M.D., Ch.M., F.R.A.C.P.,
F.R.A.C.S.

We record with much regret the sudden death on September 6 of Dr. Mervyn Archdall, who less than a week before, on his 73rd birthday, had retired from the editorship of the *Medical Journal of Australia*. He won his great reputation as a medical editor not just by achieving seniority in his profession but by his long-continued and remarkably successful efforts to advance the science of medicine in Australia. The Federal Council of the British Medical Association in Australia recently gave fitting recognition to his outstanding services by awarding him the Gold Medal of the Association in Australia.

Mervyn Archdall was born in the Sydney suburb of Balmain, New South Wales, on August 31, 1884, the son of the Rev. Mervyn Archdall, rector of St. Mary's, East Balmain. From Sydney Grammar School he went on to the University of Sydney to study medicine, graduating M.B. in 1907. After holding a resident post at Sydney Hospital, he went into general practice in Queensland and then returned to practise in Balmain. He had an inclination towards surgery, and after proceeding to the M.D. in 1912 he took the degree of Ch.M. in the same year. At Sydney Hospital he worked for a time as honorary relieving assistant surgeon, and when he joined the Australian Army Medical Corps during the first world war he went to France as a surgeon on the staff of the Second Australian General Hospital, and towards the end of the war was in charge of a surgical team. On his return to Australia Archdall went back into general practice, until 1922, when he was appointed part-time assistant editor of the *Australian Medical Journal* under Dr. Henry William Armit, who had been editor since 1914. Dr. Armit died suddenly in 1930 and Archdall succeeded him. Thereafter, with very little help, he kept the journal in the forefront of weekly medical periodicals. His insistence on the publication in Australia of the results of medical work carried out in that country not only raised the status of Australian medicine but helped to give his own journal the scientific reputation it now enjoys. But Archdall's efforts did not end with the *Medical Journal of Australia*. When the *Journal of the College of Surgeons of Australasia* (now the *Australian and New Zealand Journal of Surgery*) was founded in 1928 he edited it in his spare time and continued to do so for 20 years. He established the *Proceedings of the Royal Australasian College of Physicians* in 1946 (now expanded into the *Australasian Annals of Medicine*) and he edited the *Transactions of the Ophthalmological Society of Australia* for 14 years. Not surprisingly he received numerous honours from his Australian colleagues: the Fellowship of the Royal Australasian College of Surgeons and of the Royal Australasian College of Physicians, and the honorary membership of the Ophthalmological Society of Australia and of the Australian Orthopaedic Association.

One of the ways by which Archdall kept in touch with the readers of his journal was by paying regular visits to the Branches of the B.M.A. in Australia. This entailed travelling huge distances, but the policy was warmly approved by the board of directors of the Australasian Medical Publishing Co. Ltd. In 1938 he visited Europe and North America and attended the Annual Meeting of the B.M.A. at Plymouth; ten years later he came with the late Sir Archibald Collins as a delegate to the General Assembly of the World Medical Association in Geneva. He paid his last visit to Europe in 1954, again attending the General Assembly of the W.M.A., this time in Rome.

Two years ago, when Dr. Archdall had completed 25 years as editor of the *Australian Medical Journal*, a dinner

was held in his honour at Sydney, with Sir Henry Newland, chairman of the directors of the Australasian Medical Publishing Co. Ltd., in the chair. Many tributes were then paid to him by eminent members of the medical profession in Australia, and his portrait, painted by Mr. Jerrold Nathan, was presented to him.

During the last two or three years his health had not been good, but he had continued at work until recently, and on his retirement at the end of last month the directors of the Australasian Medical Publishing Company appointed him consultant editor.

Mervyn Archdall gave one the impression of being a largely built man, and this was in part because he had an openhearted, generous, and friendly nature, disliking sham and humbug and insincerity. But he always saw the best in people, and was widely tolerant of their eccentricities and failings. He was a deeply religious man, whose firm beliefs governed his life and his conduct: he was indeed a good man, one whose goodness was free from pietistic veneer and shot through with a gaiety of spirit that delighted those fortunate enough to discover it. Archdall was very attached to the "home country," and nothing pleased him more than the opportunities given him by the Australasian Medical Publishing Company to travel abroad and in particular to visit Britain. He was here for the Annual Meeting of the B.M.A. in Plymouth in 1938, when he took a great delight in helping the *British Medical Journal* staff in reporting the meeting. His influence on the *Medical Journal of Australia* was immense. Under his guidance it went from strength to strength. The *Journal* bore the mark of his character, especially in leading articles on general professional themes, some of which have been collected together in book form. Archdall was scrupulously careful and exact in his editing, no detail being too small for his acute but kindly eye. He enjoyed the stimulus of good talk, and loved to the full the humane arts of a civilized life, especially music. Mervyn Archdall has left behind him a host of friends who will mourn his departure, and who will wish to extend to his widow deep sympathy in her loss.

E. G. RECORDON, M.D.

Mr. E. G. Recordon, consultant ophthalmic surgeon to Addenbrooke's Hospital, Cambridge, and to the East Anglian Regional Hospital Board, died suddenly on August 24 at the early age of 53.

Esmond Gareth Recordon was born at Norwood on April 11, 1904, and was educated at Berkhamsted School and at St. John's College, Cambridge, going on to St. Bartholomew's Hospital for his professional training. He graduated B.Chir. in 1928, obtained the M.B. in the following year, and proceeded to the M.D. in 1936. After graduation he held resident posts at the Norfolk and Norwich Hospital and at St. Bartholomew's, and, having decided to follow a career in ophthalmology, took thereafter several posts leading to that of senior resident officer at Moorfields Eye Hospital and thence to his appointment in 1933 as honorary ophthalmic surgeon to Addenbrooke's Hospital. In 1938 he had joined the R.A.M.C. as a Territorial officer and was called up with the 20th General Hospital when war broke out, serving in France as the ophthalmic specialist with this hospital and later in other military hospitals in the British Isles. A member of the British Medical Association for nearly thirty years, he was a vice-president of the Section of Ophthalmology at the Annual Meeting of the Association held at Cambridge in 1948.

R. W. B. writes: Mr. Recordon served Addenbrooke's and the region well indeed, building up the department that owes so much to his hard work and organizing ability. Always kind, always generous with his time and his sympathy, but always shrewd and practical, he was universally beloved by his patients and his colleagues. His great professional skill and the very high standard of his operative work were the marks of a true artist, for he was satisfied only by perfection. He impressed all who knew him by his

patent personal and intellectual integrity. His quiet manner tended to hide the great store of knowledge of many subjects which he possessed, although his understanding and enjoyment of music and painting were well known to many. Apart from his work and his family, to whom he was so devoted, these were perhaps his most enduring interests. He was, too, a lover of the country and of many outdoor activities, and was all his life a keen and very skilful fly fisherman. In 1933 he married Frieda Robertson, who, with their two sons, survives him. To them his colleagues and his many personal friends, and all those others who in their gratitude for his help share their sorrow, extend their most sincere sympathy.

F. J. HENRY, M.C., M.B., F.R.C.S.Ed., D.P.H.

Dr. F. J. Henry, who was a chest physician in Middlesbrough for many years, died there on July 14. He was 78 years of age.

Francis Joseph Henry was born on March 7, 1879, and came of a well-known Glasgow family, being the last surviving son of the late Councillor Stephen J. Henry, J.P., of Kelvinside. He was the first of several members of his family to study medicine. His younger brother, the late Dr. Stephen J. Henry, and his sister, the late Dr. Nora G. Henry, both became well known in general practice in Glasgow. His younger brother, Jack, had started medicine before being killed in air combat in France in 1918. Two nephews of Dr. Henry are members of the profession in Scotland. Educated at St. Mungo's Academy and St. Aloysius's College, Glasgow, Francis Henry secured first place in the general bursary examination of Glasgow University, and went on to graduate M.B., Ch.B. in 1901. After a period in general practice in the Govan district of Glasgow, Dr. Henry was appointed medical superintendent of the Highfield Infirmary, Liverpool. In 1909 he obtained the D.P.H. of Cambridge University, and in 1913 was admitted a Fellow of the Royal College of Surgeons of Edinburgh. Soon afterwards he became a barrister-at-law of Gray's Inn. During the first world war he served in France with the R.A.M.C. and in 1916 was awarded the Military Cross. In 1919 he settled in Middlesbrough, specializing in respiratory diseases, and was for many years tuberculosis medical officer for Middlesbrough. A member of the British Medical Association for nearly fifty years, he was chairman of the Cleveland Division in 1937-8. He is survived by his wife and two sons, the elder of whom is head of the legal department in the British Section of the Allied Control Commission for Germany.

ARCHIBALD FAIRLEY, O.B.E., M.B., Ch.B.

Surgeon Captain Archibald Fairley, formerly principal scientific officer at the Chemical Defence Experimental Station at Porton, died on August 20 at the age of 73.

Archibald Fairley was born on November 1, 1883, and studied medicine at Glasgow University, where he graduated M.B., Ch.B. in 1907. After holding the appointments of house-surgeon and house-physician at the Victoria Infirmary, Glasgow, he entered the Royal Navy as a surgeon, serving until 1928, when he retired from the Navy with the rank of surgeon commander. Four years later he was appointed superintendent of the physiological department of the War Department Experimental Station at Porton, and held the appointment until 1952. He was appointed O.B.E. in 1946.

Group Captain ADAM MUIR writes: Many officers of the three Services will join with colleagues in the medical and scientific fields in mourning the death of "Bill" Fairley. He had long been their leading authority on the medical aspects of chemical warfare, and for many years he was recognized on both sides of the Atlantic as one of the greatest living experts on military toxicology. The cloisters of Gilmorehill had combined with the Royal Navy to form a character rugged, honest, and loyal, and the oft-times gruff exterior was soon found by his associates to cover a heart

of gold. Advice on all aspects of his specialty, as well as on the multifold problems of daily life, was widely sought and freely given, and a bountiful fund of common sense leavened by a sardonic but kindly humour was ever available to stimulate and fortify his colleagues and assistants. A deep-rooted aversion to humbug, cant, and insincerity in all its guises was matched only by the profound devotion he cherished for the fighting Services in general and the Royal Navy in particular. Though his wit could disconcert and even annoy those who did not observe the twinkle that invariably blunted the barb, none could fail to be impressed by his courage in the face of adversity and prolonged physical affliction. In the laboratory and in discussion his flair for extracting the kernel of a complicated problem and explaining it in language devoid of technical jargon at times seemed to border on the uncanny. Allied to this endowment was his knack in conference of relieving tension and abating argument by tersely summarizing the issue in a pungent and crushing sentence, and his invariable production of the *mot juste* delighted and disarmed the opposition. The wise old sailor has finally slipped his cable, and an irreplaceable "character" will long be remembered by those who worked for him.

GEOFFREY COWAN, M.D.

Dr. Geoffrey Cowan, who was in practice at Thetford, Norfolk, for many years, died at Edinburgh Royal Infirmary on September 1, one week before his 79th birthday.

Geoffrey Cowan was born in Edinburgh on September 8, 1878, the son of Dr. Alexander Oswald Cowan. From Sedburgh School he went on to King's College, Cambridge, returning to Edinburgh for his clinical studies. Having graduated M.B., B.Chir. in 1905, he proceeded to the M.D. five years later. After holding appointments of house-surgeon at Edinburgh Royal Infirmary and house-physician at the Royal Hospital for Sick Children, Edinburgh, he went to Paris and Vienna for postgraduate study before settling, about 1910, at Thetford, where he remained until he retired to Edinburgh in 1945. At Thetford he was also medical officer of health to the rural district council and to the Brandon rural district council.

T. L. O. writes: Dr. Geoffrey Cowan was a beloved physician for over thirty years in Thetford in partnership with the late Dr. Archibald Oliver, who died during the second world war. He was an ideal country physician, and early became interested in the maternity and child welfare movement after the first world war, and for many years conducted his own clinics in the village of Elveden. Many will remember his quiet, grave, and gentle figure as it came into the home, for he was a friend of all the family and gave much wise and sympathetic counsel. His relaxations were golf, fishing, and a little shooting, and he kept a beautiful garden. He was a founder member of the Thetford golf club and was made an honorary life member when he retired in 1945. Our sympathy goes out to his widow, two sons, and daughter in their sad loss of a beloved husband and father—a great general practitioner.

OSCAR OLBRICH, Ph.D., F.R.C.P.Ed.

Dr. Oscar Olbrich, consulting physician in charge of the geriatric service of the Sunderland group of hospitals, died suddenly at his home in Sunderland on August 22. He was 56 years of age.

Oscar Olbrich was born at Prague on February 2, 1901. He came to Britain in 1939 as a refugee, and after a period of study at Edinburgh took the Scottish triple qualification in 1941. In the following year he obtained the London Conjoint diploma and the M.R.C.P. of Edinburgh, becoming a Fellow of the College in 1946. He was granted the Edinburgh degree of Ph.D. in 1947. After qualification he held an appointment at Edinburgh Royal Infirmary, and,

later, having been in general practice for a time, he became physician in charge at Queensbury House (House of Refuge for the Destitute) in Edinburgh. In 1943 he was appointed a clinical tutor at Edinburgh Royal Infirmary. He went to Sunderland in 1950 to take up the post of director of the gerontological department under the Newcastle Regional Hospital Board. Dr. Olbrich was a member of the executive committee of the British Society for Research on Ageing and honorary secretary of the clinical gerontological research committee of the International Association of Gerontology. He leaves a widow and two children.

Dr. V. KORENCHESKY writes: Dr. Oscar Olbrich was an outstanding research worker in clinical gerontology and a remarkable personality. After coming to Britain as a refugee in 1939 he became a successful practitioner in Edinburgh, but all his inclinations were for clinical medical research. When I visited Edinburgh in 1943 he explained to me that he had decided to give up his lucrative medical practice and to take any job, with even a very modest remuneration, so long as it would give him the opportunity to do research work. At Edinburgh University his intellect, talent for research, energy, and devotion to clinical gerontological work were appreciated to the full, and at the end of his training at the Royal Infirmary he was recommended for the post of director of the gerontological department in the large general hospital at Sunderland. There he found proper research work to be impossible because of the lack of a clinical laboratory and technical laboratory staff. He was fortunate in that the senior administrative medical officer of the Newcastle Regional Hospital Board was the late Dr. W. G. Patterson, a clever and gifted administrator, who took an interest in, and appreciated the urgent need for, clinical gerontological research. Thus Dr. Patterson and his board, on Dr. Olbrich's request, provided him with a grant for a small research laboratory. The further necessary funds were obtained by Dr. Patterson with great difficulty, but eventually a proper laboratory was established. Dr. Olbrich published 23 papers on biochemical-clinical research relating to the changes with ageing in the blood, the function of the kidneys, heart, prostate, and on the water and electrolyte metabolism in the aged. His research work and that of his department gained the respect of gerontologists in this country and abroad, especially in the U.S.A. Let us hope that the outstanding work in a comparatively small provincial town of two gifted medical men with a vision of the future will be continued and serve as a brilliant example to other geriatric hospital departments in this country.

OTTO POPPER, M.B., F.R.C.S.Ed.

Mr. Otto Popper, senior surgeon to the Transvaal Memorial Hospital for Children, Johannesburg, died at his home in Johannesburg on August 14. He was 68 years of age.

Otto Popper was born in South Africa on March 28, 1899, the son of Viennese parents. He spent his early years in Johannesburg, being educated at St. John's College there, but he came to Edinburgh to study medicine, taking the Scottish triple qualification in 1922 and the Edinburgh degrees of M.B., Ch.B. in the following year. He was elected a Fellow of the Royal College of Surgeons of Edinburgh in 1925. After qualification he held house appointments at Edinburgh, Hull, and Nottingham. Thereafter he specialized in ear, nose, and throat surgery, and worked for several months with Professor Heinrich Neumann in Vienna. He was appointed assistant ear, nose, and throat surgeon to the Bristol Royal Infirmary, and for a time he was honorary secretary of the Bristol Division of the B.M.A. But he left Bristol in 1927 and returned to London. He then practised as a consultant in Wimpole Street and Nottingham, and was on the staff of the Hospital for Diseases of the Throat, Golden Square.

While in London Popper designed various surgical instruments, including an adenotome and a bronchoscope with

proximal lighting to facilitate visualization of the upper-lobe bronchi. In 1931 he returned to practise as a consultant in South Africa. He was in charge of the ear, nose, and throat department at the Transvaal Memorial Hospital for Children and was senior ear, nose, and throat surgeon at the General Hospital, Johannesburg. In 1949 he was invited to lecture and demonstrate his new approach to fenestration of the internal ear in America, the Scandinavian countries, and in France and England.

G. F. G. PRIDEAUX, M.B., Ch.B.

Dr. G. F. G. Prideaux, of Mossley Hill, Liverpool, died while bathing in the sea at Trearddur Bay, West Anglesey, on August 20. He was 59 years of age.

Gerald Frank George Prideaux was born on June 22, 1898, and studied medicine at Liverpool University, where he graduated M.B., Ch.B. in 1922. After graduation he held the appointments of house-physician at the Royal Southern Hospital and resident medical officer at the Walton Hospital, Liverpool. He then settled in the Mossley Hill district of Liverpool, where he was in general practice until his death. His widow was formerly a sister at Walton Hospital.

V. C. C. writes: Frank Prideaux took an active part in the medical life of the neighbourhood and was a regular attender at the meetings of the Liverpool Medical Institution, on the council of which he recently served. He was also a member of the Liverpool Medical Committee. He took a keen interest in British Medical Association affairs and was a member of the executive committee of the Liverpool Division and of the Merseyside Branch council. This year he had attended the Special and Annual Representative Meetings, and had taken his duties as a representative most seriously. He was most conscientious in everything that he undertook, and his cheerfulness and loyal support will be greatly missed in local B.M.A. circles.

Medico-Legal

DEATH FROM EXHAUST FUMES

The case of a child who died from accidentally inhaling exhaust fumes during a journey from London to Cornwall was the subject of an inquest on August 28. It was held by Mr. E. W. Gill, county coroner for Bodmin district.

The dead child's father, Mr. D. A. Shewry, said that he, his wife, and their son and daughter (aged 14 years) started for Cornwall on the evening of Saturday, August 24. Their car was a 14 h.p. 1938 Vauxhall, bought 14 months before. Several times during the journey Mr. Shewry noticed fumes in the car, and he carried out running repairs—by-passing a leaking oil filter, and breaking a piece off the silencer to let the fumes come away easier. By the time they reached Callington, in Cornwall, the next morning, the daughter had been sick four or five times and the son twice. The girl was always sick on a long journey. When they reached Pentewan, their destination, the girl did not get out of the car, but remained lying on her side. Artificial respiration was applied and a doctor sent for; he continued it on arrival, but in due course pronounced the child dead.

A post-mortem examination by Dr. F. D. M. Hocking confirmed that death was due to carbon monoxide poisoning. The blood showed 42% saturation with this gas.

Mr. J. Pomery, police constable at Mevagissey, said the exhaust of the car was not in first-class condition. The silencer had been patched, and he could detect fumes coming round the patches. He could see fumes passing from the silencer into the boot, the inside of which was black with soot on the near side. There was also soot inside the car by the back window.

A verdict of accidental death by carbon monoxide poisoning was returned.

Universities and Colleges

UNIVERSITY OF OXFORD

In Congregation on August 3 the degree of B.M. was conferred on A. J. Ferris, S. R. Coverley, Mrs. Ruth S. Davies, and Mary M. Addison.

Dr. P. J. R. Phizackerley has been appointed to the Betty Brookes Fellowship for three years from November 1, 1957.

UNIVERSITY OF CAMBRIDGE

Dr. A. N. Griffith has been elected into the E. G. Fearnside Scholarship for 1957.

Dr. M. M. Bull, University Lecturer in Anatomy, has been elected into an official Fellowship at Queen's College.

UNIVERSITY OF DURHAM

In Congregation on July 6 the honorary degree of D.C.L. was conferred on Sir John Stopford, M.D., F.R.C.P., F.R.S., until recently Vice-Chancellor of Manchester University.

On July 5 and 6 the following degrees and diplomas were also conferred:

M.D.—S. Ludkin, *J. A. Carr, *J. Gilroy, *K. S. Henley, *F. W. G. Wolff, E. W. Walton, A. E. Wright, *L. M. Franks.
Ph.D. IN MEDICINE.—R. J. Merrills, *M. R. Choudhury, *B. V. U. Puttaraj Urs.
M.B., B.S.—S. A. Adegbite, S. N. Afoakwa, P. W. R. M. Alberti, Rosemary A. Archer, G. A. Ashford, J. B. Ball, O. A. Banjo, D. D. Barwick, A. I. Benkinsop, A. H. Brown, G. Chalmers, W. J. B. Cherry, Dorothy A. Christie, Gloria Cohen, A. Denham, Maureen M. Denham, J. D. Eden, J. B. Emslie, P. J. Enoch, G. H. Greatrex, G. A. Grebneff, J. Tardy, R. Hart, V. B. Hicks, K. N. Howson, P. S. Hunter, R. M. Jamieson, J. E. Johnson, Sheila M. Johnson, L. J. Jones, J. M. Kendall, J. I. King, J. Kirkbride, O. Kwamina-Amoah, J. A. Lennox, E. F. M. Luke, Fiona M. McCallum, L. F. W. McMahon, A. F. J. Moreton, S. MacD. Murray, R. E. D. Nelson, J. M. Parkin, B. H. Posner, F. C. Robson, Eileen E. Sanderson, H. A. Seedat, Barbara Spence, Rosemary A. Spencer, W. R. M. Thompson, Margaret A. Thornton, Enid A. Wallace, Edith S. Warriner, Delma R. Welch, T. Westgarth, G. K. Wilson, Shang-Hsien Yuan, *M. S. Bennett, *P. Braunstein, *G. L. Featherstone, *D. C. G. Henderson, *P. P. Lakra, *M. J. Smith.

DIPLOMA IN PSYCHOLOGICAL MEDICINE.—R. Chambers, Monica D. Rowbotham.

*In absentia.

UNIVERSITY OF LONDON

The following degrees were awarded in July:

M.D.—S. Dische, K. R. Dempster, A. E. Dormer.
M.S.—M. Cairnc, J. C. S. Leverton.

The following have been reappointed or renominated as representatives of the University on the governing bodies of the institutions indicated in parentheses: Sir Archibald Gray and Dr. C. F. Harris (British Postgraduate Medical Federation); Sir James Paterson Ross and Dr. J. Forest Smith (Guy's Hospital Medical School); Dr. M. I. A. Hunter and Dr. Katharine G. Lloyd-Williams (Royal Dental Hospital of London School of Dental Surgery); Mr. E. G. Slesinger and Professor J. Z. Young, F.R.S. (St. George's Hospital Medical School); Professor W. C. W. Nixon (St. Mary's Hospital Medical School); Sir Archibald Gray (University College Hospital Medical School); Professor R. Hare (Wright-Fleming Institute of St. Mary's Hospital Medical School); Dr. A. J. W. Beard (King's College School, Wimbledon).

The following have been recognized as teachers of the University in the subjects indicated in parentheses: *University College Hospital Medical School*, Mr. G. L. Bunton (Surgery); Dr. F. V. Flynn (Chemical Pathology); Dr. Eva M. Graves (Clinical Pathology); Mr. D. P. Greaves (Ophthalmology); Dr. C. J. Hodson (Radiology); and Dr. Elizabeth J. Stokes (Pathology (Bacteriology)). *Postgraduate Medical School of London*, Dr. C. M. Fletcher (Medicine); Dr. D. L. Mollin (Pathology). *Institute of Psychiatry*, Dr. T. C. N. Gibbins (Mental Diseases). *Royal Free Hospital School of Medicine*, Dr. S. W. Hardwick (Mental Diseases). *Guy's Hospital Medical School*, Mr. D. M. Macdonald, F.R.C.S.Ed. (Dental Surgery). *London Hospital Medical College*, Dr. R. G. F. Parker (Pathology). *St. Mary's Hospital Medical School*, Dr. D. Sutton (Radiology); Dr. W. H. H. Andrews (Pharmacology). *Westminster Medical School*, Dr. J. B. Wyman (Anaesthetics). *London School of Hygiene and Tropical Medicine*, Dr. J. Knowelden (Medical Statistics and Epidemiology).

The Laura de Saliceto Studentship, first awarded to Dr. H. J. G. Bloom for the session 1953-4, has been further renewed for the session 1957-8.

On July 30 the degree of M.S. was awarded to W. H. W. Jayne.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending August 24 (No. 34) and corresponding week 1956.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included). London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenza pneumonia.
§ Includes puerperal pyrexia.

Vital Statistics

Poliomyelitis

Poliomyelitis notifications (uncorrected) in England and Wales in the week ending August 31 were as follows, with the figures for the previous week in parentheses: paralytic 151 (188), non-paralytic 156 (175), total 307 (363). Total cases in Scotland were 5 (3), Northern Ireland 29 (24), and Eire 1 (3).

The main local increase in the number of notifications was in Nottinghamshire, where 16 cases were reported (Nottingham C.B. 7, Arnold U.D. 5). The incidence of the disease declined in the other chief centres of infection. In Warwickshire 32 cases were reported (Birmingham C.B. 10, Coventry C.B. 6, Leamington Spa M.B. 4), in Kent 27 cases (Southborough U.D. 3), and in Essex 18 (Walthamstow M.B. 3). Of the 4 cases notified from Lincs (Lindsey), 3 were from Gainsborough R.D. and 1 from Lincoln C.B. In London 22 cases were reported (Holborn 5, Wandsworth 4), and in Middlesex 15 (Harrow M.B. 3). The outbreak in Hertfordshire, whence cases have been notified from early in the year, continued with 10 notifications (Stevenage 3). In Devon 11 cases were reported (Exmouth 6).

The incidence in Northern Ireland remained rather high, with 29 cases (Belfast C.B. 9, County Down 9, County Antrim 8).

Venereal Diseases

In England and Wales during the quarter ending March 31, 1957, 1,292 new cases of syphilis were registered as attending the clinics. Of these 184 were classified as primary, secondary, or latent in the first year of infection. 6 cases of congenital syphilis in children aged under 1 year were reported and 141 cases in persons over that age. New cases of gonorrhoea numbered 5,073, of chancroid 77, and of non-gonococcal urethritis (males only) 3,662.—*Monthly Bulletin of the Ministry of Health*, August, 1957.

U.S.A. View of Influenza Vaccine

The Surgeon-General of the U.S. Public Health Service, Dr. Le Roy E. Burney, makes the following comment on influenza vaccine (*J. Amer. med. Ass.*, 1957, 164, 2029):

"In recent years the nature of influenza in the United States has not warranted the use of influenza vaccine except on a group basis to minimize absenteeism or in so-called priority groups. However, the present influenza epidemic, with its rapidity of spread and high attack rate, is sufficiently unusual to press for immunization against the new strain of influenza virus. As a properly constituted vaccine is the only preventive for this disease, the Public Health Service with the Association of State and Territorial Health Officers and the American Medical Association plans to promote the use of the vaccine as soon as it becomes available. To accomplish this we plan to embark upon an educational and promotional campaign to encourage all persons who want it to seek influenza vaccine on a voluntary basis. Any such campaign must be conducted in an orderly fashion to avoid confusion and hysteria in the public and will call for the combined efforts of all of us."

Week Ending August 31

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 245, whooping-cough 1,010, diphtheria 6, measles 3,005, acute pneumonia 184, acute poliomyelitis 307, dysentery 224, paratyphoid fever 11, typhoid fever 2.

Infectious Diseases

Infectious diseases were less prevalent in England and Wales during the week ending August 24. The falls in the number of notifications included 2,353 for measles, from 6,620 to 4,267, 98 for whooping-cough, from 1,205 to 1,107, 51 for food-poisoning, from 387 to 336, and 23 for scarlet

fever, from 278 to 255; the only rise of any size was 49 for dysentery, from 238 to 287.

Falls of 100 or more in the number of notifications of measles were recorded in six counties; the largest fall was 333 in Yorkshire West Riding, from 674 to 341. Scarlet fever occurred mainly as sporadic cases; the largest number of notifications in a county was 31 in Yorkshire West Riding, and the administrative area with the most cases was Birmingham C.B. with 19. The region with the largest fall in the incidence of whooping-cough was Wales, with a decrease of 30, from 70 to 40. 6 cases of diphtheria were notified, being 5 more cases than in the preceding week. 3 of these cases were notified in Kingston upon Hull C.B.

9 of the 12 cases of paratyphoid fever were notified in Bradford C.B.

The chief centres of dysentery were Yorkshire West Riding 55 (Leeds C.B. 24), Lancashire 50 (Liverpool C.B. 10), and London 26.

The largest outbreak of food-poisoning was 22 in Cornwall, St. Ives M.B.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the years 1948-56 are shown thus - - - -, the figures for 1957 thus ———. Except for the curves showing notifications in 1957, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Medical News

Government Statement on Poliomyelitis Vaccine.—"The Government have decided to offer immunization against poliomyelitis before the summer of 1958 to all children under 15 and to expectant mothers. At present it is only offered to children under 10. The present scheme for immunization is based on the advice of the Medical Research Council that the vaccine used in this country should have a composition different from that of the American or Salk vaccine. British vaccine is believed to be the safest and most effective available. It does not contain the Mahoney strain of virus which—escaping the tests to detect any remaining live virus—was held to be responsible for the incident in the United States in 1955 when a number of cases of poliomyelitis occurred. To carry out the programme now decided upon by the Government, it will be necessary to supplement the supply of British vaccine. At the end of July last the M.R.C., while maintaining their view that the British vaccine was superior, advised that the risk of using Salk vaccine (pending the availability of adequate supplies of the British vaccine) should be weighed by the Government against the risk of leaving substantial numbers of children unvaccinated during the summer of 1958. On receiving this advice the Government sent doctors to Canada and to the U.S. to investigate and report. In the light of their reports, the Government have now weighed all the known facts, including the American experience in 1955 and the extent to which Salk vaccine has been since used without further mishap. They have decided that, to fill the gap until a sufficient supply of British vaccine is available, a supply of Salk vaccine should be ordered forthwith. The imported vaccine will be subject, in this country, to the same stringent tests of safety, potency, and purity as our own vaccine. These tests will be in addition to the tests in the country of manufacture. If parents object to Salk vaccine they will be offered another opportunity with British vaccine later."

Donations to Medical Research.—Mr. EDMUND HOWARD, among donations to a number of charitable funds totalling £250,000, has given £100,000 to the British Empire Cancer Campaign and £20,000 for research on poliomyelitis. Other beneficiaries of Mr. Howard's generosity include the Putney Hospital for Incurables (£50,000), the Royal School for the Blind (£15,000), and Dr. Barnardo's Homes (£50,000). Mr. Howard, who is 76, is chairman of the City of London Real Property Company.

Medical Research in Eire.—The Medical Research Council of Ireland's report for 1956 once again draws attention to the inadequacy of its income. "The funds available from the Department of Health are so limited," states the council, "that grants can only be made at levels much lower than is reasonable." In 1956 the Government provided £23,000 for general research and research on the chemotherapy of tuberculosis, and a special grant of £5,000 for a serological survey of poliomyelitis antibody levels. Besides this survey and its grants for general research, the council has planned a two-year investigation of the causes of perinatal mortality, in parallel with similar studies in Sweden and Holland, basing it on material from three Dublin maternity hospitals and the district surrounding the Central Hospital, Galway. The chemotherapy unit at Trinity College, Dublin, under Dr. VINCENT BARRY, has followed up its studies of "hinconstarch" with an investigation of a new series of phenazine derivatives stated to have "remarkable biological activity" in experimental tuberculosis. There were also clinical trials of hinconstarch in pulmonary tuberculosis (72 cases) and renal tuberculosis (20 cases). The council also undertook the revision of its *List of Medical Journals in Dublin Libraries*, first published in 1938.

W.H.O. Committee for Europe.—The World Health Organization's regional committee for Europe began its seventh session in Copenhagen on September 10. Its main tasks are to review the work of W.H.O. in Europe during the current year, make adjustments in the programme for 1958, and plan a regional European programme and budget for 1959. In addition, the committee will hold an informal technical discussion on the integration of preventive, social, and curative medicine in health services. The United Kingdom representatives are Sir JOHN CHARLES and Mr. W. H. BOUCHER, of the Ministry of Health.

Caleb Fiske Prize.—The trustees of the Caleb Fiske Fund of the Rhode Island Medical Society have chosen as the subject for this year's prize dissertation "Hormonal Relationships in Breast and Prostatic Cancer—Their Practical Application." This is stated to be America's oldest medical essay competition, and the prize for the winning essay is \$350. Dissertations, which must be typewritten (double-spaced), should not exceed 10,000 words. The last date for entries is December 31. Further details may be obtained from the Secretary of the Fund, Rhode Island Medical Society, 106, Francis Street, Providence, 3, Rhode Island, U.S.A.

Gift to Australian Medical School.—A gift of just under £A.154,000 has been made to the new medical school of the West Australian University by Mrs. B. M. BAINE, a Perth hotel proprietress. Mrs. Baine is quoted in *Radio Australia News* as stating that the gift consists of shares in four hotels in Perth left her when her husband died of a cerebral thrombosis last February. She has given her husband's entire estate to the medical school for research on the condition. An article by Dr. A. TALBOT ROGERS describing the foundation of the medical school at Perth was printed in the *Journal* last year (March 3, 1956, p. 509).

Appeal for Medical Equipment.—The Oxford Committee for Famine Relief, a body registered under the War Charities Act, 1940, is appealing for medical equipment. The committee exists mainly for the relief of suffering due to war, natural disaster, or poverty in any part of the world, without regard to race, religion, nationality, or creed. For the past ten years it has been sending assistance to hospitals and clinics in places such as Korea, India, Vietnam, and the Near East. From many different parts of the world the committee receives requests, far beyond its ability to meet them, for all kinds of medical and surgical supplies, including vitamins, antibiotics, and dressings. The committee therefore appeals to medical men for any surgical instruments, drugs (other than those subject to D.D.A. export regulations), dressings, or manufacturers' samples which can be spared. (One clinic is kept going almost entirely on supplies of samples.) Packages should be sent to Dr. H. ROBERTSON, c/o Davies, Turner & Co., 50a, Bourne Street, London, S.W.1.

London University.—Mr. W. T. IRVINE, lecturer in surgery at Glasgow University, has been appointed to the London University readership in surgery tenable at the London Hospital Medical College. Mr. Irvine was educated at Glasgow University, where he graduated B.Sc. in 1944, M.B., Ch.B. in 1947, and Ch.M. (Honours) in 1956.

Dr. Laura Veale, of Harrogate, celebrated her 90th birthday on August 30. Coming of a medical family, she herself graduated M.B. London from the London School of Medicine for Women in 1904. Subsequently she had the distinction of being the first woman doctor to be appointed to a hospital in Leeds; she was also the first woman member of several medical societies.

Dr. J. T. Shepherd is relinquishing his appointment as reader in physiology at Queen's University, Belfast, to join the staff of the Mayo Clinic and the University of Minnesota.

Dr. M. A. Peyman, senior medical registrar at Charing Cross Hospital, has been awarded an Evans medical research fellowship. He will work under Dr. W. DAMESHEK at the New England Centre Hospital, Boston, Massachusetts.

COMING EVENTS

Clinical Demonstrations in Neurology.—Tuesdays at 5.30 p.m., September 24 to December 17, at the West End Hospital for Neurology and Neurosurgery, 91, Dean Street, London, W.1. Open to medical practitioners and medical students free of charge. Details from the secretary of the West End Hospital Medical School.

British Tuberculosis Association and Midland Thoracic Society.—Provincial meeting, Birmingham, September 27 and 28. Details from the administrative secretary, British Tuberculosis Association, 59, Portland Place, London, W.1.

Institute of Diseases of the Chest.—Clinical demonstrations, Fridays at 5 p.m. from September 27 to December 13, at the Institute (in the grounds of the Brompton Hospital, Fulham Road, London, S.W.3). Open to medical practitioners without fee.

Westminster Medical School.—The Right Hon. Sir ERIC HARRISON, High Commissioner for Australia, will give the inaugural address at 3 p.m. on October 7, at Church House, Great Smith Street, London, S.W.1.

"Work Study and Hospital Services."—Fourteenth conference in the series "The Nation's Nurses" at the Royal College of Nursing, November 12 to 14. Members of the medical profession, hospital administrators, and others are invited to apply for further information, before October 11, to the conference secretary, Royal College of Nursing, Henrietta Place, Cavendish Square, London, W.1.

Ophthalmological Society.—The 1958 annual congress of the Ophthalmological Society of the United Kingdom will be held in Cardiff from April 17 to 19, 1958. Members wishing to read a paper or show a film should submit the title (together with an abstract in the case of a paper) by November 30, 1957, to Mr. K. C. WYBAR, F.R.C.S., at 45, Lincoln's Inn Fields, London, W.C.2.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked •. Application should be made first to the institution concerned.

Tuesday, September 17

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Erasmus Wilson Demonstration by Dr. J. B. Walter: Some Aspects of Acute Inflammation.

Thursday, September 19

NORTH-EAST LONDON CLINICAL SOCIETY.—At Prince of Wales's General Hospital, Tottenham, N., 2.30 p.m., meeting.

Friday, September 20

BIOCHEMICAL SOCIETY.—At Department of Biochemistry, Queen's College (University of St. Andrews), Dundee, 10.30 a.m., 365th meeting.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. J. G. Scadding: Clinical demonstration.

APPOINTMENTS

LIVERPOOL REGIONAL HOSPITAL BOARD.—D. C. Watson, M.D., M.R.C.P., Consultant Physician Superintendent at Sefton General Hospital; A. G. Mackinnon, M.B., Ch.B., F.F.A.R.C.S., Consultant Anaesthetist to United Liverpool Hospitals and the North Liverpool Area.

BIRTHS, MARRIAGES, AND DEATHS

DEATHS

Bell.—On August 23, 1957, at Sandown Cottage, Reydon, Southwold, Suffolk, Hamilton Joseph Bell, L.R.C.P.&S.Ed., L.R.F.P.S.
Cozens.—On August 17, 1957, at his home, 8, The Downs, Herne Bay, Kent, Frederick Cyril Cozens, M.B., B.Chir., aged 65.
Gibson.—On August 22, 1957, at his home, 23, Clifton Wood Road, Bristol, John Boyd Gibson, M.B., Ch.B., formerly of Edinburgh, aged 86.
Houchin.—On August 22, 1957, at 12, Scarsdale Villas, Kensington, London, W., Edwin Augustus Houchin, L.S.A., Lieutenant-Colonel, R.A.M.C., T.A., retired.
McCarthy.—On August 19, 1957, at his home in Hayes, Middlesex, Daniel McCarthy, M.B., B.Ch.
Macfarlane.—On August 23, 1957, at Balhodie House, Dunblane, Perthshire, Robert Maxwell Macfarlane, M.D., D.T.M., aged 78.
Penson.—On August 23, 1957, John Patrick Penson, M.R.C.S., L.R.C.P., of 226, Wokingham Road, Reading, Berks.
Pick.—On August 20, 1957, at 9, Adamson Road, London, N.W., Arthur Pick, M.D., aged 85.
Prideaux.—On August 20, 1957, while on holiday, Gerald Frank George Prideaux, M.B., Ch.B., of 40, Menlove Avenue, Mossley Hill, Liverpool, aged 59.
Recordon.—On August 23, 1957, Esmond Gareth Recordon, M.D., of 51, Bateman Street, Cambridge, aged 53.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Catabolism of Drugs

Q.—What factors determine the rate of catabolism of drugs by the liver?

A.—The rate at which the liver will metabolize drugs depends upon the chemical nature of the drug and the availability of enzyme systems within the liver to attack the drug and break it down. The behaviour and properties of an important group of these enzymes have been studied by B. B. Brodie and his colleagues.^{1,2} This work has been mainly done in the test-tube. The effectiveness of any enzyme system depends up to a point upon the concentration of the substance being metabolized. It must reach a certain minimum concentration, but after that a direct relationship of the rate of metabolism with blood concentration does not necessarily exist. The best-known example is alcohol, which is metabolized at a constant rate.³ Antipyrine in dogs is also metabolized at a constant rate.⁴ Barbiturates are mainly metabolized in the liver.⁵ Judged by the anaesthetic effects, experimental animals "metabolize" barbiturates in quantities proportional to the amounts present in the body.⁶ However, these indirect observations do not prove that it was metabolism by the liver that was responsible for the disappearance of the anaesthetic effect. The drug probably disappears into the body fat and is then slowly released, to be metabolized at a constant rate.⁷

Ultrasonic Therapy

Q.—What are the indications for the use of ultrasonic therapy in physical medicine? Is a physiotherapist using an ultrasonic machine liable to suffer any ill effects from it?

A.—Workers in the field of physical medicine in Great Britain have not obtained the results claimed for ultrasonic therapy on the Continent. It seems, however, that this physical agent has some place in the treatment of conditions which result in undesirable fibrosis or in contractures due to fibrosis.

Ultrasonic vibrations do not appear to have any deleterious effects on the tissues at intensities below those which cause cavitation or burning. It is, moreover, very doubtful whether field strengths of such magnitude would ever be developed except from the applicator of the instrument. The risk to the operator is therefore negligible.

Transporting Injured Miners

Q.—What is the best position for transporting miners with possible fractures of the spine a considerable distance for medical examination? Should they be prone or supine?

A.—The prone position has been tried in British mines but has not found general acceptance for several reasons: (1) It is not always practicable—e.g., when there are associated injuries to legs, pelvis, or chest. (2) If the patient is shocked or dazed, breathing is liable to become obstructed in the prone position. (3) The supine position is universally applicable and perfectly safe.

The real danger in the first-aid treatment of an injured spine is not the position on the stretcher but the manœuvres that occur between extricating the patient from the position

in which he is found and placing him on the stretcher. In mining accidents he may have to be manhandled over a distance of many yards in a confined space to the nearest point to which a stretcher can be brought, and if he is lifted by the armpits and the knees it can be extremely dangerous. The really dangerous injuries—i.e., those in which the spinal cord or cauda equina are vulnerable—are the unstable fracture-dislocations (about 20% of the whole), and these are unstable in both flexion and rotation. The whole emphasis, therefore, should be on the avoidance of flexion and rotation during the process of extrication and manhandling to the stretcher point. Once the patient is lying flat on the stretcher with his lumbar curve supported by a folded blanket, there is no danger of damage to the cord or nerve roots during transport. Another point is that in about 50% of fracture-dislocations the facets are "locked," and in these circumstances the prone position not only fails to correct the displacement but may actually increase pressure on the cord.

Risks of Oil Sprays

Q.—What are the risks to workers in motor garages employed in spraying the undercarriage of cars, under high pressure, with (a) paraffin and (b) heavy hydrocarbon oil diluted with some volatile vehicle?

A.—Many cases of pneumonia in children following the accidental ingestion of paraffin oil (kerosene) have been reported in the literature,¹ but there appears to be no information on the direct inhalation of paraffin oil mists. Aspiration of liquid paraffin (liquid petrolatum) leads to acute lipoid pneumonia or to the development of "paraffinomas," hard fibrous masses containing oil droplets.² A case of chronic lipoid pneumonia following occupational exposure to liquid paraffin sprays has been reported.³ Paraffin oil is generally free from carcinogenic hydrocarbons, but there may be traces in the heavy oil. The "volatile vehicle" used with the heavy oil might itself have some effect. Petroleum vapours have some anaesthetic and narcotic action, and solvents such as trichloroethylene are powerful anaesthetics too. If the mists are deposited on the skin there is also some risk of dermatitis or oil acne. It might be possible to control the mists with a system of local exhaust ventilation similar in principle to that used for dust control in foundries.⁴

Dangers of Ultra-violet Light

Q.—If pulmonary tuberculosis has been excluded by radiography, what are the dangers (if any) of parents treating a child at home with an ultra-violet lamp?

A.—Pulmonary tuberculosis is always cited as a contra-indication to exposure of the chest to ultra-violet rays. This is because of the danger of precipitating haemoptysis, though the actual risk is difficult to estimate and the mechanism obscure. Apart from pulmonary tuberculosis, any disease associated with light sensitivity (e.g., congenital porphyria, systemic lupus erythematosus) is also a contra-indication. In addition certain drugs, including chlorpromazine and the sulphonamides, and certain heavy metals may act as sensitizers and make the administration of ultra-violet light less safe. The chief danger of home irradiation with ultra-violet light is that of overdosage, as the safety margin may be quite small. The makers' instructions should therefore be carefully adhered to. Goggles should invariably be worn by both the patient and the person supervising treatment. Most modern ultra-violet lamps are of the mercury-vapour electronic-discharge type, and these are to be preferred to

the carbon-arc model. The latter requires replacement of the carbons from time to time, constitutes some danger from sparking, and is also more expensive to run.

Pain over Pubis

Q.—Ten days after a normal birth of a large baby the mother developed pain over her symphysis pubis. It has persisted for a year now. It is brought on by lifting and walking and can be reproduced by pressing outwards on the anterior iliac spines. A recent radiograph of the symphysis showed no abnormality. What is the likely diagnosis and prognosis in future pregnancies? What treatment might help?

A.—The patient probably sustained a tear or strain of the ligaments controlling the symphysis pubis. This may not have been obvious immediately after delivery; it would be more noticeable when she became active again. Even disruption of the symphysis pubis is a possibility; the separation or increased mobility of the joint would not necessarily show radiologically unless the exposures were taken with the patient standing on one or other leg.

Even a minor lesion of the symphysis can remain painful and tender for some considerable time. The only treatment necessary is rest, together with a corset which grips the pelvic girdle firmly. The condition should become symptomless in time, but it is likely that the joint will be painful again during the latter part of a subsequent pregnancy, and for a short time afterwards. The amount of discomfort, however, should not be enough to deter the patient from further pregnancy, especially if she wears a corset throughout.

Winter Infections

Q.—What factors account for the increased prevalence of diseases such as influenza and the common cold during the cold, damp months of the year? Does the type of summer weather experienced have any important effect on people's resistance or on the "carry over" of virus or of reservoirs of infection into the succeeding winter?

A.—All infections believed to be spread largely by airborne droplets tend to an increased prevalence in the winter seasons in all parts of the world. It seems likely that cold, damp weather favours the dissemination of droplets, and hence the spread of respiratory viruses, and unlikely that it causes any alteration in specific resistance to infectious agents. During the winter the human nasopharyngeal flora is altered quantitatively, and this may be due to changes in local factors such as ciliary action and secretion of mucus. Too little is yet known about resistance to human respiratory viruses to say that chilling exerts no effect. Various agents provoke attacks of latent virus infections such as herpes febrilis. Adenoviruses are known to be latent within the nasopharyngeal adenoid tissue, and some infections by these viruses could therefore be endogenous rather than exogenous.

It seems highly unlikely that summer weather can exert any effect on immunity or the survival of virus until the following winter.

Halitosis

Q.—What are the most likely causes of halitosis, and what treatment is recommended?

A.—The almost invariable cause of halitosis is some infection in the mouth or respiratory tract. Such diseases as bronchiectasis and lung abscess may cause it, and the teeth should be carefully scrutinized by a dentist and any gingivitis or cavity treated. In many patients chronic infection of the tonsils is responsible, and this can often be convincingly demonstrated by rubbing the tonsil with the finger, which will then yield olfactory proof of the origin of the fetor. Chronic nasal disease, such as atrophic rhinitis or sinusitis, is another possible cause, and these conditions should be excluded.

NOTES AND COMMENTS

Exanthem Resembling Measles.—Dr. JOHN WINKLER (London, S.W.1) writes: The illness described ("Any Questions?" July 20, p. 171) may well be roseola infantum (exanthem subitum or "sixth disease" in U.S.A.). This mild febrile illness may be either unrecognized or diagnosed as an "atypical" or "slight" attack of measles or rubella. Failure to make the diagnosis explains, I think, the often obtained history of several attacks of measles or rubella. Further questioning brings out that one of the attacks was slight or doubtful in some way, while the other was the typical illness. An annotation in the *Journal* of October 14, 1950 (p. 876), has dealt fully with the clinical picture and diagnosis. The outstanding features are the age incidence (91% under 3 years), a remittent fever often with high temperatures up to 105° F. (40.6° C.) lasting three to five days, slight but constant posterior cervical gland enlargement, and finally a rash resembling rubella but less extensive, appearing within 48 hours of the end of the fever. The rash may be fleeting, lasting several hours, but often lasts 24 hours, and is usually completely gone within 48 hours. Roseola infantum is worth considering in the differential diagnosis of an unexplained high fever, or of a rubelliform rash, in the first three years of life.

Female Orgasm and Conception.—A Medical Practitioner writes: The following case may be relevant to the reply on this subject in "Any Questions?" (August 10, p. 366). I was called to a married woman (2 para) aged 40 late one evening to remove a condom which was caught in the vagina. On examination the teat end of the condom was firmly gripped in the cervical os. Traction failed to disengage it, and after fixing Spencer Wells forceps as high up as possible it was released by twisting as one does for a placental removal. This does appear to indicate that at orgasm the os was patent and the teat end was sucked into the os.

Welfare Foods.—Dr. W. T. C. BERRY (Joint Secretary, Joint Subcommittee of the Standing Medical Advisory Committees) writes: My attention has been drawn to an error on page 15, paragraph 58, in the report on welfare foods made by the Joint Subcommittee of the Standing Medical Advisory Committees, and published by H.M. Stationery Office (see *Journal*, August 3, p. 284). It is there stated that, when the British Paediatric Association carried out its investigation into the incidence of rickets (1943), dried milk and infant cereals were not fortified with vitamin D, yet rickets was rare in the 12-18 months age group. We are now informed that certain dried milks and cereals were, in fact, then fortified. Though the subcommittee decisions were not affected by this misapprehension, we feel that attention should be drawn to it because a proportion of children in this age group presumably did receive vitamin D from these sources.

SYSTEMIC LUPUS ERYTHEMATOSUS*

BY

LESLIE C. HILL, M.D., F.R.C.P.
Physician, Royal United Hospital, Bath

The story of systemic lupus erythematosus opens in 1872 with Kaposi's paper, "Neue Beiträge zur Kenntniss des Lupus Erythematosus." What manner of man was its author?

When we turn back the leaves of history an unexpected or forgotten but brilliant page breaks to the view. England was settling with Victorian stoicism to the fourth year of Mr. Gladstone's first ministry; Europe was gasping at the fall of France and the failure of the banks; in Vienna the sun shone. This was the hour of Johann Strauss and Fanny Elssler, this the first years of the Ringstrasse and the New Opera House. Vienna, at that time a city of 600,000 souls, was astir. Brückner had just been appointed to the Conservatorium, and Brahms had finally returned to this cultural centre of Europe and of the world. One of his friends, Billroth, was professor of surgery; with him Brahms would often spend a musical evening playing duets before Billroth's great contemporaries.

In these days, when we turn our thoughts westward across the Atlantic for refreshment and quickening, we sometimes overlook the greatness of this Viennese school of medicine founded by a Dutchman, van Swieten, whom the wise Maria Theresa invited to lead the new faculty within the University. His famous contemporary was Leopold Auenbrugger. The new school soon acquired a substantial centre in the 2,000-bedded Allgemeine Krankenhaus, the development of which the Emperor Joseph II entrusted to Peter Frank, a versatile genius who, among many activities, founded a corps of police surgeons, revolutionized and rationalized the treatment of the insane, and sponsored Jennerian vaccination. On these sturdy foundations the great era of Viennese medicine began during the nineteenth century under the direction of Rokitsansky, Skoda, and Hebra.

Moritz Kaposi

Ferdinand von Hebra was Skoda's pupil and was encouraged by him to undertake the systematic study of

*The first of two Lumleian Lectures (abridged) delivered before the Royal College of Physicians of London on April 2 and 4, 1957.

FIG. 1.—Moritz Kaposi.

diseases of the skin, thereby laying the foundation of dermatology as a separate discipline. In his turn Moritz Kaposi (Fig. 1) was Hebra's pupil and eventually his son-in-law and successor as professor of dermatology. Thus in 1872 we find the brilliant pupil already preparing, with his father-in-law, the textbook on diseases of the skin which they published three years later (Hebra and Kaposi, 1875). He also found time to review Hebra's (1845) earlier work on lupus erythematosus and to widen and enrich our knowledge of this disease.

Hebra and Kaposi built on the work of Théodore Bielt (1828), who wrote an early account of the skin lesions of lupus erythematosus in the textbook edited by Cazenave and Schedel (1838). An even earlier account was given by a distinguished French physician, Pierre Rayer, whose contributions to medicine have, I believe, received too little attention in this country. In 1827, under the title of "Flux Sebace," he described the sebaceous origin and typical distribution of the scaly eruption. He was also author of a book on diseases of the kidney. Perhaps he was overshadowed by our own Richard Bright, whose contemporary he was. Cazenave developed Bielt's ideas and, impressed by the destruc-

tion and scarring of the advanced disease, classed it with lupus vulgaris. In 1851 he coined the unfortunate term "lupus erythematoses," which has the single virtue of being grammatically more correct than our present usage.

When Kaposi published his paper in 1872 he was, I believe, aware that he was breaking new ground and not just extending a furrow. He included the word "Kenntniss" in the title: he was widening the understanding of lupus erythematosus, not merely adding to the list of physical signs. His account, bedevilled a little by the minutiae of skin lesions and their Latin classification, is thorough and in places has a modern tang: indeed, considering the few clinical tools which he commanded, I am reminded of some words which "Q" wrote about a minor poet of the seventeenth century: "A wonderful performer, Traherne, on an instrument of at most a few strings."

Kaposi refers to observations over the previous 20 years. "Lupus erythematosus," he says, "is not only

a local disease of the skin but various and severe general symptoms may develop in connexion with or as a consequence of the affliction which may even endanger the life of the patient." He describes in detail the two classes of rash which Hebra (1845) had depicted in his *Atlas*, L.E. discoides and L.E. discretus et aggregatus, the former being relatively benign, localized, and chronic, the latter more widely distributed and potentially dangerous, since it may become generalized with severe constitutional disturbance. His enumeration of the signs and symptoms of this generalized disease is surprisingly comprehensive. He describes the "aching, boring, deep-seated pains in the bones," nodules the size of hazel nuts, swellings around joints with associated changes in the skin, adenitis, and a terrible complicating erysipelas. "During this phase, patients exhibit symptoms of a severe and generalized febrile disease. They lie on their backs, have a hot dry skin, dry fissured tongue, general prostration, and are more or less unconscious. In the course of two to three weeks death ensues, being preceded by increased mental disturbance, coma, or by pleuro-pneumonia." To his eye, there could be another ending: "... the fever vanishes, the tongue becomes moist, the swelling of the face diminishes, the crusts fall off, and the patients recover."

Before coming to the next great figure I must mention that in 1884 Jonathan Hutchinson described "chilblain lupus," the first reference we have to the sensitivity to cold and the Raynaud phenomenon, a feature of many cases to-day.

William Osler

With the papers which William Osler contributed to the *American Journal of the Medical Sciences* between 1895 and 1903, we arrive in modern times. It is difficult to realize that 60 years have elapsed since he wrote of the "Visceral Complications of Erythema Exudativum Multiforme": "By exudative erythema is understood a disease of unknown aetiology with polymorphic skin lesions—hyperemia, edema, and hemorrhage—arthritis occasionally, and a variable number of visceral manifestations of which the most important are gastro-intestinal crises, endocarditis, pericarditis, acute nephritis and hemorrhage from the mucous surfaces." He mentions the tendency to remission, the variability in the skin eruptions, and the fact that the disease may run its full course to death without skin involvement.

The physical description of systemic lupus erythematosus began in the early years of the nineteenth century: Pierre Rayer (1827) and Théodore Bielt (1828) crystallized the first nebulous thoughts about the skin changes. Moritz Kaposi (1872) added another dimension (Table I). William Osler (1895) put the disease in its medical perspective and began that hunt for its causes which later workers, notably Klemperer and his co-authors (1942a, 1942b), have continued to the present.

TABLE I.—Early Titles Applied to Lupus Erythematosus

Flux sebace (Pierre Rayer), 1827.
Erythème centrifuge (Théodore Bielt), 1828.
Hypertrophie folliculorum (Robert Willis), 1841.
Schorrhoea congestiva (Ferdinand von Hebra), 1845.
Lupus erythematosus (Cazenave), 1851.
Herpes cretace (Devergie), 1854.
Erysipelas perstans faciei (Moritz Kaposi), 1872.
Exudative erythema (William Osler), 1895.
Ulerythema centrifugum (Unna), 1896.

Apart from a comprehensive review by Jadassohn in 1904, little was heard of the systemic features of the disease until in 1924 Libman and Sacks published their famous description of four cases of non-bacterial endocarditis, two of which had the typical skin lesions of lupus. Neither they nor Gross (1932), who subsequently drew attention to the peculiar changes in the myocardium and the pericardium, appear to have been aware of Osler's contribution.

In 1941 Klemperer, Pollack, and Baehr (see Asboe-Hansen, 1954) reintroduced the term "fibrinoid degeneration," first

mentioned by Neumann in 1880 and again used by Klinge in 1933, in describing the most significant finding in the hypersensitivity state. A year later these authors (1942a), under the title of "Diffuse Collagen Disease," introduced the concept that a fundamental alteration of the collagenous elements of connective tissue is responsible for the seemingly heterogeneous organ lesions of systemic lupus erythematosus and allied diseases. They never intended the term to be a diagnostic label but used it merely to stress the significance of connective-tissue involvement and encourage its study.

In 1948 Hargraves, Richmond, and Morton discovered the L.E. cell in the bone marrow of patients with systemic lupus, introducing not only a valuable diagnostic aid but a new and important facet of the problem comparable perhaps with Kaposi's contribution three-quarters of a century earlier.

Dr. William Osler began his Goulstonian Lectures to the Royal College of Physicians in 1885 as follows: "It is of use, from time to time, to take stock, so to speak, of our knowledge of a particular disease, to see exactly where we stand in regard to it, to inquire to what conclusions the accumulated facts seem to point, and to ascertain in what direction we may look for fruitful investigations in the future." It is in this spirit that I have undertaken the study of systemic lupus erythematosus, approaching it as a practising physician faced with a disease the interest and popularity of which are evidenced by the already vast and accumulating literature.

Morbid Anatomy

For a disease so widespread and so frequently deadly, the macroscopic findings at necropsy are often surprisingly meagre. Even histological changes may have to be sought diligently. The lesions are capricious in distribution and variable in their severity. Some viscera, however, are more prone to exhibit the distinctive features.

Heart.—The heart sometimes shows a very striking lesion—the well-known verrucose endocarditis of Libman and Sacks (1924). These authors drew attention to a form of endocarditis which was associated with "a negative blood culture, cutaneous petechiae and some form of renal disease." One of their cases had vegetations on the tricuspid and pulmonary valves. Characteristically the vegetations tend to spread away from the contact margins of the cusps; they may extend on to the adjacent mural endocardium (Fig. 2). These non-bacterial vegetations, granular,

FIG. 2.—Characteristic vegetations in the mitral valve.

pink, or tawny in colour, and variable in size, are derived from pale thrombi deposited on an inflamed valve cusp. In the underlying cusp there is fibrinoid degeneration in the connective tissue with areas of necrosis which may become aggregated into the conglomerate masses of nuclear debris and basophilic fragments of cytoplasm known as haematophyl bodies. Myocarditis is found in about half of the cases and consists of foci of fibrinoid degeneration in the interstitial tissue, accompanied generally by a pronounced exudative reaction of leucocytes. Occasionally there may be myocardial infarction from arteritis and occlusion of a coronary vessel. Pericarditis is very frequent and an effusion may develop; this is rarely large and commonly takes the form of a fibrinous exudate which organizes to form adhesions.

Spleen.—This may be enlarged. The characteristic histological feature is the concentric fibrosis around the central arterioles (Fig. 3); the "onion skin" lesion. This appearance, however, is sometimes found in other and unrelated conditions.

Lung.—Pleurisy is common. There may be an effusion, usually serofibrinous and containing a few leucocytes. Organization naturally leads to adhesions. Terminal bronchopneumonia is common, but the lung also frequently exhibits a form of chronic interstitial pneumonitis whose similarity to other connective-tissue diseases depends upon a seemingly uniform and diffuse arteritis. Foldes (1946) and Baggenstoss (1952) have each described this condition, which may lead to collapse and, at times, to respiratory failure. The alveolar walls and perivascular connective tissues were the sites of low-grade inflammation with focal necrosis and alveolar thrombi leading to obliteration of the alveolar spaces.

Kidney.—Most cases of systemic lupus have some renal involvement. If severe, it is usually associated with a clinical picture of nephrosis. According to Harvey *et al.* (1954)

FIG. 3.—Concentric fibrosis around a central arteriole of the spleen. (×300.)

there is a remarkable lack of correlation between the clinical and histological findings. Macroscopically the kidneys show no special feature. They may be swollen, with a few tiny petechiae on the surface.

Microscopically the important lesions are found in the glomeruli and consist of haematophyl bodies (Fig. 4), focal necroses, and deposition of hyaline material in the tuft. The

FIG. 4.—Kidney. Haematophyl body in a glomerulus. (×350.)

haematophyl bodies, which stain purple with haematoxylin and eosin, are quite small and may be of any shape; occasionally large masses may arise from the fusion of several smaller bodies. They may occur as isolated bodies in the lumen of glomerular capillaries or in association with the second feature, focal areas of tuft necrosis. The third feature, capillary loop thickening, may affect the whole or part of the glomerular tuft. This thickening is a hyaline deposit which gives a positive histochemical test for protein. The hyaline material may clothe capillary loops, lie between them, or appear within their lumen. A point stressed by Smith (1955) is that the association of this hyaline protein material with haematophyl bodies is virtually diagnostic of systemic lupus. Histochemical studies strongly suggest that both haematophyl bodies and hyaline material result from breakdown of nucleoprotein.

The renal arterioles may show necrotic lesions; sometimes there is an arteritis resembling polyarteritis nodosa. There is indeed considerable overlapping of the renal histology in these so-called collagen diseases. One of our cases of systemic lupus (Case 31) showed at necropsy widespread lesions of polyarteritis nodosa. The kidneys shared in this arteritis but showed no wire-looping and no haematophyl bodies. On the other hand, I have seen a case of scleroderma which showed all the renal lesions regarded as typical of systemic lupus together with other visceral lesions of polyarteritis. Another example of this overlap occurs in the report by Gillespie and Poteliakhoff (1951) of a case of asthma with eosinophilia. Necropsy revealed an eosinophilic polyarteritis associated with Libman-Sacks endocarditis; there was no wire-looping of glomerular tufts.

Nervous System.—Lesions in the central nervous system appear to be predominantly related to vascular damage. Until recently there was no reference to involvement of the peripheral nerves. Bailey, Sayre, and Clark (1956) reported five cases of peripheral neuritis with necropsy in two. Focal degeneration of nerves and posterior root ganglia were demonstrated at necropsy with secondary diffuse degeneration of the posterior columns and, in one case only, vascular lesions. The authors consider that vascular changes alone do not account for the neuritis in all cases. One of our cases (Case 31) had peripheral neuritis, and sections showed a widespread polyarteritis involving many tissues, including the spinal cord (Fig. 5) and peripheral nerves (Fig. 6).

Skin.—In the skin there is a lymphocytic infiltration mainly around the blood vessels and sweat glands (Fig. 7).

The elastic and collagen fibres in the dermis show degenerative changes with the appearance of fibrinoid. Oedema at the junction of epithelium and connective tissue may lead to liquefaction necrosis of the basal layer of the epithelium with the formation of bullae.

Nature of Fibrinoid.—Much attention has been focused on fibrinoid material. Its presence in the lesions of systemic lupus, polyarteritis, and allied conditions has led to much speculation regarding some common basis for the so-called collagen diseases. The fact that these diseases share common pathological features does not justify the assumption of a common aetiology. The capacity of connective tissue to react to injury is limited to a few basic patterns; it is there-

fore inevitable that the changes produced by these diseases should have some resemblance to each other.

Klemperer, Pollack, and Bachr (1942a) originally used the term "collagen disease" to focus attention on changes in the extracellular connective tissues in systemic lupus and scleroderma. Among those changes, alteration of collagen fibres and the presence of fibrinoid, believed to derive from altered collagen, were prominent. The term "collagen diseases," stressing as it does the changes in a particular fibrous protein and ignoring those in other connective-tissue elements, must therefore be used only as Klemperer *et al.* intended—to draw attention to the importance of the connective tissues as the site of morbid changes in these diseases and not to imply their aetiological or pathogenetic identity.

Clinical Pathology

The clinical laboratory plays an essential part in the diagnosis and management of patients suffering from S.L.E. Most of the abnormalities are well documented; I shall therefore refer only to those of particular clinical importance or of controversial significance.

Anaemia is common, typically of the normocytic, normochromic type, and of moderate degree; it usually improves as the disease is controlled by therapy. Since we are dealing mainly with women whose iron balance is frequently precarious, iron deficiency may also be present at any stage, but particularly in patients who have passed through a long period of rheumatoid arthritis. In the quieter phases parenteral iron may relieve the deficiency; it is less effective in the active stages. Both types of response are exemplified in Case 33.

Case 33.—A woman, who developed rheumatoid arthritis at 46, was first seen six years later. She had severe arthritis with a haemoglobin of 69%. After intravenous iron the haemoglobin rose to 79%, with disappearance of slight microcytosis and central pallor. Later she relapsed, her haemoglobin fell to 48%, and L.E. cells were found; the red cells were now normal in size and staining. The introduction of cortisone was followed by improvement in the general condition and in the haemoglobin level, which reached 90% in three months.

FIG. 5.—An acute arteriolitis in one of the anterior roots of the spinal cord. ($\times 150$.)

FIG. 6.—Showing an arteriolitis in a vessel in the sciatic nerve. ($\times 110$.) The arteriolitis is to the left of a nerve bundle.

FIG. 7.—Biopsy showing lymphocytic infiltration around vessels in the deep part of the dermis. ($\times 210$.)

Anaemia was present at some time in every one of our cases. During the benign phases normal haemoglobin levels were sometimes found, particularly when iron deficiency has been relieved. It invariably accompanied relapse. I regard the absence of anaemia as a favourable portent, even when the clinical picture points to deterioration.

Case 38.—A woman developed a vague febrile illness after dental extraction, thought at first to be subacute bacterial endocarditis. Eventually L.E. cells were discovered. Despite constitutional upset and severe Raynaud's phenomenon necessitating bilateral cervical sympathectomy, the haemoglobin was only reduced on one of many estimations. Three and a half years later she was in good general health and improving steadily. Her haemoglobin was 102% and L.E. cells were not present.

The genesis of this normocytic, normochromic anaemia is obscure. We find no regular or significant abnormality in the sternal marrow. Hypoplasia is reported, but the diagnosis of this from examination of aspirated marrow is notoriously unreliable. The fact that the red-cell count may become normal during steroid therapy, that the marrow can respond to the development of haemolytic anaemia by gross hyperplasia, and that, in the analogous refractory anaemia of rheumatoid disease, the count can be raised to normal by giving cobalt, suggest defective regulation of haemopoiesis as an explanation rather than a specific deficiency or depression by hypothetical toxins.

Overt haemolysis is not usually an important feature, though in the more acute phases excessive red-cell destruction, recognizable only by shortening of the life-span of transfused erythrocytes, may be of clinical significance and analogous to that sometimes found in advanced renal failure and malignant disease.

Frank haemolytic anaemia is a well-recognized, if uncommon, manifestation, and may be the presenting feature. Splenectomy for the relief of "idiopathic" acquired haemolytic anaemia has sometimes (Dameshek, 1955) been followed by widespread evidence of systemic lupus.

The haemolytic anaemia has been attributed to hypersplenism, which was defined by the late Sir Lionel Whitby (Hayhoe and Whitby, 1955) as "the state in which an enlarged and overactive spleen is primarily responsible for the development of neutropenia, anaemia, or thrombocytopenia or a combination of these cytopenias." Any other possible cause should be carefully excluded before falling back on this explanation; such another cause, red-cell antibody, can be revealed by the Coombs test in S.L.E. Furthermore, Dameshek (1955), who has nurtured the concept of hypersplenism, declares that "an all-important feature of hypersplenism is that splenectomy shall result in the correction of the cytopenia." In very few reported cases has it done so, and our experience accords with that of Chertkow and Dacie (1956), who have treated various types of auto-immune haemolytic anaemia and report that steroid therapy is more effective than splenectomy in arresting haemolysis.

The white-cell count is frequently low. Michael *et al.* (1951) found a leucopenia at some time in 68 of 111 cases. Seven out of the 12 of our patients, who had five or more counts performed, showed levels below 5,000 at some time. On the other hand, several had, in the absence of infection, a leucocytosis which persisted during clinical remission. At the time when L.E. cells were found, only 17 of 37 of our cases showed leucopenia. The importance of leucopenia is sometimes overstressed, and a normal or raised white count in no way invalidates the diagnosis.

Gross thrombocytopenia has occasionally been reported and lesser degrees of platelet depression are fairly common, though probably without clinical significance. Michael *et al.* (1951) found a count below 150,000 in about half of the 83 patients examined. Gross haemorrhagic manifestations may usher in the disease, and in any case of "idiopathic" thrombocytopenic purpura L.E. cells must be looked for. While remission of the purpura has usually followed removal of the spleen, generalization of the systemic lupus has sometimes seemed to be precipitated by the operation (Dameshek and Reeves, 1956).

Case 31.—A woman of 39 suffered from a cutaneous anaphylactoid purpura for eight years, with two episodes of abdominal pain and bloody diarrhoea, before the emergence of a dusky red facial rash followed by peripheral neuropathy, the finding of L.E. cells, and a positive skin biopsy established the diagnosis.

This case raises the question whether renal failure, which the textbooks tell us is the only dangerous complication of anaphylactoid purpura, is not in fact a later manifestation of systemic lupus.

The sedimentation rate is usually very rapid and remains high during remissions. It exceeded 50 mm. in 1 hour in 38 of 42 of our cases at the time when L.E. cells were first found.

Serum protein changes are usual, with reduction or reversal of the albumin/globulin ratio. Electrophoresis shows a fall in albumin with sometimes a slight rise in α_2 - and usually a big rise in γ -globulin. These changes are in no way specific and are so frequent in rheumatoid disease as to be valueless for distinguishing cases of systemic lupus. In a patient without rheumatic symptoms this electrophoretic pattern would be hardly more suggestive of lupus than a very high sedimentation rate.

The Rose test was positive in 20 out of 25 of our patients. The fact that this test is usually done when the patient has joint symptoms may explain this high proportion. It was, however, also positive in two patients, one of whom had only extremely slight and vague aches and pains and the other had none at all. Hess (1957), who reviews the literature, reports an overall figure of 46% of positive results in systemic lupus. She also draws attention to the close association with joint involvement.

Patients with S.L.E. seem prone to form abnormal plasma proteins of the antibody type. These give rise to a variety of clinical phenomena, the commonest being the biological false-positive test for syphilis. A positive reaction was found in 44% of cases by Montgomery and McCreight (1949) by repeated testing. In our series one test only was performed and 1 out of 14 gave a positive result. Most interesting are those apparently healthy people who give a persisting false-positive reaction. Moore and Lutz (1955) and Moore (1956) have reported 148 such cases followed for from 1 to 20 years. Ten have developed proved S.L.E.; in 45 this is strongly suspected; 13 others show either rheumatoid features or are undiagnosed with a bizarre type of illness. Thus almost half the cases have already developed an illness of the systemic lupus type.

At the Royal National Hospital the Berger 2 modification of the Kahn reaction is performed upon all new in-patients. The records since 1950 contain 25 patients with unexplained positive tests. All were among the 2,100 diagnosed as having rheumatoid arthritis; not one was found in the 990 patients with other chronic rheumatic diseases. This is a statistically significant difference. The average sedimentation rate of the sero-positive cases was 9 mm. in 1 hour higher than that of a random sample of 300 sero-negatives: we shall follow the future of these cases with great interest.

Other abnormal proteins occasionally reported include circulating anticoagulants (Frick, 1955), cold agglutinins (Gold and Gowing, 1955), and cryoglobulins (Barr *et al.*, 1950). Frequent reactions after blood transfusion and the development of multiple antibodies are reported. Nine of our patients received blood, three on several occasions. Apart from slight pyrexia, none showed reaction in the ordinary sense of rigor, collapse, or haemolysis. One case of haemolytic anaemia had many transfusions without incident, though the effect on her haemoglobin was very transient.

The L.E. cell phenomenon (Hargraves *et al.*, 1948) is now widely used as a diagnostic test. Many techniques have been evolved, the essence of the test remaining the same—namely, the lysis and ingestion of dead nuclear material by intact white cells, usually polymorphs, under the influence of a factor present in the serum in systemic lupus, with the production of a characteristic bloated cell. The test is negative in a small proportion, probably 5–10% (Haserick, 1951).

of undoubted cases of S.L.E. False positives are very rare. They have been reported in severe drug reactions, particularly to penicillin (Walsh and Zimmerman, 1953). I suspect that some cases at least reflect insufficiently strict criteria for identification, and in others perusal of the notes shows that clinical features, very suggestive of the early stages of systemic lupus, were present before the allegedly offending drug was given. Many "false-positive" reactions stem from failure to recognize how chronic and how restricted a condition systemic lupus can be: it is the authors' view of the natural history of the disease that is false and not the test. From a practical point of view, I feel that the finding of L.E. cells is diagnostic of S.I. E. in the broad sense; it does not at once imply a severe illness running a malignant course. Their absence, however, does not exclude the diagnosis, nor does their persistence during remissions, either natural or induced, affect the prognosis.

Natural History

The term "disseminated," which Kaposi used in 1875 to indicate extension of the rash and the development of constitutional symptoms, is open to objection and should be abandoned. It implies the scattering of the seeds of disease from a local focus, as in disseminated miliary tuberculosis. It is a fundamental feature of our present views of systemic lupus that the disease exhibits a widespread and simultaneous involvement of the connective tissues as a whole. "Systemic" epitomizes this idea.

The distinction between acute, subacute, and chronic seems to me both arbitrary and artificial in such a protean disease. Systemic lupus is in some ways analogous to hypertension, which may be an observation without symptoms, a benign clinical state, or a malignant illness. I would like to suggest that systemic lupus may usefully be described as "benign" or "malignant."

The recognition of the benign or malignant phase is essentially a matter of clinical judgment, resting upon a balanced assessment of the case as a whole and not on any single symptom, sign, or laboratory finding. Features suggesting the malignant phase are severe constitutional disturbance, with weight loss and fever, serous membrane involvement, falling haemoglobin level, or frank blood dyscrasia; affection of the central nervous system; or persistent renal disease (Table II). The benign phase commonly declares itself as an arthritis of the rheumatoid type, as chronic discoid lupus, or perhaps as a false-positive Wassermann reaction. The coexistence of chronic skin and joint manifestations does not necessarily imply a malignant course, though it does suggest that the patient is near to the precipice.

Mode of Onset.—Malaise with loss of weight and an irregular fever, joint pains, and skin lesions, either together or independently, are perhaps the commonest initial complaints. Such symptoms may disappear spontaneously, only to recur later with increased severity. Evidence of dysfunction in any system may, however, be the presenting feature.

Table III indicates the mode of presentation in our 49 cases.

Age, Sex, and Race.—In most of the larger series (Jessar *et al.*, 1953; Dubois, 1956; Shearn and Pirofsky, 1952; Harvey *et al.*, 1954) females constitute between 80 and 90% of the total. There were 39 women in our 49 cases. In 25

TABLE II.—Course of the Disease

Malignant course from onset	11 (4 male, 7 female)
Benign course at first	38 (6 " 32 ")
Subsequent course of the 38 cases initially benign:	
Have entered the malignant phase	22
Have so far remained benign	14
Developed another benign feature (chronic arthritis following discoid lupus)	2

TABLE III.—Mode of Onset in 49 Cases (10 men and 39 women)

Chronic arthritis	29	Neuropathy	1
Arthralgia	10	Pleurisy	1
General illness	6	Raynaud's phenomenon	1
Rash	4		

The onset of arthralgia was accompanied in two patients by general illness and in one by neuropathy. The average age of onset of the earliest features was 43 years (range 13–69).

the onset occurred between the ages of 30 and 50. Brunsting *et al.* (1950) claims that females with red hair and light-sensitive complexions are more susceptible. On the other hand, the pigmented skin of the negro does not protect (Shearn and Pirofsky, 1952).

Family History.—Several instances of familial occurrence are reported, notably by Brunsting *et al.* (1950) and Shearn and Pirofsky (1952), and both Haserick (1951) and Jessar *et al.* (1953) have found patients with systemic lupus in families in which other members have chronic discoid lupus and rheumatoid arthritis.

Past History.—Most of the patients in our series had excellent health before developing the disease. In the few instances in which recurrent chest infections were reported, these may well have been early manifestations. The possible influence of gold will be discussed fully later.

Incidence.—Undoubtedly many cases of systemic lupus have gone unrecognized in the past. In 1894 Morris stoutly maintained that no dermatologist in this country had met a patient with Kaposi's disease. Twenty years ago a case of systemic lupus was a great rarity in the medical wards. Today it seems more common than rheumatic fever. Dubois (1953) reported only 11 patients diagnosed in the Los Angeles County Hospital during 1948 and 1949, but 44 in the next two years. This increase, coinciding with the development of a new diagnostic test, need not indicate a change in incidence. Nevertheless, many observers are convinced that the disease is becoming more common.

Prognosis

"The essence of prognosis," says Hippocrates in the introduction to *The Prognostics*, lies in recognizing "the nature of the affection." The more we study the natural history of this disease with its infinite variations the less inclined are we to foretell the future. Personal experience and the facts of contemporary history combine to paint a sombre picture. Approximately 80% of patients in the series reported have died within five years of coming under supervision; death within one year is not uncommon (Table IV).

TABLE IV.—Prognosis of Benign and Malignant Phases

11 cases initially malignant:	
4 died after 9 months to 5 years, average 2 years.	
7 alive after 6 months to 7 years, average 2½ years.	
38 cases initially benign:	
16 remained benign for 1 to 21 years. Average 9½ years.	
(1 died of lymphosarcoma.)	
22 became malignant after 1 to 25 years, average 6½ years.	
8 died after 6 months to 5 years, average 3 years.	
14 alive after 6 months to 5 years, average 2 years.	

Perhaps the most accurate picture emerges from a comparison of two large series. The first, by Jessar *et al.* (1953) includes 103 patients followed up before the era of the L.E. cell and hormone therapy; their starting-point was the onset of the disease. In the second series of Harvey *et al.* (1954) 99 patients, 75 of whom were treated with hormones, were followed between 1949 and 1953; their starting-point was the first diagnosis. Both report an unfavourable prognosis. Of Jessar's patients, 38% were alive at the end of four years as compared with 52% of Harvey's. Of all the survivors in any one year about 10% died in the subsequent 12 months. To attribute this difference to hormone treatment is tempting but facile; no comparable figures exist for untreated patients in the same era of diagnosis, nor could such a control series be justified.

Dubois (1956) is more encouraging. In an earlier series the median duration of life of 59 untreated or inadequately treated patients was 24 months. In the recent series of 138 patients adequately treated and ill for 24 months or more, less than 10% have died. Interpreting these figures with caution, hormone treatment does appear to prolong expectancy of life. The more effective treatment of secondary infection by antibiotics under a steroid cover may also be a factor.

[The second lecture, with a list of references, will appear in our next issue.]

THE LUPUS ERYTHEMATOSUS CELL AND ITS SIGNIFICANCE*

BY

M. WILKINSON, M.D., M.R.C.P.

AND

L. S. SACKER, M.B., B.S.

From the Departments of Medicine and Pathology, Post-graduate Medical School, Hammersmith

While it is accepted that the lupus erythematosus cell (L.E. cell) can be demonstrated in the blood of most patients with systemic lupus erythematosus, it remains uncertain whether L.E. cells can be demonstrated in patients with various other diseases.

This report deals with three years' experience of L.E.-cell tests in patients with systemic lupus erythematosus and other diseases. Our results are compared with those of other workers, and various aspects of the literature are reviewed.

Methods

We have used two techniques for demonstrating the L.E.-cell phenomenon. For the first, and preferred, method defibrinated blood from the patient is incubated for two and a half hours at 37° C., then centrifuged, and smears are made from the leucocyte layer. The second method is convenient when multiple tests are being run together or when only serum is available. For this test, fresh normal leucocytes are suspended in the patient's serum, incubated for two and a half hours at 37° C., then centrifuged, and smears are made from the leucocyte button. Both of these methods have been fully described by Dacie (1956).

With sensitive and easily repeated peripheral-blood techniques available, methods involving marrow biopsy hardly seem justifiable and are probably less sensitive because of the presence of anticoagulant.

Certain practical points are worthy of comment.

Incubation Time.—The L.E. cell requires a considerable interval of time for its formation. By counting the number of L.E. cells per 1,000 polymorphs after varying incubation times we have found two and a half hours to be optimal. After this period the number of L.E. cells is maximal and degenerative changes in the leucocytes are not conspicuous.

Effect of Anticoagulants.—Similar counts of the number of L.E. cells produced in specimens of blood with and without anticoagulants confirm the findings of Zimmer and Hargraves (1952) that anticoagulants depress L.E.-cell formation. Even a moderately positive test with a clotted-blood technique may be matched by negative or weakly positive results when citrate, heparin, oxalate, or sequestrene is present.

Interpretation of Films

In Romanowsky-stained films the L.E. cell is usually a neutrophil polymorph containing within its cytoplasm the L.E. body, a homogeneous, purple-staining spherical inclusion of variable size, but usually large enough to displace the cell nucleus to the periphery. The L.E. body is completely homogeneous, with no evidence of nuclear struc-

*Part of the material in this report was taken from an M.D. thesis submitted by one of the authors to the University of Cambridge.

ture. Occasionally the inclusions are multiple. Rarely inclusions occur in eosinophil or basophil polymorphs and in monocytes.

Only the finding of a fully developed L.E. cell can support a diagnosis of systemic lupus erythematosus. The finding of free homogeneous bodies or rosettes—that is, clusters of polymorphs surrounding one of these bodies, and preparing to engulf it—is a suggestive but not conclusive finding, and should stimulate further scrutiny for typical L.E. cells and, if necessary, repetition of the test. Since occasional cases of systemic lupus erythematosus show very few L.E. cells it is important to study each film carefully. In the present study all films were examined for at least 10 minutes under the 1/3-in. (8-mm.) objective before a negative report was given. Special attention was paid to the edges of the film, where L.E. cells tend to accumulate, and all suggestive cells were examined under a higher magnification.

Difficulties of interpretation may arise from confusion with three structures.

(1) *The "Tart" Cell, or Nucleophagocytosis.*—This is a monocyte or polymorph which has ingested a free nucleus and the nuclear structure of the inclusion is blurred to a variable degree by autolysis. The differentiation from the true L.E. cell depends upon finding some residual nuclear structure within the "tart" cell inclusion. Sometimes the centre of the inclusion may appear homogeneous, but a dark rim of condensation may betray its true identity. Nucleophagocytosis has no particular significance, as it is seen in many samples of blood from normal and diseased people. Nucleophagocytosis seems to occur more frequently in preparations using the defibrinated blood technique, and is said to be especially common in association with drug-hypersensitivity reactions (Meyler, 1954).

(2) *Erythrophagocytosis.*—This should be fairly easy to distinguish from the L.E. cell because the phagocytosed erythrocyte retains to a variable degree the pinkish colour of haemoglobin. It is the size of a red cell and smaller than the usual L.E. cell inclusion.

(3) *Platelet Aggregations.*—In preparations using the serum method, aggregations of platelets may form free globular bodies, often with surrounding rosette formation. These aggregations have a granular appearance, tend to stain blue rather than purple, and are rarely ingested.

A difficulty not encountered in this study is due to amyloid bodies (Trubowitz, 1950). In amyloidosis bone-marrow smears stained with Romanowsky stains may show inclusion phenomena indistinguishable from the L.E. cell. These inclusions are said not to stain with Feulgen's reagent but to give most of the reactions which characterize amyloid infiltrations in other situations: they are clearly not L.E. cells.

During the past four years we have examined 699 specimens from 514 patients, and in our experience the L.E. cell has proved almost specific to systemic lupus erythematosus.

Results of L.E. Tests on Patients with Systemic Lupus Erythematosus

Of 19 patients diagnosed on clinical grounds as suffering from systemic lupus erythematosus (5 cases were subsequently confirmed at necropsy), the blood from 18 showed the L.E.-cell phenomenon, and in the remaining patient it had been demonstrated at another hospital prior to cortisone therapy, though at the time of our single test it was negative.

It seems to be generally agreed that, while most cases of systemic lupus erythematosus show the L.E.-cell phenomenon at some stage in the disease, occasional clinically and histologically typical cases have shown no L.E. cells despite repeated tests. Furthermore, L.E. cells may not be constantly demonstrated. In one of our patients the tests were negative during an initial typical systemic episode. The disease then remitted, and, apart from mild cutaneous manifestations, the

patient remained well for a period of three years until a further systemic episode, when abundant L.E. cells were demonstrable. Table I shows the incidence of positive L.E. tests in several reported series of cases of systemic lupus erythematosus.

TABLE I.—Incidence of the L.E.-cell Phenomenon in Published Cases of Systemic Lupus Erythematosus

Author	No. of Patients Tested	Patients L.E. Positive		Technique of Test
		No.	%	
Dubois (1953)	70	48	68	Heparinized blood
Gold and Gowing (1953)	15	6	40	Heparinized blood or serum + donor W.B.C.s
Harvey <i>et al.</i> (1954)	96	79	82	Heparinized blood
Haserick (1951)	23	23	100	Anticoagulated blood or plasma + donor W.B.C.s
Lee (1951)	25	24	96	Clotted blood
Shearn and Pirofsky (1952)	31	29	94	Plasma + normal bone marrow
Snapper and Nathan (1955)	21	20	95	Clotted blood + dead leucocytes
Soffer <i>et al.</i> (1954)	32	32	100	Not stated
Suksta and Conley (1951)	21	14	67	Blood or marrow + anticoagulant
Total	334	275	82	

Haserick (1951) suggested that the intensity of L.E.-cell production is related to the severity of the disease; this is certainly not invariable. On two occasions we have encountered patients severely ill with untreated systemic lupus erythematosus in whom the L.E. test was only weakly positive. Furthermore, an exacerbation of the disease process in any case is not necessarily associated with a shower of L.E. cells.

It has been reported that during steroid therapy of systemic lupus erythematosus the L.E.-cell phenomenon may sometimes disappear (Macdonald and Simmon, 1950; Shearn and Pirofsky, 1952), persist though often to a lesser degree (Soffer *et al.*, 1954), or be unaffected (Fallet *et al.*, 1955). The most extensive work on this aspect comes from Dubois (1956), who observed the effect of steroid therapy on 54 patients and found that a reduction or disappearance of L.E. cells was usual.

Of the present series of cases, nine had multiple L.E. tests which could be related to their treatment. In seven patients the effect of adequate hormonal treatment was to cause a marked reduction in the number of L.E. cells demonstrable in their peripheral-blood specimens—for example, Fig. 1—but in all cases a few L.E. cells (fewer than

FIG. 1.—Effect of cortisone therapy on L.E.-cell production.

3 per 1,000 polymorphs) persisted either constantly or intermittently for periods up to three years of follow-up. Two patients continued to show moderate numbers of L.E. cells during treatment despite good clinical control of the disease.

Results of L.E. Tests in Diseases Other Than Systemic Lupus Erythematosus

During the period of study 578 blood specimens from 495 patients with diseases other than systemic lupus erythematosus were tested for the L.E. cell phenomenon, and only in two cases were L.E. cells found (see Table II). The first

case was that of a young woman with portal cirrhosis, which is described later. The second patient presented a complex problem of myasthenia gravis treated by thymic irradiation with subsequent development of hypothyroidism. She was clinically unlike a case of systemic lupus erythematosus, and since only one abnormal cell was found on a single occasion we hesitate to call this a definite false-positive result. In every other case the test was negative. Table III shows the results of several similar studies of the L.E.-cell test in diseases other than systemic lupus erythematosus.

At this point it is convenient to discuss some of the diseases in which false-positive L.E. tests have been reported.

Chronic Discoid Lupus Erythematosus

A number of workers have now reported the occurrence of scanty L.E. cells in a few cases of discoid lupus erythematosus, and Rasponi (1954) found this association in the surprisingly high proportion of 9 out of 20 sufferers from chronic discoid lupus erythematosus, most of whom were sensitive to sunlight. It is well recognized that the borderline between cutaneous lupus erythematosus and the systemic disease may be indistinct and that the former condition may in rare cases develop systemic manifestations, sometimes after exposure to sunlight. Recent studies (Marten and Blackburn, 1956; Dubois, 1956) have emphasized this close relationship between the two conditions, and it would seem reasonable to describe any case of lupus erythematosus showing bona-fide L.E. cells as a systemic disease. We have not found L.E. cells in cases of discoid lupus erythematosus, but our experience is too slight to be of significance.

Rheumatoid Arthritis

L.E. cells have been reported in three groups of patients suffering from rheumatoid arthritis.

Slocumb (1953) has reported the appearance of a transitory panmeseenchymal reaction, sometimes associated with a demonstrable L.E.-cell phenomenon, occurring when patients with rheumatoid arthritis were maintained on large

doses of cortisone and then reduced to a smaller dose. This reaction consisted of fatigue, myalgia, arthralgia, fever, and sometimes pleurisy, pneumonia, or pericarditis. Apart from the demonstration of the L.E.-cell phenomenon in 14 such cases, Slocumb found an increased sedimentation rate, and sometimes false-positive serological tests for syphilis, and three patients showed biopsy or post-mortem evidence of arteritis. Hargraves (1954) also mentions finding L.E. cells in a few cases of rheumatoid arthritis on cortisone treatment, but makes no reference to alterations in dosage.

In the present series, cases have been seen with what appears to be an exacerbation of rheumatoid arthritis after a reduction of steroid dosage, and five such patients had L.E. tests with negative results. It seems possible that Slocumb's panmeseenchymal reaction is no more than a rather florid exacerbation of the underlying disease, precipitated by cortisone reduction or withdrawal. Furthermore, it is quite possible that some of his cases showing the L.E.-cell phenomenon were in fact cases of systemic lupus erythematosus unmasked by the cut in steroid therapy, for this condition does occasionally masquerade as rheumatoid arthritis. In the present series four patients were considered to have rheumatoid arthritis for periods up to three years before the true diagnosis became obvious.

The second group of patients are those described by Ogryzlo (1953) as "diffuse systemic rheumatoid disease," rare but severe cases of rheumatoid arthritis with visceral involvement such as pleurisy, myocardial fibrosis, interstitial pneumonia, and necrotizing arteritis. These patients often progress rapidly to a fatal termination. Ogryzlo has reported four such patients with positive L.E. tests.

The presence of a severe deforming arthritis and the absence of histological evidence of lupus erythematosus makes such a diagnosis unlikely. However, such advanced cases of rheumatoid arthritis may be complicated by amyloidosis, and the so-called L.E. cells may in fact be amyloid-containing cells. It would be interesting to know more detailed staining properties of these cells.

Finally, L.E. cells have been reported in a few cases of typical rheumatoid arthritis (Weiss and Swift, 1955), and in one case of Sjögren's syndrome with arthritis (Maclean and Robinson, 1954).

The present study includes 132 tests on the peripheral blood of 106 patients with rheumatoid arthritis without a single positive result.

Other Collagen Diseases

Collagen diseases other than rheumatoid arthritis and systemic lupus erythematosus claimed to be associated with a positive L.E. test include polyarteritis nodosa (Lincoln and Ricker, 1954), dermatomyositis (Ogryzlo, 1955), scleroderma (Voplé and Hauch, 1955), and one case of "probable collagen disease, type undetermined" (Berman *et al.*, 1950). We failed to demonstrate the L.E.-cell phenomenon in the blood of 12 such cases (6 of polyarteritis, 3 of scleroderma, and 3 of dermatomyositis), which agrees with the results of most other workers.

Drug Reactions

A positive L.E.-cell phenomenon has been reported in patients suffering from various drug reactions. The most interesting of these is hydralazine (Dustan *et al.*, 1954), which when given over several months, usually in heavy dosage, causes in a few patients an arthritic syndrome temporarily indistinguishable from rheumatoid arthritis or even systemic lupus erythematosus. The more severe instances of this reaction may be associated with a positive L.E. test, but symptoms usually remit immediately the drug is discontinued.

We have tried to produce this syndrome in rabbits but without success, although Comens (1956) has recently succeeded in dogs.

Other drug reactions said to be associated with a positive L.E. test include penicillin, phenylbutazone, hydantoin, and

antitetanus serum. Many of these reports are unconvincing, being supported by illustrations which resemble "tart" cells rather than L.E. cells. Also it is claimed that cases of systemic lupus erythematosus are unusually prone to develop drug sensitivity, so it may be that some of the reported cases suffer from this combination. Certainly one of the cases reported by Walsh and Zimmerman (1953) is now running a course compatible with systemic lupus erythematosus (Jacobs, 1955).

We have examined the blood of 20 patients suffering from various drug (chlorpromazine, mersalyl, carbimazole, penicillin, phenylbutazone, and streptomycin) and serum reactions, but have found no L.E. cells.

Cirrhosis

Joske and King (1955) reported the L.E.-cell phenomenon in the blood of two patients with active chronic hepatitis, and three further cases have been described (Bettley, 1955; Bearne *et al.*, 1956; Heller and Zimmerman, 1956).

In the present study, moderate numbers of L.E. cells were found in three out of four tests on the peripheral blood of a young woman with portal cirrhosis. The abnormal cells (see Fig. 2) were found with both defibrinated blood and

FIG. 2.—Typical L.E. cell found in the blood of a patient with portal cirrhosis.

serum techniques, and when stained with Feulgen, Unna-Pappenheimer, and Romanowsky stains the cells were indistinguishable from those seen in systemic lupus erythematosus. This patient also suffered from spontaneous hypothyroidism (adequately treated when L.E. cells were found), and she presented unusual endocrine features such as a moon-face, hirsutism, acne, amenorrhoea, abdominal striae, and a strikingly high serum gamma-globulin, similar to the group of young female cirrhotics described by Bongiovanni and Eisenmenger (1951). At subsequent post-mortem study the portal cirrhosis was confirmed, but no evidence of systemic lupus erythematosus was found.

Out of 51 tests on 44 patients with portal or biliary cirrhosis only the three tests on the above-mentioned patient were positive.

Why a few patients with portal cirrhosis should exhibit the L.E. cell phenomenon is quite unknown. While systemic lupus erythematosus commonly causes abnormalities of the empirical liver-function tests, it rarely causes anatomical changes in the liver (Kofman *et al.*, 1955). The possibility that these patients were suffering from a hepatic form of systemic lupus erythematosus is therefore unlikely. The absence of other clinical, laboratory, and, in two of the above published cases, histological evidence of systemic lupus erythematosus makes the coincidence of this disease similarly improbable. It

seems likely that the apparent L.E.-cell phenomenon in these cases is somehow related to the cirrhosis. It cannot be due simply to the presence of a high serum gamma-globulin, for the L.E.-cell phenomenon is due to a particular protein fraction which electrophoretically moves with gamma-globulin rather than to the total amount of gamma-globulin present. Under highly artificial conditions proteins may be precipitated to form globules which after phagocytosis may resemble L.E. cells (Inderbitzin, 1953), but these inclusions do not stain with Feulgen's reagent (Marmont, 1955).

Joske and King (1955) speculated on the possibility that the L.E.-cell phenomenon in systemic lupus erythematosus and in cirrhosis has an immunological basis, that it is in fact an equivalent of the Coombs test on leucocytes. Unfortunately, leucocyte suspensions are unsuitable for this test because they invariably clump when washed with saline. While anti-human leucocyte sera produced in animals are able to cause nucleophagocytosis and it has been claimed that they sometimes cause inclusion phenomena indistinguishable from the L.E. cell, no author has yet produced a convincing illustration of this point.

Haemolytic Anaemia

Barman *et al.* (1950) and Lee *et al.* (1951) reported a case of haemolytic anaemia in which the L.E.-cell phenomenon was demonstrated. These were regarded as false-positive results, especially since the spleen of the latter case did not show histological evidence of systemic lupus erythematosus. However, Dubois (1952) later reported three cases of systemic lupus erythematosus which presented with haemolytic anaemia. Also Dubois (1953) mentions that the case of Lee *et al.* later developed the typical picture of systemic lupus erythematosus. This sequence is now well recognized.

Despite 24 tests on 17 patients with acquired haemolytic anaemia, a positive L.E. test was not encountered, but two further patients presented with acquired haemolytic anaemia and had other manifestations suggestive of systemic lupus erythematosus. Both patients gave a positive L.E. test. Although actual haemolytic anaemia is uncommon in systemic lupus erythematosus a number of cases do show a positive Coombs test. This was noted in 6 out of 34 cases mentioned by Harvey *et al.* (1954) and in 5 out of the 10 tested in the present series.

Amyloidosis and Myelomatosis

As already mentioned, cells containing amyloid deposits may closely resemble L.E. cells when stained with Romanowsky stains, and similar cells may be found in marrow preparations from patients with myelomatosis complicated by amyloidosis (Trubowitz, 1950; Lee *et al.*, 1951; Weiss and Swift, 1955). We have not encountered such cells.

Glomerulonephritis

Nephropathy is a common complication of systemic lupus erythematosus, and this diagnosis must be considered in any case of renal disease showing the L.E.-cell phenomenon (Parelhoff, 1953). Two cases reported by Parelhoff were examined at necropsy without revealing any histological evidence of systemic lupus erythematosus. Only one of these cases is described in detail, and the illustration which accompanies it shows a rosette and not an L.E. cell as its legend implies. But for this unfortunate illustration the case sounds a convincing example of a false-positive L.E. test.

Miscellaneous Conditions

The L.E.-cell phenomenon has been recorded in single cases of pernicious anaemia, leukaemia, Hodgkin's disease, dermatitis herpetiformis, miliary tuberculosis, moniliasis, and pemphigus. None of these reports includes a convincing illustration of the L.E. cells found.

Constituents and Mechanism of the L.E.-cell Phenomenon

The morphological events involved in the production of the L.E. cell are relatively undisputed. Supravital and microcinematographic studies have shown first a swelling and blurring of the nuclear pattern of one or more lobes of a polymorph nucleus (Rohn and Bond, 1952, 1953). As this nucleolysis occurs, the cell membrane ruptures, setting free a homogeneous mass which is seen in stained smears as the L.E. body. This body, presumably because of chemotactic influences, becomes surrounded by leucocytes, forming the rosette. Finally the homogeneous body is completely ingested by a leucocyte, producing the L.E. cell. There are thus two stages to the L.E.-cell phenomenon—namely, nucleolysis and phagocytosis—and it is important to realize that in the L.E.-cell phenomenon nucleolysis precedes phagocytosis, whereas in the formation of the "tart" cell nucleolysis occurs after the inclusion has been ingested, and is always incomplete.

It is commonly agreed that there are at least three constituents in the L.E.-cell phenomenon—namely, a source of nucleoprotein to be transformed into the inclusion body, a factor present in the serum and plasma of patients suffering from systemic lupus erythematosus which causes nucleolysis, and, finally, an active phagocyte. For convenience these are considered individually.

The Nucleoprotein Substrate

The L.E.-cell inclusion stains strongly with Feulgen's reagent and weakly with methyl green, from which it may be deduced that it consists of partially depolymerized deoxyribonucleic acid (Gueft, 1950). The "tart" cell inclusion stains the same way but is not completely homogeneous. The L.E.-cell inclusion can result from the nucleus of any cell, but the mature polymorph appears to be more susceptible to the action of any L.E. factor present in the surrounding medium. As Snapper and Nathan (1955) have emphasized, the L.E. factor probably attacks only the nuclei of dead cells. This is supported by the work of Zinkham and Conley (1956), who showed that rotation of a specimen of blood with glass beads to traumatize the leucocytes will increase the yield of L.E. cells.

The L.E. Factor

This is a protein or protein-bound substance present in all the body fluids and exudates and in the urine of patients with systemic lupus erythematosus. Placental transmission of the L.E. factor has been shown by its transient presence in the blood of the newborn child of a patient suffering from systemic lupus erythematosus (Bridge and Foley, 1954). It is associated with, though immunologically distinct from, normal gamma-globulin (Haserick and Lewis, 1950). In systemic lupus erythematosus the serum gamma-globulin is generally raised, but probably only a small part of this increase can be attributed to the L.E. factor, for repeated L.E. tests on a single specimen of serum cause a gradual loss of potency, without much change in the gamma-globulin content.

The L.E. factor keeps indefinitely if frozen, but is destroyed by heating to 65° C. (Haserick, 1950).

The L.E. factor is quite distinct from the Coombs factor present in the serum of some patients with systemic lupus erythematosus, for, as Pisciotto *et al.* (1951) showed and we have confirmed (Table IV), this antibody globulin eluted

TABLE IV.—L.E. and Coombs Tests on Peripheral Blood and on Red-cell Eluates from the Same Blood Samples of Two Patients Suffering from Systemic Lupus Erythematosus

Patient	Peripheral Blood		Red-cell Eluates	
	L.E. Cells/1,000 Polymorphs	Direct Coombs Test	L.E. Cells/1,000 Polymorphs	Indirect Coombs Test
M.R.	1	+++	0	+++
F.S.	14	++	0	+

from the erythrocytes of patients with systemic lupus erythematosus is incapable of provoking the L.E.-cell phenomenon, though still able to give a positive indirect Coombs test.

Since L.E. cells are rarely encountered *in vivo*, and are less frequent in the blood with anticoagulants than in specimens of clotted blood, Hargraves (1954) suggested that the L.E. factor is inactive *in vivo* but is activated during coagulation. However, L.E. cells can be demonstrated in blister fluid (Watson *et al.*, 1951), in capillary blood after the circulation has been obstructed by a tourniquet (Sickley *et al.*, 1955), and on one occasion L.E. cells have been demonstrated in direct blood smears from a patient in the terminal stages of systemic lupus erythematosus (Chomet *et al.*, 1953). It seems more likely, as Snapper and Nathan (1955) suggest, that the L.E. factor is active only against dead cells, and these are likely to be present in the above situations.

How the L.E. factor causes depolymerization of nucleoprotein remains uncertain. Kurnick *et al.* (1953) have suggested evidence favouring an enzymatic process. They suggest that normal leucocytes contain an inhibitor which prevents the interaction of intracellular deoxyribonuclease and that the L.E. factor somehow releases this inhibition, allowing depolymerization of deoxyribonucleic acid to occur.

On the other hand, many authors favour an auto-antibody mechanism. In favour of this are the occurrence of the L.E.-cell phenomenon in hydralazine and possibly other drug-hypersensitivity reactions, the commonly associated positive Coombs test and false-positive serological tests for syphilis, and the high serum gamma-globulin. Unfortunately the inclusion phenomena induced as a result of experimentally produced antinuclear antibodies resemble "tart" cells rather than L.E. cells (Zimmerman *et al.*, 1953).

The frequent occurrence of the L.E.-cell phenomenon and the chemically related haematocrit bodies in systemic lupus erythematosus does suggest a rather fundamental relationship to the pathogenesis of the condition.

The Phagocytic Leucocyte

Here there is general agreement that the phagocyte which ingests the L.E. body is usually a neutrophil polymorph, but on rare occasions L.E. bodies are ingested by eosinophils, on rare occasions L.E. bodies are ingested by eosinophils, basophils, myelocytes, and monocytes. Although Berman *et al.* (1950) and Ogryzlo (1955) reported L.E. inclusions within lymphocytes, we have never observed such a phenomenon. Indeed, this finding would be rather surprising, since the lymphocyte is not usually regarded as a phagocytic cell.

Summary

The L.E.-cell phenomenon was demonstrated in 18 out of 19 patients with systemic lupus erythematosus.

Steroid therapy caused a striking reduction in the number of L.E. cells demonstrable in seven out of nine cases studied.

L.E. tests were performed on 495 patients with diseases other than systemic lupus erythematosus, and only one patient with portal cirrhosis gave a positive result. A post-mortem examination on this patient revealed no evidence of systemic lupus erythematosus.

The literature dealing with false-positive L.E. tests is discussed, and it is concluded that the L.E.-cell phenomenon, if properly interpreted, is almost specific, but rare false-positive results are seen in patients with hydralazine reactions and cirrhosis.

The mechanism of the L.E.-cell phenomenon is discussed.

The National Council for the Unmarried Mother and Her Child has issued its thirty-seventh annual report, covering the period from May, 1956, to April, 1957. The report discusses generally the problem of the unmarried mother, and in particular the foreign unmarried mothers in the U.K. An analysis of the new applications dealt with in the case department for the year under review is included. The report also considers the work of the homes and hostels affiliated to the council, and the difficulties of adoption; a detailed financial statement of both donations to the council and grants made by the council is given. Also included in the report are the addresses of affiliated homes and hostels; the number of live births registered in the U.K., and the infant mortality, for each year since 1919; the number of yearly affiliation orders made since 1925; the balance-sheet for the year ended April 30, 1957; and the names of council members. A list of publications of the council is appended, all of which may be obtained from the National Council for the Unmarried Mother and Her Child (Inc.), 21, Coram Street, London, W.C.1.

CARE OF THE ELDERLY IN GENERAL
PRACTICE

A SOCIO-MEDICAL REASSESSMENT

BY

JOHN FRY, M.D., F.R.C.S.

General Practitioner, Beckenham, Kent

For a number of reasons care of the elderly is presenting the community with problems that demand urgent consideration and suitable planning for the future. The causes that have made the problem so acute to-day are a combination of social and medical factors such as an increasing number of the aged, probably as a result of better medical and social care; a decrease in the size of families; a state of full employment; and a shortage of hospital beds and home nurses. Some of these circumstances have to be accepted as inevitable and we therefore have to seek alternative measures whereby our elderly folk will be able to reach the goal of old age freed from the anxieties of social and economic insecurity and confident of receiving sympathetic and adequate medical care.

It is good to observe the interest and thought being given to the matter, as is evident from the work and publications of Rowntree (1947), Sheldon (1948, 1950, 1954), and Hobson and Pemberton (1955), and also from the efforts that are being made by the political parties to provide some economic security. All this work, valuable as it undoubtedly is, comes "from the top," and little has been heard so far from the family doctor, who is, according to Sheldon (1954), responsible for between 90 and 95% of our population over the retiring age. The valuable and stimulating essays by general practitioners of the calibre of Grant (1955), Gillie (1956), and Gibson (1957), however, must be recognized and appreciated. In an attempt to examine the situation of the elderly in a typical London suburban practice a simple investigation has been carried out.

Methods

It is very important to define what we understand by the term "elderly." There is at present a considerable discrepancy between the "official" and the "natural" onset of old age. The official age may be taken as that at which contributory pensions become payable—namely, 60 for women and 65 for men. The natural age may be taken as that at which there begin definite limitations of activities (Sheldon, 1950). The onset of natural old age varies from individual to individual, but Sheldon concludes that it begins to make itself apparent in most people at 70–75, and it is this quinquennium that is the critical period where the donors of the community become debtors. There is therefore a discrepancy of 5 to 15 years between the official and natural onset of old age. In this study only patients of 70 and over are regarded as "elderly."

On December 31, 1955, there were 315 patients aged 70 years and over in this London practice. Clinical records were kept over that year (1955), together with special information on various social aspects, and the report that follows is based on these records.

Social Assessment

These 315 patients represented almost 6% of the practice population and accounted for 10% of the total volume of work. The sex distribution is shown in Table I.

Number at Work.—Thirty-four of the men and five of the women were still being gainfully employed, two of the

TABLE I.—Sex Distribution

	70–79	80 and Over	Total
Men	105	25	130
Women	147	38	185
Total	252	63	315

men being over 80. Their occupations were chiefly of a light nature such as printers (3), shop assistants (2), caretakers (5), clerks (12), gardeners (6), and light engineering (4). Although housework is not usually classed as a "gainful occupation" its proper performance requires a considerable degree of mental and physical fitness, and it is interesting to note that 89 women and six men were carrying out full household duties for themselves and their families, where present, with little outside help. Therefore some 30% of the men were still at work, but many more were just as fit for work but were in compulsory retirement, and 57% of the women were carrying out full household duties. Hobson and Pemberton (1955), in the Sheffield survey, also found that 24% of their men over 70 were being gainfully employed. It seems that a large proportion of those over 70 are fit for work but that many are prevented from doing so by present-day regulations.

Domicile

The place of residence of the elderly folk is of importance if we are to plan properly for the future. How many live alone and have no near-by friends or relatives on whom to rely in case of sickness? These are the "isolates" who are responsible for many domestic and medical problems. How many are living with their spouse? How many are living with their families? How many are living in homes or hospitals? All these are matters of importance, but it must be appreciated that the proportion will vary with the different areas and with differing social customs.

The proportions in this particular practice are shown in Table II. This shows certain fascinating differences and trends. With increasing age more old folk live with their

TABLE II.—Domiciles of 315 Elderly Patients

	"Isolates"	With Spouse	With Family	Totals
70–79				
Men	16 (15%)	62 (60%)	27 (25%)	105
Women	34 (23%)	46 (31%)	67 (46%)	147
Total	50 (20%)	108 (43%)	94 (37%)	252
80 and over				
Men	3 (12%)	12 (48%)	10 (40%)	25
Women	8 (21%)	9 (24%)	21 (55%)	38
Total	11 (17%)	21 (33%)	31 (50%)	63

families, as would be expected. A higher proportion of women live with their families, possibly because they outlive their husbands.

The proportion living alone remains more or less the same in the two decades, and again the women outnumber the men, but it is the male "isolates" who are more of a problem than the female, possibly because they are less well able to look after themselves.

When we come to those who live with their spouses we find that many more men are living with their wives; this apparent anomaly is explicable by the fact that the ages of their wives do not correspond and many wives are quite a good deal younger than their husbands.

TABLE III.—Number of Those Living Alone or with Spouse who have no Family in the Neighbourhood

	"Isolates"	Living with Spouse	Total
70–79			
Men (78)	10 (13%)	15 (19%)	35 (45%)
Women (80)	10 (12%)	15 (19%)	35 (44%)
80 and over			
Men (15)	5 (33%)	4 (27%)	9 (60%)
Women (12)	5 (42%)	4 (33%)	9 (75%)

The importance of the family's responsibility and burdens in the care of the elderly is obvious from the facts that 37% of those in the eighth decade live with their families and 50% of those in the ninth decade. The part played by the family is more obvious still if we consider the numbers of those in the other two groups—those living alone and those living with their spouse. Table III shows the numbers of those in these two groups who have no available family living in the neighbourhood with whom to maintain social contact and on whom to rely for assistance in case of need. It can be seen that in only 44 (14%) of the total of 315 is there no family help available. It is obvious that it is the family who will be responsible for the bulk of the care of the elderly and who will require assistance. Plans must also be made to help this group of isolates, who will account for a greater proportion of problems than this small figure suggests.

Hospital and Homes

In the past great stress was laid on the importance of providing a large number of hospital beds and half-way welfare homes for the aged. It is interesting to note, therefore, the proportion of patients in this particular practice who were in hospital or in a home during 1955.

Table IV shows that only 8.5% (27) of all the 315 old people in my practice population were in hospital or in a home during any part of the year, and more than half of

TABLE IV.—Proportion of Patients who Required Care in Hospital or in a Home in 1955

	Short Stay (Less than 3 Months)	Long Stay	Total
70–79			
Men	4 (3.5%)	3 (3.5%)	7 (7%)
Women	5 (3.5%)	6 (4%)	11 (6%)
80 and over			
Men	3 (5.7%)	3 (5.7%)	6 (11.4%)
Women	2 (5.3%)	1 (2.6%)	3 (8%)

these were in for short periods (less than three months). The hospital and welfare, or nursing, home can play only a small part in the care of the aged in this country, and it is their domiciliary care which is of prime importance. The hospital and welfare home have, nevertheless, a very important part to play in accepting and treating those patients who are suddenly and acutely ill and also those who have got beyond the ability of their families, with suitable assistance, to care for them.

It is interesting to note that Sheldon (1954) also states that "the assumption that 90% (of the aged) are still looked after at home would appear to be well within the truth."

Disability

In assessing the health of the elderly it is much more important to base this on "effective function" rather than on the incidence of various pathological states, which may well never interfere with their daily lives. Such an assessment was attempted in this group by noting the incidence of disability: the case was graded as "severe" if the patient was prevented from going out by himself, and as "moderate" if there was some definite disability but the patient was able to go out without assistance. Table V shows the numbers and proportions who were disabled.

TABLE V.—Numbers Moderately and Severely Disabled

	Moderate Disability	Severe Disability	Total
70–79			
Men	19 (18%)	12 (11%)	31 (30%)
Women	31 (20%)	25 (17%)	56 (37%)
Total	50 (20%)	37 (12%)	87 (35%)
80 and over			
Men	6 (24%)	6 (24%)	12 (48%)
Women	5 (13%)	9 (24%)	14 (37%)
Total	11 (19%)	15 (24%)	26 (41%)

Of the 70–79 group 35% were disabled, of whom 12% were severely disabled. There appears to be a somewhat higher proportion of women who were severely disabled, but this may be a local peculiarity. In those of 80 and over the proportion of disabled was naturally higher, and this was accounted for by a higher proportion of those severely disabled.

These old folk who are disabled account for a minority, since 65% of those aged 70–79 and 59% of those 80 and over are not sufficiently disabled for their daily routine to be appreciably interfered with.

The causes of these disabilities are seen in Table VI. Cardiac failure of various types was responsible for the majority of cases, followed by osteoarthritis and rheumatoid arthritis, the effects of chronic bronchitis, cerebrovascular accidents and Parkinsonism, new growths, and a miscellaneous collection of conditions.

TABLE VI.—Causes of Disabilities

Disability	Cardiac Failure	Rheumatism	Chronic Bronchitis	C.N.S.	New Growths	Misc.	Total
70–79							
Severe	16	5	5	7	4	—	37
Moderate	15	12	10	3	—	10	50
80+							
Severe	6	4	2	—	2	1	15
Moderate	3	—	3	3	1	1	11
Total	40	21	20	13	7	12	113

Outside Help

In spite of adequate facilities, help from the various ancillary public health services in this area was necessary for only 20 out of the 315 patients. This may be due to some lack of appreciation of the availability of these services or to a very small demand for them—the former is probably the correct explanation.

Clubs.—There is a "club" for old people in the area, and it plays a real part in their social welfare. By its means old friendships are maintained and new friends made, and often a new sense of responsibility is acquired by an old person in having the opportunity of looking after some frailer member or in taking an active part in the management of the affairs of the club. In spite of this facility only 20% of men in the 70–79 group and 12% of those 80 or over avail themselves of it. In women the proportions who attend the clubs are 35% and 20% respectively.

Medical Assessment

In making any medical assessment of patients in general practice the methods and techniques employed in this field of medicine must be appreciated and understood. The family doctor, to use a well-worn phrase, is the first line of medical defence and is consulted first in the course of any illness. These consultations, or doctor-patient contacts, serve as a suitable measure of morbidity. Their number alone gives an estimate of illnesses which require medical advice and treatment, and, although this may vary from practice to practice, depending on the outlook and habits of doctor and patient, in any one practice it serves as a useful guide.

The other way of measuring morbidity is to seek out the diseases that account for the greatest mortality and sickness. In general practice we are dealing principally with the non-fatal conditions, and if suitable records are kept it is possible to give an account of the common disabling illnesses.

General Morbidity.—Those over 70 account for 6% of the practice population and for almost 10% of all the work

TABLE VII.—Average Attendance Rates per Patient per Year

Age	1955	1954	1953	1952	1951
70–79	5.5	5.6	5.8	6.4	7.0
80 and over	6.2	6.2	6.2	7.7	7.7
Average for practice	3.2	3.1	3.2	3.2	3.3

done. Thus they require a greater proportion of care than the average. This is further evident from Table VII, which shows the rates of consultations in the two age groups over the past five years and compares these with the average for the practice as a whole in each of these years.

It is of interest to note how the rate has gone down over these five years, and it may well be that preventive attitudes are beginning to pay dividends.

Incidence of Disease

A study of the incidence of the most frequent groups of diseases shows that there is a marked difference between those that occur in general practice, those that predominate in hospitals, and those that are responsible for deaths.

The Report of the Ministry of Health for 1954 (part 2, p. 32) states that in people over 65 the leading causes of sickness and death in the three different spheres were:—in *general practice*: bronchitis, arthritis, and rheumatism and heart disease; in *hospitals* (in-patients): neoplasms, accidents, genito-urinary diseases, and heart diseases; and the most frequent *causes of death* were heart diseases, neoplasms, diseases of the nervous system, and bronchitis.

This suggests that we cannot base our care of the elderly at home on the findings of hospital records and mortality statistics but rather on the experiences in general practice.

Records from my practice substantiate the statements of the above Report, and Table VIII shows the incidence of the common groups of diseases in the elderly during 1955.

TABLE VIII.—Prevalence of Groups of Diseases During 1955, Expressed in Percentages of Those at Risk

		Rheumatic	Digestive	Cardio-vascular	C.N.S.	Respiratory	Upper Resp. Infect.	Skin	Neuroses
70-79	M	16	21	21	14	24	18	13	7
	F	25	14	17	11	11	13	9	7
80 and over	M	13	12	40	16	28	8	8	1
	F	28	14	25	16	9	11	9	3

The figures are expressed in percentages of the numbers at risk. Thus we see that 40% of men aged 80 and over were seen for some disorder of the cardiovascular system during that year, whilst only 25% of women of that age required attention for these conditions. It is obvious that cardiovascular disorders, rheumatic conditions, and diseases of the respiratory tract, the digestive tract, and the central nervous system are the five most common groups of diseases in the aged.

Certain clinical and epidemiological facts are of interest. The sex differences in rheumatic, cardiovascular, and respiratory disorders are significant and have been observed in other surveys and at other ages. The explanations may have an important bearing on prevention, and further studies are necessary. The low incidence of infections of the upper respiratory tract and the affective neuroses differ greatly from that of other ages, and here again the answers may have an important bearing in elucidating the causes of these most common conditions of our community.

With the more specific conditions it was found that *cardiac failure* in its various forms and causes was far and away the most common specific condition in the aged, accounting for 15% of those at risk in the eighth decade and 27% of those in the ninth. *Chronic bronchitis* and troublesome *osteoarthritis* were responsible for sickness in 10% of those aged 70-79 and in 15% of those aged 80 and over. *Neoplasms*, on the other hand, accounted for sickness in only 2.5% of those at risk in the 70-79 group and in 8% in the next decade.

These few facts show the groups of disorders which are most likely to require treatment in general practice and indicate in which direction our energies should be directed.

Clinical Problems and Pitfalls

There are no special diseases peculiar to old age and few from which it is exempt. Nevertheless the manifestations of many morbid processes are modified in their manner of presentation and course. These different reactions to disease processes add greatly to the difficulties of accurate diagnosis. In particular we should constantly beware of the dangers of "the diagnostic label." "Bronchitis" may mask chronic fibroid tuberculosis and "arthritis" may delay the discovery of a primary new growth that has caused pains in the limbs or back from secondary deposits.

Just as we are now beginning to appreciate that there are many "normal abnormalities" in children that require no specific treatment, so are we now realizing that many "diseases" of the elderly are to be accepted as normal accompaniments of age, and more work should be done on defining and stressing these baselines. As examples of the pitfalls in diagnosis I would like to refer to some of the diagnostic problems that have occurred in my own practice over the past few years.

Heart failure is a very common condition in the elderly patient, and in the majority it is the result of degenerative effects of hypertension and coronary atherosclerosis or as part of the syndrome of cor pulmonale, but it may also be caused by rarer and readily curable disorders that are easily missed if they are not kept in mind. Anaemia in old people is most often the result of iron deficiency due to faulty diets or failure of absorption, and cardiac failure is often precipitated by even a moderate anaemia that can easily be corrected by suitable and simple treatment. It must, of course, be pointed out that since there are other causes of anaemia these should be excluded before treatment is begun. Both overactivity and deficiency of the thyroid have been responsible for heart failure in elderly patients in my practice in recent years, which has been completely controlled by suitable therapy directed to the thyroid. Two patients with subacute bacterial endocarditis presented as cases of heart failure, and as a result of intensive treatment with antibiotics both recovered.

It is well to remember that not all aches are due to *rheumatism*, and among causes of generalized aches and pains have been cases of carcinomatosis, osteoporosis, Paget's disease, and myelomatosis.

Chronic bronchitis is so common in the British Isles that it is sometimes referred to as "the English disease." Its symptom-complex is particularly common in elderly men, but there are also a number of other more sinister conditions with identical features. The last six new cases of pulmonary tuberculosis in my practice have all been in men over the age of 60 with symptoms of "chronic bronchitis."

Affections of the *central nervous system* present some of the most pathetic problems with their crippling effects and mental changes, which are usually the results of cerebrovascular degeneration. Here again it is necessary that a careful assessment of other possible causes be made, for similar states of mental confusion and odd behaviour may result from remediable conditions such as myxoedema, prostatic uraemia, diabetes, and infections.

Functional disorders of the *digestive tract* are rare in old age, in marked contradistinction to middle age. On the other hand, new growths, diverticulitis, faecal impaction, and nutritional deficiencies are common. The elderly person who has to buy and cook his own meals is often neglectful and either misses meals altogether or lives on a diet of "bread, marmite, and marmalade."

Management

The proper care of our ageing population is essentially a national problem that requires a uniform central policy that must be adapted to the circumstances prevailing in the locality. Although there is this need for a unified policy on basic principles such as pensions and retirement, the individual care of the elderly must ultimately depend on a

spirit of co-operation between the family, the family doctor, the medical officer of health and his staff, the hospitals and homes, and the many voluntary organizations.

The *family* still has the most important part to play in caring for the elderly, and, in spite of all that has been said and written of the changing attitudes of the family, in the vast majority of instances it is still carrying out its tasks with great devotion and skill. When one takes into account the rise in the total number of aged, a fall in the size of the family, and the existence of full employment, and when one considers the difficulties that the care of the aged involves, it becomes obvious that, however well the family is coping with its present tasks, it cannot carry on without planned assistance from the community by the provision of extra domiciliary nursing and social services.

The introduction of the National Health Service has provided the *family doctor* with opportunities to practise a high level of medical care in our aged, and he should be alive to his responsibilities. The family doctor alone, however, cannot undertake to provide the best possible care without appropriate assistance and co-operation from hospital and public health services. Understanding mutual co-operation is surely the key to our problems.

In caring for his elderly patients the family doctor should at the outset endeavour to define his aims and plan the ways and means of achieving his objectives. As a first principle his aim must be to maintain his elderly patients in as active and independent a situation as possible. Whether they live with their families or alone they should be encouraged to remain independent for as long as possible with suitable assistance from the family and outside sources. Admission to a hospital or a home is the most drastic upheaval, and should be undertaken only when all else fails. The old, just as the young, fare best in home surroundings.

As a second principle the family doctor must practise preventive medicine to the full. He must appreciate the "normal abnormalities" of the aged and accept them as inevitable, and at the same time be constantly on the look-out to detect the early stages of preventable conditions in order to avoid irreversible changes. As well as the major lesions, the minor ones require a preventive approach, for they are apt to cause almost as much disability. Obesity, corns, deafness, and refractive errors are just as troublesome as, say, hypertension.

What of the ways and means? With a fairly constant practice population the family doctor should be able to get to know all his patients over 70 and make a point of maintaining regular contact with them. Gibson (1957) suggests a "register of the aged." This contact should be established and maintained by encouraging attendance at a special surgery session set aside for the elderly. Just as we run a children's surgery, so we should run one for the aged. Those who cannot attend must of course be visited. In such ways our patients can be classified into those requiring outside help and those maintaining satisfactory independence and suitable provisions made for their care.

What should our aims be at our clinics? The general situation of the individual should be assessed, and loneliness, boredom, and financial insecurity might be remedied by arranging for advice and help from various social bodies. Medically, early diagnosis of preventable conditions should be aimed at, and our patients should be periodically examined for early skin neoplasms, feet disorders, obesity, deafness, visual failure, early heart failure, diabetes (by a urine test), anaemia (by a haemoglobin estimation), and pulmonary tuberculosis, especially in bronchitic old men (by chest x-ray examination).

The *medical officer of health* has, I believe, a vital part to play in caring for the aged. He should emerge from his present withdrawn administrative shell and enter the field of clinical medicine as a consultant in social medicine and act as a co-ordinator of the many social services that exist in a haphazard fashion at present, and which must in the course of time be increased in numbers and efficiency. Like the family doctor he should make a register of old people on

whom he should keep as close observation as he does at present on his infants. The onus should be on all medical officers of health to approach the general practitioners in their areas now and arrange informal and personal discussions on the ways in which his staff can co-operate with the family doctor. Ideally the family doctor should be able to call in his local M.O.H. on a domiciliary consultation to arrange for the extra care of his old patients. This might then be followed up by visits from health visitors or district nurses, and meals might be provided and clothes laundered where necessary.

The *hospital* should have a much smaller part to play than it has now. Admission to hospital should be reserved for those ill enough to require treatment. There should, however, be no trouble in admitting cases when the need arises.

No praise can be too high for the *voluntary* bodies that help in the care of the aged, such as the Red Cross and the St. John Ambulance Brigade, the W.V.S., the Church, and even the Boy Scouts. There will always be a need for them in the most highly developed welfare state.

Conclusions and Summary

There is a need for the development of a national policy to cope with the ever-increasing problems of our ageing population. It is also necessary to define the roles of the various bodies and individuals who are responsible for the care of the elderly at more local levels.

In the development of any such policy a reassessment of the status and place of the elderly in our community must be carried out. Pensions must be provided to enable the old folk to live independently, comfortably, and respectably. The age for retirement must be carefully considered. In general the present official age of retirement is at least 10-15 years in advance of the natural old age of 70-75, when physical and mental disabilities become manifest. Every effort should therefore be made to encourage people to remain at work beyond the present retirement levels.

A first principle in the care of the elderly is the encouragement and maintenance of mental and physical independence for as long as possible, and when this begins to fail then it is upon the family and the family doctor that the burden falls. The importance of the family is shown by the fact that in this suburban practice 86% of those over 70 years of age had regular contact with their families. The remaining 14%—the "isolates"—presented great problems when they fell ill. The family, whatever its importance, cannot these days be expected to provide alone all the care for the aged, and assistance is required, both social and medical, if it is to carry on its tasks.

In arranging for these various forms of domiciliary help the medical officer of health must occupy a vital place. He must act as a co-ordinator and as a consultant in social medicine and be available constantly to help the family doctor to provide all the ancillary services that may be necessary to keep the old patient at home and well cared for.

In the actual management of the aged sick it is essential to realize that there are no special diseases of old age, but that its presentations are merely the results of modifications from degenerative processes. The commonest causes of morbidity and disablement were found to be cardiac failure, chronic bronchitis, and various forms of "rheumatism." The pitfalls in diagnosis and the scope of curative therapy are discussed.

The family doctor should plan his work in this field essentially on a preventive basis by early diagnosis of

curable major and minor disorders and by the prevention of social loneliness, boredom, and poverty. In carrying out these tasks the importance of establishing and maintaining close contact with one's ageing patients is stressed and the value of special clinics for the elderly is noted.

The present is still a phase of transition in the development of the Welfare State; the future presents great scope in the development of medical and social services to cope with the problems of the aged.

VULVAL AND PERINEAL TOILET IN THE PUERPERIUM

BY

R. T. MARTIN, M.B., M.R.C.O.G.

H. E. REISS, B.M., M.R.C.O.G.

AND

SHELAGH E. MILNE, M.B., B.Ch.

From the Obstetric Unit and the Department of Clinical Pathology, University College Hospital, London

The nursing care of the vulva and perineum in the puerperium has two main objectives—the prevention of infection of the genital tract and the hygiene and comfort of the patient. Details of the procedure vary in individual hospitals or midwifery districts; swabbing the vulva with cotton-wool pledgets soaked in antiseptic solution is part of the routine commonly employed, and was practised until recently in University College Obstetric Hospital. The object of the present study is to determine whether the use of ordinary tap-water, employed as a douche, can replace swabbing of the vulva and perineum with antiseptic solution, without a significant rise in the incidence of puerperal infection of the genital tract.

Technique.—The study was conducted in two phases. The first was a controlled trial to compare the effect of swabbing with antiseptic solution with that of jug douching with tap-water on a group of lying-in patients. The second phase was a study of the incidence of notifiable puerperal infection of the genital tract over a period of 17 months after the introduction of jug douching throughout the hospital. This incidence of infection is compared with the incidence in previous years when antiseptic swabbing was employed throughout the hospital.

Phase I

A controlled trial was started in May, 1954, in a 24-bedded ward. This ward is divided into two separate self-contained 12-bedded units. One sister is in charge of the whole ward, but each unit has its own junior nursing staff. Swabbing was employed in unit A and jug douching in unit B. The trial lasted 14 months. Half-way through the trial the units were changed over in order to eliminate bias introduced by possible local factors such as the amount of dust or minor differences in nursing technique.

Bacteriological studies were carried out during the time, and clinical criteria established to compare the incidence of complications in the two groups of patients.

The antiseptic employed in this study was liquor chloroxylenol *B.P.* 1:10, diluted with hot water to 1:20 just before use.

According to the *British Pharmaceutical Codex* "solution of chloroxylenol is used as an antiseptic for the skin in surgical and obstetric practice, and for this purpose should not be diluted more than 1 in 4." While this concentration is applicable for intact skin, it cannot be used in contact with the mucous membrane of the vulva and vagina or with perineal wounds. The recommended concentration in *Martindale's Extra Pharmacopoeia* (1952) is liquor chloroxylenol 1:80 for wounds and abrasions, and 1:40 as a vaginal douche. One of the best-known brands of chloroxylenol solution was formerly recommended by the manufacturers to be used at a dilution of 1:20, but is now claimed to be twice as effective, and a 1:40 dilution is recommended.

Nursing Procedure

A. Swabbing.—The following technique was employed.

Equipment.—(1) One bowl containing liquor chloroxylenol *B.P.* 1:20, with six sterile cotton-wool swabs. (2) One bowl containing dry swabs and towel.

Method.—The patient was placed on a douche-pan. Unsterile gloves were donned by the nurses and then scrubbed. The labia majora were swabbed separately from above downwards, and then parted with the left hand so that the vestibule could be swabbed. The surrounding parts were then swabbed away from the vulva. The areas were dried and a sterile pad was applied. Next the patient was turned on her side, and the perineum inspected, swabbed, and dried. Finally the pad was adjusted to cover the perineum also.

This routine was carried out three times a day, at 6.30 a.m., 12.30 p.m., and 6.30 p.m., after the routine use of bed-pans, but not if bed-pans were used at other times. It was followed until removal of perineal sutures on the seventh day, or, in patients with intact perineum, until the fifth day.

B. Jug Douching.—The following technique was employed.

Equipment.—(1) Two-pint (1,140-ml.) jug containing tap-water at body temperature. (2) One bowl containing dry sterile swabs and towel.

Method.—The patient was placed on a douche-pan. Unsterile gloves were donned by the nurse and then scrubbed. After preliminary testing of temperature over the nurse's gloved hand, the water was poured over the vulva from a height of about 6 in. (15 cm.) above the symphysis pubis. The vulva was then dried with cotton-wool swabs and a sterile pad applied. Finally the patient was turned on her side, and the perineum dried and also covered by the pad.

Initially in Phase I this routine was carried out twice a day, at 6.30 a.m. and 6.30 p.m., after routine use of bed-pans. Later, in Phase II, it was followed three times a day, at 6.30 a.m., 12.30 p.m., and 6.30 p.m. It was followed until removal of perineal sutures on the seventh day, or, in patients with intact perineum, until the fifth day.

Bacteriological Investigations

A study of the bacterial flora of the perineal skin was made in order to assess differences in the two groups of patients.

Technique.—Five patients, irrespective of the duration of the puerperium, were used as samples from each ward each week. The sampler employed was a sterile filter-paper disk of 2-cm. diameter. This was placed over the perineal body so that the anterior edge of the disk came to the posterior vaginal margin. Each disk was held in place lightly for 10 seconds by means of the metal cap of a 1-oz. (28-ml.) screw-capped bottle. The cap had been flamed to sterilize it and then dipped in sterile saline to render the disk slightly damp so that bacteria would be more easily picked up. After sampling, the disk was transferred with sterile forceps to a bottle containing 10 ml. of 10% broth saline. On returning to the laboratory, the bottles containing the disks were

shaken for two minutes in a mechanical shaker. Part of each sample fluid was then diluted 1:100 in saline, and 1 ml. of this dilution was mixed with Nagler medium in a pour-plate. This medium, which contains 20% human serum and 5% Fildes extract, was chosen because it is transparent and highly nutrient. The plate was incubated overnight in air, and the following day the numbers of organisms on it were counted. A standard 3-mm. loopful of the original undiluted specimen was spread on blood agar and incubated anaerobically to detect the presence of *Cl. welchii* and haemolytic streptococci. Finally a further loopful of the undiluted specimen was spread on MacConkey agar to estimate the numbers of *Bact. coli* present.

Results.—These are expressed (see Table I) as fewer than 10,000 organisms, from 10,000 to 20,000, from 20,000 to 50,000, and more than 50,000 organisms obtained from the original sample. The method does not allow a more accurate estimation than this. The actual numbers of colonies of *Cl. welchii*, haemolytic streptococci, and *Bact. coli* were noted. Except where stated in Table II a few colonies only were found.

TABLE I

No. of Organisms Present in Sample of 10 ml.	No. of Patients on Antiseptic Swabbing	No. of Patients on Jug Douching
Fewer than 10,000	17	13
10,000 to 20,000	7	7
20,000 to 50,000	21	22
More than 50,000	25	28
Total	70	70

TABLE II

Pathogens	No. of Patients on Antiseptic Swabbing	No. of Patients on Jug Douching
Lactose fermenters	7	13
Group A streptococci	2	3
" B "	2	1
" G "	1	1
<i>Cl. welchii</i>	1	1

Clinical Assessment

All patients delivered vaginally after the 28th week of pregnancy were assessed. Those delivered by caesarean section were not included, as the factors studied were not applicable.

Infections of the genital tract were classed as either notifiable, according to the Puerperal Pyrexia Regulations, 1951—that is, cases where a temperature of 100.4° F. (38° C.) or more occurred within 14 days of delivery, or as minor pyrexia where a temperature of 99.4° F. (37.4° C.) or more had been sustained for 24 hours or recurred within that time.

The diagnosis of infection of the genital tract was based on clinical and bacteriological findings. Organisms for bacteriological study were obtained by means of a high vaginal swab. Even in the absence of positive bacteriological findings, cases were included as infections of the genital tract if such were diagnosed clinically or no other obvious cause of puerperal pyrexia was found.

In addition to the incidence of notifiable infection of the genital tract and minor pyrexia, delayed healing of perineal wounds necessitating one or more extra days in hospital and the resuture rate of perineal wounds were employed as possible criteria of sepsis.

TABLE III

	Antiseptic Swabbing Series	Jug-Douching Series
No. of cases	325	330
Notifiable infections of genital tract	10 (3.1%)	6 (1.8%)
Minor pyrexias	8	9
Delayed healing	12	11
Resutures	6	6
Intact perineum	61	59

Results.—These are shown in Table III. On the basis of the criteria outlined, no significant increase in the rate of infection was noted in the preliminary trial of jug douching.

Phase II

At the end of the preliminary trial it was decided that no undue risk would be taken by applying the jug-douching technique throughout the hospital. It was further decided to use the incidence of notifiable infection of the genital tract alone as the criterion of the efficiency of this method of vulval and perineal toilet.

From August 1, 1955, to December 31, 1956, there were 1,936 vaginal deliveries, excluding abortions, in the hospital. During this time there occurred 49 notifiable infections of the genital tract. The results over this period are presented in Table IV and compared with those obtained during the preliminary trial in Phase I and during the preceding period of antiseptic swabbing. A statistical analysis of these results is submitted as an addendum to this communication.

TABLE IV

	No. of Vaginal Deliveries	No. of Pyrexia Cases	Incidence of Pyrexia Cases
Antiseptic swabbing:			
1953	1,233	28	2.2%
1954 (Jan.-May)	506	11	2.3%
1954-5 (preliminary trial)	325	10	3.1%
Jug douching:			
1954-5 (preliminary trial)	330	6	1.8%
1955-6 (method established throughout hospital):			
Aug.-Sept., 1955	236	4	1.7%
Oct.-Dec., 1955	338	9	2.7%
Jan.-Mar., 1956	356	11	3.1%
Apr.-June, 1956	338	5	1.5%
July-Sept., 1956	355	10	2.8%
Oct.-Dec., 1956	313	10	3.2%

Analysis of Infection of the Genital Tract

A detailed review was made of the bacteriological findings and associated obstetric conditions in the 36 cases of notifiable infection of the genital tract which occurred in 1956.

There had been no significant rise in the total incidence of infection; but it was considered desirable to determine the nature of the infecting organisms in the cases of infection of the genital tract. If the organisms were of exogenous origin, it might be argued that stricter antiseptic measures for the vulva and perineum could have reduced the incidence of infection. But if the organisms were predominantly endogenous and normal constituents of the vaginal flora, their pathogenic role was thought more likely to be the result of obstetric operations and uninfluenced by the technique of vulval and perineal toilet.

The organisms isolated from high vaginal swabs in these 36 cases were as follows:

Organism	No. of Cases
Anaerobic streptococci	8
fusiform bacilli	5
<i>Bact. coli</i>	5
Non-haemolytic streptococci	2
Haemolytic streptococci Group A	2
" " " Group C	1
" " " " G	2
<i>Staph. pyogenes</i>	1
<i>Staph. albus</i>	1
<i>Cl. welchii</i>	1
Mixed growth with no major pathogens	8

Associated obstetric complications in these 36 cases were as follows:

	No. of Cases
Artificial rupture of membranes	8
Forceps delivery	11
Breech delivery	3
Twin delivery	2
Manual removal of placenta	1
Retained products of conception	4
Severe anaemia (Hb below 60%)	2
Diabetes	1
Episiotomy	29
Perineal laceration	4

Discussion

The preliminary trial in Phase I revealed that the use of jug douching produced no significant rise in the incidence of notifiable or minor infections, delayed healing, or breakdown of the perineum. The bacteriological studies undertaken at the same time showed no significant difference in the bacterial flora of the perineal skin of the patients treated by the two methods.

It was considered safe, therefore, to introduce jug douching throughout the hospital in Phase II. This step was followed by no significant rise in the incidence of notifiable infection of the genital tract.

Bacteriological study of the 36 cases of infection which occurred in 1956 showed that in only three instances the infecting organisms were not normal inhabitants of the vagina:

Case 1.—Diabetic patient. Artificial rupture of membranes. Spontaneous vertex delivery. Episiotomy. Uterine infection. Haemolytic streptococcus Group A.

Case 2.—Artificial rupture of membranes. Spontaneous vertex delivery. Episiotomy. Secondary post-partum haemorrhage. Retained products of conception evacuated. Uterine infection. Haemolytic streptococcus Group A.

Case 3.—Forceps delivery. Episiotomy. Uterine infection. *Staph. pyogenes*.

In the remaining cases the infecting organisms could be regarded as of endogenous origin. In a significantly high proportion of these there had also been obstetric interference or other factors, such as severe anaemia or retained products of conception, which predispose to infection. Eleven cases had episiotomies but no other factor predisposing to infection; however, the episiotomy rate for the whole hospital is in the region of 50%, and the incidence of infection in episiotomy cases is therefore less than 1%, and no higher than was to be expected.

It is justified, therefore, to conclude that the incidence of sepsis in the hospital bears little if any relation to the types of vulval and perineal toilet employed, but is dependent on the associated obstetric complications.

The jug-douching technique is more economical, inasmuch as it reduces by half the amount of cotton-wool consumed, and dispenses altogether with the use of antiseptic agents and sterile water during the puerperium. From the nursing point of view it was found that, while the saving in time was only small, the jug-douching routine was simpler to carry out by junior nurses. Finally, of the two techniques jug douching was preferred by the patients and considered a more comfortable procedure.

Addendum by N. W. Please, B.Sc., of the Department of Statistics, University College, London

In comparing the incidence of pyrexia during the period when swabbing with chloroxylenol solution was used with that during the period when jug douching was employed, the data may be summarized thus:

	Pyrexia	No Pyrexia	Totals
Antiseptic swabbing	49 (2.37%)	2,015	2,064
Jug douching	55 (2.43%)	2,211	2,266
Totals	104	4,226	4,330

The difference in the percentage of pyrexia cases is obviously not significant. ($\chi^2=0.013$ with 1 d.f.)

There is therefore no evidence that risk of pyrexia was greater after jug douching was substituted for antiseptic swabbing.

It might perhaps be suggested that, although the average number of cases during a year has not increased, there is an increased risk of infection spreading through a ward, thus causing a sudden temporary increase in the number of fever cases. That there is no evidence that this has happened

during the period May, 1955, to December, 1956, can be seen from the data in Table IV, where the numbers of cases of fever in each three-monthly period are given.

During the period when antiseptic swabbing was used (1953 to July, 1955) the percentage of pyrexia cases was 2.374, and if the introduction of jug douching has not altered the risk of fever, then we should expect this same percentage

Diagram showing percentage of pyrexia cases with antiseptic swabbing (preliminary survey) and that with jug douching.

in each three-monthly period. The actual numbers occurring in each period will, however, fluctuate by chance, but, assuming the same constant risk, 19 out of 20 periods should have less than approximately 3.8% of fever cases. It is seen from the Diagram that this in fact was so. The data, then, are consistent with the assumption that the risk of pyrexia has remained constant during the whole period 1953 to December, 1956.

If it were desired to watch the situation closely for a further period, then future quarterly percentages could be plotted on the Diagram, assuming the number of deliveries did not vary greatly. It could be seen from the Diagram if an upward trend appeared, and it might give an indication whether there was, for example, a seasonal cycle in the percentage of fevers.

The value of the upper 95% limit, below which the percentage incidence of 19 out of 20 (95%) should fall, may be obtained approximately from the following formula:

$$\text{Upper 95\% limit} = P + 1.645 \sigma$$

$$\sigma = \sqrt{\frac{P(100-P)}{N}}$$

where P = assumed % risk (in this case 2.374, which was the incidence during antiseptic swabbing period)
 N = number of deliveries in three-monthly period

The number of deliveries per quarter varied, and hence the upper limit varied from 3.70 for the largest number (356) to 4.00 for the smallest number (236). The mean number of deliveries per quarter was 324, giving an upper 95% limit of 3.77.

Summary

Two methods of vulval and perineal toilet in lying-in women have been compared—namely, jug douching with warm tap-water and swabbing with cotton-wool pledgets soaked in 1:20 liquor chloroxylenolis B.P.

In a preliminary trial there was no significant difference in the incidence of notifiable infection of the genital tract, minor pyrexia, delayed healing, or breakdown of the perineum.

When jug douching was introduced universally in the hospital there was no significant rise in the incidence of notifiable infection of the genital tract.

Evidence is produced to show that infections that did occur are not related to the type of vulval and perineal toilet employed.

Jug douching effects considerable economies in cotton-wool, antiseptics, and the preparation of sterile water; it is simpler to carry out and more comfortable to the patients.

We wish to record our thanks to Mr. N. W. Please for constant advice in planning and carrying out this trial; to Professor Wilson Smith and Dr. Joan Stokes for invaluable help with the bacteriological aspects of the study; to Sister Curtis, who supervised the Phase I trial; to Mr. J. D. S. Flew for permission to include his patients in the trial; and to Professor W. C. W. Nixon, who suggested this study, for his guidance and encouragement.

SHOCK IN PHAEOCHROMOCYTOMA TREATED WITH NORADRENALINE

BY

NANNA GJØL, M.D.

RENÉ DYBKÆR, M.D.

AND

JØRGEN FUNDER, M.D.

From the Hospital of "The Old People's Town," Copenhagen

The administration of noradrenaline to a patient suffering from phaeochromocytoma seems rather absurd outside surgical practice. Yet this treatment is the logical measure in those rare cases where "spontaneous" hypertensive crises are succeeded by severe shock.

As this treatment has not hitherto been tried the following case is of interest.

Case History

A 77-year-old widow was referred to the Hospital of "The Old People's Town" on April 15, 1953. Until this date blood-pressure values above 170/90 had never been registered.

She was rather adipose and showed signs of cerebral arteriosclerosis, enlargement of the heart to the left, and slight pulmonary hypostases. The blood pressure was 160/110 mm. Hg. Electrocardiographic findings were normal. Roborant treatment had a gratifying effect, and she was mostly up and about until April 25, 1955, when bilateral pneumonia, later complicated by deep phlebitis in the left leg, necessitated bed rest.

At 5 p.m. on May 22 she suddenly felt unwell, was pale and perspiring, dyspnoeic, and anxious, and complained of thoracic pains; her temperature rose to 100.4° F. (38° C.), and pulse rate to 100; the blood pressure was 130/85. On account of auscultatory findings a pulmonary embolus was diagnosed and anticoagulants were given.

At 6.30 p.m. the symptoms became acute, and severe precordial pains together with excitement and shivers set in. Her pulse rate was 120; blood pressure 180/100 (see Chart). The heart sounds were inaudible. Oxygen, procaine penicillin, and intravenous and oral digitalis were administered, but the condition steadily worsened, and at 9.30 p.m. a severe circulatory collapse was manifest: She was cold and perspiring, pale and remote; the palpated blood pressure was 60. As the blood pressure could not be measured by auscultation, only the palpated blood pressure is recorded.

Infusion with L-noradrenaline, 4 mg. in 1 litre of 5% glucose, was instituted, the drip rate being about 30 a minute (about 2 ml. a minute). The patient responded only slowly; but an increase in the noradrenaline concentration (see Chart) fixed the blood pressure at 120, and the noradrenaline concentration could be reduced the following day.

At 5 a.m. on May 25 she was suddenly taken ill with heavy shivers, polypnoea, and a hurried, unequal, but regular pulse at a rate of about 150. The blood pressure was 160 mm. Hg, rising steeply within a few seconds to 200. The noradrenaline infusion was stopped immediately, but the blood pressure did not fall until 30 minutes later, when the alarming symptoms disappeared. At 5.47 a.m. the blood pressure was 90 and the patient showed symptoms of imminent shock; the noradrenaline infusion was resumed, but with no avail until the noradrenaline concentration had been increased.

At 3.40 a.m. on May 26 another spontaneous steep rise in blood pressure occurred accompanied by the same symptoms as before, and the drip had to be stopped for 20 minutes.

This was the first occasion on which the diagnosis of a phaeochromocytoma was suggested, and surmise turned into belief when two typical paroxysms occurred within the next few days. On May 30—nine hours after the last of these attacks—the noradrenaline could be discontinued.

Within the ensuing five days six crises occurred: when most severe they were characterized by shivers so violent that the bed shook; the pulse rate, temperature, and blood pressure rose steeply. There was a pronounced general restlessness, and the patient became voluble, mentally confused, and at periods unconscious. At the onset of the paroxysms she became cold, pale, and cyanotic, but when the attack subsided her complexion became reddish and flushed, and perspiration was profuse. The crises lasted from 30 minutes up to two and a half hours, and were followed by extreme prostration.

During a paroxysm on June 1 a phentolamine ("rogitine") test was carried out. Within a few minutes 5 mg. of intravenous phentolamine caused a fall in blood pressure from 205 to 120 followed by a steep rise up to 185, after which the attack finally subsided.

A sample of venous blood taken during a paroxysm on June 3—that is, four days after noradrenaline had been discontinued—contained 19 µg. of noradrenaline + adrenaline per litre. (Our thanks are due to Dr. Alf Lund, who made the analysis.) The technique applied (Lund, 1950) gives normal values less than 2 µg. per litre (Lund, 1952, 1956).

Simultaneously with a paroxysm on June 4, a pronounced tachycardia occurred; the pulse was often too hurried to be counted, and the blood pressure fell from 170 to 70; every symptom of a severe shock was apparent. As "cedilanid" (lanatoside C) and quinidine had proved of no avail, and since the shock might have been due to the rapid heart action, 500 mg. of intravenous procaine amide was administered; the result was a fall in pulse rate and, unfortunately, also in blood pressure.

The shock was now so profound that the patient was considered to be beyond treatment; however, the noradrenaline infusion was resumed with increasing concentrations. A rise in blood pressure followed, but recurrent symptoms of incipient shock necessitated a further increase in the noradrenaline concentration and noradrenaline proved indispensable for 24 days.

During the second period of noradrenaline treatment no typical paroxysms occurred until June 28, when a hypertensive crisis demanded an interruption of the infusion. When the paroxysm subsided the blood pressure remained normal, and so noradrenaline was definitely abandoned.

From May 30 cortisone and/or corticotrophin were administered in order to improve the patient's general condition; also, nine blood transfusions were given. Severe hallucinations, even actual psychoses, which failed to respond to other therapy, had to be treated by chlorpromazine ("largactil").

From June 5 all peroral administration of drugs, vitamins, proteins, and nutriment (mostly saccharose, cream, and stout) was by stomach tube, which was retained for two and a half months.

At first the polyethylene catheter was repeatedly inserted into new arm veins because of phlebitis or clotting; when the veins were difficult to locate this was an acute problem. After the institution of intermittent heat treatment of the arm, and particularly after 1,500 units of heparin had been added to each litre of infusion fluid, the constant intravenous therapy presented no further problems.

After June 30 operation was under consideration, but had to be abandoned, since the patient sank rapidly and a left-sided pleural empyema occurred. The establishment of pleural drainage (performed by Mr. K. H. Köster) and irrigation of the empyema cavity resulted in typical hypertensive crises—the last to occur. When, on August 13, treatment of the empyema was finished, the patient recovered steadily and at the time of writing she was up and about. Her blood pressure ranged around 130/80, the pulse rate around 80, and there was no indication that she should be the carrier of a "veritable pharmacological bomb" (Aranow, 1952).

Relevant Laboratory Findings

Haemoglobin (100% = 14.8 g. per 100 ml.): 83%, 56%, 79%; colour index and differential count, normal. Non-resting blood-sugar, not above 156 mg. per 100 ml. Urinalysis; generally, + protein; repeatedly, — blood; — sugar. Blood urea, 48, 167, 88, 255, 35 mg. per 100 ml. Electrocardiogram: normal findings until after the paroxysm on May 22; later slightly depressed STI, rather pronounced QIII, slightly elevated STIII, and negative slightly coronary TIII. These changes had disappeared on May 31. Besides some digitalis effect, a left-axis deviation had developed and persisted. Unfortunately, no electrocardiograms were taken during the periods of fluctuating heart rate.

Ophthalmological findings:—June 24: narrow arteries, irregularly calibrated. July 4: thin arteries with uniform calibres; no venous stasis. Normal branch angles.

Radiography of thorax (supine position) (July 9): moderate enlargement of the heart and the great vessels; a shadow

observed the left lung, probably due to pleural exudate. Intravenous pyelography with tomography of the kidneys (July 9): pyelogram blurred by intestinal gases. Pelvis and calices, presumably normal findings. No abnormal soft-tissue shadows at the site of the adrenals.

Intravenous pyelography with tomography (May, 1957) showed nothing abnormal except a rather low position of the right kidney.

December, 1955: All laboratory findings normal, including the basal metabolic rate, and adrenaline + noradrenaline in the urine.

Comment

A 77-year-old woman developed symptoms which were diagnosed as a pulmonary embolus and were followed by a severe vascular collapse. During the subsequent noradrenaline treatment repeated hypertensive paroxysms occurred, suggesting the diagnosis of phaeochromocytoma. This diagnosis was confirmed by the demonstration of increased content of adrenaline-noradrenaline in venous blood sampled during a paroxysm four days after noradrenaline was abandoned.

Hypertensive crises occurred almost daily, and one of these was followed by another severe shock requiring the noradrenaline treatment to be resumed for 24 days.

An exploratory operation could not be performed because of the patient's poor condition, which had further deteriorated on account of a pleural empyema. After her recovery from the latter she improved gradually and no hypertensive paroxysms have occurred since.

Discussion

Symptoms in paroxysmal forms of phaeochromocytoma are often so characteristic that the clinical diagnosis can be made without any hesitancy. The final proof can be obtained by operation, or by demonstration of increased noradrenaline-adrenaline contents in the urine or in the blood.

In the present case a pulmonary embolus occurred at 5 p.m. on May 22, followed by an attack which, though not

realized until several days later, showed several clinically characteristic features of a phaeochromocytoma paroxysm, including shivers, restlessness, and rising blood pressure (cf. beginning of Chart). The subsequent shock very nearly became fatal, but noradrenaline treatment was started, and the clinical condition improved.

The hypertensive crises within the next few days suggested the diagnosis of phaeochromocytoma. An overdose of noradrenaline could not be the explanation of the sudden and violent increase in blood pressure, as the hypertension lasted for about 60 minutes after closure of the drip; between the crises, withdrawal of noradrenaline was invariably followed by immediate shock. Furthermore, the paroxysms continued in rapid succession when the noradrenaline was stopped on May 30.

A phentolamine test was positive but, unfortunately, was without much diagnostic value, as an increased blood urea (95–130 mg. per 100 ml.), and the administration of certain drugs (barbiturates and pethidine) within the preceding 24 hours, are known occasionally to cause false-positive depressor reactions (Hightower, 1955).

A blood analysis revealed an increase in the content of pressor amines—19 µg. of noradrenaline + adrenaline per litre—and thus established the diagnosis of a phaeochromocytoma; further pharmacological tests were therefore considered superfluous and massage of the adrenal areas was too dangerous. The normal content of noradrenaline + adrenaline in venous blood is less than 2 µg. per litre (Lund, 1952, 1956).

By the same technique von Euler (1952) found moderately increased values in some patients with essential hypertension, and Manger *et al.* (1954) found, with a different and less specific fluorimetric method, increased values in a few patients with uraemia (blood urea in the present case was 130–167 mg. per 100 ml.); yet values as high as 19 µg. have never been encountered except in patients with phaeochromocytoma. Blood for analysis was sampled four days after abandonment of the noradrenaline, thus precluding the administered pressor hormone as contributing to the high blood concentration: elimination of noradrenaline is almost instantaneous.

The very high content of pressor hormones in the blood during a paroxysm seems inconsistent with diagnoses other than phaeochromocytoma, and the hypertensive attacks often conformed to classical descriptions of the typical crises in phaeochromocytoma: a steep rise in blood pressure, pulse rate, and temperature, violent shivers, and cold, pale, cyanotic skin. When the paroxysm subsided the blood pressure decreased rapidly, the patient became warm, flushed, and profusely perspiring; the pulse rate and temperature fell more slowly.

Noradrenaline treatment of our patient was instituted at a time when her condition was highly critical and the blood pressure rapidly falling. At that time a pulmonary embolus was assumed to be the cause of the shock. When a phaeochromocytoma was surmised, and later verified, we were first inclined to consider the treatment as "carrying coals to Newcastle." But the treatment proved indispensable, and the patient would have succumbed without it. The total amount of noradrenaline administered was 414.3 mg.

Conclusion and Summary

Only a few records are available of treatment of shock induced by "spontaneous" crises in phaeochromocytoma, as the occurrence is rare. Occasionally adrenaline injections have been used, but only with transient effect—for example, Evans (1937)—but noradrenaline was never given in such cases.

In the case of phaeochromocytoma here reported the diagnosis was confirmed through an analysis of the blood sampled during a hypertensive crisis. On two occasions these attacks were followed by severe shocks, which

were successfully treated with 414.3 mg. of L-noradrenaline during 7 and 24 days. Noradrenaline should always be tried in similar emergencies.

Our thanks are due to Dr. Torben Geill, chief physician of The Old People's Town, for his readiness always to assist us in the solution of the therapeutic problems, and his kindness in placing the facilities of his department at our disposal. We are grateful to Mr. M. Andreassen, senior surgeon, the State Hospital, Department D, Copenhagen, for his assistance and advice during the period when an operation was considered. We are indebted to colleagues and technicians for their assistance during several months.

The chart was drawn by Mr. Preben Saggau.

Special thanks are due to the nurses who tended the patient throughout days and nights for several months. Without their never-failing vigilance this case history might have had quite a different ending. The nurses were: Miss Solveig Pors, Miss Irma Klein, Miss Marie Louise Fugl Svendsen, Miss Kirsten Vestergaard, and Mrs. Rigmor Grønlund.

TUBERCULOSIS IN MAN, DOG, AND CAT

BY

V. M. HAWTHORNE, M.B., Ch.B.

W. F. H. JARRETT, Ph.D., M.R.C.V.S.

I. LAUDER, M.R.C.V.S.

W. B. MARTIN, D.V.S.M., M.R.C.V.S.

AND

G. B. S. ROBERTS, M.B., Ch.B., B.Sc.

Tuberculosis in the last few years has almost everywhere been associated with a falling death and notification rate and a reduced morbidity, so that now its eradication is regarded as practical policy. With this amelioration of the situation it has become reasonable to study aspects of the disease which would have been regarded as unimportant a decade ago, and it was therefore thought worth while to find out if tuberculosis in dogs and cats was making any contribution to the general pool of infection.

References to the incidence of tuberculosis in dogs followed quickly on the recognition of *Mycobacterium tuberculosis* by Koch in 1882. Faulenborg and Plum (1935) quote Frohner, in Berlin, as noting an incidence of 0.04% in 62,500 clinical examinations between 1886 and 1895, and Eber, in Dresden, who observed an incidence of 2.75% in 400 necropsies in 1893. In the United Kingdom it was not until 1929 that Smythe recorded a rate of 0.3 to 0.4% in dogs examined clinically at the out-patient department of the Royal Veterinary College of London. Lovell and White (1940) found tuberculosis in 4.6% of 543 canine necropsies. In Glasgow in 1955 an analysis of 175 consecutive dogs, submitted for pathological examination at the University of Glasgow Veterinary Hospital over a four-months period, showed generalized tuberculosis in all organs in eight, a rate of 4.5%.

Synoptic curve recording the entire period of noradrenaline treatment. TA=typical attack. AA=atypical attack—i.e., paroxysms lacking one or more of the classical symptoms. S=spontaneous shock. D(=drop)=blood-pressure fluctuations released by unwanted variations in the noradrenaline supply caused by clotting in the catheter, venous spasms, leakage, difficulties of regulation during spontaneous blood-pressure fluctuations. BT=bronchial toiletage causing either a fall or a rise in blood pressure.

Discontinuation of the drip for less than one hour (involuntarily or during paroxysms) has been impossible to record in the noradrenaline diagram.

The following drugs which may have induced hypotension are recorded below the blood-pressure curve: C=cetilid; L=largactil; PE=pethidine; PR=procaine amide; R=rogitine; Polyeth=polyethylene catheter in vein.

For long periods the blood pressure was measured once a minute; in less critical periods once every 5 to 10 minutes. The curve is based on a selection of the most characteristic readings.

The noradrenaline dosage is given as (1) noradrenaline concentration in mg. per litre of 5% glucose; (2) total 24-hour dose in mg. (the estimated error is on the last figure). A more relevant curve would show the one-hourly noradrenaline dose (or rather the one-minute dose), but the range of such a curve would be 5,761 to 4 µg. per hour.

The sparse measurements of the temperature are all given in the curve. The pulse curve is based on chosen characteristic values.

Varying incidences of tuberculosis have also been noted in cats. Dobson (1930), in a study at the Veterinary College in Edinburgh, found evidence of the disease in 11 out of 505 cats examined at necropsy, and quoted rates varying from 2% to 11% as reported from Europe by Abel, Petit, Yost, and Nieberle. In the United Kingdom, Loveland White (1941) discovered an incidence of 3.6%.

Feldman (1955) has collated information regarding the type of mycobacterium responsible for 182 cases of tuberculosis occurring naturally in dogs in the British Isles, Europe, the Dutch East Indies, and U.S.A.—137 were of human type, 44 were bovine, and one was avian. In cats, of the 56 cases in the literature up to 1941, 52 were bovine in type. The remaining four were reported as human, although the data did not permit complete confirmation of this point. Jarrett (1955) has recorded a case of human type tuberculosis occurring in a cat, a finding confirmed by culture and virulence tests.

Investigation of the source of an animal's infection was undertaken by Lovell and White (1940), who reported a history of tuberculosis in the owner's family in 3 out of their 22 cases. Smythe (1929) noted 4 out of 20 cases; Stableforth (1929) 4 out of 16 cases; and Hjärre and Herlitz (1935) 6 out of 25 tuberculous animals. Herlitz (1939) reported two cases where the dogs almost certainly infected the humans, having been infected probably themselves by humans in the neighbourhood. In a further five cases the dogs probably infected the humans. The remainder of the group under consideration consisted of six dogs and two cats, and all these animals were probably infected by the humans. Thornton (1948) drew attention to the dangers of the sale of uncooked meat, sometimes from tuberculous carcasses, at pet-food shops.

Present Investigation

Glasgow appeared to be a city well suited to an inquiry into the possibility of interrelationship between tuberculosis in humans, dogs, and cats. Apart from the fact that probably at least 15 in every 100 of the population owned a dog or a cat, or both, the reservoir of tuberculosis in the city, and in the West of Scotland generally, was still substantial. It seemed possible that the household pets might have been overlooked as a factor contributing to the incidence. Examination of the humans whose pets had been destroyed for tuberculosis would explore the situation in respect of sick animals, and an extension of the traditional examination of the contacts of a known active human patient to include the household pets might secure information with regard to apparently healthy animals.

A scheme, called the Animal Health Scheme, was designed by the University of Glasgow Veterinary School and the Glasgow Mass Radiography Centre whereby the Veterinary Hospital supplied the names and addresses of the owners of animals found to have tuberculosis to the Mass Radiography Centre in order that these persons might be offered x-ray examinations; and the Mass Radiography Centre arranged to send the apparently healthy dogs and cats owned by patients with known active pulmonary disease to the Veterinary Hospital.

To implement the scheme a medico-veterinary group was formed under the auspices of the Veterinary School and the Department of Infectious Diseases of the University of Glasgow, comprising two veterinary clinicians, a veterinary pathologist, a veterinary radiologist, a medical pathologist and bacteriologist, and a chest physician. The Dog and Cat Home clinics in the city acted as receiving and clearing centres for the animals on their way to and from the Veterinary Hospital. The scope of the scheme was limited

in order not to exceed the ordinary working capacities of the laboratories and clinics taking part, and before it began the Director of Veterinary Education approached all the practising veterinary surgeons in the West of Scotland for their assent to free animal examinations.

Results

X-ray examinations were made of 34 humans who had had in their households one of the 14 dogs subsequently found at necropsy to have lesions characteristic, macroscopically and microscopically, of tuberculosis. The diagnoses were confirmed by culture or animal inoculation.

Although there were 60 humans in the households, only 34 (56.6%) would submit to examination. 22 (64.7%) of these examinees were radiologically normal, while the remaining 12 (35.2%) had radiographs which showed evidence of tuberculosis. The lesions of nine (26.4%) of these patients required attention, varying from hospital treatment to routine observation. Five of the nine cases were previously undiagnosed.

Table I shows the relationship between the number examined in each household owning a tuberculous dog and the number of human cases discovered. As the percentage of humans examined in each household rose there was a proportionate increase in the number of human cases discovered, until in the two households where all members were examined a human case of tuberculosis was found in each household.

Table II attempts to demonstrate the proximity of the relationship of human and pet, and points to the ease with which mutual infection might occur.

A reverse approach to the problem was made—namely, an attempt to examine 42 animals owned by 37 sputum-positive patients who were undergoing treatment for active tuberculous lesions. Of the animals at risk only 20 dogs and 15 cats were obtained for examination at the Veterinary Hospital. Each examination consisted of a general check, using normal clinical methods, supplemented by dorso-ventral and lateral x-ray films of the chest, rectal and throat swabs, and, in most cases, catheter specimens of urine, for bacteriological investigation, and tuberculin testing by either the subcutaneous or the intravenous temperature elevation method. Two dogs and two cats, apparently normal in every respect, gave unexpected and unexplained positive cultures from swabs of their alimentary tracts. The four animals were obtained from their owners for destruction when the results of the culture became known. Before the two

cats were humanely destroyed several rectal and throat swabs were taken in an unsuccessful attempt to repeat the recovery of *M. tuberculosis*.

Table III shows the bacteriological findings. All specimens were inoculated on to Löwenstein's medium, and, to

TABLE III.—Abnormal Findings in Bacteriology

Case No.	Nature of Specimen	Morphology of Culture	Guinea-pig	Rabbit

" MR15A	"	"	"	Human
Cat MR26	" and rectal swabs	"	"	"
" MR30	Rectal swab	"	"	"

provide for the inhibition experienced with certain bovine strains on that medium, parallel inoculations were made on to Dorset egg medium. Quick-growing saprophytes are common contaminants of faecal samples, especially in the cat, and, to obviate this possible error, cultures were examined at weekly intervals and early growths discarded. Slow-growing saprophytes were excluded by awaiting the result of secondary culture before accepting a positive finding. Direct examination was used in confirmation at this point.

Morphologically both dog (MR14 and MR15A) and cat (MR26 and MR30) secondary cultures appeared human in type. The growths were all eugonic, warty, and with varying degrees of yellow pigmentation. The virulence tests in respect of all four animals were carried out in guinea-pigs and the resultant lesions were typical of the human strain. Rabbit inoculation of the organism obtained from the cats (MR26 and MR30), using 10 mg. of moist culture subcutaneously, produced the localized lesion associated with the human type when the rabbits were killed at 12 weeks. Rabbits were not inoculated with the organism obtained from the two dogs.

Table IV shows the corresponding necropsy findings. Histological examination was not possible in dog MR14

TABLE IV.—Abnormal Findings at Necropsy

Case No.	Macroscopic Findings	Microscopical Findings	Z.N. Staining	Bacteriology
Dog MR14	—	—	—	—
" MR15A	Prescapular gland	" Reactive "	No "acid-fast"	—
Cat MR26	Mesenteric	"	"	Negative
" MR30	Submandibular and mesenteric glands	"	"	"

because of decomposition. The only lesion found in dog MR15A was an enlarged prescapular gland. Cat MR26 had an enlarged mesenteric gland; and in cat MR30 both the submandibular and mesenteric glands were enlarged. None of the cat glands yielded bacilli, either on direct examination with Ziehl-Neelsen staining or on subsequent culture. The gland from dog MR15A was examined for bacilli only with Ziehl-Neelsen staining and none were seen. Microscopical section did not reveal a single typical tuberculous follicle. The glands showed reactive changes—namely, marked congestion with periadenitis. No germinal centres were apparent and the cells of the sinuses showed proliferation. The small vessels were "cuffed" here and there by lymphocytes. An excess of lymphocytes in each field seemed suggestive of a chronic rather than an acute inflammatory change. Giant cells of the Langhans type do not usually occur in dogs and cats.

Discussion

The results of this preliminary survey fall naturally into two parts, the first being concerned with the examination of the humans in contact with the tuberculous animals; and the second being concerned with the investigation of the apparently healthy animals in contact with the sputum-positive humans.

Humans in Contact with Tuberculous Animals

The first part of the results was based on the 14 tuberculous dogs, and here the examination of just over half of the human contacts produced nine patients who had tuberculous lesions in varying need of attention. Only three of these patients came into the category of new active adult reinfection type pulmonary tuberculosis requiring early anti-tuberculous treatment, but they represented an active tuberculous rate of 8.82%. In 1954 the Mass Radiography Service of the Western Regional Hospital Board examined 43,150 persons of all ages resident in Glasgow, and Miller (1954) reported the incidence of new active adult reinfection type pulmonary tuberculosis as 0.72%. While it is unwise to make any comparison of this figure with the equivalent of 8.82% in the present small sample of persons in contact with tuberculous dogs, the difference is so large as to justify further study of the problem.

Even at this stage of the investigation there is already no doubt that a veterinary diagnosis of tuberculosis calls for early and complete examination of the humans in the animal's household. The extra effort required to cover this small group would be negligible in terms of the probable resulting yield of new cases of active tuberculosis or, perhaps more important, latent exacerbations of known "inactive" lesions. Until the extent of the problem is ascertained it is premature to consider the related question of a legal requirement of notification.

Any further estimate of the incidence of tuberculosis in the dog and cat will depend on the general awareness of the distribution of the disease in animals, based on the work that has been carried out in the West of Scotland; and it will also be important for those concerned to realize the contribution that exact veterinary diagnoses can make to this particular problem. Unfortunately, the disease produces few characteristic early symptoms or signs in either dog or cat, and may not be recognized until post-mortem examination. Knowledge of the extent of the problem might encourage veterinary surgeons and others to have dogs examined at necropsy where indefinite illness had preceded death.

The volume of material for diagnosis could be increased further if the medical side, and the animal owners, were prepared to consult a veterinary surgeon more readily over household pets.

In dogs, most cases of tuberculosis occur in mature adults, but the disease has been observed in animals as young as 9 months. The history is not always helpful. Owners may have observed some loss of appetite, dullness, loss of weight, coughing, or emesis, but frequently in the early stages little deviation from normal will have been noticed. Breathlessness or rapid breathing of apparently sudden onset may be the first sign of importance seen by owners.

Many affected dogs are in reasonably good condition, with no emaciation. Most cases show clinical signs consistent with hydrothorax or ascites. Some have palpable enlargement of liver, spleen, kidney, or mesenteric nodes, while a few show lymphadenitis of superficial lymph nodes which may be accompanied by ulceration of the overlying skin. The nodes usually involved are those of the head and neck, but ulceration over the popliteal node has been encountered. Elevation of the temperature over the normal level, $101.5 \pm 1^\circ \text{F.}$ ($38.6 \pm 0.55^\circ \text{C.}$), frequently occurs. Haematology shows no constant characteristic change, but leucocytosis has been a feature of a few cases.

Tuberculosis in the cat is usually associated with infection of the liver and mesenteric nodes, often with an ascites, but has become a rare occurrence in the West of Scotland within recent years. This reduced incidence has probably been brought about by the eradication of tuberculosis in cattle and the pasteurization of milk.

In the 14 tuberculous dogs under consideration the average length of time the animal was observed to be markedly ill was three months. One animal which died of tuberculous bronchopneumonia had been under treatment for more than

a year before the diagnosis was made at necropsy. Another animal, whose symptoms began two years previously, died of bilateral pulmonary tuberculosis with cavitation associated with liver lesions. When Griffith (1911) was conducting the modification experiments on the bovine type of *M. tuberculosis* for the Royal Commission on Tuberculosis, he fed 19 dogs an average dose of 62 mg. of culture. These animals all had to be killed after an average period of 206 days despite the fact that at necropsy all were found to have lesions of varying extent. Gunn *et al.* (1943) report similar findings. One of their dogs was found to have an active lesion more than three years after artificial infection.

From the foregoing it can be seen that little reliance can be placed on the quick death of the animal as a convenient form of natural self-limitation of a source of infection.

Animals in Contact with Sputum-positive Humans

The second part of the results was based on the investigation of the 20 dogs and 15 cats living in contact with sputum-positive humans, and here the abnormal findings in the two dogs (MR14 and MR15A) and the two cats (MR26 and MR30) must raise the question of the advisability of allowing dogs and cats to live in tuberculous households.

The possibility must be considered that the bacilli recovered had been ingested and that the positive cultures were simply an indication of their transit through the bowel. Floyd and Page (1943) found that *M. tuberculosis* could survive exposure to the gastric juices of dogs for periods of one to twelve hours without the loss of pathogenicity noted in guinea-pigs after longer periods. Kuwabara (1938), injecting 5 mg. of human-type bacilli intravenously into cats, noted a few bacilli in the spleen, liver, and lungs two months after the injection, but no bacilli at three months. There were no associated histological changes. It would thus seem that bacilli can be present for at least eight weeks in animals with natural resistance without causing lesions. In the present series, both dogs and one of the cats, MR30, had been separated from the household source of infection for more than three months at the time of examination.

It might be argued that these findings represented an early stage in the disease in dogs and cats, a stage about which there is little, if any, factual knowledge.

At present it is not considered advisable to speculate on the exact significance of these findings, but there is enough evidence to warrant continuation of the survey in this area, and to draw the attention of others to this interesting problem. The correct interpretation, indeed substantiation, must await the outcome of further study.

The combined results indicate the existence of a small field in which full investigation may produce findings having a restricted application in the epidemiology of tuberculosis.

Summary

An account is given of an investigation into the inter-relationship of tuberculosis between humans and dogs and cats.

The human contacts of 14 tuberculous dogs underwent x-ray examination and 9 significant cases of tuberculosis were found among them.

The dogs and cats owned by 37 patients with active tuberculosis were examined, *M. tuberculosis* being recovered from swabs of the alimentary tracts of two dogs and two cats.

Further investigation of all aspects of the subject would be materially assisted by a wider appreciation of the possibility of the occurrence of tuberculosis in dogs and cats.

We are indebted to Professor W. L. Weipers, Director of Veterinary Education, University of Glasgow, and also to Dr. T. Anderson, Reader of Infectious Diseases, for many of the technical facilities used and for much material assistance and guidance. Further indebtedness is acknowledged to Dr. T. J. R.

Miller, Medical Director of the Glasgow M.M.R. Centre, for the use of the Centre and its facilities in the human examinations; to Dr. W. F. Tyrrell, of the Glasgow Northern Division of the Tuberculosis Service; to Dr. W. McNaught, of the Pathology Department, Ruchill Hospital, Glasgow; and to Mr. D. D. Lawson, of the Department of Veterinary Medicine, University of Glasgow. We are also grateful for the co-operation of the veterinary practitioners, the People's Dispensary for Sick Animals, and the Glasgow and West of Scotland Dog and Cat Home clinics.

CORRELATION OF HUMAN AND ANIMAL RINGWORM IN WEST OF SCOTLAND*

BY

J. C. GENTLES, B.Sc.

AND

J. G. O'SULLIVAN, M.R.C.V.S.

(Departments of Bacteriology and Veterinary Pathology, University of Glasgow)

WITH THE ASSISTANCE OF

W. A. DEWAR, M.C., M.D., F.R.F.P.S., I. C. LAMONT, M.B., J. F. FERGUSON SMITH, M.B., I. M. LAUDER, M.R.C.V.S., A. POTTIE, M.R.C.V.S., and J. M. ROBERTSON, M.R.C.V.S.

(Department of Dermatology, Stobhill Hospital and the Victoria and Western Infirmarys, Glasgow; Department of Veterinary Medicine, University of Glasgow; the West of Scotland Division of the B.V.A.; and the Veterinary Investigation Department, Auchincruive, Ayrshire)

As a result of reports in the medical and veterinary press of the existence of an animal reservoir for many human ringworm infections a committee on human and animal dermatomycoses was formed in Glasgow in November, 1954. This report by a subcommittee appointed to investigate cases of human ringworm suspected to be of animal origin covers the first two years of the work. During the first year the survey area consisted of South and West Glasgow, the county of Ayr, and parts of the counties of Dunbarton, Renfrew, and Stirling. After a year this area was extended to include the whole of Glasgow and the South-west of Scotland.

Method

At first dermatologists who diagnosed ringworm of possible animal origin submitted a specimen for identification and asked the patient to have any suspected animal

*A report to the Committee on Human and Animal Dermatomycoses. Members of the Committee: Professor W. L. Weipers (chairman), Dr. R. W. Carslaw, Dr. T. Cochrane, Professor J. W. Emslie, Dr. A. Girdwood Fergusson, Mr. J. C. Gentles, Dr. W. A. Greig, Mr. I. M. Lauder, Mr. J. G. O'Sullivan, Mr. A. Pottie, Dr. J. F. Ferguson Smith, Dr. Mary Smith, Dr. J. Sommerville, Mr. A. Thomson, and Mr. A. L. Wilson.

examined by a veterinary surgeon. Later it was found more satisfactory to request a veterinary surgeon to visit the suspected premises and to forward a specimen from any animal with suspicious skin lesions. By arrangement with the West of Scotland and Ayrshire Divisions of the British Veterinary Association these examinations were carried out free of charge. Veterinary surgeons were also asked to advise any persons whom they encountered in contact with ringworm-infected animals and who had suspicious skin lesions to seek medical advice. Animal specimens were submitted mainly by veterinarians in private practice, but in Ayrshire this was done by the veterinary investigation officer, and in the vicinity of Glasgow the small animal suspects were examined by veterinary members of the subcommittee. Co-operation was good, and few named contact animals were not investigated, particularly during the latter part of the survey.

Correlation of Cases and Clinical Considerations

A summary of the laboratory results from the 163 cases in which there was some evidence that a human ringworm infection had been contracted from an animal is given in Table I. Zoophilic dermatophytes were isolated from 109

† Cases when different dermatophytes were cultured from human and cited animals.

(67%), and anthropophilic species from 8 (5%) of the individuals. Specimens from 11 (7%) persons were positive by microscopy only, and in 18 (11%) cases no evidence of infection was obtained by laboratory examination. The remaining 17 (10%) persons from whom specimens were not received were reported to have suspicious skin lesions and to be in contact with animals proved to be infected.

Cultures were obtained from 78 (48%) of the suspected animals, 6 (4%) were positive by microscopy, and in 17 (10%) cases the animals were not found to be infected. In the remaining 62 (38%) cases specimens from the animal were not received, in 11 of them because animal contact was denied.

Generally only one human infection could be related to each of the animal premises, but this was not always so, as 21 infections were traced to only eight premises. On the other hand, more than one animal was usually affected in each of the premises investigated. Fifteen cats and 14 dogs were proved to be infected on only two premises containing in all 24 cats and 19 dogs, and similarly on 96 farms there were 726 cattle clinically affected. The fungi isolated were: *Trichophyton verrucosum*, var. *discoideus*,† *T. mentagrophytes*, *Microsporum canis*, *M. audouini*, *T. rubrum*, and *T. sulphureum*.

†The only variety isolated during the period covered by this report.

Trichophyton verrucosum

This fungus is rarely recovered from animals other than bovines, and infection of these animals with other dermatophytes seldom occurs. It is clear therefore that, although the correlation of a human infection with an animal source may be considered indisputable only where a culture of the same dermatophyte is obtained from both, a culture of *T. verrucosum* from a human, together with a history of contact with infected cattle, provides strong presumptive evidence that cattle were the source of infection.

Of the 82 cases where *T. verrucosum* was isolated from a human, 35 suspected animals were proved to be infected with the same dermatophyte, four were found to have a large-spored ectothrix infection, and six were known to have been clinically affected although free from infection when examined. Specimens were not obtained from 33 bovines, although they were reported to have been affected. On four occasions contact with animals was denied; with the exception of these four cases there is little doubt that all of the *T. verrucosum* infections in humans originated from cattle. Three cases were indirect contacts; in two of them the infection was presumably carried by a close relative, and on the other occasion it may have arisen from contact with infected woodwork.

On 30 occasions *T. verrucosum* was isolated from cattle, and humans in contact with the animals were reported to have ringworm. Specimens from seven of the humans were positive by microscopy, six were negative on laboratory examination, and specimens were not received from the remaining 17 persons.

Seasonal Incidence

The frequency of the infection in humans over the two-year period is shown in Table II, from which it can be seen that the highest rate occurred in January, February,

TABLE II.—Monthly Incidence of Human Infections with *T. verrucosum* Over the Two-year Period

Jan.	Feb.	Mar.	Apr.	May	June	July	Aug.	Sept.	Oct.	Nov.	Dec.	Total
10	12	16	4	8	19	0	5	0	5	2	1	82

and March and that there was another peak rate in June. Only 16% of the infections occurred during the last six months of the year.

Since most of the animal material was selected it is not possible to draw conclusions regarding a seasonal incidence in bovines. During the winter months farm-workers are in close contact with infected animals and the high incidence of ringworm in humans from January to March is not unexpected. From April, however, the animals are out at grass, so that frequency of contact with humans is much reduced. A possible explanation of the high human incidence in June is that the individuals become infected from byres and calf-pens which have housed infected animals, as after the cattle have gone to grass it is usual for the pens to be cleaned down and the accumulated manure to be put out.

Clinical Data

Human.—Detailed clinical information was available in 66 cases of *T. verrucosum* infection. The affected adults were farm-workers with three exceptions, of whom two had

indirect contact with cattle and the third could not suggest any possible source of infection; all the children except one lived or played on a farm. The age incidence as shown in Table III does not permit conclusions to be drawn regarding the question of acquired immunity in older farm-workers, since no information concerning the number at risk in each age group is available. For the same reason no comment can be made on the sex incidence. The arms and face were the most commonly affected areas. Kerion reaction was noted in 7 children and 16 adults; in the children, except in one case, such lesions were found only on the scalp, while in adults either the region of the beard or that of the limbs was affected. Kerion formation did not occur in adult females. On the other hand, non-inflammatory lesions were present in 20 children, in 5 adult males, and in 5 adult females, while inflammatory lesions occurred in 9 children, in 10 adult males, and in 1 adult female.

Animal.—Information was obtained regarding 77 bovines infected with *T. verrucosum*. Although the majority of cases occurred in young stock, 6 (8%) of the animals were 3 years and over (Table IV). This age distribution has

already been noted by Sellers, Sinclair, and La Touche (1956). The part of the animal most frequently affected was the head, particularly the regions of the eye, the ear, and the muzzle, and there were lesions on the neck in over 50% of cases. In addition to the typical light-grey plaques of mature lesions there were numerous early stages which could be felt through the hair and which became obvious only when the hair was removed. Each of these lesions was a small discrete aggregation of inspissated yellowish exudate which clumped together the bases of a group of hairs. On removal of the firmly adhering exudate a moist red surface was revealed and the underlying skin was palpably thickened. All of these lesions did not develop to the mature stage.

Trichophyton mentagrophytes

This dermatophyte is known to have a wide range of animal hosts, and correlation of a human infection with a source is not possible unless a culture is obtained from the suspected animal. The 15 cases of human infection with *T. mentagrophytes* were isolated ones and each originated from a separate source. Eight of the affected individuals suggested animals as the probable source of their infection, and the results of investigation of the animals were: *T. mentagrophytes* (1), *T. verrucosum* (2), negative (2), no specimen received (3). The seven remaining persons denied contact with animals, and thus only one animal source was confirmed. All the isolates were of the typical powdery strain with the exception of one *niveum* strain which was isolated from a child of 2 years for whom no animal contact was known.

There has been considerable speculation on the source of *T. mentagrophytes* infections in humans, and Carlier (1954) and Rook (1956) were apparently convinced that cattle were responsible for infection of a number of their patients. There is, however, only one previously published record of the isolation of *T. mentagrophytes* from cattle in Britain (Muende and Webb, 1937) as opposed to the isolation of *T. verrucosum* exclusively on 41 occasions by Ainsworth and Austwick (1955), on 36 occasions by Mortimer (1955), and from animals on 28 farms by Sellers *et al.* (1956). In the U.S.A., Georg (1956) records only one isolation of *T. mentagrophytes* but 50 of *T. verrucosum*. The dermatophytes

isolated from cattle ringworm cases in the West of Scotland over a four-year period were *T. verrucosum* (99) and *T. mentagrophytes* (1) (Gentles and O'Sullivan, 1957). It is clear, therefore, that cattle ringworm due to *T. mentagrophytes* is rare and that cattle are unlikely to be a frequent source of this type of infection in humans.

Two of our human cases did, in fact, suspect cattle as the probable source, but only *T. verrucosum* was isolated from the animals, and it is of interest that Georg (1956) gives details of two cases when she obtained a like result. She has suggested that rodents are frequent hosts of *T. mentagrophytes*, and Feuntes, Bosch, and Boudet (1954) present evidence that on occasion rodents and cats may be clinically normal carriers of this infection. Our only confirmed case of *T. mentagrophytes* ringworm linked a boy with his pet mouse, which had cultural but no clinical evidence of ringworm. Another of our cases occurred in an individual who had frequent contact with laboratory rodents which had been apparently free from infection but were destroyed before they could be examined. Two dogs from which we could obtain no evidence of infection might possibly have been other examples of clinically normal carriers, but it is more likely that they were instances of a wrong source having been suspected.

Clinical Data

Twelve of the patients were children and three were young adults, and the sites affected were: scalp (6), upper limbs (5), lower limbs (1), neck (2), buttocks (1), and fingers (1). With regard to the six cases of scalp infection kerion reaction was present in two of them, non-inflammatory lesions were noted in two others, and information was not available in the remaining two. On the other sites affected, seven lesions were non-inflammatory and two were inflammatory.

Microsporum canis

It is generally assumed that the majority of *M. canis* infections in man originate from cats and dogs, and our findings from 12 cases are not at variance with this view. These animals were confirmed as the source of infection for six patients. Three other persons were in close contact with a cat, which was not available for examination, and the three remaining people, members of the same family, suspected a bovine source; only *T. verrucosum* was isolated from the cattle, and a small animal reservoir could not be traced.

Clinical Data

Human.—The sites of infection in the 12 patients (5 adults and 7 children) were as follows: scalp (6), forearm (4), trunk (1), neck (1). One of the scalp infections was unusual in that the patient was an adult (male, aged 33) and that the infection, which was only mildly inflammatory, continued for nine months in spite of local treatment.

Animal.—Only two premises were traced as the source of human infections with *M. canis*, and there were 15 cats and 14 dogs affected. One outbreak involved an entire kennel of boxers, and the 11 pups which were seen initially when they were 6 weeks old had the most severe and widespread lesions; two adult dogs were also infected. The animals were examined at intervals over a period of six months, by which time the infection could no longer be demonstrated. The lesions in the young animals when first examined were mainly on the almost hairless abdominal skin and consisted of circular areas up to 1 in. (2.5 cm.) in diameter, each with a raised inflammatory periphery. Significant fluorescence under Wood's light was not seen at this stage. In seven days the weal was no longer evident, but its site could be recognized by slight exfoliation. Under Wood's light, evidence of widespread infection was then noted and small bare spots had appeared on the head, body, and limbs. Seven to 14 days later the oldest lesions were clearly defined. Some of these had reached 1 in. (2.5 cm.) in diameter, many had developed grey discoloration, and some were raised above the surface of the surrounding skin. At this stage numerous

new lesions became apparent as palpable small discrete spots of crusted exudate, clumping the bases of the hairs. The crusts did not fluoresce until they were removed, when a few hair bases protruding from the underside of the scab were seen to fluoresce. Many such small lesions became bare but did not increase in size, while the original lesions developed darker pigmentation and the skin over them became thickened, although remaining fairly smooth. One pup kept in a veterinary hospital appeared to clear in three months. The remainder of the litter developed a systemic viral infection about six weeks after ringworm had been diagnosed. The fungous infection became much more widespread and did not disappear until six months after onset. The protracted course may have been associated with the concurrent infection.

On the other premises there were 24 cats and six dogs, all of which were examined by Wood's light, and the infection was found in 15 cats and one dog. The cats were in poor condition owing to a chronic respiratory infection and poor concurrent external parasitism. The severity of the ringworm varied from discrete lesions of $\frac{1}{4}$ in. (6-13 mm.) in diameter to a generalized involvement of the head, body, and limbs. The claws were not affected and the generalized condition occurred in three of the animals, two of which were over 5 years of age.

In the two outbreaks six adult cats and three adult dogs were affected, and, although there can be little doubt that young animals are more susceptible, we do not agree with Beare and Cheeseman (1953) that *M. canis* infections in animals are not usually seen after puberty.

Anthropophilic Dermatophytes

Eight individuals who suspected animals as the probable source of infection were found to be infected with anthropophilic dermatophytes. *T. sulphureum* was isolated from six persons. One of the suspected animals, a bovine, was infected with *T. verrucosum*, and the other animals, either cats or dogs, were free from infection. A finger-nail infection with *T. rubrum* was at first thought to have been derived from a rabbit, but was found to have originated from the patient's feet. A scalp infection in a young girl was considered likely to have been acquired from a cat which had bald patches on its head; the cat was free from infection and the dermatophyte cultured from the girl was *M. audouini*. It is clear that without cultural investigation these cases might well have been attributed to the suspected animal source.

Comment

While it cannot be claimed that all cases of ringworm of animal origin in humans in this area are included in this report, it is nevertheless believed that the results are significant. These indicate that cattle are mainly responsible for human infections with animal-type fungi in the West of Scotland. This is contrary to the statement of Mortimer (1955), that the domestic pet is the most frequent source of

TABLE V.—Details of Cases When a Small Animal Was Named as the Source of a Human Infection

these infections in Britain, a view supported by the results of the surveys of Walker (1950) and Carlier (1954). In our series small animals were suspected to be the probable source of infection on only 25 occasions and confirmed as the source on seven of them (Table V). This would appear to be a surprisingly low number of cases, but there is other evidence that ringworm in small animals is not common in this area. All cats and dogs, mostly strays, brought for destruction to a veterinary clinic in Glasgow in September, 1955, were examined by one of us (J.G.O.S.). The animals were examined clinically and by Wood's light, scrapings being taken from any suspicious areas. There was no evidence of dermatophyte infection in any of the 103 cats and 16 dogs so examined.

It should be noted, moreover, that Whittle (1956) states that there has been an apparent increase in the number of human infections with *T. verrucosum* in recent years. This may be a result of the greater amount of laboratory work now being done, but it is also possible that there has been a true increase in *T. verrucosum* infections in humans.

With regard to these infections our clinical findings appear to support the theory that involvement of the deeper hair follicles plays an important part in kerion formation (Whittle, 1956). In women and children, apart from kerion formation on hair-bearing areas, *T. verrucosum* infections apparently occur most commonly as non-inflammatory reactions. Our observations afford no evidence that the type of lesion (kerion, inflammatory or non-inflammatory) can be related to its duration. The arms are commonly affected, and this is not surprising, since farm-workers come into frequent contact with the neck and head of cattle when tying the animals.

Although it has been confirmed that animals form a large reservoir of ringworm infection, evidence has also been provided that a number of human infections may be wrongly attributed to an animal source or to a wrong species of animal. Full cultural investigation should obviate these errors.

Summary and Conclusions

The results are given of an investigation in the West of Scotland of 163 cases of human ringworm infection which were suspected to be of animal origin. Dermatophytes were cultured from 117 (72%) of the humans, and the isolates were: *T. verrucosum*, 82; *T. mentagrophytes*, 15; *M. canis*, 12; *T. sulphureum*, 6; *T. rubrum*, 1; *M. audouini*, 1. From 78 (48%) suspected animals, cultures were obtained of: *T. verrucosum*, 71; *T. mentagrophytes*, 1; *M. canis*, 6.

On 42 (26%) occasions the same dermatophyte was cultured from the human and the suspected animal; on 5 (3%) a different zoophilic dermatophyte was isolated from each source; and in 8 (5%) instances the human infection was caused by an anthropophilic fungus. Cattle were found to form the main animal reservoir of infection, and there were 78 (48%) confirmed cases. Only 7 (4%) human infections were traced to a small animal source. None of the human infections with *T. mentagrophytes* was found to originate from cattle.

It is confirmed that in this area animals form a reservoir of ringworm infection. Cattle rather than small animals—for example, domestic pets—are the main source of human infection.

We are indebted to the staffs of the Departments of Dermatology of the Ayrshire Group and Dumfries and Galloway Hospitals, the Southern General and Stobhill Hospitals, and the Victoria and Western Infirmarys, Glasgow, and of the Veterinary Investigation Department, Auchincruive, Ayrshire, for their assistance. We thank Miss C. O. Dawson and Miss F. Overend, of the Departments of Bacteriology and Veterinary Pathology of the University of Glasgow, for laboratory assistance, and also the general medical practitioners and the members of the West of

Scotland and Ayrshire Divisions of the British Veterinary Association, without whose help the work could not have been accomplished.

ADDENDUM.—Since this paper was written a further 44 cases have been investigated. From humans with suspected animal ringworm the laboratory results were: *T. verrucosum*, 31; *T. mentagrophytes*, 3; *T. rubrum*, 1; *T. sulphureum*, 3; micropositive, 5; negative, 1. The results from specimens obtained from 23 of the animals were: *T. verrucosum*, 11; *T. equinum* and *M. equinum*, 1; micropositive, 4; negative, 7. Horses were given as the source of two human infections which were positive by microscopy only. *T. verrucosum* was isolated from one of the horses and both *M. equinum* and *T. equinum* from the other.

INFANTILE HYPERCALCAEMIA WITH KERATOPATHY AND SODIUM DEPLETION

BY

A. C. KENDALL, M.B., M.R.C.P., D.C.H.
 Consultant Paediatrician, Coventry and Nuneaton Group Hospitals

Infantile hypercalcaemia, a condition which presents with failure to thrive, is known to occur in two forms, the benign (Lightwood, 1952) and the severe (Schlesinger, Butler, and Black, 1956). The essential feature in both forms of this condition is the raised serum calcium level, and, although the cause of this remains uncertain, the symptoms of anorexia, vomiting, and failure to thrive are ascribed to this increase in the serum calcium.

Treatment, therefore, is directed towards bringing about a fall in the serum calcium level, and to this end the child's intake of calcium is reduced. A low calcium milk, a proprietary preparation of which is now available ("locasol"), is usually given and no vitamin D supplements are allowed. In the case described below treatment in this way was successful in bringing about a fall in the serum calcium level, but was followed by a marked degree of sodium depletion. The case is also unusual in that during the course of the illness a band keratopathy developed, and, while this has been described as occurring in a number of conditions associated with a raised serum calcium level (Albright and Reifenstein, 1948), it does not appear to have been described hitherto in a case of infantile hypercalcaemia.

Case Report

The patient was first seen at the age of 1 week, when he presented with many extensive areas of subcutaneous fat necrosis of typical distribution—the external surfaces of the limbs, the buttocks, and the posterior part of the chest wall being affected. He seemed otherwise well at that time, but his general progress thereafter was unsatisfactory, so that by the time he was 3 months old he was only 9 oz.

(255 g.) above his birth weight. He then developed a bilateral otitis media and, a few days later, persistent vomiting, which necessitated his admission to hospital.

He was pyrexial, temperature 105° F. (40.6° C.), he had bilateral otitis media, and one of the areas of fat necrosis situated in the left deltoid region was now fluctuant and evidently the site of a secondary infection. This subsequently had to be incised, and about 1 oz. (28 ml.) of thick yellow pus was evacuated. Swabs were taken of the aural discharges and a heavy growth of *Staphylococcus aureus*, coagulase-positive, was obtained. This organism was sensitive to penicillin, streptomycin, chloramphenicol, erythromycin, and the tetracyclines.

He was treated with intramuscular penicillin, 100,000 units six-hourly, intramuscular streptomycin, 100 mg. twelve-hourly, and sulphadiazine, 0.25 g. six-hourly. Initially he appeared to respond, but within 48 hours had developed head retraction, and a lumbar puncture showed the cerebrospinal fluid to be opalescent. Analysis of this gave the following results: leucocytes, 300 per c.mm., 70% of these being lymphocytes; protein, 100 mg. per 100 ml.; chlorides, 675 mg. per 100 ml.; sugar, 62 mg. per 100 ml. The culture was sterile.

He remained acutely ill for about two weeks, during which time he had several convulsions, and he was intermittently febrile. Treatment was continued with chloramphenicol and later with oxytetracycline, and the C.S.F. became normal in every respect.

It was thought likely that he had had an intracranial thrombophlebitis, and his vomiting was at first ascribed to the effects of this. But not only did he continue to vomit intermittently, he also became increasingly fretful, anorexic, and constipated. His urine contained a trace of albumin with an occasional granular and hyaline cast, and examination of his blood on August 8, 1956, by which time he was 4½ months old, gave the following results: serum calcium, 20 mg./100 ml.; serum phosphorus, 5.2 mg./100 ml.; alkali reserve, 56.7 vols per 100 ml.; serum sodium 330 mg./100 ml.; serum potassium, 20.5 mg./100 ml.; serum chloride, 625 mg./100 ml.; urea, 64 mg./100 ml.; blood cholesterol, 182 mg./100 ml.

A diagnosis of infantile hypercalcaemia was now made and he was started on treatment with locasol. One week later the serum calcium had fallen to 13.5 mg. per 100 ml. and, after a further week, to 11.3 mg. On all subsequent occasions the serum calcium was found to be within normal limits.

In spite of the fact that his serum calcium remained normal, his symptoms showed no improvement. He remained fretful, anorexic, and constipated. It was possible to induce him to take only in the region of 20 oz. (570 ml.) of milk a day, although he was thirsty and would readily take extra drinks of water. He showed no consistent gain, his weight fluctuating between 10 and 11 lb. (4.5 and 5 kg.).

On October 31 the electrolytes were checked once more. The findings were within normal limits, serum sodium being 310 mg. per 100 ml. When these determinations were repeated on January 1, 1957, it was found that there had been a marked fall in the serum sodium level to 285 mg. per 100 ml.

It was decided that, without any other change in his feeding regime, added sodium chloride should be given, and this was done by making up the feeds of locasol with one-fifth normal saline instead of with distilled water. This increased his intake of sodium chloride by approximately 1 g. a day. There was an immediate change, which was apparent first in the child's behaviour. He became a happy, friendly, and responsive infant. He also ceased vomiting, his appetite increased, until he was taking 40 oz. (1,140 ml.) of milk a day. When solids were introduced into the diet, these too were taken well and the sodium chloride supplement was discontinued. His weight increased steadily during the next six weeks, the increase averaging 12 oz. (340 g.) a week. His serum sodium level at the end of a week had

risen to 300 mg. per 100 ml. and, after a further week, to 305 mg. He was discharged home on February 14, and his good progress continued.

Bilateral corneal changes were first noticed on July 8, when he was 3½ months old. These consisted in both eyes of a horizontal band of opacity present in the superficial corneal layers, and having the appearances described by Albright and Reifenstein (1948) as band keratitis. These opacities gradually diminished, and at the time of his discharge both corneae had returned to normal.

Discussion

The most usually adopted form of treatment in infantile hypercalcaemia is the substitution of a low-calcium milk for ordinary milk. Locasol, as reconstituted in the proportions advised by the manufacturers, has a calcium content of not more than 56.8 mg. per pint (100 mg. per litre). The sodium content is also less than that which is found in cow's milk, 1 pint (570 ml.) of reconstituted locasol containing 0.28 g. of sodium chloride, while cow's milk contains 0.78 g. of sodium chloride per pint. According to Butler and Talbot (1944) the average requirements of sodium chloride per day in infancy is about 1 g. Locasol, therefore, while being low in calcium, also provides an intake of sodium which is less than the average normal requirements. Two factors appear to have been responsible for this child's sodium depletion. Firstly, the diet which was offered was of itself deficient in sodium, and, secondly, the intake of milk was severely reduced because of anorexia. That his symptoms of anorexia, vomiting, and failure to thrive, which initially were due to hypercalcaemia, were eventually due to sodium depletion was shown by the immediate improvement in the child's condition when the intake of sodium was increased, and also by the rise in serum sodium level which followed. The insidiously rise in serum sodium level which followed is particularly noteworthy and indicates the need for regular determinations of the serum electrolyte levels in similar cases.

According to Albright and Reifenstein (1948) two types of lesion occur in cases of hypercalcaemia, whether due to vitamin D poisoning, hyperparathyroidism, or other causes such as sarcoidosis or the syndrome associated with excessive milk and alkali intake: (1) a band keratopathy as was seen in the present case, and (2) conjunctival crystals, which appear medially and laterally to the limbus. Both these lesions are said often to be visible only with the slit-lamp. In this case changes were present at the age of 3½ months; they were clearly visible to the naked eye and, had their significance been appreciated, the diagnosis of hypercalcaemia would have been made a month earlier than it in fact was.

Summary

A case of infantile hypercalcaemia is described in which corneal opacities developed in the early stages of the disease and sodium depletion was a late complication.

A gramophone record on how to relax has been made by Miss MARGARET SMITH, M.C.S.P. It is intended for the "tense" patient. On the first side Miss Smith discusses the importance of abolishing tension and describes the technique of relaxation in a general way; on the other side the patient is given detailed directions, in slow time, on how to relax the muscles of the various parts of the body. The record (No. RSL/1243) is obtainable from Recorded Sound Ltd., 127, Bryanston Street, London, W.1. Price 21s. (postage 2s.). Royalties on the sale of the record are being given to the Iona community.

THE SEQUELAE OF KERNICTERUS

BY

A. R. H. WORSSAM, M.B., M.R.C.P.

Lately Registrar in the Department of Clinical Pathology,
 Guy's Hospital, London

It is well recognized that neurological symptoms in later life may follow haemolytic disease of the newborn, and a number of such cases have been reported. Lande (1948) described eight cases and Evans and Polani (1950) reviewed the literature, adding 16 cases of their own. The serological diagnosis of the disease at birth has been satisfactory only since Coombs, Mourant, and Race (1946) introduced the anti-human-globulin test, and all the published reports have been of children or young adults. Little is known at present about the subsequent fate of affected children, and the following case showing neurological sequelae in an adult may be of interest, especially since it was possible to obtain confirmation of the aetiology by laboratory tests.

Case Report

A warehouseman aged 44 was admitted to hospital under the care of Sir Charles Symonds following an epileptiform attack during which he had lost consciousness for a few minutes. He stated that he had suffered for many years from episodes occurring two or three times a year, each lasting a few minutes, during which he felt dissociated from his surroundings and objects appeared to recede into the distance. He had lost consciousness on only one previous occasion five months earlier, when he had an attack in bed. That episode had been preceded by an involuntary cry, and terminated with incontinence of urine. The following history was obtained from the patient and his mother.

The patient was the younger of two siblings. His elder sister had died of tuberculosis, and his father was also dead. The patient had become deeply jaundiced soon after birth and had remained so for a few days. When 5 years old he developed chorea. He recovered from this slowly, and at the age of 10 was well enough to attend school, where his record was satisfactory. His subsequent development was uneventful.

The birth and childhood of his elder sister were normal. His mother had never had a blood transfusion nor an intramuscular injection of blood. She had had no miscarriages. No other member of the family had suffered from epilepsy.

On clinical examination the patient appeared to be of normal intelligence, and no abnormal physical signs were found other than a slight dysarthria.

Investigations.—The C.S.F. was normal. The Wassermann and Kahn tests in blood and C.S.F. were negative. An electroencephalogram was normal. An audiogram revealed bilateral perceptive deafness. An x-ray picture of the skull showed extensive calcification in the region of the basal ganglia and dentate nuclei. No similar changes were found in x-ray pictures of his mother and of three maternal relatives.

The combination of calcification of the basal ganglia and perceptive deafness, together with his history, suggested that he might have been affected by haemolytic disease of the newborn. His blood group was A Rh-positive, probable genotype CDe/cde. His mother's group was A Rh-negative, genotype cde/cde, but no antibodies to the Rh antigens C or D were detected in her serum, and an indirect anti-human-globulin test was negative. As she was aged 70, and in good health, it was thought justifiable to investigate the effect upon her of a small injection of Rh-positive blood. With her permission, after the nature of the investigation had been explained to her, she was given an intravenous injection of 5 ml. of fresh heparinized group A Rh-positive

blood, genotype CDe/CDe. She had no clinical reaction to the injection, but one week later she was found to have developed a pure anti-D antibody to a titre of 1 in 64 in both saline and albumin media. Two weeks after the injection the titre increased to 1 in 512 in saline and albumin, and was still at that level when she was last seen, six weeks after the injection.

The patient was discharged from hospital, and his epilepsy was controlled with anticonvulsant drugs.

Comment

The sequence of events during this patient's childhood is strongly suggestive of kernicterus supervening upon haemolytic disease of the newborn. The deep jaundice noticed immediately after birth is characteristic; and although his mother does not remember whether he developed head retraction or other manifestations of kernicterus at that time, he was nursed in the dark, and this suggests that he showed signs of cerebral irritation.

The majority of infants affected by kernicterus who survive the neonatal period develop athetotic or choreiform movements (Evans and Polani, 1950); although the latent period is usually shorter, being measured in weeks or months. In this case, slight dysarthria is the only residual motor symptom of that illness after 40 years. Deafness occurs in at least 30% of survivors, whilst mental deficiency and blindness are less common. This patient was deaf, but apparently of normal intelligence, although formal tests were not performed.

Staining of the basal and medullary nuclei is a characteristic finding at necropsy in children dying from kernicterus, but calcification in this area does not appear to be common. Whilst convulsions are often seen in infants with severe kernicterus, this disease does not usually cause epilepsy in later life, and none of the cases reviewed by Evans and Polani nor the 30 survivors reported by Gerrard (1952) were epileptic. In this case the epilepsy may have been unrelated to the disease, or it may reflect the greater degree of cerebral damage associated with calcification.

From the blood groups of the patient and his mother it can be deduced that his father was Rh-positive, although it is not possible to determine whether he was homozygous or heterozygous for the D gene. Many Rh-negative women married to Rh-positive men escape becoming sensitized to the D antigen even in their second pregnancy. However, the antibody response shown by this patient's mother after a single small injection of Rh-positive blood strongly suggests previous sensitization, the high titre and its appearance only a week after the stimulus being characteristic of a secondary response.

It is interesting that the patient's mother remained sensitized to the D antigen for more than 40 years, and might have had a severe reaction if transfused with Rh-positive blood.

I wish to thank Sir Charles Symonds for access to the patient and his family, and for permission to publish this case, and Dr. A. E. Mourant for carrying out the genotyping and the identification of the antibody.

A Reuter statement from Wellington, New Zealand, issued on September 12, states: "The Minister of Health, the Hon. J. Ralph Hanan, said to-day that New Zealand would not have to follow Britain's example and import Salk vaccine from the United States. Mr. Hanan added that there were sufficient supplies of polio vaccine in sight to treat the remaining 70,000 children of 5 to 9 years of age who were being vaccinated in this programme. New Zealand has been obtaining vaccine from the United Kingdom and Australia. It is understood that, even if stocks should run short, additional supplies could be obtained from Australia. None is manufactured in New Zealand."

Medical Memoranda

Asian Influenza in Kuwait

The following commentary on influenza is based on the 156 patients who were admitted to the male medical ward of a Kuwait State hospital during July, 1957, with this diagnosis. In view of the large number of cases seen and diagnosed as influenza in the out-patient department, only the more serious could be admitted. The criteria for admission were a high temperature and/or severe malaise. A few cases were admitted on social grounds—patients who had no one to look after them.

A standard form, devised at the outbreak of the epidemic, was completed for all cases diagnosed as influenza and admitted to this ward. An analysis of these forms is presented in the following table:

Max. Temp.	No. of Cases	Days in Hosp.	No. of Cases	Main Symptoms	No.	Age Incidence	No.
°F. (°C.)							
99 (37.2)	3	2	16	Headache	153	Under 20	30
100 (37.8)	10	3	37	Cough	83	20-30	103
101 (38.3)	9	4	44	Chest pain	62	30-40	17
102 (38.9)	26	5	22	Malaise	106	40-50	3
103 (39.4)	56	6	11	Generalized pains	75	50-60	2
104 (40.0)	38	7	12	Sore throat	10	60-70	0
105 (40.6)	14	Over 7	14	Vomiting	11	Over 70	1

It will be seen that the general picture is of the sudden onset of fever with headache, cough, chest pains, generalized muscular pains, and malaise. The temperatures of the patients admitted varied between 99° F. (37.2° C.) and 105° F. (40.6° C.), but were mostly between 102° F. (38.9° C.) and 104° F. (40° C.). This fever lasted about 48 hours and then returned to normal. All patients were put on a four-hourly chart on admission. A typical chart and form are shown. The fall to almost normal within 24 hours of admission, the rise during the following day, and the return to normality on the third day are quite typical, and representative of the majority of cases.

The presenting symptoms were remarkably similar for most of the patients. Only 10 complained of sore throat. Twenty complained specifically of pains in the quadriceps muscles and 29 of backache. However, all of these patients complained of associated generalized muscular pains. Eleven had vomited either just before admission or during their stay in hospital.

All patients had a white blood cell count and differential performed on the day of admission. In all but seven the white cells numbered under 10,000 per c.mm. and the differentials were within normal limits. Of the seven, six developed acute bronchitis and one a left lobar pneumonia.

The duration of stay in hospital varied from 2 days to 20 days in the case of the patient who developed pneumonia. The majority of the patients were kept in hospital for three or four days. The overall average duration of hospitalization was 4.5 days. The patients' ages ranged from 16 to 75 years, but the majority were in the 20-30 age group.

MALE MEDICAL WARD; INFLUENZA REPORT

Name: Age: 26
Date of admission: 14/7/57
Date of discharge: 17/7/57 Days in hospital: 4
Main complaints: 1, Fever. 2, Headache. 3, Cough. 4, Generalized pains. 5, Chest pain. 6, Backache.
Duration before admission: About 6 hours.
Maximum temperature: 104.5° F. (40.2° C.).
White blood count: 8,000/c.mm.
Differential white count: Neutrophils, 72%; lymphocytes, 23%; monocytes, 1%; basophils, 1%; eosinophils, 3%.
Urine examination: No abnormality.
Treatment: A.P.C., 2 tabs. t.i.d. Codeine linctus B.P.C., 1 dr. t.i.d.
Complications: None.

SEPT. 21, 1957

Chart of a typical case.

No similar detailed survey was done in the women's medical ward, but the general impression was that there were no significant differences.

The treatment to which the majority of patients responded was 2 tablets of A.P.C. administered three times a day, a sedative cough mixture given three times a day, light diet, and plenty of fluids. The complications—six cases of bronchitis and one of pneumonia—were treated with antibiotics in the accepted manner. A post-influenza depression was a fairly constant feature for which no treatment was given.

In a number of these cases there was an associated mild heat exhaustion. However, probably they were mostly cases which had been on a minimum salt intake before the onset of the influenza, and subsequently the fever and excessive sweating were sufficient to create a mild salt deficiency. It is notable that the number of patients admitted with a diagnosis of heat exhaustion was far lower during the influenza epidemic than in previous years, although the climate was not dissimilar to that of other years. Constipation proved to be a troublesome complaint in many cases, again presumably due to fluid loss, a state of affairs not uncommon in cases of mild heat exhaustion.

The Singapore report on Asian influenza noted a high incidence of sore throat. This was not found in the present series, and in fact there was little if anything to distinguish this epidemic of Asian influenza from the influenza seen in other years. Mutation of the causative virus is not an improbable cause, and further reports as the epidemic spreads westwards may possibly confirm this.

Senior Medical Officer, Health Department, Kuwait.

Fatal Pulmonary Embolism in Pregnancy

The following case is worth reporting because of the unusual site of primary thrombosis unassociated with trauma or infection.

CASE REPORT

A booked maternity patient, a para 1 aged 29, was admitted to the antenatal ward complaining of breathlessness on exertion for the past three days. By her dates she was 29 weeks pregnant, and her antenatal course had up till then been completely uneventful. There was nothing of note in her family, past medical, or menstrual history. In 1947 she had a spontaneous term delivery at her home of a male child weighing 7 lb. 8 oz. (3.4 kg.). The antenatal period and puerperium were uneventful.

She booked at the antenatal clinic when she was 16 weeks pregnant. No abnormality of the head, neck, chest, or abdomen was found, her blood pressure was 125/70, and there was no sugar or albumin in the urine. A routine chest x-ray examination at the time showed nothing of note, and her haemoglobin was 12.2 g. per 100 ml., group O rhesus positive. She was referred to the county council clinic until the thirty-sixth week of pregnancy, where she attended at regular intervals.

Three days before admission she became slightly breathless when walking up a flight of stairs while at work, but on

resting for a few moments recovered completely. She was sent home to rest, and was perfectly well until the day before admission, when her breathlessness became more noticeable, the slightest exertion causing discomfort. She was quite comfortable at rest, did not complain of chest pain, and had no other symptoms.

Examination on admission showed a pale young woman lying in bed, in no apparent distress. The temperature and pulse were normal and the respiration rate was 20. No abnormalities were noted in the head, neck, chest, cardiovascular system, or abdomen. The blood pressure was 130/80. The uterus was enlarged to correspond with a 30 weeks' pregnancy, a single foetus was present, and the foetal heart was heard. There was no oedema, nor were there varicosities of the lower extremities. Vaginal and speculum examination revealed no abnormality. The urine contained no sugar or albumin.

A full blood count and a chest x-ray examination were ordered. A physician's opinion was obtained, and although he asked for an electrocardiogram he felt that the cause of the breathlessness was more likely to be ascertained by the blood examination. The haemoglobin was found to be 9.1 g. per 100 ml. and white cells 16,000 per c.mm.; no abnormalities were noted in a blood film. The chest x-ray examination showed nothing of note.

On the following day, while the electrocardiogram was being taken, the patient became cyanosed. Oxygen was given, but her pulse became extremely fast and of poor volume, and she collapsed and died soon afterwards.

As the foetal heart was still audible, a post-mortem caesarean section was performed and a living male infant was delivered; it died, however, an hour after delivery.

A post-mortem examination was performed by the pathologist appointed by the coroner, and following is a relevant extract from the report. *Lungs*: There was minimal congestion at the bases of both lungs posteriorly. Numerous small ante-mortem clots were present in the pulmonary arteries, but there was no evidence of infarction. *Heart and pericardium*. The heart was of normal shape, size, and development. The pulmonary artery was blocked by a large ante-mortem clot. *Pelvic organs*: The veins on either side of the vagina were thrombosed and clots could be traced into the left internal iliac veins. There was no evidence of trauma or infection. The cause of death was given as pulmonary embolus secondary to thrombosis of the perivaginal plexus of veins.

COMMENT

Damage to the intima of blood vessels by trauma or infection, slowing of the blood stream, and a natural or acquired tendency due to changes in the plasma and cellular elements of the blood are all factors which promote clotting of blood in the vascular system. In obstetric practice a large proportion of cases occur as a complication of cardiovascular and pulmonary disease, and thrombosis of varicose veins of the extremities accounts for a number of cases. Ophuls and Dobson (1932) found that 52% of their cases of pulmonary embolus were associated with cardiac disease. In cases of induced abortion, trauma or sepsis may also give rise to pulmonary emboli.

This case is instructive in that none of the specific conditions mentioned above was operative, and the cause for the thrombosis at the primary site remains unexplained. Although pulmonary embolus is one of the first conditions to be considered in the differential diagnosis of the sudden onset of breathlessness, absence of symptoms or physical signs indicating a primary site made a positive diagnosis difficult.

I thank Professor J. C. McC. Browne, of the Institute of Obstetrics and Gynaecology at Hammersmith Hospital, under whose care the patient was admitted, for permission to publish this case.

M. B. WINGATE, M.B., F.R.C.S.Ed.,
Late House-surgeon to the Obstetric Department,
Hammersmith Hospital, London, W.12.

Reviews

EMERGENCIES IN GENERAL PRACTICE

Emergencies in General Practice: Specially Commissioned Articles from the British Medical Journal. January, 1955, to June, 1956. (Fully revised.) (Pp. 470+x; illustrated. 25s.) London: British Medical Association. 1957.

With this book, the logical successor to the three books of Refresher Courses already published, the editor of the *British Medical Journal* and his staff have surpassed the high standard of the previous volumes. The first chapter by Sir Heneage Ogilvie is on "Shock," the last by Mr. Norman C. Lake on "Common Mishaps." In between other experts write about obstetric, abdominal, neurological, and psychiatric emergencies, pulmonary and cardiovascular accidents, burns and electrocution, poisons, and anaesthetics.

There are at least three reasons why this book should be in the hands of every general practitioner. First, it is in itself a refresher course. The experts sometimes differ, as experts sometimes should. Much of the coaching is conventional, as much good coaching is—"Take a careful history and make a thorough examination! (Keep a straight bat and your eye on the ball!)." But nearly every contributor has something distinctive to say. Whether he reads Dr. Elkington's clear and scholarly exegesis on "Apoplexy" or the imaginative but more didactic article by Mr. Frank Stabler on "Ante-partum Haemorrhage," the general practitioner will feel he is being taught by an expert who can teach—refreshment indeed!

Secondly, this book demonstrates, if demonstration is still needed, that much that is learnt in hospital can be used by the general practitioner to-day. It is true, and the writers recognize this, that the immediate diagnosis of an emergency must be made by the general practitioner on his clinical judgment alone, but there are many hospital techniques with which he should be familiar if he is to give proper treatment. At least one general practitioner has completely overhauled his emergency bag after reading this book.

Thirdly, it points a finger, perhaps a somewhat wavering finger, towards proper integration of consultant and general-practitioner services. There are many references to the importance of such and such a case being transferred to hospital, but often what is meant is the team-work most conveniently obtained in hospital. Now that hospital buildings are crumbling and infested with resistant organisms, it is more than ever necessary, if British medicine is to hold its own, that consultant and general practitioner should so fuse their respective teams that treatment will be a combined operation wherever the patient lies.

This volume is so good that I hope the editor will follow with a collection of essays on aftercare and rehabilitation. Then we may see how much of what is called hospital treatment can be efficiently carried out in the home.

C. W. WALKER.

SURGERY OF ANUS AND RECTUM

Surgery of the Anus, Anal Canal, and Rectum. By E. S. R. Hughes, M.D., F.R.C.S., F.R.A.C.S. Foreword by C. Naunton Morgan, M.S., F.R.C.S. (Pp. 303+xi; illustrated. 50s.) Edinburgh and London: E. and S. Livingstone Ltd. 1957.

This is a good book, clearly written, profusely illustrated, and containing several novel features. Mr. Hughes states that he gained his inspiration to become a specialist in rectal surgery from Mr. John Turner, but his training was chiefly at St. Mark's Hospital and much of his teaching has its origin at that famous hospital. Mr. Naunton Morgan has written a most encouraging foreword.

The last 35 years have seen a great advance in the major surgery of the rectum, and those of us who were in active practice while the change was taking place can only marvel at the excellent results now obtained by experts in the art. To be able to record only ten deaths in a series of 227

patients submitted to combined excision of the rectum for carcinoma is a surgical triumph which would have rejoiced the heart of Ernest Miles, who persevered bravely when his mortality was more than seven times that figure. The minor surgery of the rectum has not altered to the same degree. It is true that the operations for treatment of piles by clamp and cautery, by clamp and suture, and by excision of the pile-bearing area (Whitehead's operation) have disappeared, but greater prominence is now given to the old-established operation of ligation. Mr. Hughes is a convinced and convincing advocate of immediate skin-grafting of the wounds left after operation for fistula and fissure, and following excision of the affected skin in severe cases of pruritus ani. After an operation for fistula patients are able to leave hospital within two weeks, which is a month earlier than by the old methods. It is true that the complete operation may take three, four, or more hours to perform, but the ultimate saving of time in hospital is thought to justify this. We shall wait with interest to see if this new technique becomes the general practice. For that condition which has hitherto proved very difficult to treat—complete prolapse of the rectum—the author recommends an abdomino-perineal operation, which in his opinion holds out the best prospect of cure.

Throughout the book are interspersed many interesting facts of surgical history, and at the end some famous names are recalled. One would like to see the names of Allingham and Salmon added to the list. The frontispiece is an excellent photograph of Dr. Cuthbert Dukes; this is a delightful and well-merited compliment to the pathologist who has done more than anyone else to elucidate the pathological problems of diseases of the rectum.

ZACHARY COPE.

BETHNAL GREEN TO GREENLEIGH

Family and Kinship in East London. By Michael Young and Peter Willmott. Foreword by Richard M. Titmuss. (Pp. 232+xix. 25s.) London: Routledge and Kegan Paul. 1957.

This is an account of a sociological study designed to examine the effects of the new housing estate upon family life, the chosen borough being Bethnal Green and the housing estate an anonymous Essex overspill called Greenleigh. The authors worked either in the borough or on the estate throughout the three years; one lived with his family within the borough.

Bethnal Green had already changed much since the time of Charles Booth, and still more from that of Mayhew and the days when Shaftesbury and Barnardo poked in dead of winter under the tarpaulins of Covent Garden for children. One of the main differences has been the greater identification of the husband with the home—a new kind of companionship between husband and wife, and a rise in the status of the young wife and children. The boundaries between the sexes are no longer so rigidly defined. Nevertheless Bethnal Green has a strong family group, with the main links running through from wife to wife's mother. The deep significance of this attachment can be seen in many ways—for example, in the tendency to matrilocal residence, in the support given to the mother of the young family in child-bearing and in sickness, and in the tendency to divide the loyalty of the wife.

Bethnal Green is painted as a happy place, where people are judged for themselves and where social distinctions hardly exist. In modern jargon the authors make it seem "mentally healthy," whatever may be its physical disabilities—that is, healthy in terms of human relations and the strong community ties which both prevent and relieve anxiety. In Greenleigh all is very different—not that the authors fail to give the new housing estate a full appreciation for what it offers in higher standards of living, particularly for the children. The husband is seen to have taken a stage further the partnership of himself and his wife, already seen to be growing in Bethnal Green. He has given up so many luxuries to make the new home possible. The chief difference

lies in the isolation of the family units—from the grandparents, and from the innumerable friends and acquaintances of Bethnal Green, and also the new neighbours and all the others on the estate. The friendliness of Bethnal Green is replaced by a new standoffishness, the window-to-window relationship of suburbia and its exclusiveness. It is now bad policy to make friends. Lives are no longer centred upon people in a daily round of encounters both studied and by chance. Life now centres upon the home, with Mrs. Jones inexorably driving each family into competition with others: the home first, then the telephone, television, lawnmowers, car, curtains, and so forth.

Is this a temporary change? Bethnal Green, when the Huguenots came, was once a Greenleigh. Will Greenleigh in time develop like Bethnal Green with its own family clusters, its friendly personal relationships, its values based on people rather than possessions? To some extent, yes, since when those who moved are old there will be grandparents and children. Every area must be able to create its own kinship network, given time. But in a sense, no; the values of society are changing, so that perhaps what Bethnal Green stood for in human relationship is doomed; who knows? Then there is the future problem of housing. What happens when the children grow up? Where will they find a house? The housing estates will be bursting at the seams, and in contrast the schools will suddenly be empty. Children cannot any longer take on the home vacated by their parents. They must move again. The advantages for housing which a three-generation community presents are lost. When the grandparents die the children cannot move in and later move on; a two-generation structure is always on the move.

No short account can do justice to this book, charmingly written, engaging, absorbing. It is to be hoped that town-planners will read it, and think more deeply about the need to do more to re-create our existing towns.

C. FRASER BROCKINGTON.

NORFOLK DOCTOR

Left-handed Doctor. By Peter Quince. (Pp. 194. 16s.) London: J. M. Dent and Sons Ltd. 1957.

This is an unusual autobiography. In it the author tells the story of his seven years in family practice in Norfolk villages 25 years ago. There is nothing sinister about Dr. Quince, despite his titular description, for he takes a delight in human nature and describes with a rare relish the commonplaces of human relationships and the oddities of mankind. He has observed himself as acutely as he has studied any of his subjects, and he draws an ingenious self-portrait, revealed sometimes through the delineation of his other sitters and sometimes by the comments upon them which illustrate his own personality. We see him as a man determined to do what he wanted to do and enjoying the doing of it—a man, who eschews cant in himself and dislikes humbug in too, who is therefore, albeit a successful family doctor, not to be easily confined to the mould of general practice.

His left-handedness is explained in the amusing drawing on the wrapper. He gave to the practice of medicine no more than his left hand, while his right hand was occupied with the training of village choirs and with the production of comic operas, thus fulfilling a destiny laid upon him by his devotion to a music-master of his schooldays. (James Barrie related that his "unpleasant" plays, like *Mary Rose*, were written with his left hand, and his pieces of sentiment like *The Admirable Crichton*, with his right.) The story of his right-handed devotion to music-making is completed in a penultimate chapter of hints and tips for choir-trainers, while the summation of his experience of 30 years of both left-hand and right-handed doctoring (for we infer that he cultivated ambidexterous doctoring in middle age) is told in a testament delivered to a St. Luke's Day audience in the parish church of Norwich in 1953. We learn little of the 20 years between his departure from the family practice and the St. Luke's Day address. There is, therefore, another book, *Right-handed Doctor*, waiting to be written. The coming of the National Health Service makes it more diffi-

cult, for those who began by practising left-handed medicine, later to devote their powerful right hands to the service of the slighted goddess, though this was by no means an unusual pilgrimage in the author's generation.

This is a book both sensible and gay, well worth the writing and well worthy to be read.

D. V. HUBBLE.

MUSCLE RELAXANTS

Muscle Relaxants in Anesthesiology. By Francis F. Foldes, M.D. Illustrated by Margaret M. Croup. (Pp. 210+xx. 42s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1957.

The literature on the relaxants is now profuse, but strangely enough, apart from an early historico-pharmacological book, no monograph on these drugs has yet appeared. Now this deficiency has been made good by Foldes, a tireless worker in this field and internationally known for his original contributions. His interests have centred almost exclusively on the depolarizing relaxants, and in particular on succinylcholine. As would be expected, therefore, his book is weighted in almost every way in that direction. In the last six chapters, for example, which are devoted to clinical use, there is hardly one in which succinylcholine is not claimed with some emphasis to be superior to the others. Many British and European anaesthetists, on this account alone, will probably take exception to many of the clinical opinions of Dr. Foldes. Once this bias on the part of the author is allowed for, the book appears as an excellent review, carried out in masterly fashion, of the literature on the relaxant drugs. The pharmacological section, easily the best, describes exhaustively, albeit concisely, what is known about the mode of action of the relaxants. The references to original sources are so numerous (over 400 are listed) as sometimes to be a hindrance to the reader. However, they make the value of the book as a guide to the literature unquestioned. If only the title had been "Succinylcholine and Other Relaxants" praise would have been unreserved, for the message of the book would have been clear. As it is, the clinical sections must be studied with some caution. The book as a whole is a contribution of the highest order to an important field of pharmacology and anaesthesia, and Dr. Foldes is to be congratulated on his achievement.

W. W. MUSHIN.

SCHIZOPHRENIA

Schizophrenia: Somatic Aspects. Edited by Derek Richter. (Pp. 181+vi. 40s.) London, New York, Paris: Pergamon Press. 1957.

As the editor explains in the introduction, this volume is the result of discussions held by a small group of scientists and clinicians working in this country that culminated in a "discussion party" arranged with the assistance of the Mental Health Research Fund and held at the Ciba Foundation in London. It contains a number of valuable reviews of the present state of knowledge concerning different aspects of schizophrenia, which "from some points of view . . . is the biggest single problem in the whole of medicine." Dr. Denis Hill deals with the electroencephalogram in schizophrenia; Dr. Derek Richter with the biochemical aspects; the late Dr. D. E. Sands with the endocrine changes; and Mr. G. B. David with the pathological anatomy. Other noteworthy papers include "Physical Characteristics of the Schizophrenic Patient," by Dr. W. Linford Rees, and "Interaction of Genetic and Environmental Factors in the Causation of Schizophrenia," by Professor Martin Roth. The last paper includes much valuable and interesting genetic and sociological data. The striking point that emerges is that, despite a vast amount of careful research, physical investigations have so far proved essentially negative in schizophrenia, except possibly in the small group of recurrent catatonia. It is, however, valuable to have this authoritative account of what is known and of current investigations. Some of the contributions (not mentioned by name) do not reach the high standard set by the others.

DESMOND CURRAN.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY SEPTEMBER 21 1957

THE GOVERNMENT PRESCRIBES

The Government's decision to import poliomyelitis vaccine, announced last week as we went to press,¹ was the only one possible on the facts. The roll of drums from the daily newspapers before the Government finally brought off its somersault showed which way public opinion was turning. In endeavouring to give expression to at least some informed medical opinions last May a leading article in this *Journal* concluded, "There is certainly a strong argument for importing the best brands of American vaccine, if that is possible."² But as was pointed out then, and subsequently,³ the conflicting data and arguments that had to be considered were very incompletely known to medical men in general. Even now the main factors that have influenced the Government are hard to discern. At the end of June the Minister of Health told the public that he had "accepted the expert medical advice that Britain should not run the risk of importing poliomyelitis vaccine."⁴ The decision then seemed to be the medical advisers'. But in the latest statement we learn of the Medical Research Council four weeks later advising that "the risk of using Salk vaccine . . . should be weighed by the Government against the risk of leaving substantial numbers of children unvaccinated during the summer of 1958." It would be interesting to know what questions the Government has been putting to its various advisers, and who is responsible for what.

In the ordinary way doctors might have expected the medical problems, as distinct from the financial, of supplementing supplies of British vaccine by imports of American vaccine to be openly discussed at medical meetings and in the medical press, advice being openly given to the Minister of Health from time to time by the recognized medical body or bodies. Instead, there are various groups of distinguished advisers whose advice is sought, and given, under

conditions of secrecy more appropriate to the negotiation of a treaty with a nervous foreign power. At intervals the curtain is drawn aside and a Government spokesman utters an announcement that is apt to be oracular rather than illuminating. Usually his words are addressed not to the medical profession but to the public—or, as it is sometimes called, the electorate. This system has no doubt grown up without much thought about where it is leading, but its results so far are not reassuring. One consequence of it is that medical decisions of great moment to individual patients are made without their doctors being able to explain them fully or even to put before their patients all the arguments for and against. Moreover, opinions that dissent from what comes to be an official view are apt to be looked on with disfavour, yet in this field, as often in medicine, the probabilities are exceedingly difficult to estimate from the scanty data, and there is room for an understandable difference of opinion, or of preference, in drawing conclusions from them.

A second consequence is that the Government is beguiled into posing before the electorate as a kind of medical institution. The public learns from the latest statement, for instance, that "the Government have decided to offer immunization against poliomyelitis . . ." Further on: "To carry out the programme now decided upon by the Government . . ." "the Government have now weighed all the known facts," and "they [the Government] have decided that to fill the gap . . ." and so on. Clearly the Government has been very busy. But what is its business? Last year we had a Minister⁴ assuring the public that poliomyelitis vaccine is "absolutely safe," a statement that was not only inaccurate but inapplicable to any vaccine. Later on another Minister declared, with a handful of phoney statistics, that Britain's vaccine had been a success,⁵ when it was far too early to say. These were more than the injudicious slips of enthusiastic Ministers; they revealed politicians assuming all too easily a role they are not cast to play. The process deserves noting because it is increasing and is dangerous. Successive Governments of this country are naturally concerned to promote public health, and, with the aid of the medical profession, create and operate statutory instruments to that end. But more than once they have shown signs of treating doctors as though they were rule-of-thumb technicians. The handling of the poliomyelitis vaccine has all along been symptomatic of this. It is an attitude that could quickly undermine public confidence in the medical profession, and, moreover, do untold harm to the practice and development of medicine in Great Britain.

LIMITATIONS OF THEOPHYLLINE

Given intravenously, aminophylline is of great benefit in the treatment of status asthmaticus and acute left-sided heart failure. Nevertheless it may often cause such side-effects as flushing, hyperpnoea, sweating, and faintness. The recently synthesized neutral theophylline compounds cause fewer side-effects, but their therapeutic efficacy seems to be lower. D. N. Phear¹ has compared with aminophylline two such substances—dihydroxypropyl-theophylline ("neutrathylline") and theophylline-ethanoic acid with diethylenediamine ("etophyllate"). These compounds were given intravenously to patients with chronic bronchitis and asthma. Though no side-effects were noted with neutrathylline and only slight flushings or faintness with etophyllate, while the usual side-effects were frequent with aminophylline, neither of the new compounds produced the increase in the rate of expiratory flow which resulted from giving aminophylline. It seems, therefore, that for the prompt, though transient, relief of bronchospasm from any cause intravenous aminophylline remains the most valuable agent despite the relatively high incidence of side-effects.

Frequent intravenous therapy is obviously impracticable for maintenance treatment, and the pain produced by the intramuscular injection of aminophylline is severe. In consequence, for maintenance treatment oral theophylline compounds have often been given. Since the incidence of bronchial asthma in the adult population of England and Wales has been estimated² as 904 per 100,000, or 1 in 110, it is not surprising that over 50 million tablets of aminophylline were dispensed in these countries in 1951. Attempts to evaluate the therapeutic effects of aminophylline by mouth have given rise to controversy. M. Turner-Warwick³ has suggested that, for oral theophylline compounds to be effective in relieving bronchospasm, plasma theophylline levels of about 1 mg. per 100 ml. must be attained. In her series of 25 patients no side-effects were noted after single oral doses with aminophylline, or with theophylline compounds of choline, dihydroxypropyl, sodium glycinate, and ethanoate of piperazine. Effective plasma levels were obtained only with aminophylline and choline theophylline. Further observations on 12 patients given maintenance treatment with the new compounds showed that the patients receiving choline-

theophylline in doses of 200 mg. four times a day experienced nausea, epigastric pain, and "fullness" when levels of plasma theophylline exceeded 1 mg. per 100 ml. No side-effects resulted from the use of the other compounds, but the concentrations of plasma theophylline obtained were well below the effective therapeutic level, even though their total daily dosage was two to three times larger than that of choline-theophylline. Turner-Warwick suggests that the recommended dosage of the last three preparations be increased. It remains to be seen whether this will also lead to the production of side-effects, some of which, at least, may be related to the levels of plasma theophylline irrespective of individual total daily dosage.

R. Fife and colleagues⁴ in a carefully controlled "double-blind" trial have compared aminophylline in varying doses with dihydroxypropyl-theophylline given orally to patients with angina of effort. These workers also made use of placebo tablets to take account of the well-known part played by suggestion in the patient's response to treatment. They found that neither dihydroxypropyl-theophylline nor aminophylline had any advantage over the placebo in suppressing anginal pain. It is also noteworthy that 30% of their patients experienced side-effects when aminophylline was given in 0.2 g. doses, while over 8% had side-effects with 0.1 g. doses. Similar side-effects arose in over 7% of the patients receiving dihydroxypropyl-theophylline and even the placebo. When given in the usual doses, it seems doubtful whether aminophylline increases the coronary blood-flow in man. If side-effects could be overcome, so that aminophylline or the newer theophylline compounds could be given in higher dosage, then these drugs might have a place in the suppression of anginal pain.

Another plea for larger oral doses of aminophylline is made by J. C. Brocklehurst.⁵ In studies of a patient with prolonged Cheyne-Stokes respiration single oral doses of not less than 0.5 g. of the drug had a perceptible effect in restoring the respiratory rhythm to normal, but smaller doses were valueless. As to the action of aminophylline on the respiratory centre, Brocklehurst suggests that the oral dose should be at least 0.5 g. four-hourly. He observed no side-effects with this regime in this particular patient, who seems to have been very tolerant to the drug, but higher doses caused nausea and retching.

Side-effects may be reduced by administering aminophylline in the form of suppositories, though the rate of absorption is variable. Long-term treatment by this route is usually unsuccessful, for many patients find it inconvenient or distasteful. Transient

¹ Phear, D. N., *British Medical Journal*, 1957, 2, 74.² Stocks, P., *Studies on Medical and Population Subjects*, No. 2. *Sickness in the Population of England and Wales, 1944-47*. London.³ Turner-Warwick, M., *British Medical Journal*, 1957, 2, 67.⁴ Fife, R., Howitt, G., and Roy, J. R., *Scot. med. J.*, 1957, 2, 11.⁵ Brocklehurst, J. C., *ibid.*, 1957, 2, 17.⁶ McKee, M., and Haggerty, R. J., *New Engl. J. Med.*, 1957, 256, 956.

diarrhoea due to mucosal irritation, and rectal pain, are sometimes troublesome. But many adults with nocturnal bronchospasm obtain a good night's sleep after the insertion of a suppository before retiring, especially when combined with a sedative by mouth. A potential danger with aminophylline suppositories is overdosage in children, leading to serious toxicity. Adult full-strength suppositories may be swallowed by them accidentally, while the normal adult dose per rectum frequently repeated may cause irritability, intractable vomiting, dehydration, convulsions, and even death. In reporting a child's death which they attributed to such a cause, M. McKee and R. J. Haggerty⁶ review 35 cases of aminophylline poisoning in children. They suggest that a safe paediatric dose per rectum should not exceed 7 mg. per kg. body weight every six to twelve hours. Despite these possible risks, rectal aminophylline is preferable to the intravenous route in young children for obvious reasons, and is very often equally successful in alleviating severe bronchospasm.

In clinical practice, therefore, it would appear that the newer theophylline compounds have not yet supplanted aminophylline. It may be that the problem of reducing side-effects while retaining therapeutic effectiveness is virtually insoluble, for the active principle of all these xanthine derivatives is, in fact, theophylline. The higher doses which seem to be necessary for the relief of bronchospasm or anginal pain are often prohibited by the concomitant side-effects. Until these are overcome the place of oral theophylline compounds in practice is likely to be limited.

MEETING OF MEDICAL EDITORS

Medical editors from 24 countries met at B.M.A. House last week for the first international congress on medical editing to be held in Britain. It was at the same time the Third Congress of the International Union of the Medical Press, and the meeting was held under the presidency of the Editor of the *British Medical Journal*. Those responsible for organizing the meeting had chosen eight topics for discussion, a full account of which is printed in this issue of the *Journal*. Apart from the fact that the participants shared a common interest, this congress of the medical press made it possible for men and women from nearly all the European countries, from Egypt and Israel, from Africa, and from Canada and the U.S.A. to become acquainted and to discover they had many things in common. It was particularly gratifying to the B.M.A. as organizer and host at this congress to be able to welcome the distinguished delegation from France, for it was in Paris that at the end of the last century

the idea of an international union of the medical press was born. The present union was established at Brussels in 1953 under the presidency of Professor M. Loeper, of Paris, and now has some forty countries in its membership. Last week's congress showed, we believe, that there is a real need for such an organization. Medical journals have an important influence in professional life, and their readers will certainly benefit from the existence of an international forum for discussion of editorial practice and standards.

ENDOTRACHEAL COMPLICATIONS

In the past endotracheal intubation has been blamed for many post-operative complications. Some were real, but others, perhaps less well documented, are undoubtedly fictitious. The real complications have been well recognized and described in the literature, though the incidence with which they are said to occur varies greatly. Attempts to probe these mysteries are further confused by the radical change in techniques adopted by anaesthetists during the war years. This change was due entirely to the introduction of muscle-relaxant drugs, which both simplified intubation and at the same time made the passage of an endotracheal tube almost a necessity of modern anaesthesia. W. D. Wylie¹ drew an interesting comparison between the effects of intubation after deep ether or cyclopropane anaesthesia and after the administration of thiopentone and D-tubocurarine. Trauma was caused in both groups—often by laryngoscopy alone—but was less commonly seen in those patients who received the muscle relaxant. Nevertheless, the fact that it still occurred, and was probably responsible for a large number of sore throats, encourages the thought that direct damage to pharyngeal and laryngeal mucosa may be the cause of other complications of intubation.

S. S. Epstein and P. Winston² have drawn attention to intubation granuloma. It has hitherto been regarded as a rare complication of intubation, but they consider it to be occurring with greater frequency. In 1932 H. R. Griffith³ described five cases of granuloma following 1,500 intubations, and P. J. Flagg⁴ reported 101 cases. In Great Britain 55 cases were reported between the years 1932 and 1954, and Epstein and Winston describe a further ten. These statistics give little idea of the incidence of this complication, but unpublished data suggest that it may be as high as 4% of intubations and depend on the site and nature of the operation. But in all these surveys an element of inaccuracy must remain, since the figures given are dependent on the development of symptoms by the patient within a reasonable post-operative period or on the performance of a post-operative examination of the larynx. Neither can be guaranteed or expected. Symptoms of laryngeal granuloma, of which hoarseness is the most common, are

¹ Wylie, W. D., *Anaesthesia*, 1950, 5, 143.

² Epstein, S. S., and Winston, P., *J. Laryng.*, 1957, 71, 37.

³ Griffith, H. R., *Curr. Res. Anesth.*, 1932, 11, 206.

⁴ Flagg, P. J., *Arch. Otolaryng.* (Chicago), 1951, 53, 439.

⁵ Moulden, G. A., and Wynne, R. L., *Brit. J. Anaesth.*, 1951, 23, 92.

⁶ Stevens, W. J., *ibid.*, 1951, 23, 199.

inevitable, but may be delayed for months, and indeed sometimes not until all connexion with the past operation and anaesthetic has been forgotten. On the other hand hoarseness in the immediate post-operative period may be overlooked or disregarded altogether. Since, too, granulomas can become pedunculated and be coughed up, the patient sometimes achieves a spontaneous cure. Thus he may give a history of hoarseness with recovery, and subsequent examination will be negative. Others may have symptoms persist until the granuloma has been removed surgically. Fortunately, the condition is benign, and since operative removal of the lesion is fairly simple no harm results except to the pride of the anaesthetist who considered that his laryngoscopic technique was beyond reproach.

The exact aetiology of post-anaesthetic granuloma is somewhat obscure, but it is unlikely that more than a few lesions of the type result from direct injury with the laryngoscope or from insertion of a tube. There is more evidence to incriminate indirect or passive injury while the tube is in place. Epstein and Winston support this view, which was suggested previously by G. A. Moulden and R. L. Wynne⁵ and others. Classically, the lesion is seen on the posterior third of the cords, usually unilateral, but occasionally bilateral, and affecting women more commonly than men. It is suggested that when the endotracheal tube is in place the natural springiness of the rubber tends to force the tube posteriorly against the arytenoid cartilages and adjacent parts of the cords. With long-continued pressure ischaemia would undoubtedly result, yet in the case reported by Wylie the tube was in position only for 15 minutes. W. J. Stevens⁶ has recommended the use of plastic tubes which assume the contours of the upper respiratory passage when warmed to body temperature, thus avoiding the pressure effect of the curved rubber tube with its retained resilience. Other factors which may be contributory^{*} deserve investigation. Of these, movements of the tube within the glottis, as in coughing or even deep breathing, or movement of the larynx over the tube, as when the patient's head is moved, come to mind. Extension of the head is known to force the tube posteriorly, but little attention has yet been paid to the influence of the vertebral curves in the thoraco-cervical region, which might determine the fulcrum of this pressure effect, or to the inherent differences between the male and female glottic openings. Further investigation may show how best to avoid these complications of intubation. Until then anaesthetists and surgeons may find that in exercising the utmost gentleness they keep them down to a minimum.

CHRONIC MENTAL DISEASE

When the Report of the Royal Commission on the Law Relating to Mental Illness and Mental Deficiency appeared recently it was welcomed for its progressive spirit.¹ Existing law is recognized as obsolete, and the Commission proposes new administrative ways of dealing with the mentally ill which reflect many of the missionary enthusiasms of mental health in the last

decade or so. The unlocking of doors, the rehabilitation of chronic patients through work, intensive use of physical treatments and psychotherapy, and the creation of out-patient and follow-up clinics to keep people out of mental hospital, are some of the signs of the keen wind blowing through the psychiatric hospitals. There has been, too, a big propaganda effort to convince the public that mental hospitals can be homely places and that most mental illness is curable. This is supported by those psychiatrists who hold what may be called a sociological view of mental illness and mental deficiency. The patient is in hospital because he is not adjusted to the society in which he has to live: treatment consists in readjusting him. Such views have inspired much humane and vigorous work inside the mental hospital, though not everyone would agree with the way they are sometimes expressed. Examination of actual populations in mental hospitals shows the large prevalence of schizophrenia among the chronic population,² an illness probably organic and certainly genetically determined. Other organic nervous illness, such as post-encephalitic, epileptic, presenile, senile, and arteriosclerotic psychoses, represent a relatively small proportion, but one not to be neglected. Modern physical therapies such as insulin coma, electric convulsion, and drugs often induce remissions, though without affecting the ultimate prognosis, especially in schizophrenics. Hospitals have adopted the praiseworthy policy of discharging patients home in remission; but many chronic patients still need care, and there is every likelihood that their numbers will remain high in the immediate future. Certain symptoms of prolonged hospitalization under inadequate conditions will disappear; but carefully devised administration and legislation should not be swept away under the mistaken impression that precarious social adaptation of the patient in his family is a cure.

Likewise a cautious appraisal seems appropriate to the Royal Commission's proposals on mental deficiency. The existing law relating to the treatment of mental defectives probably needs revision, and sociological considerations are of greater account than in the case of mental illness. As was said in the B.M.A.'s evidence to the Royal Commission,³ treatment within the community should be developed, especially by increase of occupation centres and of home training. But, while many high-grade defectives live among us and are never suspected of being abnormal, others are crippled by a great variety of organic brain conditions, such as mongolism, cretinism, epiloia, hydrocephaly, phenylketonuria, and they represent an institutional burden which cannot be lightened by social measures only. Some training is possible, but patients with these diseases remain a challenge to differential diagnosis and treatment. It can hardly make for progress to group the great variety of these conditions under one heading, "severely subnormal." The Commission's suggestion for a change of terminology is thus questionable, for it is harsh and unimaginative to lump together every grade of intellectual and social

¹ *British Medical Journal*, 1957, 1, 1349.

² Cross, K. W., Harrington, J. A., and Mayer-Gross, W., *J. ment. Sci.*, 1957, 103, 146.

³ *British Medical Journal Supplement*, 1955, 1, 211.

inadequacy, abandoning the subdivision into three grades (feeble-minded, imbecile, and idiot) which, for practical purposes, has proved its value. If guardianship, a desirable and progressive step, is to be used extensively, a subdivision of this kind, perhaps in different words, will be needed to make it effective.

The Commission has attacked with admirable courage the controversial question of the "psychopath." But without definition the newly introduced concept will not be easily applied in legislation. Here sociological notions seem appropriate because the psychopath is often within the limits of psychological normality. Treatment of him should not be expected from the psychiatrist in the ordinary mental hospital. Special centres are desirable for this purpose, where each case gets individual study and benefits from the experience in treatment gained in research centres in Great Britain and in Denmark and Holland.

SMOKERS' LUNGS

More information about the effect of tobacco smoke on the human lung has recently been published. Last year the preliminary results of a histological survey of the bronchial mucosa in heavy smokers were discussed in these columns.¹ The survey² was carried out by O. Auerbach and six collaborators in the Veterans Administration Hospital, New Jersey, U.S.A., and their full report is awaited with considerable interest. The New Jersey group examined 41 lungs. Several varieties of abnormal growth of the bronchial epithelium including squamous metaplasia were described, but simple hyperplasia of the germinal or basal cells of the bronchial mucosa appeared to be more severe and more extensive in smokers than non-smokers, and its most severe form seemed to be confined to heavy smokers. The results of a similar investigation carried out in the Pathological Department of the University of Toronto by J. D. Hamilton and others³ have now appeared, and their general conclusions are remarkably similar to those of Auerbach and his colleagues.

The Toronto group examined 65 lungs, 45 of which were from heavy smokers, and in these unmistakable basal cell hyperplasia of the bronchial epithelium was present in 80%. The hyperplastic epithelium showed little or no differentiation, and inflammatory changes in the submucosa were not impressive. Squamous metaplasia in the mucosa was not clearly associated with heavy smoking. On the other hand the bronchial epithelium of 40% of 20 non-smokers also showed basal cell hyperplasia, but this growth abnormality was significantly less severe in degree and was more frequently accompanied by inflammatory changes in the submucosa than in the bronchi of heavy smokers.

The ciliated epithelium and the mucus-producing cells of the bronchial mucosa are fully differentiated adult cells incapable of proliferation. Normal wear and tear causes heavy loss of these superficial protective cells,

and this is continuously made good by mitotic division of the small deeply placed germinal or basal cells, whose hyperchromatic and relatively large nuclei proclaim their fertility. Few would deny that it is from these cells that primary bronchial carcinoma arises. It would be unwise to prejudge the significance of these histological researches until a much larger volume of material has been examined, but it is impossible at the moment to accept basal cell hyperplasia of the bronchial epithelium as a specific lesion due to tobacco smoke unless we make the rather rash assumption that heavy smokers contaminate the common atmosphere to such an extent that they become responsible for the production of bronchial cancer in non-smokers.

THE PORTUGUESE MAN-OF-WAR

The extent to which warning of the dangers from being stung by *Physalia* has been circulated at South Coast resorts might surprise bathers on beaches at Las Palmas in the Canaries. There the Portuguese man-of-war is abundant from time to time every year, and yet bathers appear to take no notice of "agua viva" until they are stung. The local children delight in popping the bladders on the sand with their bare feet. In consequence it is perhaps not surprising that hundreds of cases of bad stings are treated at the Victoria Hospital, Las Palmas, every year. The urticarial weals sometimes cause great pain, but records of fatalities are very few. At Las Palmas the usual treatment is administration of an antihistamine and in severe cases sometimes of morphine. The antihistamine may be applied in a cream and, in severe cases, given by mouth also. Rest and careful observation for at least twenty-four hours is advocated.¹ The first-aid treatment commonly given is the application of urine, picric acid, or ammonia to the skin, and rubbing the skin with sand, but it is questionable whether such treatment could be of much use.

Physalia is a hypertrophied larva which acts as nurse or carrier to thousands of buds of other larvae as well as of minute, sexual, medusa-like adults. It maintains itself very successfully, and has no need to search for food. The flying fish on which it chiefly subsists get caught frequently in the long trailing tentacles as the animal is drifted along by wind and surface currents at 45 degrees to either left or right of the down-wind current. J. H. Welsh² has recently obtained evidence that extracts of its tentacles contain 5-hydroxytryptamine, a potent cause of pain and a known releaser of histamine. It is a vasodilator, and has been detected also in wasp venom and in the stinging hairs of nettles. In addition he found evidence for the presence of two or more quaternary ammonium bases. There is hope for a more certain identification of the mixture of substances contained in the animal's stinging capsules now that J. H. Phillips⁴ has introduced an improvement on the old practice of using crude extracts of tentacle. It is based on maceration of the tentacles in sucrose,

separation by centrifugation of the capsules, and their subsequent discharge. Chromatographic analysis of the hydrolysates from material injected into the prey of the sea-anemone *Metridium senile* suggested that it was a mucoprotein with either adsorbed or free hydroxyindoles, one of which resembles bufotenine. Some of the effects caused by injection into various animals of crude extracts of cnidarian tentacle are: burning pain at the site of contact, urticarial weals, somnolence, paralysis, anaesthesia, digestive disturbance, prostration, respiratory interference, anaphylactic shock, and in small animals even death.

ACUTE HAEMORRHAGE FROM PEPTIC ULCER

Manifest haemorrhage from chronic peptic ulcer occurs at some time in 25% of cases,¹ and is the most frequent complication of the disease. In the earlier years of this century patients with bleeding peptic ulcer were treated by sedation with morphine, rest, and starvation. Nowadays treatment is governed by the principles of early feeding, rehydration, and blood transfusion, with surgical intervention in selected cases. A major factor influencing the immediate prognosis is the severity of the haemorrhage.² When the loss is small and non-recurrent, mortality is exceedingly low, and rapid recovery follows bed rest, ample oral fluids, and a bland type of diet. In about a third of cases³ the bleeding is severe, recurrent, or continuous; its severity can best be assessed by estimation of the plasma volume.⁴ Even so, as much as half of the circulating blood volume may be lost in a short time.¹ Death under those circumstances usually results from anoxic heart failure, or from coronary or cerebral thrombosis, and even if the patient does recover he runs the small but appalling risk of blindness from optic atrophy.

The first 72 hours are critical for the patient who has severe or continual bleeding. The aim in blood transfusion should be the replacement of the quantity estimated to have been lost.⁴ In the elderly patient with associated cardio-respiratory disease the administration of packed red cells diminishes the risk of overloading the circulation and is preferable to giving whole blood. But blood transfusion does not increase the risk of recurrent bleeding,^{4,5} and the theoretical danger that it may dislodge the clot from the aperture in an arterio-

sclerotic vessel can be disregarded, for the gastric arteries are rarely involved in generalized arteriosclerosis.⁶ Sedation is usually, but not invariably, required. Intramuscular phenobarbitone is to be preferred to morphine, which, apart from its occasional emetic effect, can be lethal to emphysematous patients.⁷ Liberal oral fluids may be allowed from the outset. Although some prefer to give milk in small, frequent feeds or by intragastric drip,⁸ it should not be overlooked that the immediate need of the patient is for salt and water,⁹ best given in the form of $\frac{1}{2}$ N saline flavoured with fruit juice. Oral fluids are better tolerated if a small-bore stomach tube is passed into the stomach on admission¹⁰ and the fluid content aspirated. This often relieves nausea, and is particularly useful should operation be necessary later. Further, examination of hourly aspirates is often of diagnostic value,¹¹ and may give early warning of recurrent haemorrhage.

Surgical intervention will be required in about 10% of all cases.¹² The most important indications for it are continual or recurrent bleeding from a known chronic peptic ulcer, especially when abdominal pain persists after the initial haemorrhage.¹⁰ The experience of J. D. Stewart and his colleagues¹³ is of special interest. Their series consisted of patients with massive bleeding who required blood transfusion and operation, and the average age of the patients was higher than usual. Half of them had associated disease, especially coronary atheroma and emphysema, which were present in three out of four who died. The mortality rate was 3% below the age of 50, and 18% above this age: this accords with general experience. In their view advanced years and associated disease were an indication for, rather than a deterrent to, operative treatment. The late prognosis has been studied by A. B. Chinn and colleagues,¹⁴ who noted that within five years of the "index" haemorrhage 31% of ulcer patients had sustained a second one, while of those who survived a further five years recurrent bleeding had occurred in 64%. These findings underline the fact that recurrent haemorrhage is one indication for elective operative treatment.

Multiple acute peptic ulcers are said to account for about 20% of cases of upper alimentary haemorrhage,¹⁵ and pose a special problem, which is mainly one of diagnosis. Bleeding from gastric erosions is sometimes inferred if there has been no previous dyspepsia, but this negative information is of limited value in the individual case, since a small group of patients with chronic peptic ulcer present with haemorrhage as the first clinical manifestation.⁹ Barium-meal examination is frequently impracticable in the severely anaemic subject. Gastroscopy after lavage may sometimes reveal the source of the bleeding, and is best performed in the anaesthetic room pre-operatively.⁷ Fortunately, the principles of treatment remain the same. When multiple erosions are strongly suspected as a source of bleeding, the gastric instillation of styptic agents has its advocates,¹⁶ but should not be performed at the expense of other measures. Again, if bleeding continues or recurs, partial gastrectomy is indicated; any lesser operation, including laparotomy alone, is futile.¹⁷

THE AGED IN THEIR OWN HOMES: A FURTHER SURVEY

BY

H. D. CHALKE, O.B.E., T.D., M.R.C.P., D.P.H.
Medical Officer of Health, Camberwell

In 1950, in two Metropolitan boroughs, Lewisham and Camberwell, a preliminary survey was made of households that were being assisted by the domestic help service because of general illness. This survey aimed at obtaining a general picture of the severity of the problem of home care of the aged and chronic sick. An account of the findings (Chalke and Benjamin, 1951) stressed the need to provide domestic assistance before the old people living alone became bedridden and helpless, and before infirmity, aggravated by lack of assistance, had become irreparable; it emphasized the importance of obtaining better co-operation between the many voluntary and statutory bodies concerned in this problem; it indicated that home care was not only cheaper than hospital care but was vital to the morale of the old person; and it drew attention to those needs of the aged which are not met by the domestic help service—the need for real help with laundry and the need for companionship, especially at night.

A further survey undertaken in the same area in the latter months of 1951 (Chalke and Benjamin, 1953) underlined these findings and provided more detailed information of the conditions in which the old people lived.

To bring the picture up to date a further survey was carried out in the same area and of the same types of household, in 1956. A systematic sample (1 in 5) was taken

of all households containing persons over the age of 65, and assisted by the domestic help service. It must be emphasized that, as in previous surveys, we are dealing *ex hypothesi* with extremity of the spectrum of social needs of old people. By the same token, however, they are the needs that press heavily on the resources of public and voluntary bodies. There were 413 households in the sample, containing 483 people aged 65 (Table I). Twelve were aged

TABLE I.—Age and Sex of Patients

Age Groups	Males		Females		Total

90 or more; the oldest was aged 98. As in previous surveys more than half the people were concentrated in the age group 75-84, and a large proportion, in this case three-quarters (as in 1950, but rather more than in 1951) were women. The excess of women arises from their greater longevity; of the general population at these ages women constitute 60%, and among the widowed they form 76%.

The disabilities existing among members of the households were recorded (Table II), distinction being made between those ailments severe enough to require treatment and those which were not being treated. Naturally, in such a segment of the population, most of the complaints, whether treated or not, related to degenerative conditions—heart or other circulatory disease, high blood pressure, cerebral vascular lesions, and chronic bronchitis as a condition so often associated with degeneration. There were cases of diabetes, a few advanced cases of cancer, and a few elderly tuberculous. There were larger numbers with rheumatism or with a whole complex best described by the term "senility," but only one was on the waiting-list of a hospital; only two

had recently been discharged from hospital treatment. Hospital treatment is a very small part of the problem; for the rest it is the familiar picture of chronic sickness—the lesser illness but the major worry of restricted movement, pain, and discomfort—requiring some regular nursing and medical care (four-fifths were receiving some kind of treatment), but most of all constant companionship and encouragement.

The degree of infirmity was measured. Only two males and nine females (3% of the total) were permanently bedridden, 10% were bedridden intermittently, while 87% were ambulant. Of the men 18%, and of the women 33%, were confined to the house by restriction of movement; this included a third of those who were ambulant at home (Table III). The percentage of bedridden persons is very much

TABLE III.—Degrees of Infirmity

Total Persons	Ambulant		Bedridden, Intermittent		Bedridden, Permanent
	Not Confined to House	Confined to House	Not Confined to House	Confined to House	
Males	119	94 (79%)	9 (7.6%)	2 (1.7%)	2 (1.7%)
Females	364	229 (62.9%)	89 (24.4%)	8 (2.2%)	8 (2.2%)

lower than when the last survey was undertaken (1951); this is no doubt associated with the increased hospital and intermediate accommodation now available. As in the last survey, cases of incontinence were rare (only one man and two women): the general practitioner was visiting about 80% of the old people regularly, usually less often than weekly. Only a seventh were under nursing care by the district nurse.

With regard to chiropody it was found that 8% of men and 12% of women were receiving foot treatment, and a further 4% of men and 2% of women were in need of such treatment though not yet receiving it (Table IV). These

TABLE IV.—Chiropody

	Males		Females	
	No.	%	No.	%
Chiropody obtained	9	7.6	43	11.8
" required	5	4.2	8	2.2
" not required	105	88.2	313	86.0
Total	119	100.0	364	100.0

proportions are lower than in the previous surveys, especially so for the proportions requiring but not receiving treatment, which were 9% for men and 11% for women in 1951. The situation therefore appears to have improved. It is significant that of those who had received chiropody nearly a half had obtained it privately.

Social and Recreational Life

A tenth of the men and a quarter of the women were alone at night (Table V). These proportions also are much smaller than in 1951 (a fifth of men and a third of women). If representative these figures indicate that some progress has been made in dealing with the most serious need.

TABLE V.—Loneliness

Age Group	Total Males	Males Living Alone		Total Females	Females Living Alone	
		No.	%		No.	%
65-74 years	33	1	3.0	130	32	24.6
75-84 "	71	9	12.7	188	45	23.9
85+ "	15	2	13.3	46	7	15.2
Total	119	12	10.1	364	84	23.1

Inquiries were made regarding the extent to which these old people were visited. Some two-thirds of both men and women received visits from near relatives, and these proportions tallied with the numbers of near relatives who were separately alleged to be living in London. Friends as visi-

tors were fewer in number, covering rather less than half of both sexes. Churches in the main managed to cover only those who were members of church organizations and came to notice in that way (Table VI).

TABLE VI.—Social Life

No visitors	4	14	28	73	—	8	32	26.9	95	26.1

As before, comparatively few of the old people claimed to have any link with outside social organizations such as old people's clubs. About three-quarters (four-fifths in 1951) of both sexes had no such link, and, since most of these people were ambulant, there appears to be virtually no diminution in the need for further development of clubs, which must be an integral part of any scheme for the care and welfare of the aged (Table VII).

TABLE VII.—Outside Social Activities

Age Groups (Years):	65-74		75-84		85+		Total			
	M	F	M	F	M	F	No.	%	No.	%

Note: Some multiple answers in some cases and hence percentage totals add to more than 100.

How did these people amuse themselves? It was found that reading (60% of both sexes) (5% were blind or nearly so, 70% sought advice for failing sight, and 4% could not read), and radio (70%) were the mainstays. The proportion of women who occupied themselves with needlework or knitting (14-23%) was small, partly, no doubt, because of failing sight. Generally there was still little mention of home activity, and, though possibly there was some understatement due to diffidence, there is an indication that these people have drifted into inertia from which they need to

be extricated by stimulation of interest. Cinema-goers were still few (13% of men and 7% of women), but television sets were not so rare as previously (11% of men and 13% of women), compared with 3% for both sexes in 1951 (Tables VIII and IX).

Assistance and Meals

The total volume of domestic assistance given to the household either by home helps or by relatives and friends was examined. The home helps do general cleaning in all cases, some shopping (40% of households), a little cooking (5%), and some light washing (25%); carrying coals and lighting fires form an important duty. The average period of service per week was 4.8 hours (5.8 in 1951), but assistance from relatives and friends was limited, on the whole, to shopping and companionship, which was extended to about two-fifths of the households.

In those instances where relatives existed but gave no assistance, inquiries were made for the reason of this failure to help. Nearly one-half of these relatives lived too far away, one-third were too preoccupied with their own affairs, and one-tenth were ill or too old. Only one of them could but would not help.

An attempt was made to assess the additional services that were most badly needed. Most of the "grumbles" were economic—the need for higher pensions, cheaper fuel, milk, transport. Only a handful requested more home-help hours or week-end service. Some asked for more visitors or to be taken out, and it was evident from some of the replies that many of those confined to the house were lonely, and would have been most grateful for an occasional car outing or a visit to a club. Only a dozen had difficulties (mainly a desire to get on a ground floor) of housing accommodation. Two-thirds of the old people had no "grumble" at all.

An important aspect of the care of old people in their homes is the preparation of meals. Meals were prepared with some assistance by the home help in 48% of cases. Fortunately in only 36 of these would withdrawal of the home help have resulted in a failure to obtain any meals. The small number of households on which health visitors were calling is a matter for surprise.

Housing, Money, and Costs

With regard to housing, it was found that 23% of the households were in houses, 36% in flats, and 41% in rooms in divided accommodation (these proportions are similar to those previously recorded). In only nine dwellings were sanitary defects reported. A more important feature was that in 29 households (7% as in 1951) there was difficulty of access—that is, the old person was living in the upper floor of a building and the climbing of the steps was a deterrent to going out of the dwelling.

It is of interest and importance that 49% of households had been resident in their present accommodation for more than 10 years, and 18% for more than 30 years. These deep roots and the obvious affection for the existing environment complicate the problem of rehousing, although it is evident that much improvement could result from readjustments of existing accommodation.

In only 15% of households was there a definite shortage of money. For the domestic help service 27% of the households paid the charges in full, 7% made part payment, and in 66% the cost had to be borne by public funds. This is an improvement from 1951, when 81% were wholly subsidized and 14% partly assisted.

Discussion

On the whole the general position of the old people seems to have improved slightly since 1951; there is no doubt that contributory factors have been better liaison with hospital geriatric departments, a greater emphasis on rehabilitation, an expansion of the home-help service, and closer co-ordination of effort between the statutory and voluntary agencies concerned. The employment of an

assistant medical officer as a co-ordinator and liaison officer has played an important part.

Although there has been progress, a great deal remains to be done. Rehousing problems are difficult to solve, more long-stay accommodation is required, and there are not enough clubs, especially for the frail and less mobile. Inertia in the home has to be combated, and disabilities detected early—there is ample evidence that "examination-in-health" clinics can fulfil an important function. It appears that little more help can be expected from relatives, and there is an urgent need for more volunteer visitors, especially in the evenings and at week-ends. The home-help service is playing a part which cannot be measured in terms of hours of work, or domestic duties performed—it goes far beyond that, and no statistical survey can give a complete picture of the assistance and companionship it provides both during and after official visiting hours.

It will be noted that the majority of those questioned had no complaints to make—although many might well have done so. A number of the ambulant wished for reduced prices in public transport, and those in the older groups for cheaper coal. A few wanted milk at reduced prices and higher pensions. There was ample proof of the desire to preserve independence: five persons over 90 and many more in the 80's (including some who were totally blind) lived alone and prepared their own meals, and with a little domestic help they were far better off in their own homes than anywhere else. Unfortunately, some of those who needed it badly did not take kindly to domestic aid, and they would have been more suitably accommodated elsewhere; in cases of this nature there were occasional complaints from the other occupants of the house. In general, however, the survey reaffirms the value, financial and otherwise, of a domiciliary service for old people, and suggests ways in which it should be expanded.

My thanks are due to Mr. B. Benjamin, statistician, General Register Office, for his statistical advice. I am also indebted to the staffs of the Divisional Office (Div. 7, L.C.C.) and the Camberwell Public Health Department for their assistance in compiling the tables, and to the home-help organizations, Division 7, for the considerable field work involved.

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE

[FROM A SPECIAL CORRESPONDENT]

The 119th annual meeting of the British Association, which took place from September 4 to 11, was the first to be held in Dublin for almost 50 years. The president, Professor P. M. S. BLACKETT, F.R.S., who has been a frequent visitor to the East, described the ever-widening gap which technological advance is opening between the *modus vivendi* of peoples of these regions and those of the West. He outlined measures which would help the newly autonomous nations of Asia to improve their standard of living.

The Nervous System

Sir LINDOR BROWN, F.R.S. (department of physiology, University College, London), introduced the first two sessions of the Physiology Section by outlining, in his presidential address, modern knowledge of chemical transmission at nerve endings. He pointed out how our extensive information on acetylcholine metabolism contrasts with our ignorance of the method of formation and destruction of noradrenaline and adrenaline. It was not necessarily valid to extrapolate the phenomena of cholinergic transmission to those of adrenergic transmission. The metabolism of adrenaline and noradrenaline was described further by Dr. H. BLASCHKO (department of pharmacology, Oxford), who suggested that there are five stages in the synthesis of adrenaline,

with noradrenaline as its immediate precursor. This pathway of synthesis was probably followed in the neurones of the sympathetic nervous system as well as in chromaffin tissue. It had been possible, by using the ultracentrifuge, to isolate from the adrenal medulla granules containing comparatively large quantities of the catechol amines (adrenaline precursors), together with adenosine triphosphate. The storage of these substances in close proximity provided a probable explanation for the rapid mobilization of adrenaline when the cell was stimulated. Dr. J. S. GILLESPIE (department of physiology, University College, London) discussed the fate of adrenaline at nerve endings. He showed that the theory that amine oxidase is responsible for the destruction of adrenaline-like substances is open to serious doubt, and suggested instead that these substances are inactivated by combination with the tissues upon which they act.

The role of acetylcholine in the transmission of nervous impulses in the central, as opposed to the peripheral, nervous system was discussed by Dr. CATHERINE HEBB (Institute of Animal Physiology, Cambridge). Neurones second in the chain connecting the sense organs to the brain were always cholinergic. There was also a high proportion of cholinergic neurones in the caudate nucleus and rhinencephalon, but the majority of circuits in the human cortex were probably non-cholinergic. Dr. PAUL FATT (reader in biophysics, University College, London) had worked on inhibitory action in crustacean muscle. Impulses in the excitatory nerve fibre increased the voltage existing between the inside and outside of the muscle fibre; impulses in the inhibitory nerve reduced this voltage change. Close similarities had recently been shown to exist between these mechanisms in crustacea and excitatory and inhibitory actions in the spinal cord of mammals. It seemed that the effect of the inhibitory impulse on the nerve cell was to increase its permeability to wards certain ions. This suggestion also applied to the heart, where Dr. Fatt's colleague, Dr. O. F. HUTTER, showed that the inhibitory effect of the vagus was to increase the membrane permeability to the potassium and possibly also the chloride ion.

The Zoology Section also devoted two sessions to neurological function. The president of the Section, Professor J. Z. YOUNG, F.R.S. (department of anatomy, University College, London), was prevented by illness from attending. His address, which was read by Professor E. J. W. BARRINGTON (department of zoology, Nottingham University), concluded with a plea for more research correlating neuroanatomy with behaviour. This plea was met by several subsequent speakers, including Dr. H. P. WHITING (department of zoology, Bristol), who had made such studies in trout, dogfish, and the lamprey, and Dr. M. J. WELLS (fellow of Trinity College, Cambridge), whose subject had been the octopus. Dr. Wells said that the octopus could learn to discriminate between different surfaces with its arms. The discrimination was made by distinguishing the characteristic frequencies that the texture produced in the afferent nerves. Dramatic support for the theory that nervous conduction is carried by means of frequency modulation came from Dr. W. K. TAYLOR (department of anatomy, University College, London), who described an electronic device which by using frequency modulation performed the functions of part of the brain. In the machine the cones of the retina were represented by photoelectric cells, and a microphone served as an ear. The device was able to read six letters of the alphabet and to integrate simple aural and visual stimuli; it also had a voice under the control of four sets of frequency-modulated impulses, all within the physiological range of frequencies. Dr. Taylor played a recording of this voice saying the words "British Association" in intelligible, if guttural, tones.

Aetiology and Biology of Cancer

The proceedings in the Chemistry Section were opened by its president, Dr. J. W. COOK, F.R.S. (vice-chancellor, Exeter University), with a review of current knowledge of

the aetiology of lung cancer. As a non-statistician he was prepared to accept the statistical evidence that a causative relationship existed between smoking and lung cancer, and was also impressed by the evidence incriminating atmospheric pollution. Turning to the experimental work that had been done, he said that the carcinogen 3:4-benzpyrene was known to occur in tobacco tar, but its concentration was so low that it was unlikely to be the sole carcinogen, and the effect of other substances such as arsenic and radioactive potassium, as well as the recently discovered 3:4-9:10-dibenzpyrene, was being studied. The quantity of carcinogens was not the only factor, though, for tar from tobacco smoked in pipes caused twice as many tumours in the skin of mice as condensate from cigarette smoke, yet it had been substantiated that pipe smokers were less liable to lung cancer than cigarette smokers. Dr. Cook felt that the importance of 3:4-benzpyrene in atmospheric pollution had been overestimated also, for potent carcinogenic tar fractions had been obtained which seemed free of benzpyrene, and there was evidence that the soot found in the lungs of town-dwellers retained its benzpyrene in a firmly bound, innocuous state.

The cytology and pathogenesis of cancer were later discussed at length by the Zoology Section. The sessions were introduced by Professor A. HADDOW (director of the Institute of Cancer Research, London), who pointed out that, although carcinogens had been shown to act directly on the cell nucleus, changes had also been detected in the cytoplasm and surface of cancer cells. Several methods of investigating the surface of cancer cells were subsequently described. Using the electron microscope Dr. E. H. MERCER (Institute of Cancer Research) had detected an intercellular cement in healthy tissue. In some anaplastic tumours, however, this cement was partially absent and intercellular gaps were common, a finding which suggested that weakened intercellular adhesion might be a property of such cells. A closely analogous conclusion was drawn by Dr. M. ABERCROMBIE (reader in embryology, University College, London), who said that the invasive property of the malignant cell was due to its motility. In healthy adult tissue motility was seen in fibroblasts during wound repair, where new cells were directed towards the space of the wound by the inhibitory powers of the surrounding cells. On the other hand the malignant cells of a sarcoma were able to overcome these inhibitory powers and thus spread through intact healthy tissue. Differences between the surface properties of cancer cells and healthy cells had also been detected by Dr. and Mrs. G. C. EASTY (Institute of Cancer Research), using immunological techniques. The treatment of cancer was touched upon by Professor E. S. HORNING (Institute of Cancer Research), whose subject was hormones and cancer. He pointed out that, although hormone treatment of certain neoplasms of endocrine glands, or of organs under endocrine control, was encouraging, it should be looked upon as palliative, for it was effective only in a certain proportion of cases. Even if treatment were successful at the outset, the growth commonly ended by shaking off therapeutic restraint and becoming autonomous. A possible explanation for this phenomenon lay in the statement by Professor P. C. KOLLER (Institute of Cancer Research) that the component cells in a neoplasm are rarely homogeneous in their chromosome content. Therefore a few which were not controlled by the hormones might finally come to dominate the majority that were.

Industrial Psychology and the Psychology of Ageing

In his presidential address to the Psychology Section Dr. H. G. MAULE (lecturer in applied psychology, London School of Hygiene) reviewed the development of the science of industrial psychology, starting with the appointment of the first factory inspectors over 110 years ago (in the days of the 69-hour week). He emphasized that in the average year nowadays 280 million man-days are lost through sickness as compared with 18 million man-days through accidents, and a paltry three and three-quarter million man-days through

industrial disputes. Of the time lost through sickness, as much as one-third might be due to such psychological causes as a man being employed in a job to which he was not suited, or to a lack of comradeship and team spirit among workers. Dr. Maule's theme was developed by Dr. C. B. FRISBY (National Institute of Industrial Psychology), who said that the adjustment of the worker depended on his achieving a balance against various environmental pressures. The proper design of machines should include consideration of the worker's convenience and comfort, and Dr. Frisby suggested that the training of engineers who were to design such machines should include a study of human behaviour. The importance of a system of wage incentives and bonuses which could be easily and fully understood by the workers was stressed by Miss SHIMMIN and by Mr. LESLIE BUCK, both of the Medical Research Council's industrial psychology unit.

In a session on the psychology of ageing Mr. D. B. BROMLEY (lecturer in psychology, Liverpool) reported experiments which indicated that the rate of creative intellectual output decreases after a peak period at 30-35 years of age, a suggestion which confirmed the work of other authors. It was not only that older people had fewer good ideas, but they were also apparently less able to discern the worth of the ideas they did have. Mr. Bromley concluded, however, with a caution that present research methods in this field are unsatisfactory and findings sometimes difficult to appraise.

Anthropology and Blood Groups

The Aran Islands have long been looked upon as the last outpost of Celtic culture and language. Historians, however, have suggested that the inhabitants are not pure Celts because garrisons of English soldiery on the islands intermarried freely with the inhabitants, a suggestion which found support in the anthropological survey of Hooton and Dupertuis in the 1930's. Dr. E. HACKETT (reader in clinical pathology, Dublin), in a study of the distribution of ABO and Rh blood groups, brought further support for this view by showing that the Aran Islanders bear a much closer resemblance to the population of the eastern counties of England in this respect than to the population of the western portion of the Irish mainland. He had also found the "English" pattern of blood-group distribution among the people living in the counties which used to make up the Pale.

Taeniasis in Britain

Between 3% and 6% of domestic cattle in the British Isles are infected with *Taenia saginata*, according to Dr. P. H. SILVERMAN. He thought the source of their infection was either the drinking of water directly polluted by human sewage or the contamination of pasture by the droppings of seagulls which had consumed human excreta at seaside outfalls. Dr. Silverman pointed out that a significant amount of meat for human consumption was never inspected, and stressed the need for a comprehensive meat inspection service. It was also important that medical practitioners should be aware of the problem and that methods of disposal of sewage, particularly at the seaside, should be reviewed.

Underwater Swimming and Diving

On the final day of the meeting the Physiology Section considered some of the hazards of deep-sea diving and prolonged underwater swimming. In his introduction of the subject, Dr. H. J. TAYLOR (Royal Naval Physiological Laboratory) pointed out that the dangers were twofold: first, that any gas, physiological or inert, had irritant or toxic effects if breathed at high pressure; and, secondly, decompression. Oxygen respired at a pressure of over two atmospheres induced epileptiform seizures, but the Royal Navy had lately achieved some success in a search for a drug to increase resistance to this effect. The mechanical and technological

methods which are being used to improve man's efficiency whilst working under water were described by Captain W. O. SHELFORD, R.N. (retired), of Messrs. Siebe, Gorman and Co. By using a new closed-circuit system operated from the surface it was now possible for a diver to operate at a depth of 600 ft. (183 m.) below sea-level.

Future of the B.A.

In a final press conference the president, Professor BLACKETT, intimated that the British Association hoped to extend its activities. An approach made to a few major industrial concerns for additional funds had met with an encouraging response, and with these financial resources in view plans were being made for a series of short interim meetings during which problems of urgent topical importance to scientists would be discussed. There was also a prospect of a special meeting for young people being held next year.

MENTAL HYGIENE

The European League for Mental Hygiene and the World Federation for Mental Health held their annual conferences in Copenhagen from August 11 to 17.

The European League, under the presidency of Professor HANS HOFF (Vienna), discussed the mental hygiene of the family and the young child. Professor Hoff, in his opening paper, strongly supported the view that the normal development of a child depends on its mother's attitude towards it. Children born or conceived during the occupation in Austria, and in Germany the so-called *Besatzungskinder*, were in danger of both social and maternal rejection. However, the great majority of mothers, even those who had been raped, showed a great love for their children and refused to have them adopted. In Germany, where there were some 40,000 mothers with *Besatzungskinder*, only 118 mothers had consented to be separated permanently from these children. Professor Hoff felt it was essential to have an adequate medical advisory service to deal with the psychological difficulties of all young mothers, but especially the unmarried ones. The desire for abortion needed to be dealt with from the psychological angle as well as the physical. In Austria therapeutic abortion was permitted if the mental state of the mother was so disturbed as to involve a risk of suicide.

Dr. DORIS ODLUM, the immediate past president, then gave an account of the medical and social services for the family and young child in England and Wales. Discussing the psychological pros and cons of confinement in the home or hospital, she said that on the whole she thought home confinement was better for the baby, the other children, the husband, and in many cases for the mother also, as it did not lead to so much disturbance of home life and family relationships; but, if the home background was unsuitable, or the birth likely to be difficult, hospital confinement was preferable. Education and preparation for parenthood were increasing and from the physical angle were fairly adequate, but the psychological aspect was still not fully appreciated. The importance of the father's role had only recently been realized, and facilities for educating fathers were now increasing.

Professor REITER (Denmark) said that, although his country had a high standard of living and one of the best systems of social service in the world, it also had the highest incidence of divorce and suicide. There was considerable unrest among adolescents, and illegal abortion was rife, but a new law had recently been passed which enabled a woman who wished to terminate her pregnancy to have her case investigated by a special tribunal. He felt that they were in danger of creating an abortion neurosis. Alcoholism was also a serious problem, with a relatively high incidence of alcoholic psychoses. This suggested that

security and material welfare did not necessarily lead to psychological stability or human happiness.

A lively discussion followed. It was resolved that in view of the importance of the subject a questionnaire should be sent to all the national leagues of mental hygiene, asking them to report on the social services for the family and young child in their countries and the mental health problems which had arisen in relation to them. A summary of these reports would be prepared and presented at the League's next annual conference in Vienna in September, 1958.

World Federation for Mental Health

"Problems of Growing Up in a Changing World" was the subject for debate at the meeting of the World Federation for Mental Health. Dr. MARGARET MEAD, the retiring president, opened the meeting with a paper on "Growing Up in Different Cultures." Growing up in normal families and in problem families were considered by Dr. DONALD BUCKLE (W.H.O.) and Dr. PAUL SIVADON (France) respectively. Dr. ERIC STROMGREN (Denmark) read a paper on the genetic aspects of mental health, in which he discussed the inheritance of Huntington's chorea and schizophrenia. The differing cultural patterns of separate ethnic groups within the same nation, and between nations, were reviewed by Professor OTTO KLINEBERG (U.S.A.) in a paper entitled "Growing Up for Co-operation or Conflict." Some of the problems of adolescence were discussed by Dr. ANNE AUDEOUD-NAVILLE (Switzerland) in a paper on puberty and sexual morality, and Professor TSUNG YI-LIN (University of Taiwan, Formosa) spoke on delinquency in Chinese society. In addition to the plenary sessions two special sessions were held: on the work of the United Nations in relation to the mental health problems of changing cultures, and on mental health and the work of the United Nations in the field of crime prevention and the treatment of offenders.

At the administrative session Dr. BROCK CHISHOLM (Canada) was inducted as president by Dr. MARGARET MEAD. At next year's conference in Vienna the subject for discussion will be "The Mental Health Problems of Refugees."

Preparations and Appliances

A COMBINED COMMODE AND VISITORS' BEDSIDE CHAIR

Mr. MCKIM MCCULLAGH, F.R.C.S., F.R.C.O.G., writes: Bedpan sessions are humiliating, undignified, and uncomfortable, and often fail in their object because of the mechanical difficulty of emptying the bowel and bladder whilst lying on one's back, poised on a bedpan on a soft bed. The bedpan has then to be removed by the nurse after cleaning the patient, and carried out covered by a small sheet to the sluice-room, in view of the ward patients and others who may be present. Surely these humiliating and unsightly duties can be abolished or reduced to a minimum.

With this object in view I have designed, with the aid of Messrs. Thackray, of Leeds, a commode chair which I think will be an aid to nursing and a contribution to the comfort and care of bed-patients, both medical and surgical. This structure is a tubular tub chair with a silent wheel on each front leg, a metal loop handle on the top of the back of the chair, a seat with metal holding-hooks, which can be lifted off, exposing a "perfection" bedpan in a rubber-covered metal cradle. This bedpan is so well hidden that visitors do not object to using the chair as a seat. The chair moves on its two front wheels, when it is eased off the ground by lifting the back of the chair with the loop handle. It is readily wheeled to the bedside and put in position. The seat is lifted and the patients are helped out on to the chair on one

or two occasions only; they do their own toilet and clamber back into bed. The nurse comes back at her own convenience, replaces the lid, and wheels the chair off to the sluice-room—a much more dignified procedure than carrying bedpans face-high. In the sluice-room the bedpan is emptied, washed, and sterilized, and a clean bedpan is placed in the chair.

The medical advantages to the patient of this chair are that the patients like it, as it is so comfortable. Cardiologists have investigated the strain caused by defaecation, and have found it so lessened by using a commode that they are now forbidding the use of bedpans. Ward nurses observe that post-operative retention of urine is less frequent and that the rectum, and vagina in the case of female patients, are more efficiently emptied of faeces and clots if this commode is used. The cleanliness of the bedpan with its narrow metal front edge is nearer gap-seat perfection than is the cleanliness of the wooden commode chair, which is so difficult to move, and its function is so obvious that visitors cannot be asked to sit down on it. Few matrons nowadays condone the use of wooden commodes, because of possible cross-infection.

Labour ward sisters approve of the use of this chair during labour; sitting on it allows the vertical weight of 7 or 8 lb. (3.2 or 3.6 kg.) to press on the os uteri and help its dilatation. By leaning forward the patient can press downwards on the fundus, during a pain, with her diaphragm. There is no danger of injury to the foetus if it is born unexpectedly into the bedpan, as the distance is short.

The most valuable aid of a bedside commode is that it encourages a patient to get in and out of bed soon after operation, which is the best possible post-operative exercise. To find a patient in a toilet with the door locked, and dead from pulmonary embolism several days after operation, is not unknown. Using a bedside commode early would lessen mental worry and physical inconvenience, especially for these slight-pyrexia patients who are so apt to develop embolism or thrombophlebitis.

I have been planning this commode for several years past, and feel that at last it is worthy of trial by those interested. I find it is looked on by nurses and sisters as a labour-saving device in ward work, as patients are encouraged to do more for themselves, and to do it earlier.

The chair can be procured from Messrs. Chas. F. Thackray, Ltd., Park Street, Leeds, or from their London Branch in Welbeck Street, W.1.

The Association of Psychiatric Social Workers has published in book form a symposium, *The Boundaries of Casework*. The book consists of 10 papers which were read at a residential refresher course held by the association in 1956. The symposium comprised five sections: psychiatric social work and social casework in other fields; psychotherapy and social casework; supervision, education, and social casework; social research and social casework; the caseworker, the welfare officer, and the administrator in the social services. In addition to the papers a summary of the discussion is included. *The Boundaries of Casework* is obtainable from the Association of Psychiatric Social Workers, 1, Park Crescent, London, W.1, price 7s. 6d. net.

INTERNATIONAL UNION OF THE MEDICAL PRESS

THIRD CONGRESS IN LONDON

The Third Congress of the Union Internationale de la Presse Médicale was held at B.M.A. House from September 13 to 15 under the joint auspices of the Union and the British Medical Association. The president of the Congress was Dr. HUGH CLEGG, Editor of the *British Medical Journal*. Some 120 medical editors from Europe, Africa, the Near East, and the American continent attended the Congress, many accompanied by their wives. The subjects chosen for discussion at the eight plenary sessions were all concerned with the editing and production of medical journals: they included such topics as the relationship between editor and author, illustrations, the place of the specialist journal, multilingual summaries, and editorial responsibility for advertisements. In addition there was a business meeting, and a full social programme for members of the Congress and their ladies.

OPENING ADDRESS

In welcoming colleagues and friends from the 24 countries represented at the Congress, Dr. CLEGG said they would all deeply regret that illness had made it impossible for Professor M. Loeper, the president of the Union, to be with them. They greatly appreciated the effort which Professor Loeper had put into the formation of this society of medical editors to which he was so firmly attached. The Congress greeted this statement with acclaim, and it was agreed unanimously to send Professor Loeper a message expressing regret at his absence and hopes for his restoration to health. Dr. Clegg cordially welcomed Dr. André Plichet, editor of the *Press Médicale*, whom Professor Loeper had asked to take his place.

Dr. Clegg recalled that an international union of medical editors had come into being in Paris in 1900 when 16 countries constituted its membership. The first world war brought it to an end. However, in 1924 there was formed the Federation of the Latin Medical Press, but that, too, had not been on its feet very long before another world war came along and knocked it down. For the third time, out of the ashes of the two previous organizations, a phoenix arose in Brussels in June, 1953, in the form of the present Union.

The International Union existed to study, represent, and to defend the material and moral interests of the medical press, to promote friendly relationships between those representing the medical press of different countries, and to maintain scientific and literary standards in medical periodicals. The unit of membership was usually the national association of the medical press: most European countries had such associations. There was, however, provision in the Articles of the Union for representation of medical journals in those countries which had not taken that formal step. On those two bases of membership there were now some 45 members of the I.U.M.P. Medical publishers came into the membership of the Association of the Medical Press in Europe, and in fact he knew how valuable had the help been to the Union of the great publishing firms of Masson in Paris and Minerva Medica in Italy. Whether or not some similar association of the medical press would be formed in Britain was still very much an open question.

Dr. Clegg referred to the second edition of *World Medical Periodicals*, to be published on October 1. This edition had been brought out under the editorial guidance of a joint committee of the World Medical Association and the International Union. One of the special objects of this valuable list of periodicals was to standardize the abbreviation of their titles on the basis of an accepted international code. Finally, Dr. Clegg thanked those who had helped in preparing for the Congress.

The preliminary proceedings were concluded by Dr. PLICHET, who read a message of good will from the president of the Union, Professor Loeper.

THE PRESS AND MEDICINE

"The Press and Medicine" was the theme of the first session. Dr. PLICHET (Paris), opening the discussion, said that however uncultured a man might be he, like everyone else, was now interested in medicine, just as formerly he would have been interested in presages and omens. There were many reasons for this. First was the instinct of self-preservation, dormant in everyone, which made those who read of a medical discovery immediately apply it to their own case, or to that of their family or friends. But, although this searching for medical information could be readily understood, there was a good deal to say about the way in which the facts were presented to the public.

Nowadays any newspaper, book, or film dealing with medical matters could be sure of an audience. Some newspapers were prominent offenders in presenting medical news which was distorted, dressed up, stressed the alarming aspects, or was associated with erroneous conclusions. Instead of limiting themselves to news concerning basic concepts of general health, proper feeding, and ethical standards, instead of concentrating on campaigns aimed at showing the disastrous results of alcoholic drinks, newspapers and television programmes reproduced operations which neither reader nor viewer could possibly understand. There were grounds for fearing that popularization would lead to a false kind of science, and that the patient would think that he knew more than his doctor and would want to control him, not to mention the possible incidence of hypochondria and nosophobia. Then, too, the physician could lose his importance and be replaced by drugs or instruments. Knowledge, intuition, experience, the art of diagnosis were replaced by a powder, by some product launched by a mighty publicity campaign. The miracle doctor was replaced by the miracle drug and by machines.

Was there a remedy for that false presentation of medical news? asked Dr. Plichet. In France they had sought it by approaching the medical correspondents of the daily papers in order to find ways of keeping the public suitably informed. First, however, they had had to overcome certain prejudices on the part of doctors. A joint committee had been established, with a membership drawn from newspaper medical correspondents, representatives of the Association of Scientific Writers, and representatives of the medical journals. That committee was supposed to meet every two months, but it might meet more often if some scientific or medical event warranted it. The way in which medical news was presented to the public had been improved by these meetings. There were less sensational headlines, less mistakes, less unbelievable statements in the newspapers, and on reading their newspapers medical men had less cause for irritation.

To enable newspapers to check agency stories, especially from abroad, the French National Association of the Medical Press, in conjunction with the Association of Scientific Writers, which had organized a similar service for science in general, had established a telephone information service. A list of doctors who had agreed to give medical information, free of charge, had been sent to the major newspapers. Those doctors either provided or verified information, and most of them were both consultants and acquainted with journalistic procedures.

Canadian "Code of Co-operation"

Dr. S. S. B. GILDER (Toronto: *Canadian Medical Association Journal*) said it was interesting to hear from Dr. Plichet that an increasingly liberal attitude towards the public press was being taken by the profession in France. That was the attitude which had been taken in Canada, and the results obtained were by and large very satisfactory. Earlier in the year a "Code of Co-operation" between organized medicine and individual physicians on the one hand and the press,

radio, and television on the other had been published. This "Code of Co-operation," published by the public relations committee of the Canadian Medical Association in co-operation with representatives of the news media, had been drawn up for the guidance of divisions of the Canadian Medical Association, its branch societies, and members. It was also a guide for the news media in the gathering and dissemination of medical news. It was not a code of censorship or suppression. It imposed on the participants certain duties and responsibilities. By its acceptance the news media had agreed to consult qualified sources for medical stories and to present fairly and accurately news thus gathered, in order to raise the public confidence in the quality of medical reporting. Doctors, for their part, had agreed to be available to the news media within the spirit and measure of the Code and to accept certain social obligations in the matter of health education of the public.

There were, of course, two aspects of the problem. In the first place there was the question of the right of an attending physician to release information about his patients; and there was the question of the general dissemination of the medical knowledge by members of the profession. The press code stressed the obligation of the attending physician to respect his patient's confidence and not to release news without the consent of the patient or of those authorized to speak for him.

As to the dissemination of medical news in general, problems might arise in two connexions. First, a physician might be asked to contribute an article to the press or for that matter might be asked to participate in a radio or television programme, or he might be asked to speak in public with the press present. Secondly, he might be asked to give a medical opinion on something. The question then arose in both situations whether an individual physician was justified in meeting the wishes of the press. In Canada the onus had been laid on the local medical society. Each local medical society had been asked in electing its officers to anticipate the needs of news media and to prepare for distribution to them a list of spokesmen in each field of medicine. Those spokesmen nominated by the medical society were the proper persons to give information to the press and to prepare articles or other communications for the information of the public. It was understood that once a man had been appointed by his local medical society to fulfil one of those tasks, he was automatically exempted from any charge of breach of the Code of Ethics or of advertising. In North America it was considered quite in order for spokesmen of local medical societies or speakers at scientific meetings to be named and photographed in news releases.

Press Bulletins in Austria and Germany

Dr. G. R. JOSEF (Vienna: *Österreichische Ärztezeitung*) said that the entire Austrian medical profession was kept regularly informed on all important questions by means of the *Österreichische Ärztezeitung*, which was issued by the Austrian Medical Association's own publishing firm. This journal appeared twice a month and was issued free of charge to the 13,400 Austrian doctors as well as to those Austrian doctors who were sent abroad. It contained no scientific papers but dealt exclusively with political, ethical, legal, and economic questions.

Since the beginning of the year the press office of the Austrian Medical Association had issued an information bulletin to daily and weekly newspapers, the *Ärzt-Presse-Medizin*. The aim was to make the public more aware of political, ethical, economic, and legal questions affecting the medical profession. In Austria many newspapers published a medical page once a week, so scientific questions were also occasionally discussed in the bulletin. Last year the press office began a so-called "press round-up" (*Presse-Rundschau*) on a weekly basis with the intention of providing further information to the various Austrian publications on medical and scientific questions. Thus individual journalists were invited to contribute serious and accurate news and

medical officials had the opportunity of acquainting themselves with the current press handling of specific problems. Extracts from the press round-up were included in the *Österreichische Ärztezeitung*.

Hitherto it had unfortunately not been possible to use the mass communications media such as broadcasting, although their political affairs were always referred to on the radio. For some time now, however, Radio Vienna had had individual medical advisers as well as medical reporters and commentators.

Dr. B. RODEWALD (Cologne: *Ärztliche Mitteilungen*) said that in the age of social security a constant war was being waged against the freedom of the doctor. The control of medicine had passed into the realm of government and parliaments, and it was important to remember that by the time governments were ready to take action the profession's opportunity for action had passed. Steps must be taken to control those trends. For that reason *Ärztliche Mitteilungen* was now being published. It did not deal with medical questions as such, but with social, political, and economic trends. One important point in connexion with the information service was that while doctors of course should deal with medical questions, journalists, sociologists, and economists should handle other questions, for doctors alone could not bring sufficient influence to bear.

EDITOR AND AUTHOR

In opening a discussion on the relationship between editor and author, Dr. A. M. COOKE (Oxford: *Quarterly Journal of Medicine*) said there was no escaping this problem: doctors would write papers and those papers must be edited. What were the editor's duties? One of his chief was to the author—to help him place his work before the public in the best possible way with speed and economy. Another was to his journal—to its proprietors on the financial side, but also an unwavering duty to the journal's standards, tradition, and ethics. The editor had also an allegiance, less tangible but no less important, to medicine and literature. His journal might travel to the ends of the earth, a silent witness to the standards of medicine in his country.

Difficulties between author and editor arose from a variety of reasons. The editor naturally felt that he must have the last word about what appeared in his journal, but the author felt equally that he must have the final say about what appeared in print under his name. The editor probably believed that there had never yet been a paper written which could not be improved by shortening. The author wondered why the editor always seemed to suggest deletion of the best paragraphs. The truth was that editing was an art, not a science, and the editor soon learnt that the difficult part of his work was that dealing with people and not the technical problems.

Conflicts between editor and author could be reduced in number and severity by a little conscious effort on both sides. The editor must maintain his standards, but also be pliant and tactful. He could help the author, and himself, by propaganda on the right and wrong ways of preparing papers. On the author's side, he should inform himself of the basic facts of the art of printing. Difficulties certainly arose from the ignorance of authors about the processes of printing. It was often not realized how much labour might be caused by alterations in page proofs. For example, in the *Quarterly Journal of Medicine* a page of type contained about 3,500 pieces of metal, and the two formes from which a sheet was printed about 56,000 pieces. If an author overran from page 1 to page 2, both formes had to be unlocked, and the whole 56,000 pieces of type metal thus put into unstable equilibrium. It might be necessary to move type by hand from each of the 16 pages to its neighbour on the other forme. That was a costly labour and a fruitful source of error in a hitherto perfect sheet. Editors should lose no opportunity of impressing on authors that alterations in the MS. cost nothing and were infinitely preferable to alterations in proof.

Editorial "Improvements"

Professor W. DOOLIN (Dublin: *Irish Journal of Medical Science and Journal of the Irish Medical Association*) referred to the question of whether an editor should try to improve a paper, and said that the operative word was "improve." Thinking it over there arose in his mind the old Italian saying, *traduttore, traditore*—the translator is a betrayer. English was a language in which it was very easy to be lazy, and in present times of torrential journalism, broadcasts, and television one feared that all our words from loose or indifferent usage had lost their meaning. The author was often an offender, and his English might need correction or alteration. The editor was fully justified in improving a phrase or sentence faultily presented; the author was the only one who would get credit for the clearer presentation thus effected. But the editor who, aiming at greater clarity, considered that elision or rearrangement of the text was necessary, should, in Professor Doolin's view, first secure the complete agreement of the author that such alteration was advisable. The paper was the author's—not the editor's—brain-child, and had some claim to retain the external evidence of its parentage.

The major difficulties in Professor Doolin's experience were the author who took a hundred words to say what could be said in forty, and the rejection of a paper as "unsuitable." Mark Twain had once commented wryly that "he didn't mind the fellow who was just plumb ignorant; the man who gave him most trouble was the fellow who knew a lot of things that just weren't so." The faddist or fanatic was the editor's worst headache.

Dr. P. BRAUN (Budapest: *Orvosi Hetilap and Therapia Hungarica*) described how they dealt with manuscripts at his editorial office in Hungary. They had tried two different organizations. First an editorial committee consisting of the heads of the scientific sections of the Hungarian Medical Association was set up. That seemed to be a fairly good solution, but, despite good will, the organization did not work. It was too expensive and the members were far removed from everyday editorial problems, so another system was adopted. A survey was made of the experts active in the different fields of medical science, and for refereeing a switch was made from well-known authorities to young scientists who might be in closer touch with the subjects of the manuscripts submitted.

Then a new consultative board was instituted, consisting of five members, each in charge of several related clinical or theoretical sectors. Their task was to advise the editor on questions in their fields, but at the same time they represented a committee to which the author could appeal in the event of disagreement with the editor. As a result of such discussions, papers were often published with editorial comments. It was important to note that even in obviously unworthy cases refusal without reason was avoided. By means of suggestions and putting the author in touch with medical authorities or institutes efforts were made to further his work.

Rejection of Papers

Professor L. P. GARROD (London: *British Journal of Experimental Pathology*) said it should not be overlooked that the amount of work which was being done in medicine and which merited printed description had greatly multiplied, whereas the number of journals available in which to make it known had not increased to the same extent. Consideration should be given to the terms in which the rejection of a paper was conveyed to an author—whether reasons should be given or not—and also what considerations should guide an editor in his choice between one journal and another. One factor which caused him some anxiety was how far an editor was under an obligation to accept papers from foreign countries, especially those countries where facilities for such publications did not exist.

Dr. J. THOMAS (Ibadan: *West African Medical Journal*) suggested that experienced editors, when returning manuscripts, should at the same time give some advice or guid-

ance to authors about other publications to which their material might be sent. A clearing house for manuscripts was needed. He also made a plea for a greater number of specialized journals, particularly on surgical subjects.

Dr. D. NANU (Bucharest: *Rumanian Medical Review*) said that the various specialist reviews of the Society of Medical Sciences in Bucharest were edited by an editorial committee generally formed by members of the boards of the respective sections. The team comprised editor, assistant editor, and eight to fifteen members. Usually the editor was also the chairman of his section of the Society of Medical Sciences. Papers were distributed to the members of the editing team, who sent in their observations and criticisms, and these, in turn, were forwarded to the authors. The latter were free to accept or reject the observations made by the referee, which dealt only with textual matters. On the very rare occasion when there was serious disagreement between author and referee, the editor decided whether or not the paper would be published.

Dr. C. E. HEDINGER (Zurich: *Schweizerische Medizinische Wochenschrift*) said that papers from abroad constituted an important problem to his journal. Publication was in four languages—German, French, Italian, and English—and something like 50% or more of the incoming manuscripts were from abroad. They published only those papers from abroad which either introduced something new from the scientific standpoint or had been read at one of the many international meetings in Switzerland.

Dr. F. FUCHS (Copenhagen: *Ugeskrift for Læger*) said that those countries whose languages were not understood abroad faced a special difficulty. There were two courses open to them—namely, to publish journals in foreign languages, or for authors to submit their papers to foreign journals. He hoped that journals abroad would continue, and possibly extend, their practice of accepting papers from countries in this predicament.

ILLUSTRATIONS IN MEDICAL JOURNALS

Dr. J. GUILLEMIN (Paris: *Semaine des Hôpitaux de Paris*), who had collaborated with Professor L. Justin-Besançon (Paris), opened the discussion. In writing on scientific matters, he said, the accuracy of the words with which the author endeavoured to suggest, represent, or synthesize facts for the reader was often markedly inadequate, and illustrations must therefore be used to achieve the desired aim. Most journals had made considerable efforts in the last few years to increase the quantity and quality of their illustrations.

Illustrations used in scientific journals must satisfy several requirements. First, they must be used as examples closely linked with the text of the article in which they were included. Secondly, they must be explanatory and make the meaning of the author's ideas or facts clearer. Thirdly, they must, in general, contribute to an understanding of the concepts included in the article and to their being remembered by the reader. They must be carefully chosen and of the highest quality. Although some negatives could be re-touched or changed, or be divided into several pictures, any possibility of blurring or of ambiguity must be eliminated. Those requirements were particularly applicable to radiology, haematology, and histology. The number of illustrations used must also be considered, since authors were apt to want too many. The underlying concept must always be the achievement of a suitable balance of illustrative material.

The various kinds of illustration could be grouped into (1) tables and graphs; (2) explanatory diagrams and drawings from life; and (3) photographs. Tables had the advantage of assembling and stressing various factors, such as the results of laboratory tests based on one or several groups of observations. Graphs also aimed at making the reader's task easy by summarizing a series of highly distinctive facts through their expression in terms of lines, curves, or conventional symbols. The only criterion for the inclusion of diagrams,

however, was simplicity. Drawings from life were used with the same aim and had very much the same characteristics.

Photography was the real basis of illustrations in medical journals. Whatever the subject, the careful selection of the pictures to be used and the quality of the originals were still of major importance.

As to future trends, it seemed undesirable to follow the example set by some non-medical publications which were using pictures more and more at the expense of the printed word. Sometimes this resulted in an unbalanced production, encouraging the reader to be so lazy that he finally looked only at the picture, its caption, and the title of the article.

Publisher's Views

Mr. C. MACMILLAN (Edinburgh: Messrs. E. & S. Livingstone, Ltd.) said that the one outstanding feature of medical journals to-day was the progressive increase in the use of illustrations. Speaking as a publisher entrusted with many important medical journals, Mr. Macmillan suggested that it would not be out of place to make a plea for a higher minimum standard for illustrations. The best-illustrated books at the present time were reasonably good—some were truly excellent—but at the other end of the scale there were illustrations which reflected but little credit on their publishers. Many of these were drawn by non-professional hands—by the authors themselves in some cases—and editors might have a certain hesitancy in rejecting them. It was, however, in the interests of both author and publisher that they should be rejected, for the illustrations caught the eye of the reader before he had even looked at the text, and the impression they produced was very important.

Great care should be taken not to waste space. The fact that unnecessary surroundings were included on the negative was no reason why available space in a journal should be devoted to such extraneous material. Secondly, the ideal picture was always carefully planned. Often it took much longer to illustrate an article adequately than to write it. Thirdly, illustrations should be reduced in size as much as possible. It was a good practice to make all illustrations in an article conform to a single scale so that reductions would also be uniform.

Mr. Macmillan then discussed each type of illustration. With regard to line drawings, clean lines, jet black on pure white paper or card, were essential. Chinese white should be avoided, as it photographed as grey. Line drawings with areas of flat colour or with coloured lines or stipples should not have the colours painted directly on the drawing. The coloured parts should be drawn in black, each colour separately, on a transparent cover which was stable to atmospheric conditions, register marks being drawn to ensure accurate fitting.

As to photographs, clinical photographs for reproduction should be clear, sharp, and in proper focus. Glossy prints with medium contrast produced the best half-tone blocks; but, in addition to good contrast between light and dark, it was important to have good middle tones, and these clinical photographs often lacked. Photographic prints of radiographs were more acceptable than the films themselves; they should be sharp, medium in contrast, and of a size to require as little reduction as possible. For wash drawings lamp black, ivory black, or sepia should be used as pure wash without any mixture of white. Bled illustrations were also fashionable, but the artist must remember to leave additional background for trimming.

Mr. Macmillan concluded with some aphorisms for would-be authors: "Use line drawings wherever possible; half-tone illustrations are twice as expensive as line blocks. Prepare your drawings in a size suitable for uniform reduction in a series. Think of the reduction first before determining the size of any lettering in your drawing. Drawings which require side legends also require wide margins; remember to allow for these margins when planning your drawing. Good lettering is an essential for a good illustration; unless you are expert, indicate your requirements on an overlay."

Educational Aims

Dr. J. R. GOSSET (Paris: *Concours Médical*), continuing the discussion, pointed out that there was another type of medical journal the purpose of which was informative and educative. Here the problem of illustration was more acute than in others. The illustrations were not of a set pattern and were not linked to articles but were living, and were used in order to further the educational aims of the publication. In other words, it was tantamount to providing a post-graduate course, but replacing the blackboard by the illustration. It meant that material of a serious import did not necessarily have to be boring but could be presented in an attractive manner. In that connexion illustrations played a leading part.

It was important that illustration should not become a kind of picture puzzle. Medical draughtsmen must be specially trained in graphical presentation. Indeed, the whole question of training people to make drawings and graphs for medical publications might well be discussed. The Union might even concern itself with the training of artists as specialists in the various branches of medical work. "It does not matter if drawings encourage intellectual laziness," concluded Dr. Gosset, "so long as they enable people to learn more readily and to remember better."

Dr. R. OLLERENSHAW (Manchester: *Medical and Biological Illustration*) referred to the question of radiographs, and suggested that the director of the illustration department must be ruthless in rejecting bad ones. Radiographs were almost impossible to reproduce directly because their density range was higher than that of any processes handled. He had tried to engrave directly from radiographs, but it was costly. He pleaded with publishers to send proofs of blocks on the same paper as that on which they would be printed; and when poor paper had to be used he pleaded for line tracings with mechanical stipples.

Dr. R. PAUN (Bucharest: *Rumanian Medical Review*) divided illustrations into three categories. (1) Those which were used for demonstration purposes or in order to develop an idea. To lessen their number might reduce the value of the article. (2) Illustrations which were sometimes of greater teaching value than the written text. (3) Those which merely decorated the text and could usefully be restricted. In order to avoid having too many illustrations in Rumanian medical publications a maximum limit had been laid down according to the size of the publication. As a result the tendency to insert too many illustrations had lessened. Those which were published were first checked by a doctor and an expert in drawings.

Dr. A. PLICHET (Paris: *Presse Médicale*) said that long lists of figures which often accompanied articles were a nightmare to the editors of journals giving medical information, though in scientific articles they were necessary.

Dr. P. ELLMAN (London: *British Journal of Tuberculosis and Diseases of the Chest*) suggested that a technically satisfactory radiograph was imperative. It would, he said, be dangerous to interpret a negative which was not technically satisfactory. He also pleaded for the setting up of more hospital photographic departments under physicians experienced in the subject. At the same time, undergraduate students could with advantage be taught the principles of good clinical photography.

STANDARDIZATION OF FORMAT AND REFERENCES

Professor P. BONNEVIE (Copenhagen: *Ugeskrift for Læger*) said they had a common interest in studying the optimum format of paper size, the dimensions of columns in connexion with the format, the most appropriate use of margins, and so on, paying due regard to the sizes of tables, diagrams, pictures, and to the international standards of paper dimensions. That should be the task of the medical press through its International Union. It was also necessary to standardize the bibliographical references or,

alternatively, to have a gentlemen's agreement on using the same methods of reference. In medical literature every conceivable variation in periodical abbreviations was found, and that must lead not only to a confusion of meaning but also to a great deal of extra and unnecessary work on the part of authors and editors. Furthermore, the librarians were constantly overworked trying to find out what journal was desired by the reader using references from different journals.

In Professor Bonnevie's view, the International Standards Organization's latest proposal for "Conventional Abbreviations of Certain Generic Names of Periodicals" went too far in some cases, especially when it allowed two alternative forms, one being only a single letter. He had the impression that the proposal was drafted by bibliographers, who, dealing with tens of thousands of references, wished to omit as much as possible, and who were able to draft a set of more or less involved rules. Editors had to protect their readers, so it was not enough that abbreviations were such that the library could learn to interpret them. They must be such that the readers—and editors—could not mistake them and eventually give wrong interpretations to the librarians. The reader was under no obligation to remember rules. The less the title was abbreviated the happier he would be. He had absolutely no use for an abbreviation that could be interpreted only by means of an expensive bibliography found only in a library.

In conclusion, Professor Bonnevie drew attention to the need for international agreements on symbols, abbreviations, and contractions used in the text. Medicine was international, and medical editors, who shared in the task of keeping medicine known throughout the world, had to be internationally minded in their editing.

Easy Reading

Professor J. R. PRAKKEN (Amsterdam: *Nederlands Tijdschrift voor Geneeskunde*), continuing the discussion, said that the standardization of format did not mean the imposing of one format for all medical journals. It might be of assistance for those editors who considered a change of format if a standard existed based on international standards of paper dimensions, the technical demands of printing, etc., and, last but not least, the physiological and psychological data on the demands for easy reading. For those who considered changing to a bigger format, Professor Prakken said he had a practical warning based on bitter experience. Care had to be taken so far as advertisement contracts were concerned. Long-term contracts giving the size of advertisements in pages might cost a great deal of money.

With regard to bibliographical references, Professor Bonnevie had stressed the necessity of standardization in that field, and Professor Prakken agreed with him. The work sponsored by Unesco and the World Medical Association had paved the way, and more and more journals had abandoned old haphazard methods. General acceptance of a list of abbreviations for the names of periodicals—work to which the president, Dr. H. A. Clegg, had contributed so much—was the central point. The names of authors should be quoted in the text, followed by the year of publication. An alphabetical list of references at the end of the article, in which the author's name again was followed by the year of publication, seemed to be the system which was easiest for author, editor, layout man, and reader.

Dr. J. LEREBOLLET (Paris: *Revue du Praticien*) suggested that the Union might set up a committee, the task of which would be to draft a short list of standards in respect of bibliography and illustrations to be observed by members.

Dr. T. LODGE (Sheffield: *Journal of the Faculty of Radiologists*) pleaded for the inclusion of the title of the paper in the references, and pressed strongly for more 5- and 10-year indexes of journals.

Dr. D. NANU (Bucharest: *Rumanian Medical Journal*) presented some suggestions for the standardization of the size of reviews and of bibliographical references.

EDITORIAL RESPONSIBILITY FOR MEDICAL ADVERTISEMENTS

Dr. J. GARLAND (Boston, Mass.: *New England Journal of Medicine*) said that the problem of the editorial responsibility for medical advertisements had given rise to a growing concern because of the great expansion of the pharmaceutical industry in recent years, and its resulting pressures, and because of an increasingly uncomfortable awareness of ethical obligations in the matter.

Practically the entire industry, in the course of that phenomenal growth, had become very prosperous—or so it seemed—and the influence which had accompanied that prosperity concerned the progress of medicine in a number of ways. On the positive side it had been directed into a variety of useful channels, especially along the lines of post-graduate education, scientific research, and financial aid to many worthy projects, including the establishment and support of independently operated scientific and philanthropic foundations. On the other hand, there were indications that that growing influence, if exerted indiscriminately, might have an increasingly undesirable effect on medical progress and practice. That would certainly happen if some restraint more adequate than at present existed was not placed on it by those who directed its policies, working with a more intelligent understanding of the needs of the medical profession and, indeed, of humanity at large. That untoward effect was seen in the recommendation, through the various advertising mediums, of pharmaceutical products where they were not specifically indicated, in the encouragement of unnecessary or even undesirable combinations of agents, and in their exploitation beyond the limits of their usefulness.

As the pharmaceutical industry had become bigger business it had inevitably been drawn into an acceptance—he understood in some cases unwillingly—of the promotional methods of big business, often in violation of that unique phenomenon known as good taste. Such methods carried with them a risk that the legitimate and erstwhile mutually respected partnership between pharmacy and medicine might turn into one in which medicine became only a junior partner to the big business of pharmaceutical manufacturing, with its large-scale exploitation of potent and usually dangerous drugs; for agents that had a dynamic effect on physiological functions might alter those functions adversely as well as favourably, and their availability carried with it an added responsibility for their use.

The doctor wanted and should be given more specific information regarding the products advertised and their proper use; he wanted and should be given authoritative references when clinical claims were made, and he wanted and should be given a presentation without superfluous and distracting verbiage, although he, too, was sufficiently human to react favourably to an attractive advertising layout. The physician could not surrender to the manufacturing chemist or his advertising agents any part of his responsibility in the treatment of his patients. He must have at his service accurate information about the total effects, both beneficial and harmful, of any advertised drug or combinations of drugs, with their dosages, and he must be supplied with reliable and authoritative references to the studies that had been responsible for their acceptance. The importance of that final factor could not be over-emphasized, for it was likely to be the only reliable scientific evidence of the value of a new product. To see that he was thus served should be at least in part the business of the editor, who was directly concerned with the character of the advertisements that his journal carried, as well as with the indoctrination of his readers by means of its scientific and editorial text.

A Basis for Co-existence

Dr. T. F. FOX (London: *Lancet*) said that obviously the interests of editor and advertiser were rather different, and, although they agreed in wanting the journal to distribute

useful information, one could hardly hope that they would always agree on what was useful. Sometimes their views were bound to conflict. When that happened should the advertiser ultimately be allowed to say what he liked? Or must he say what the editor would like him to say? Or should they compromise?

Most believed in compromise and symbiosis. Happily, the great majority of advertisers showed an understanding which made such a relationship not only possible but pleasant. A journal depending on advertisements was, he suggested, like a house which the family could maintain only by taking tenants. "We do not want these tenants to live with the family in our editorial columns; they must have separate self-contained quarters. This being so, we need not insist that their manners and clothing are exactly like ours. But before accepting them as tenants we can reasonably ask for references; and we can insist that so long as they live with us they shall not scandalize the neighbours and give our home a bad name. There must be certain rules, even if they are unwritten."

The practical question posed by Dr. Garland was whether, in face of the growing tendency of advertisers to present their products prematurely, editors ought not to make their policy less liberal? Should they not henceforward demand that prospective tenants of the advertisement columns should bring testimonials not only from reliable referees but from referees who had known the applicant for two or three years rather than two or three months? Speaking for himself, Dr. Fox said he was inclined to think that, because of the great pressure exerted in selling certain products, fuller use ought to be made of the cautionary influence, small though it might be, and the rules tightened rather than slackened.

To sum up, he agreed with Dr. Garland that advertisements were a part of the journal of which the editor must be conscious, not leaving it entirely to a managerial autonomic system. He had been brought up in a tradition which allowed advertisers, like correspondents, considerable freedom of expression, and which said that the editor's responsibility for advertisements, as for letters, was limited to ensuring that they did not mislead the reader or seriously offend against good taste. But principles were one thing and their current application was another.

Dr. MARIO CARDIA (Oporto: *Médico and Acta Gynaecologica et Obstetrica Hispano-lusitana*) said that advertising represented a very considerable source of revenue to journals in Portugal, for subscriptions and retail sales were only a small proportion of the income necessary to maintain the publications. Therefore it was not possible to be too exacting about the manner in which advertisements were worded and illustrated. Generally speaking the concerns which produced pharmaceutical specialities had in their advertising departments sound and serious people, so there was no need for editors to take action. Editors must promote co-operation between the pharmaceutical industry and the medical press.

Dr. C. WILCOCKS (London: *Tropical Diseases Bulletin and Bulletin of Hygiene*) suggested that journals which carried a small number of advertisements had an additional responsibility so far as the advertising was concerned.

The PRESIDENT, Dr. H. A. Clegg, added that the reader had the right to assume that the information he obtained in advertisement columns was reliable. Describing the policy of the *British Medical Journal*, he said that advertisements were scrutinized in the office, and when there was doubt about one it was sent to an expert for an opinion. The final responsibility for rejecting an advertisement lay with the Journal Committee of the B.M.A.

Professor H. PEQUIGNOT (Paris) said it must be recognized that medical journals were being read more and more by lay persons and those working in para-medical fields, a fact which must be taken into account when endorsing advertisements. In view of the fact that the advertisers in all fields had well-established international links between them, it might be appropriate for the medical press throughout the world, under the aegis of the Union, to examine and compare all the various rules which prevailed,

and possibly agree on some charter which would serve as an inspiration to all the various countries.

Dr. S. S. B. GILDER (Toronto: *Canadian Medical Association Journal*) referred to the advertising of products which might be said to present social problems—tobacco, alcohol, and possibly contraceptives—and said there was nothing in the rules which stated that they must not be advertised, but in Canada such advertisements had always been refused on the ground that, although their absence would not be remarked on, their presence might lend colour to something which was not countenanced.

Dr. W. W. BAUER (Chicago: *To-day's Health*) stated that tobacco advertisements were no longer accepted in the *Journal of the American Medical Association*, as it was felt that the claims being made in the advertisements were growing fantastic. Great difficulty was also experienced with the advertising of certain popular sweet soft drinks and of chewing-gum, for the dentists were opposed to them. What was needed was agreement that unless something was definitely harmful it was undesirable to become too puritanical. It was necessary, however, to give careful consideration to public judgment on advertising.

ABSTRACT OR DIGEST?

Dr. J. BJØRNEBOE (Oslo: *Tidsskrift for den Norske Lægeforening*), in opening the discussion, said that the significance of abstracts and abstract journals needed no emphasis. However, they were not to be regarded as an alternative to something else. All legitimate medical literature was important to the student as well as to the research worker.

There appeared to be a disappointing lack of interest in abstract journals on the part of doctors. All agreed about the importance of abstracts as a library tool. Some editors also expected abstracts to be read "for their own intrinsic interest," and as literature to which people would turn "for the pleasure of keeping themselves informed." Unfortunately many doctors compared the pleasure of reading abstract journals with that of reading a telephone directory. The question might well be posed whether abstracts could, perhaps, arouse the appetite of the readers if they were served temptingly. There was no doubt about the value of typical abstract journals as library tools, but an objection was that they had to be unorganized. Even if the abstracts were classified according to subjects and well indexed, the author was probably better served if he could find a review article on the subject (as, for example, similar to the series published in the *Canadian Medical Association Journal*). Several journals published excellent review articles which saved the student or research worker endless hours of work, and, what was more, they were of enduring significance. Abstract journals might well reprint review articles collected from all parts of the world. When a considerable number had been published they ought to be listed in each number so that anyone searching for a subject could easily find it.

With regard to the so-called digest, the speaker thought that it rather depended on what the definition of a digest journal was. If by that was meant a commercial enterprise pirating other journals for the sake of profit, then digests could not be regarded as belonging to legitimate medical literature. In that way there was established an economic dependence which was absolutely inconsistent with freedom of the press. Finally, local editions of foreign journals were unacceptable. It was a duty as well as a right for every country to take the full responsibility for educating and informing her own doctors on medical matters.

Dr. D. I. CROWTHER (London: *Abstracts of World Medicine*) said that a digest was for all practical purposes identical with an informative abstract, and the process of preparing it was, like that of preparing an abstract, one of selection rather than digestion. Moreover, while the selection might well be sufficient to meet the needs of the general reader, it could not be regarded as a complete substitute for the original paper, otherwise there would be no point in publishing the original version at all. But although

an abstract could not fulfil the same purpose as the author's text, and although for some readers it could do no more than bring to their notice a paper which they must read in full, a good informative abstract could, and indeed often must, take the place of the original for readers whose access to the literature was restricted or whose reading of original texts must be limited to those which had an immediate bearing on their own work. That category of readers was, in the field of clinical medicine at least, a very large one, and their requirements were by no means identical. The differences between existing abstracting journals and digests in selection of papers and the nature of their contents thus reflected chiefly the different types of reader for whom they were intended and the editors' different conceptions of their readers' needs. That, surely, was the only proper ground on which any distinction could be drawn between an abstract and a digest.

But, although the type of paper selected for abstracting and the nature of the information which should be included in the abstract must differ from journal to journal, there were certain desiderata which applied to every type of abstract or digest in the medical field. Dr. Crowther then outlined some of the principles on which the editorial policy of *Abstracts of World Medicine* was based. First, it was assumed that an essential attribute of an abstract was brevity. Secondly brevity must be achieved by selection rather than by compression, and never at the expense of readability or at the risk of ambiguity. Thirdly, and perhaps more obviously, abstracts must interpret objectively the intentions of the original author, and should reflect his views and not those of the abstracter. Finally, information should be included in the abstract which enabled the reader to form his own opinion of the quality of the work reported. The abstract should, in fact, contain material for digestion and not merely the end-products of that process.

Dr. CHARLES WILCOCKS (London: *Tropical Diseases Bulletin*, and *Bulletin of Hygiene*), continuing the discussion, said he could see little difference in meaning between the words "abstract," "digest," "summary," and "synopsis," in relation to abbreviated versions of scientific papers. Perhaps digest might be the term given to a rather full account of a paper, and certainly an editor of an abstracting journal must decide whether he was to provide full accounts of a limited number of selected papers or short accounts of many more papers or a mixture of the two. He must also decide whether completely to cover all papers on his subjects or be selective.

The Bureau of Hygiene and Tropical Diseases asked expert scientists of high repute to write abstracts, and they were therefore able to judge critically the quality of the paper abstracted. The papers were chosen by the medical staff of the Bureau in their daily scrutiny of a large number of journals, and abstracters were asked to reject papers considered unimportant, and to comment, favourably or unfavourably, when comment was justified. Accuracy of detail and interpretation in the abstracts meant constant checking and rechecking, and that was particularly important, because at many stages of abstracting and publication there were possibilities of error. The abstracts varied in length and detail according to the needs of readers. For those without access to original papers full and critical abstracts were provided, and for those in touch with libraries, and who normally must read originals, short, critical abstracts were provided. Any papers of outstanding merit were likely to receive full and appreciative reviews.

Dr. J. LEREBoullet (Paris: *Revue du Praticien*) suggested that an abstract might be described as being inevitably short and explaining the contents of an article with the aim of whetting the reader's appetite, and a digest as giving a more detailed account of the original article, and possibly written in such a manner that it would not be necessary for the reader to refer back to the original.

The possibility of an international classification which could be based on the decimal system and which would

give numbers to the abstracts should be considered. That would give rapid access to abstracts and thereby increase their usefulness.

THE PLACE OF THE SPECIALIST JOURNAL

Dr. MAURICE CAMPBELL (London: *British Heart Journal*) said that few people were aware of the incredible number of special journals and the narrow fields to which some of them appealed with so much success, ranging from gardening to philately, from the leather trade to finance, or from cricket to birds of a particular area. The editor of a journal of the last type had a relatively easy task in one direction, for he knew that all his readers would be interested in those local occurrences and had not much choice in what he should put before them.

Journals might be guided by the different concepts of the subject matter that was germane to their special purpose. In *Heart*, an outstandingly successful journal, the late Sir Thomas Lewis had laid down the principle that every paper should deal with some new experimental work, feeling, Dr. Campbell thought, that this would draw in papers not then catered for elsewhere, rather than that it would of itself satisfy his readers' interest, though the latter resulted because of the high level of the work in a field that was then advancing rapidly. The *British Heart Journal* from the start had defined its range as anything pertaining to the heart and circulation, regardless of whether that was clinical medicine, pathology, anatomy, or physiological investigations; if anatomical or physiological work was important enough, it should be of great interest to all clinical cardiologists.

The most important duty of an editor of a specialist or any other journal was to see that what he published was readable. An author could force the unfortunate editor to read his paper however bad it was; he could not force anyone else and had to persuade them by the attraction of his style or the value of his subject matter. Those working on a special subject should remember that they had become very familiar with it and that some readers might not follow so readily the import of their argument or appreciate the work's setting against the general background unless that was clearly set forth. The author might have become so interested in his subject that he was fascinated by details which did not interest others and should be omitted.

Dr. E. MAZANEK (Austria: *Österreichische Ärztezeitung*) said that divergences of language between the different nations necessitated the publication of a great number of specialist journals in every country; but, owing to their small circulation, they were not always profitable, being kept alive with difficulty. In fact, in various countries the publication of several specialist journals had already had to be stopped. Some kind of reform would be vitally necessary within the next few years, and Dr. Mazanek suggested that the Union ought to study the means of coordinating the medical press in different countries. The Union might publish a list of its member countries and their specialist journals. The delegates of the various countries could interest their colleagues at home in attaining editorial co-operation between their own specialist journals and similar journals abroad, starting with those countries where the same language was spoken. So far as the further international development of some specialist journals was concerned more attention might be given to the publication of the same articles in different languages; there might be, for instance, a European edition of the *British Heart Journal*. Such journals would appear in English, French, Spanish, and German, and would have a joint editorial board to allow the collection from every country of material of real importance; all contributions would have to be very brief. Authors of such abstracts would deposit several copies of their full papers at some centre for the benefit of interested colleagues, who, however, were usually few in number. By that method every author would be able to make his original manuscript available in every country.

More or Fewer Journals

Professor L. P. GARROD (London: *British Journal of Experimental Pathology*) expressed alarm at the increase in the number of journals which had to be consulted. Libraries could not afford to buy many of them, and many people had not the time to go through them. There had appeared in this country some very highly specialized journals indeed in the last few years, and in his view it would not be a good thing for the duplication to proceed any further.

Professor P. LAMBIN (Belgium: *Revue Belge de Pathologie et de Médecine Expérimentale*) said there were a number of general journals which also included reports of interest to specialists. The danger was that the specialist would miss these papers because of their appearance in a general journal. An effort should be made to classify journals into two categories: those of general and instructional interest, and those specializing in the publication of original work.

Dr. J. LEREBoullet (Paris: *Revue du Praticien*) agreed that co-operation between journals in the same language would be very advantageous. And in those countries which could not support journals in all the various specialties arrangements should be made with journals in other countries to take articles. But to go further would be rather dangerous, and might well entail the gradual disappearance of publications if summaries of the articles were to be printed instead of the original articles.

Dr. R. PAUN (Bucharest: *Rumanian Medical Review*) suggested that the Union might well sponsor the publication of special reviews—one for each specialty—of an international character and representing the international archives of the respective specialties. The length of memoirs, general reviews, and reports in such specialist reviews could be fixed within certain reasonable limits, and collaboration between the editors would be very useful in preventing double publication of the same material.

Professor H. PEQUIGNOT (Paris) pointed out that no mention had been made of subjects which were "drawn and quartered" between several different fields. There was also the question of those specialist contributions whose circulation ought not to be restricted to their own specialty. He hoped that the situation would never arise in which there was only one publication in any field. There should always be at least two in order to eliminate the risk of a monopoly in a given subject.

Dr. J. G. M. HAMILTON (Edinburgh: chairman, Journal Committee of B.M.A.) said it would probably be agreed that specialist journals existed solely for the purpose of providing outlets for research work. That being so, if there were not a sufficiently large number of outlets, the pressure generated by the present and expected future interest in medical research would be such that the boiler would burst, and extra outlets would be found which might not be approved. The problem would not be solved by the curtailment of the number of outlets.

International readership problems might well be solved by the various suggestions made concerning international co-operation, abstracts, etc., but he pleaded for more journals and not a curtailment of the present number. There were many medical specialties where active work was going on which found difficulty of outlet because the specialist journals dealt with small and restricted fields. It was desirable, therefore, that the successful journals published in fields having a large readership should be bold in their policy: in other words, in the interests of medical science generally, let the journals which were successful carry those which were less successful.

MULTILINGUAL SUMMARIES OF MEDICAL ARTICLES.

"We live in a world in which it is to be hoped that frontiers will gradually wane and finally disappear, in the century of speed and of growing international exchanges," said Dr. C. MAYER (Brussels: *Bruxelles-médical*) in opening

the discussion. There was no doubt that the medical press had an important part to play in making scientific thought known to medical circles throughout the world, and it was felt that that aim could be achieved by printing summaries translated into two or more languages after each original article. Original articles, indeed, represented the most important scientific contribution of medical journals, and most of the major European medical publications during the last few years had been printing summaries of original articles in French, English, and Spanish. But the time and work which those summaries involved for the editorial staff had to be considered: competent translators must be found and they must hand in their work within the prescribed time limits so that publication would not be delayed. The extra cost of the translations had also to be remembered.

Professor T. OLIARO (Turin: *Minerva Medica*) said that for many years the "Gruppo Giornalistico Minerva Medica" had firmly believed that it was necessary to publish the summaries of the original articles in at least two languages in order to facilitate their circulation in the international field. In the bi-weekly *Minerva Medica* and in the other journals of the group dealing with different branches of medicine and surgery, translations in English, French, and German of about 15 lines were published at the end of the Italian original. Everyone agreed, he continued, that the preparation and the publication of the summaries in several foreign languages was a difficult task, and not easy to carry out without making linguistic mistakes. But it was necessary to persevere because the advantages which would result were so numerous that they would offset the mistakes. Professor Oliaro hoped that the example set by those journals which already published translations of the summaries of original articles would be followed by all medical journals, in order to assist the progress of science.

Summaries in Standardized Form

Dr. G. GRAHAM (London: *German Medical Monthly*) said that the manner and approach of writing a summary differed widely among different countries and traditions. A "good" summary in the language of the article might be useless when simply translated into another language, for it often need not contain information which was essential for one who was not able to refer to or understand the main article, but had to rely on the data provided in the summary. On the other hand, summaries were not abstracts. The reader had the particular article in front of him. Even should he have little or no knowledge of the language in which the article was written, he would be able to refer to tables and figures (often without text), if the summary in the language which he did understand brought them to his notice.

To avoid those difficulties it was probably necessary to adopt a standardized way of writing summaries. One might say that a summary should always include (1) a statement of the purpose for which the investigation or review was undertaken; (2) the selection of the material used or measured; (3) the methods, procedures, or treatment employed; (4) the results obtained; and (5) the author's conclusions or explanations. Even standardization of style and contents did not remove a number of specific difficulties. There was the tendency, in the name of economy, to use abbreviations in the summaries even more than in the main body of the article. All abbreviations should be abolished in summaries. The only alternative would be to have each journal to list in each issue all abbreviations used.

Measurements should be standardized. Only the decimal system should be used and all doses, etc., converted into it. Names of drugs, especially proprietary ones, represented a particularly vexing problem, and wherever necessary chemical names should be used in addition, and a generic description of the drug given when the other terms were likely to be unknown or misleading. Eponyms of diseases, operations, tests, etc., should never be used, or only if they were fully explained. Perhaps the International Union might draft specific practical suggestions for the preparation

of standardized summaries which could be circulated to editors in various countries.

Professor P. MILLIEZ (Paris), speaking as an author, said that very often he had been "betrayed" by journals which had summarized his papers in a foreign language and which had not been a true reproduction of what he had written in the original.

Dr. MARIO CARDIA (Oporto: *Médico*) said that he represented a weekly journal which did everything possible to publish as many summaries in translation as was practicable, but there was a serious financial problem to be faced. Summaries in French, and very often in English, of all original articles were published in his journal. Special issues of the journal were devoted to the medicine of other countries.

Dr. D. CROWTHER (London: *Abstracts of World Medicine*) pointed out that a translation might be academically perfect, yet, by the choice of the wrong word, might convey shades of meaning which were not intended in the original.

SOCIAL OCCASIONS

On the evening before the congress began the *British Medical Journal* held a reception for the delegates at B.M.A. House. About 200 guests attended this "get-together" party, and they were received by Dr. and Mrs. H. A. Clegg and by Dr. J. G. M. Hamilton, chairman of the Journal Committee of the British Medical Association, and Mrs. Hamilton. On September 13 half the delegates were entertained at a luncheon held by invitation of the Royal College of Surgeons and of Sir Cecil Wakeley, editor of the *Annals of the Royal College of Surgeons*, and the other half at a luncheon held by invitation of the Ciba Foundation. In the evening the *Practitioner* gave a dinner at the Royal College of Surgeons. Sir Heneage Ogilvie genially welcomed the visitors in a short speech, saying how delightful it was to see so many people of such distinction representing so many journals, and how fitting it was for an international gathering to meet together in the Hall of the Royal College of Surgeons, which itself represented a triumph of reason over destruction. Dr. Joseph Garland, editor of the *New England Journal of Medicine*, and Dr. A. Plichet, editor of the *Presse Médicale*, spoke briefly in reply. On September 14 the *Lancet* invited the delegates to a fork luncheon at 7, Adam Street.

On the evening of September 14 a banquet was given by the *British Medical Journal* in the Great Hall of B.M.A. House. After the loyal toast had been honoured, Lord Cohen of Birkenhead, a Vice-President of the British Medical Association, proposed the health of the Union Internationale de la Presse Médicale. Speaking of medical journals generally, he said they had an indispensable place in the postgraduate education of the doctor. As to editorial responsibility, he was quite certain that it should be absolute and sacrosanct: he would support that view to the death. Mentioning the question of professional anonymity, Lord Cohen of Birkenhead said that this was a problem needing careful reconsideration now that such instruments existed for the dissemination of knowledge as the radio and television. In conclusion he spoke of the charm and selflessness of Dr. A. Plichet, whose name he linked with the toast. In reply, Dr. Plichet expressed his pleasure at the outcome of the congress and thanked Lord Cohen, the British Medical Association, and all those who had contributed to the success of the meeting. The Union had grown, he said, from small beginnings, and now had members all over the world. All members were united in holding the highest standards of accuracy and objectivity, which lay at the heart of scientific and medical journalism. The medical press had a very special contribution to make at the present time. "Nous contribuons, ainsi, à édifier, à sauvegarder, et à enrichir le patrimoine scientifique de nos pays, de tous les pays, et nous aussi, nous écrivons l'histoire."

On Sunday, September 15, nearly 80 of the delegates made a whole-day trip to Cambridge. Luncheon and tea were taken in the hall of Trinity College, by kind permission of the Master, Lord Adrian, O.M.

Correspondence

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

Palliative Radiotherapy

SIR,—I would like to congratulate you on your leading article on palliative radiotherapy (*Journal*, August 24, p. 455), which I feel sure was welcomed by all who have to assist in the management of patients suffering from advanced cancer of either the breast or lung. I would, however, like to say a few words about the suggestion made in the last sentence, that there has been an increase in fibrosis of the lung since super-voltage therapy became more generally available. For some time I have been particularly interested in fibrosis of the lung following conventional deep x-ray therapy for carcinoma of the breast, and have been able to show¹ that the great majority of patients treated by this method to high dosage subsequently develop some degree of post-radiation fibrosis of the underlying lung. In Newcastle we have used the 4 meV linear accelerator in the treatment of patients for over three years, and our experience is that the local and general complications of the treatment are less severe than with conventional x-ray therapy apparatus. In the treatment of carcinoma of the breast, the use of super-voltage radiotherapy to treat either the chest wall or the regional lymph node areas appears to reduce the incidence of subsequent post-radiation fibrosis to about one-third of what it is with conventional therapy. I would be grateful if you would publish this letter, which may help to avoid misleading impressions about the possible effects of irradiation being held by general practitioners and consultants in other specialties.—I am, etc.,

Newcastle upon Tyne, 1.

WILLIAM M. ROSS.

Dietary Fat and Coronary Disease

SIR,—There seems to be an assumption in your leading article on this subject (*Journal*, July 13, p. 89) which requires qualification. It is assumed that "faster blood coagulation" has a bearing on the problem of coronary thrombosis. Leaving aside the question of what relationship, if any, exists between the highly artificial conditions of *in vitro* coagulation of blood and intravascular clotting, is there any evidence to suggest that a clot which forms in a few seconds has more serious consequences than one taking hours, unless the activity of the fibrinolytic mechanism at the same time is considered?

I believe that insufficient attention has been paid to the activity of the fibrinolytic mechanism of the blood and the effect of dietary fats and blood lipids on this mechanism. We have shown that *in vitro* fibrinolysis is inhibited by fatty meals¹ and more recently² that, of a variety of fats tested, only butter fat and egg yolks were inhibitory, vegetable oils being generally without effect or appearing to activate fibrinolytic activity. The difficulty of assessing the validity of *in vitro* studies to *in vivo* conditions applies also to *in vitro* fibrinolysis, but at all events techniques have been developed to study *in vivo* fibrinolysis.³

Using such techniques Kwaan and MacFadzean⁴ have been able to demonstrate inhibition of *in vivo* fibrinolysis in rabbits fed cholesterol. Care is always necessary, of course, in the projection of experimental results obtained in one species to another species, and in this connexion it is perhaps worthy of note that heparin parenterally does not cause activation of fibrinolysis in the rabbit, although a small dose (0.3 mg. per kg. body weight intravenously) is sufficient to cause marked, if transient, activation of fibrinolysis in man. This effect of heparin in man we attribute to activation of the lipaemia "clearing reaction" (really a breaking down of the inhibitory substances to fibrinolysis in plasma are lipoproteins.⁵

SEPT. 21, 1957

A further observation of interest is that an increase in the plasma of material metachromatically reacting with azure A is associated with alimentary lipaemia. This may or may not be heparin (we have not yet identified it), but it is bound to lipo-protein and usually cannot be detected in native plasma (cf. heparin, according to Jaques⁶) but only in plasma after ether-extraction in the cold (below -25°C). The relationship of this metachromatic material to heparin and/or heparin-activated "clearing factor" is a matter for further study.

The appearance of this material in the plasma makes me wonder if there is not perhaps a link between this observation and that of Shoulders and Meng.⁷ These workers found that intraperitoneal injection of lipid emulsions caused disruption of the peritoneal mast cells. The active factor was possibly a phosphatide. It is tempting to speculate whether the effect of alimentary lipaemia on the mast cells of the blood vessel walls may not be similar, with a release of metachromatically reacting substances into the plasma. It may depend on the composition of the chylomicrons and lipoproteins composing the lipaemia, especially in respect of phosphatides, whether such material is released. An analogy may perhaps be seen to the non-specific serum inhibitor of hyaluronidase of Glick,⁷ which is apparently a heparin-lipoprotein complex, believed to be derived from the mast cell. Indeed, certain similarities of behaviour raise the question whether these inhibitors may not be identical.

It is my belief that the "non-specific" lipoprotein inhibitors of enzymes (especially proteases) play vital roles in many physiological processes ranging from the fertilization of the egg to the control of protein synthesis in the cell. I think these observations and speculations may have a bearing on the pathogenesis of coronary thrombosis and the role of dietary fats therein and are put forward to stimulate discussion and to attempt to suggest directions other than the old, very well-worn paths along which research on this subject is largely being pursued.—I am, etc.,

Johannesburg, S. Africa.

Relief of Stokes-Adams Syndrome after Cholecystectomy

SIR,—Physiologists have noted a reflex mechanism from gall-bladder to heart. This mechanism may account for auricular fibrillation. Anginal pain sometimes seems to be triggered off by a diseased gall-bladder, and Gilbert¹ produced a variety of arrhythmias in dogs by distending the gall-bladder and other abdominal viscera. Buchbinder² found that experimentally produced sudden alterations of pressure in the gall-bladder of frogs cause asystole and sinus bradycardia by a vagal reflex, which atropine and section of the vagus abolished. From these experimental and clinical observations it is apparent that the gall-bladder may play some role in some disturbances of cardiac mechanism.

In 1955 McLemore and Levine,³ of Harvard Medical School, published reports of seven patients who had typical attacks of Stokes-Adams syncope. All had gallstones, and cholecystectomy was performed in every case. In every instance the number of attacks decreased after the operation, the purpose of which was to abolish the action on the heart of the trigger-like mechanism of a diseased gall-bladder. It appears that cholecystectomy is tolerated satisfactorily by patients with complete heart block. These reports indicate that gallstones should be searched for carefully in all cases of Stokes-Adams disease. The following case report bears this out.

A married woman, aged 51, was first seen in March, 1952, when she was unconscious from a Stokes-Adams attack. She

had had minor attacks of fainting for three months, but no total unconsciousness. Her pulse rate was between 30 and 40/min., and regular, the heart was enlarged, and the blood pressure considerably raised. An E.C.G. showed no gross abnormality. Within three days her pulse rate was back to 72/min. During the following three years she had many minor attacks of transient fainting. She was never really well, could only do her housework with difficulty, and was afraid to leave her home. She had almost continuous headaches, but she noticed that these left her during her attacks of fainting. Her blood pressure was in the region of 180/120 mm. Hg and it was presumed that her headaches were hypertensive in nature.

In 1956 the patient's attacks became worse. On September 9, 1956, I saw her when she was regaining consciousness after a major attack, during which she also had vomited. Within five minutes she lapsed once more into deep unconsciousness, there was a period of apnoea, the pulse disappeared, she became cyanosed, and the pupils dilated. Rhythmic pressure via the diaphragm was applied and continued for a short while after she had regained consciousness. Whenever the gall-bladder region was touched a distinct expression of pain was noticeable even before she had become fully conscious. She entered hospital with a pulse rate of 12-16/min. The E.C.G. showed incomplete irregular heart block. She improved rapidly on ephedrine six-hourly, and was discharged on this regime. In spite of medication her pulse rate was mostly in the region of 40/min. She was having many minor attacks again which once more brought diminution of her headaches while they lasted. The gall-bladder was now distinctly palpable and very tender to touch. Surgical opinion was then sought, and on December 20 cholecystectomy was carried out and one large and several smaller stones were found in the gall-bladder. Recovery was uneventful and no ephedrine was administered during the convalescence. Since the operation until to date—that is, for the past seven months—the patient has had neither major nor minor attacks of Stokes-Adams syndrome. She has had no medication whatsoever, apart from mild analgesics for her headaches, which since the operation, probably due to a now uninterrupted high blood pressure, have become a more or less permanent fixture. Her pulse is constantly in the region of 70/min.

My thanks are due to Dr. C. Astley and Mr. S. Mottershead, of North Ormsby Hospital, Middlesbrough, for their help with this case.—I am, etc.,

Middlesbrough.

Asian Influenza

SIR,—The recent Asian pandemic of influenza has passed through India and seems to have proceeded to Western countries. Epidemiological observations have revealed that the new Asian influenza is as infectious as that of the last pandemic of influenza in 1918-19, but the killing power of Asian influenza has fallen off. Thus unusually high attack rates have been noted, with an average estimated at 19% in the Philippines, although in individual communities higher attack rates have been reported. But mortality rates have been less than 1 per 1,000 cases. These deaths were usually in infants and debilitated persons.¹

In India there were 1,889,825 cases and 536 deaths up to the middle of July, 1957.² In view of the low mortality rate, it has been suggested in many quarters that the current Asian strain of influenza virus, determined as a variant of type A, has lost its malignancy as a result of mutation which may be due to the effect of radiation from recent nuclear tests. The much improved prognosis of Asian influenza cannot be attributed to the mutation theory alone. It must be remembered that when one compares the frequency and case fatality of influenza now with those of thirty-eight years ago one is not really comparing the actual frequency of the disease but the frequency with which the term "influenza" is used to describe a disease status by observers differing in their education and medical outlook over a period of thirty-eight years.

We should not forget that the influenza virus acts synergistically with various bacteria to produce terminal pneumonia, bronchopneumonia, etc., and the advent of

chemotherapy and antibiotics has reduced a great deal of the mortality, which remained unchecked in the years 1918-19. Moreover, virological methods of accurately determining the diagnosis were unavailable in the pandemic of influenza in 1918-19.—I am, etc.,

Calcutta.

Physique and Mental Illness

SIR,—I agree with Dr. R. W. Parnell (*Journal*, August 10, p. 351) that some of the controversy over the relationship of physique to disease is dependent upon the different statistical interpretation of results. For example, Feigenbaum and Howat¹ denied the validity of Draper's² claims that there are physical characteristics distinctive of patients with diabetes mellitus, peptic ulcer, and cholecystitis. The Leeds figures show that there is no significant relationship between somatotype and unspecified mental disorder ($\chi^2=5.92$; P about 0.3), or between somatotype and first-class honours group ($\chi^2=7.57$; P about 0.2).

For the students' benefit severe cases are treated in the University of Leeds Student Health Department with the close liaison of the University Department of Psychiatry. Also many of the Leeds cases were hospital in-patients or out-patients. Although the Oxford patients contain a higher proportion of schizophrenics it is difficult to believe that difference in selection is entirely responsible for the highly significant correlation between somatotype and psychiatric illness claimed by Dr. Parnell³ and the lack of significant correlation found at Leeds. Finally one would expect mesomorphs to be the best examination performers, as they are the commonest somatotypes amongst the students; at Leeds, in proportion to their number, they do not perform any better or worse than the other somatotypes.—I am, etc.,

Leeds, 2.

Compulsory Powers over Mental Patients

SIR,—I have just read Dr. Alexander Walk's letter on this subject (*Journal*, August 24, p. 467) and would like, late though it is, to disagree with him on several points.

He argues first that the justice's order at present necessary for compulsory admission contributes to the "stigma" of certification and of mental disease in general. Now, by immemorial tradition and universal assent, powers over the subject's liberty, however weak and ill he might be, have resided with the judiciary. The cruelty of princes, the rapacity of barons, the ambition of governments have constantly, since the time of Magna Charta, been chastened and subdued by this same essential principle of independent justice. It is therefore by no accident that the justice's order should be required for certification; it is a reminder and firm insistence that, where so absolute a sanction as incarceration *sine die* is to be summarily imposed, the action should at least have the approval of a representative of that body which, so far from having as a "main function . . . the punishment of crime," has over the centuries been the greatest, and very often the only, champion of individual liberty in the country. Thus, apart from any considerations of the social hazards of mental disease, the justice's order may more fairly be regarded not as a stigma but as a feature ennobling what would otherwise be an unconstitutional and unprecedented seizure of an individual subject.

Dr. Walk suggests that the psychiatrist already undertakes the responsibility for compulsory detention. "Our patients are not deceived and know where the responsibility lies." Of course the doctor is responsible for his opinion on his patient's condition, but it is no more than advice; responsibility for the act of arrest itself lies with the justice

of the peace, whose responsibility is in no way diminished by the psychiatrist's right to discharge his patient. Surely it is true that a physician can only offer advice; the phrase "doctor's orders" is, and should remain, meaningless.

Dr. Walk concludes that the answer lies in the provision of "review tribunals" following "informal practice." For myself, were my personal liberty at stake, I should many times prefer the opinion of a magistrate's court, however "litigious," to any tribunal, informal though it may be. "Tribunal"—it is no accident that the world should inspire dread: from the time of the French Revolution tribunals have been proposed as alternatives to orthodox courts. Unconstitutional, summary, from them there is no appeal; they represent the extreme triumph of the executive power over the common law. I hope that psychiatrists will continue to decline the responsibility for compulsory detention of their patients.—I am, etc.,

London, N.6.

D. H. HULL.

Mental Health of Students

SIR,—Your annotation on the mental health of students (*Journal*, September 7, p. 567) adds to observations on Drs. Brian Davy's and Nicolas Malleon's valuable papers (pp. 547 and 551) several disputable aphorisms. (1) "... Incipient psychosis is noticed sooner in . . . college than . . . in . . . the family." Can you cite evidence? *A priori*, the opposite appears likelier, because of closer contacts and more intimate understanding at home. (2) "There is as yet no clear picture of the incidence of the different neurotic and psychotic syndromes among students as they present themselves for help, so that one cannot say whether they are influenced by possibly stressful features of university life." Here is fallacy and confusion. Since Karl Menninger's pioneer work at Washburn¹ this differential incidence has been expounded in America by, among others, Anthonisen at Wellesley, Fry at Yale, Palmer at Pennsylvania, Raphael at Michigan, and Tillotson at Harvard; in this country by Malleon at University College, Read at the London School of Economics, and Still at Leeds. Space precludes references. The reason for distinguishing those presenting themselves for help from, presumably, those referred by others is obscure. It does not follow that revelation of the picture of this incidence leads to that of the influence upon them of university stresses. To reveal this influence controlled studies of the type mentioned below are needed.

(3) "Analysis of mental ill-health in terms of social origin and faculty might give interesting facts." Implied is a lack of controlled studies to supply these facts. As long ago as 1927 Menninger¹ differentiated mentally healthy and ill students on family history, childhood ill-health, discord in the home or with siblings. My former colleagues at Oxford and I have submitted evidence on the influence not only of faculty but also of social, financial, and university status, military service, religious change, past and family illness, home circumstances and discords, among other material. I am about to submit to that university a thesis analysing further these and other relevant factors, including immediate stress.

(4) "It is sad how little psychotherapy has certainly to offer these sufferers [neurotics and psychopaths] at present." The American literature is more optimistic, even when including psychotics: take, for example, Raphael's figures² of 85.4% much improved with proper treatment (psychotherapy the lynch-pin), 14.5% somewhat improved, and only 0.2% unhelped. Without aspiring to these heights, Dr. Davy will, I think, bear out at Cambridge the experience of my former Oxford co-therapists and myself of the value of psychotherapy among undergraduates.—I am, etc.,

Lactation and Heredity

SIR,—Dr. I. G. Wickes and Mr. M. P. Curwen's study of breast-feeding in two generations (*Journal*, August 17, p. 381) is of considerable interest. It would seem reasonable to expect that human nursing performance is to some extent genetically determined, although, without more precise information on its mode of inheritance, it may be difficult to assess the effect of countless generations in which a variably high proportion of hand-reared infants died. This may well have served to reduce genetic variation.

It would be in accord with certain psychological theories to postulate, also, an association between early infant rearing and later personality development. The subject who was herself breast-fed may be more likely to achieve a well-integrated, and later adequately maternal, personality so that she, in turn, is more likely to feed her own infant. While such a sequence would probably depend more on the total mother-child relationship than simply the act of breast-feeding, it might be possible to test this hypothesis in part by analysing further the authors' second group, "some children breast-fed," into those who were themselves nursed, and those whose siblings only were breast-fed.

It might also be valuable to study further the 148 subjects (group 4) who had no knowledge of their mother's breast-feeding habits, and the lowest successful lactation rate of all. If this group were distributed, in terms of breast-feeding history, in the relative proportions occurring among the remainder, the expected breast-feeding rate would be 56% and not 41% as found. This is the more surprising since those group 4 subjects tested had proportionately high early milk yields (Table VII). Without further information the implication seems to be that knowing whether or not oneself and one's siblings were nursed by mother affects the chances of successful lactation almost as much as having a mother of high or low feeding performance. It would be of interest to know how marked was the preponderance of "good performance" among the first generation mothers with "strongly in favour" attitudes towards breast-feeding, since, unless this were small, it might be inferred from Table V that holding strong views on the subject counteracts any advantageous genetic endowment transmitted to the daughter.

While, no doubt, many factors are operative, it may well be that psychological variables (personality differences, of which conscious knowledge of mothers' nursing qualities might be an indirect measure) account partly for differences in the lactation rates of otherwise matched groups.—I am, etc.,

London, S.E.24.

I. PIERCE JAMES.

G.P. Responsibility in Gynaecology

SIR,—Mr. J. K. Russell and his collaborators (*Journal*, September 7, p. 558) ignore the fact that practitioners have differing ability, training, interests, energy, available time, facilities, etc. For example, many practitioners find trichomonad infections and moniliasis, classified in the article as discharges warranting referral, suitable for treatment. As a trainee I was taught to carry sterile pipette and vaginal swab, and in cases of vaginal discharge, in addition to pelvic and urine examination, I obtain with the pipette a specimen of discharge and examine microscopically a suspension in normal saline on a warm slide for trichomonas, and a swab is taken for the laboratory.

Having confirmed a diagnosis of trichomonad or monilial infection, the following treatments are very effective: for trichomonad the following pessary should be inserted on nine alternate nights: zinc peroxide powder 30 gr. (2 g.), sulphathiazole powder 30 gr. (2 g.), glycolgelatin base to 2 dr. (7.8 g.). Douching is carried out with $\frac{1}{2}$ % lactic acid every morning. For moniliasis paint the cervix, vagina, and vulva carefully with 2% aqueous solution of gentian violet. One treatment suffices. These patients will be cured before they would have obtained their specialist appointments. In the case of moniliasis it is useful to remember that one can

often prevent persistent reinfection of the baby by attention to the mother.

Mr. Russell and his practitioner colleagues are really barking up the wrong tree. They should condemn treatment without first making an accurate diagnosis—a pitfall in every branch of medicine. But they should leave practitioners to decide on the basis of their own experience what they are or are not capable of treating.—I am, etc.,

Hereford.

WM. G. DAWSON.

Operative Obstetrics

SIR,—In the otherwise generous review of *Operative Obstetrics*¹ (*Journal*, August 24, p. 453) it is stated that all the references to obstetrical literature are more than four years old. As would-be readers may be led to suppose that the text of this book is less than up-to-date, I should like to point out that there are in fact no fewer than 147 references to publications within four years, including some that appeared within 12 months of the issue of the book.—I am, etc.,

Oxford.

J. CHASSAR MOIR.

REFERENCE

- ¹ Munro Kerr's *Operative Obstetrics*, 1956, 6th ed., by J. Chassar Moir. Baillière, Tindall and Cox, London.

Mass B.C.G. Vaccination

SIR,—Dr. E. F. James (*Journal*, August 17, p. 410) mentions that tuberculosis is on the run in County Tyrone; the chest hospital is now a geriatric unit. The position in Lewis is exactly the same. Dr. James boldly claims modern treatment as the cause of this very satisfactory state of affairs. Lewis was the blackest spot in Britain from 1914 till 1930 (death rate per 100,000, 1914, 210; 1930, 173), when the mortality rate began to fall coincidentally with a scheme for replacement of "black-houses" by more modern structures, and the fall continued till 1943 (death rate 50 per 100,000). Had there been no second world war tuberculosis in Lewis would have been of negligible proportions long ago—without modern treatment. The war meant that infected youths went off to live, work, or fight under abnormal conditions of diet and mental and physical strain, which factors caused their primary lesions to break down (not repeated infection), so that they returned, many in the matter of months, as open cases of pulmonary tuberculosis to set up another epidemic in the island. The result was that the death rate rose annually from 1943 to a peak of 162 per 100,000 in 1948, when the fall began. I admit that modern treatment has played a tremendous part in this fall, but housing conditions have been improving fast at the same time.

Dr. James's assumption that fewer tuberculin-positives are to be found among children has been proved in Lewis, because mass tuberculin-testing followed by mass B.C.G. vaccination was adopted in 1949. The following facts ought to be of interest to him: B.C.G. vaccinated, 5,000; "consequent tuberculous lesions" (his term), none; axillary adenitis (B.C.G. isolated), 3. Since 1949, 196 cases of tuberculosis in adolescents under 25 years of age have been notified. Of this 196, 82 were in school in 1949 and so were tuberculin-tested; 68 were positive reactors, 14 were negative but refused B.C.G. Of the 5,000 persons vaccinated, 1 has developed tuberculosis. Surely some of the 5,000 ran as much risk of contracting tuberculosis as did those 14 who refused B.C.G. That some did run the risk has been proved in scores of cases in which the annual tuberculin-test has been noted to be more pronounced in one year than in former years. B.C.G. did not prevent infection (super-infection, rather), but it did prevent disease developing.

To what extent tuberculosis in Lewis is vanishing is demonstrated by the following figures: school entrants, 1949-50, 18% positive; 1956-7, 1% positive. The factors producing such unique results have been (1) housing;

(2) diet (the diet here has always been good); (3) education; (4) co-operation of the people in all anti-tuberculosis measures with a desire on their part for early discovery and treatment; and (5) B.C.G. babies born in the Lewis Hospital are receiving B.C.G. by multiple puncture—Glaxo percutaneous freeze-dried vaccine (experimental).—I am, etc.,

Stornoway, Isle of Lewis.

R. STEVENSON DOIG.

SIR,—I am glad Dr. T. M. Pollock (*Journal*, August 31, p. 528) agrees that mass vaccination is not indicated in County Tyrone. It was not easy to avoid, since originally tuberculosis was much more prevalent here than in England, and the tide of propaganda in favour of B.C.G. kept rising. Indeed, it would have been unethical not to have applied mass vaccination, had it not been possible to show as the years went by that at least as much was being achieved without B.C.G. as had ever been supposed to have been achieved with it.

If we had been using B.C.G., we would now believe, naturally enough, that it had been a factor in bringing about the present favourable situation, and we would give it some of the credit which we know to be due entirely to the modern treatment of tuberculosis. I do not deny that B.C.G. enthusiasts have demonstrated the efficacy of vaccination, over short periods, to their own satisfaction, but if B.C.G. genuinely prevents tuberculosis its effect should be demonstrable in those places in which it has been widely used for many years. Here the evidence, far from being against me, as Dr. Pollock suggests, is entirely in my favour. It is impossible to escape the fact that B.C.G. languished almost unknown in the years between the two world wars, and did not become famous until the antituberculous drugs were discovered. Since then the pattern everywhere of tuberculosis mortality and morbidity has varied with the extent to which these drugs have been used, regardless of whether B.C.G. vaccinations have been performed by the million or not at all.

It is probable that in the past 10 years more vaccinations have been carried out under the auspices of the World Health Organization than by any other single agency. There is a voluminous literature which describes in great detail how the various B.C.G. "campaigns" have been conducted. But I do not know of a single publication by the W.H.O. of an attempt to assess the results of vaccination in preventing tuberculosis in any of the many countries in which it has operated. This strange silence is most significant and makes it reasonable to conclude that there are no results to assess. The question, therefore, is not what is the optimum age for mass vaccination, but what is the justification for mass vaccination at any age and in any country. So far none has been found, and, while there is no doubt that B.C.G. will ultimately revert to its former obscurity, it is not possible to watch without protest the waste of precious energy and resources of a pseudo-scientific ritual.—I am, etc.,

Dungannon, Co. Tyrone.

E. F. JAMES.

Nitrous Oxide Anaesthesia

SIR,—I have had several cases of carpo-pedal spasm in dental anaesthesia using a MacKesson machine. These patients were female and received nitrous oxide and 5% oxygen without rebreathing. The painful muscular spasms developed during the anaesthetic and remained for several minutes after it. Vigorous massage and hot bathing relieved the condition. One of these patients collapsed two hours after the anaesthetic with repetition of the carpo-pedal spasm. Intravenous injection of 10 ml. 10% calcium gluconate was immediately successful in removing the spasm. Three hours later it recurred, this time with early laryngeal spasm. Repetition of the intravenous calcium gluconate again proved successful.

One young girl developed this spasm on three occasions, once with 15% oxygen and rebreathing. The interesting point is that she developed a similar spasm whilst receiving

gas and air from a Minnitt's apparatus in first-stage labour. 10 ml. 10% calcium gluconate intravenously produced almost instant relief of the spasm, and for the rest of the labour there was no recurrence. I have not heard of this condition complicating either dental or obstetric anaesthesia with nitrous oxide. It may be that the overbreathing reduces the CO₂ level in the blood, thereby reducing the calcium content of the blood in people who have a mild degree of calcium deficiency. I will be interested to hear of any similar cases, and of any views on the subject.—I am, etc.,

Hawes, Yorks.

J. D. McDONALD.

Premedication with Methylpentynol

SIR,—I was interested to read the letter from Dr. G. Kagan (*Journal*, July 20, p. 161) dealing with the subject of treatment of nocturnal enuresis. Because of the similarity of the condition I am prompted to mention successful treatment of two cases of psychogenic diarrhoea using methylpentynol carbamate ("oblivion-C"). In both of these cases—full physical and pathological investigations were performed, with negative results, and in the former case six weeks' hospitalization and dietary regime was ineffective. In both cases the patient was afraid to move more than a few minutes from a public convenience, and hence activities were severely hampered. The anxiety which this caused was overwhelming. In both cases psychotherapy combined with a dose of 200 mg. methylpentynol carbamate three times daily caused remission of symptoms, and in the first case a bowel action frequency of 15 times per day was immediately reduced to a normal motion once a day. This case was followed up for a year without relapse.

I should like to mention also a small series of cases in which methylpentynol carbamate has been used most successfully as a premedication for E.C.T. 120 cases were given E.C.T., of whom 70 were premedicated with methylpentynol, as follows:

Not Premedicated	Time of Administration	Premedicated				
		Dose				
		500 mg.		600 mg.		
		Success	Improved	Failure	Success	Failure
30 anxious; 1 requested methylpentynol; and 19 undisturbed.	7 a.m.	2		0	2	0
	8 "	20	6	1	24	0
	9 "	3	2	4	0	6

Successful premedication was marked by complete absence of anxiety regarding treatment, without sopor. Treatment was given at 9.30 a.m. It seemed therefore that 600 mg. given 1½–2½ hours prior to treatment constitutes an effective dosage in this indication.—I am, etc.,

Bournemouth.

R. L. JILLET.

Removing the Pump Handle

SIR,—Dr. I. Lloyd Johnstone (*Journal*, July 27, p. 235) states that Dr. John Snow's advice to remove the pump handle "quickly ended the epidemic" of cholera in the Broad Street area in 1854. Commencing on August 2, 1854, the daily number of fatal attacks of cholera recorded by the daily number of fatal attacks of cholera recorded by Snow¹ were as follows: 8, 56, 143, 116, 54, 46, 36, 20, 28, 12, 11, 5, 5, 1, 3, etc. The fact that the majority of persons living in this district fled in terror as the danger became apparent must have had some mitigating effect on the epidemic, but there is no evidence to show that removal of the handle from the Broad Street pump on September 8 had any effect whatsoever.—I am, etc.,

Prince Rupert,
British Columbia.

W. B. LAING.

Merchant Shipping Medical Scales

SIR,—Dr. S. D. Karve's letter (*Journal*, August 31, p. 527) has admirably pinpointed the need for modern reorganization of ships' medical supplies. Usually ship surgeons have just to accept their sick-bay equipment. Often, if they demand additions, they will be referred to the Merchant Shipping Medical Scales, which are "rigidly laid down." But a glance at these lists shows the absence of really potent modern drugs and the presence of substances such as mustard leaves, alum, and the kaleidoscope of yellow, pink, and white lint.

In our experience as doctors on the British North Greenland Expedition (1952–4) we found that the small sealing vessel which took us to the Arctic was seriously deficient in medical stores despite the fact that it was exposed to the hazards of the pack ice and danger of trauma to the crew. We noted that there were only a few gauze bandages, no adhesive bandages, no aspirin, but pounds of Epsom salts. The medical equipment for the expedition itself had been assembled by a layman using the Merchant Shipping Medical Scales in the early planning stages before the appointment of the medical officers. The supplies required fairly extensive reorganization before we sailed; subsequently many unnecessary drugs were still found. On our return to Britain a complete revised list was published¹ concerning instruments and drugs (1) actually used and considered necessary, (2) which might be used, (3) considered unnecessary, (4) which should be added.

The arrangements for a polar expedition and for a small ship have much in common, and we feel that our lists might usefully serve as a basis for guidance. We know, of course, that in small vessels one can often get away with poor equipment, since the crew is usually fit and healthy. However, it is a different story on a passenger ship; a colleague recently told us that on a liner with 500 passengers there was no provision for a simple suction apparatus. Most ship appointments are temporary, and at the end of a contract the average doctor hardly considers it worth while to pursue his initial complaints, especially if he has adapted himself to the situation during the voyage. Dr. Karve is therefore to be complimented on his letter, and it is hoped that his remarks will stimulate a review and modernization of the Merchant Shipping Medical Scales and their implementation.—We are, etc.,

J. P. MASTERTON.

H. E. LEWIS.

London, N.W.3.

REFERENCE

¹ Lewis, H. E., and Masterton, J. P., *Lancet*, 1955, 2, 494, 549.

SIR,—I read Dr. S. D. Karve's letter (*Journal*, August 31, p. 527) with great interest and amusement. I believe that the late Albert Chevalier (of "My Old Dutch" fame) used to sing (dressed as a burglar) that the "curse of every profession was the bloomin' Hamatoor" (amateur).

After 10 years at sea I feel that I am in a position to criticize Dr. Karve's views. He complains of lack of planning by the shipping company. He should realize that every contingency that may arise has been provided for. The unnecessary drugs and instruments he mentions are all very useful and may be required. There are very few made-up mixtures, it is true, but enough. The mortar and pestle is essential to grind down crystalline preparations and to mix powders, such as the constituents of mist. rhei co., for example. It may be "futile and completely unnecessary" to compound prescriptions on the high seas, yet I have done so many times, with apparent success. I am sorry to learn that the present-day doctor does not know a certain amount of dispensing. How about an isolated country practice?

Dr. Karve is quite correct in saying that there is no help of any sort, not even a dresser. That is what the ship surgeon is paid for. British sailors generally are very capable and self-reliant; the surgeon is no exception. Dr. Karve thinks that no ship surgeons have had sufficient training or experience to take on a surgical operation.

Shades of P. & O. and Union Castle protect us! There are some holders of the F.R.C.S. diploma at sea. The idea of the comprehensive set of major surgical instruments is that it may be at the disposal of a surgical specialist who is travelling in the vessel as a passenger, should the ship surgeon be out of his depth (see the excellent *Ship Captain's Medical Guide*). May I conclude by saying that many a long voyage has been assisted to pass pleasantly and quickly for me by making use of the scales, mortar and pestle, urine-testing apparatus, and microscope provided? A little more experience at sea and Dr. Karve would soon be able to perform his duties in almost any kind of weather without difficulty.—I am, etc.,

Bromsgrove.

RICHARD PALMER-FIELD.

Chronic Bronchial Infection

SIR,—Your annotation on the subject of antibiotics in chronic bronchial infections (*Journal*, August 24, p. 459) considers only one factor in the cost of treatment—the cost of the drug. This is, of course, a consideration, but surely it must be set against the general picture as a whole. The morbidity and mortality figures for chronic bronchitis are among the highest of any disease in Great Britain. This is particularly relevant in the great industrial centres where the time off work is such an important factor in the nation's production capacity. The cost to the taxpayer in National Health Insurance benefit must also be considered. Acute exacerbations of the disease may often result in a stay in hospital of several weeks, and an exacerbation may precipitate congestive cardiac failure due to cor pulmonale. This may necessitate an even longer stay in hospital. In fact, Flint¹ found, in a survey of all patients with heart failure admitted to the City General Hospital, Sheffield, between March, 1952, and March, 1953, that cor pulmonale was the commonest form of heart failure among the males, and that the majority of cases resulted from bronchitis.

The average cost of a week's stay in hospital is £20–£25. Prolonged out-patient administration of antibiotics may prevent the occurrence of acute exacerbations, and recurrent acute pneumococcal infections necessitating in-patient treatment. Your annotation states that only a little benefit is achieved by long-term treatment with antibiotics. This is not the case. Edwards *et al.*² found that the improvement in the patient's clinical status was considerable. Other physicians have confirmed this point.³ What has not yet been established is the correlation between the bacteriological and the clinical findings. Although *H. influenzae* is undoubtedly a factor in the aetiology, the pneumococcus, streptococcus, and other bacteria are also involved. The exact relationship of these organisms in chronic bronchitis is unknown. Edwards,² Elmes,⁴ and Helm *et al.*⁵ have shown that clinical improvement can be obtained without much alteration in the incidence of *H. influenzae* in the sputum.

The oxytetracycline used in one of the trials mentioned above⁶ and that of the Medical Research Council⁷ was in fact supplied by this company free of charge. This is in accordance with the usual practice where clinical research investigations of this nature are initiated.—We are, etc.,

Dyspareunia

SIR,—As Dr. Mary Pollock says (*Journal*, August 17, p. 409), dyspareunia at the introitus is common in the newly married, often persists for a long time, and can lead to mental disharmony. The treatment she suggests may indeed be useful sometimes, but her letter gives an impression of a

physical phenomenon treated with simple medication, which is surely misleading. There are times, giving advice premaritally and immediately after marriage, when it is as simple as that, but when the dyspareunia is of any longer duration it is complicated by vaginismus, which requires an assessment of psychological factors. Treatment designed to stretch the hymen if it persists may still be necessary, but the most important thing then is the aftercare, to enable the patient to relax and to gain confidence in her ability to consummate. She deserves an explanation of how it has come about. She may need to use her fingers or vaginal dilators to prove to herself that she is big enough when she relaxes, but she also needs some measure of psychotherapy varying from reassurance, suggestion, etc., at a superficial level to catharsis, hypnosis, psycho-analysis, etc., at a deeper level.—I am, etc.,

ELEANOR MEARS.

Cat-scratch Disease

SIR,—The reports on cat-scratch disease (*Journal*, August 24) have a similarity to the rat-bite fever described by Sir Philip Manson-Bahr.¹ He reports that rat-bite fever occasionally occurs from a cat-bite, lung haemorrhages occur, plus adenitis, rashes, and a tendency to relapse. My main purpose in drawing attention to the similarity is that either salvarsan or neo-salvarsan is reported specific in rat-bite fever.—I am, etc.,

Cerebral Cysticercosis

SIR,—In your annotation (*Journal*, August 31, p. 516) a paper¹ is cited under my name. As this appears to have become an established reference, I should like to point out that the original source of the paper—as clearly stated in an editorial note—is the *Transactions of the Royal Society of Tropical Medicine and Hygiene* in 1934.² An earlier article on the subject appeared in the same journal in 1933,³ while still earlier I called attention to the occurrence of cases of cysticercosis in the Report on the Health of the Army for 1930. My present views, as modified by time and experience, are given in the current edition of the *British Encyclopaedia of Medical Practice*,⁴ and I do not think that the features of the disease additional to the production of fits have been neglected. One important point stressed there is the unreliability of the case histories that many of the victims of cerebral cysticercosis relate of themselves.—I am, etc.,

Acute Inversion of Uterus

SIR,—I would not disagree at all with the main contention of Dr. Henry FitzGibbon's letter (*Journal*, September 7, p. 589) that the essential treatment of shock from acute inversion of the uterus is replacement of the organ without delay, no matter how severe the degree of shock. I would question, however, his explanation of the shock as "due to pressure of the uterine musculature upon the ovaries contained in the 'inversion funnel'." In the first place the ovaries are not contained in the inversion funnel even in those cases where the uterus lies outside the vulva; they sit just above the rim and at necropsy or operation are not obviously in trouble. In the second place torsion and infarction of the ovary would seem a more drastic event than compression, and yet the degree of shock is not comparable with that in inversion of the uterus.

Would not a more acceptable explanation be that the drag on the peritoneum is the origin of the shock, and that the effect produced is proportionate to the degree of pull on the peritoneum and the speed with which it is applied?

If the uterus descends outside the vulva the displacement of the broad ligaments and pelvic peritoneum is extensive, and it is in such cases that one sees the worst degrees of shock. A well-recognized method of producing shock in experimental animals is to pull on the mesentery, and a hutch-bred slack-bellied rabbit can be shocked sufficiently to kill it by the simple device of holding it vertical and giving a jerk so that the guts drag on their mesenteries. I submit that a similar mechanism might account for the shock of acute inversion of the uterus. If the inversion takes place slowly and the uterus remains within the vagina the shock may be so little as to escape notice.—I am, etc.,

Newcastle upon Tyne, 2.

FRANK STABLER.

Liquor Amnii Studies in Prediction of Haemolytic Disease

SIR,—In support of his enthusiastic recommendation of abdominal paracentesis at 32 weeks for all Rh immunized mothers (*Journal*, August 17, p. 376) Mr. A. H. C. Walker quotes figures from a meeting at Queen Charlotte's Maternity Hospital which suggest an unduly high caesarean section rate. The actual table shown at the meeting was as follows:

30 Infants born early, 1956.				
36th week. Induction of living baby	24 cases	Rh + 16 lived.	Rh - 1 died (moribund)	
		Rh - 7 lived.		
37th " Caesarean section (for failed induction)	2 "	Rh + Both lived.		
37th " Caesarean section (obstetric reasons)	1 case	Rh + Lived.		
32nd " Caesarean section (previous history of two or more early intrauterine deaths and homozygous husbands)	3 cases	Rh + { 1 lived.	Rh - { 2 died.	
Total salvage		All Infants. 90%	Rh + Infants Only. 87%	
Salvage 36 weeks and later		97%	95%	

It can be seen that 24 of the 30 cases described were induced at 36 weeks irrespective of whether the husband was homozygous or heterozygous, but that there were only six caesarean sections, two of which were for failed induction and one for obstetric reasons. Elective caesarean section at 32 weeks for Rh immunization was only performed in the three cases where it could be predicted that the chances of a live baby at 36 weeks would be about 1 in 5. Two of these babies were, in fact, found to be moribund, but the third survived after a single exchange transfusion; spectrophotometric examination of liquor at 32 weeks could not therefore have saved either of these babies.

The purpose of this letter is not to denigrate in any way the valuable contribution of Mr. Walker, but merely to correct statements of fact.—I am, etc.,

London, W.6.

JOHN MURRAY.

Insufficiency of Internal Cervical Os

SIR,—Some recent references to my 1952 article on the cervix¹ prompt me to try to correct what I believe to be misapprehensions. The article by Aschoff,² cited by Mr. V. B. Green-Armytage and Professor J. C. McClure Browne (*Journal*, September 7, p. 589), though relevant to the views of Shaw, has of course no relation to mine. The views of Danforth³ do not differ from mine (in my opinion) so much as the acidity of his second article might suggest—not, that is, in regard to matters actually discussed. There has never been any suggestion that the cervix was not mainly fibrous, and it is agreed that there is some muscle running down the outside from lower segment to vagina, with some disagreement as to its prominence. The muscle round the internal os (which alone is likely to be of obstetrical importance as a contractile force) has not been discussed. The interested reader may confirm these statements from the penultimate paragraph of Danforth's second article, and from my reply⁴ to its criticisms of my technical heterodoxy.

To go on to the question of cervical insufficiency, in my article I reproduce two low-power photomicrographs (Figs.

Obituary

H. V. JESSOP, M.R.C.S., L.R.C.P.

Dr. H. V. Jessop, who was in general practice at Burton-on-Trent for over thirty years, died in a nursing-home there on August 23. He was 68 years of age.

Harold Vernon Jessop studied medicine at Birmingham, qualifying M.R.C.S., L.R.C.P. in 1923. In the following year he settled in practice at Burton-on-Trent, where he remained until his death. He was very active in the local affairs of the British Medical Association, and was chairman of the Burton-on-Trent Division in 1946-7. Dr. Jessop's wife died four years ago and he is survived by a daughter and a son.

W. J. V. writes: I cannot allow the death of my old friend Harold Vernon Jessop to pass without a last tribute to a really outstanding general medical practitioner and man—to one who always put service before self, who ever upheld the finest traditions of his profession. A modest and retiring disposition hid a character of surprising strength in the line of duty. Nothing was too much trouble to him, and the humblest patient received the same conscientious care and attention as the wealthiest and most important. He was one of those rare individuals who never had an unkind thought or uttered a harsh word. Such a loyal and lovable man will be sadly missed by his family, friends, and patients.

J. P. PENSON, M.R.C.S., L.R.C.P.

Dr. J. P. Penson, who had been in general practice at Reading for the past seven years, died on August 23 at the age of 36.

John Patrick Penson was born on June 1, 1921, the son of Dr. J. F. Penson, and was educated at Taunton School. He received his medical training at the London Hospital, qualifying M.R.C.S., L.R.C.P. in 1945. He then held two house appointments at the Essex County Hospital, Wanstead, before entering the R.A.F. in 1947 for National Service. Released from the R.A.F. in 1949, he spent six months as gynaecological house-surgeon at Farnham Hospital, in Surrey. In 1950 he settled in Reading, first as assistant, and later as junior partner, with his father, and on the latter's retirement in 1952 took over the practice. He was medical officer to the Earley branch of the British Red Cross Society and to the Reading National Hospital Reserve mobile first-aid unit. He was a member of the Reading Local Medical Committee and of the executive committee of the Reading Division of the British Medical Association. He leaves a widow, a daughter, and a son.

OSCAR OLBRICH, Ph.D., F.R.C.P.Ed.

The obituary of Dr. Oscar Olbrich was printed in the *Journal* of September 14 (p. 648).

I. M. J. writes: Others better qualified to do so than myself will write of the purely scientific contributions to medicine made by Dr. Oscar Olbrich, but no account of his life in this country can be complete without an appreciation of the service he rendered to a community of 400,000 people since he came here as consultant physician in charge of the newly formed geriatric unit at Sunderland General Hospital seven years ago. In a very short time he transformed a repository for the chronic sick, exhibiting all the features of a poor law institution, into a completely modern medical clinic offering any elderly sick person full medical investigation within a week of request, and in which a bed can be commanded without a single day's delay whenever either the nature of the illness or social circumstance warrant hospitalization.

The achievement of this state of affairs, which contrasts so markedly with what obtains in most areas of our country,

20 and 21), showing just such a cervix as Mr. Green-Armytage and Professor Browne have been operating on in the process of premature dilatation. The difficulty of making firm inferences from such material is not only that of deducing function from structure, but also the perennial pathological one of deducing the earlier structural pattern from the later. Thus, whether the ovum is normally retained by the cervical collagen, the muscle round the internal os, the muscle a few cm. higher up embracing the maximum diameter of the foetal head,⁵ or all three, the result of any giving way will be much the same—the lower segment will stretch, the lower end of its muscle will pull away from the cervical collagen (leaving a few scattered fibres *en route*), and the cervix will stretch and deform. In my case it seemed to me that the retreat of muscle away from the internal os was of disproportionate degree to the other factors mentioned, and therefore that giving way of this muscle was the cause of the trouble—at least in this case. No doubt this cervix might have retained its integrity with a stitch through it. I think it worth remarking, however, that any operation that narrows the cervical canal (whether by putting something into the cervix or cutting something out of it) will enable the upper cervical muscle to act at a greater mechanical advantage—a factor whose importance was recently suggested by Nixon and Smyth.⁶—I am, etc.,

London, W.C.1.

Medical Association for the Prevention of War

SIR,—Since it would appear that the Medical Association for the Prevention of War is a Communist-sponsored organization, and since it would seem to many colleagues that a medical association for the prevention of war is a good thing, why not have a non-Communist medical association for the prevention of war?—I am, etc.,

Darlaston, Staffs.

PAUL HAMMET.

St. Luke's Day Service

SIR,—May I, through the courtesy of your correspondence columns, once again draw the attention of your readers to our special service for doctors which is to be held in All Souls this year on Sunday, October 20, at 11 a.m.? We greatly value our link with the medical profession, and have been encouraged by the support which they have given these services during the last five years.

The Rt. Hon. the Lord Evans and Sir Gordon Gordon-Taylor have kindly agreed to read the lessons. We shall be happy to reserve seats for doctors and members of their families who apply for tickets in advance. Application (stating the number of tickets required) should be made to the Church Secretary, All Souls, Langham Place, W.1. by Thursday, October 17.—I am, etc.,

London, W.1.

JOHN R. W. STOTT,
Rector.

POINTS FROM LETTERS

Clinic for Homosexuals

Dr. CLIFFORD ALLEN (London, W.1) writes: I am delighted to see that at long last an attempt is to be made to establish a clinic for the treatment of homosexuality (*Journal*, August 24, p. 471), but why only this form of sexual abnormality? Surely what is needed is a psychosexual institute for the treatment of all forms of sexual aberration. For nearly twenty years I have insisted on the value of treatment in these cases and have published series of successful results (*Med. Press*, 1956, 235, 441). . . . As one who has some slight claim to be a pioneer in therapy of these cases, may I wish Dr. R. H. N. Long every success in his realization of a valuable idea, but express the hope that he will extend it to all types of sexual neurosis?

was made possible by the outlook, skill, industry, and organizing ability of Dr. Olbrich. He firmly rejected the idea that senility is inevitable and condemned the practice of allowing old people to go into a bed-ridden decline. He was interested in his patients as people, not merely as cases, and had a deep concern that they should live a full, interesting, and useful life. While directing a most active research establishment he yet found time to serve as chairman of the Old People's Welfare Committee in Sunderland, and was responsible for the inauguration of the "meals on wheels" service here.

Like a rare diamond Dr. Olbrich had many facets. His chief characteristics were his warmth and charm of manner, remarkable energy, which remained almost unaffected by serious illness, a deep understanding of human nature, a high sense of values, and great courage. Respected by all his colleagues and worshipped by his friends, he supervised all admissions to his clinic and was truly as close to the family doctor as his telephone. We never sought his help in vain. Though never intolerant of a differing point of view, Dr. Olbrich's fearlessness and integrity could make him a formidable foe to the hypocrite and the self-seeker. His own oblivion to personal reward is best exemplified by the prodigious amount of domiciliary consultation he undertook despite the fact that during the greater part of his time here no remuneration was received by the full-time consultant for such work. Several thousand elderly folk residing in this area bear living testimony to the greatness of Oscar Olbrich. He can have no finer epitaph than the continued existence of the geriatric unit whose traditions he founded so well.

Dr. H. PETER TARNESBY writes: The sudden death of Dr. Oscar Olbrich is a sad blow to the many students who had the privilege to be under his remarkable tutorship at Edinburgh. When in 1943 he first came to the medical outpatient department he made an immediate impact. It was an uphill fight for him from the start, but he could not fail to overcome all prejudice; because behind the "funny foreigner with the atrocious accent" was a truly great man, a most gifted and helpful teacher with an extensive knowledge and clinical acumen, a most likable, forceful personality with a wonderful sense of humour who could not help captivating the admiration and affection of those working with him. Soon "Ossie's" tutorials were crowded and his reputation grew high. He was one of those rare men who are inspired: he was driven by a great force which urged him to do clinical research, to overcome all seemingly impossible obstacles to do it, and to spare himself no personal hardship in its pursuit. Men who are really devoted to research are a gift of the gods, and deeply devoted he was. He has done more than publish 23 highly respectable papers on gerontology. He has perpetuated the tradition of his own original medical faculty in Prague, of which he was justly proud, and integrated it with that of the Edinburgh school which he much admired. This was his achievement; and in the spirit of his students it will live on.

A memorial service for Sir Charles D. Read will be held in All Souls Church, Langham Place, London, W.1, on Friday, September 27, at 11.45 a.m.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

In Congregation on August 3 the following degrees were conferred:

M.D.—*G. H. Dhenin, M. J. D. Newman, J. R. H. Pinkerton, J. S. Mitchell, C. B. Prowse, R. V. Walley, T. J. Rendle-Short, R. L. Huckstep, T. B. Anderson, Pow-Meng Yap.
M.B., B.Chir.—J. G. Halberstam, A. J. Hosking, *R. A. Barron, *J. E. Porrielly, N. G. A. Gracey, *T. S. Worthy.
M.B.—*D. A. Crockford, *D. C. Dumonde, *M. W. Haslett, R. A. N. Petrie, *T. R. P. Cullinan, *J. W. B. Palmer, W. J. Cliff, *R. A. Latham, *D. W. Potts, D. A. Nightingale, I. McD. Jessiman, *R. Banerjee, *J. E. Robinson, *June M. Wilby, *Elma P. Wyatt, Sonia R. Dias Bandaranaike, Anne W. Peryer, *Katharine E. Cuthbert, P. A. F. Chalk.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending August 31 (No. 35) and corresponding week 1956.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenzal pneumonia.
§ Includes puerperal pyrexia.

Vital Statistics

Poliomyelitis

Poliomyelitis notifications (uncorrected) in England and Wales in the week ending September 7 were as follows, with the figures for the previous week in parentheses: paralytic 158 (151), non-paralytic 121 (156), total 279 (307). For the third successive week the total has declined. Total cases in Scotland were 12 (5), Northern Ireland 13 (29), and Eire 4 (1).

The incidence of the disease fell in most of the main centres of infection, but a notable rise in the notifications occurred in Yorkshire West Riding 29 (Leeds C.B. 11, Bradford C.B. 4). In Kent 26 cases were notified, scattered over 18 districts, the largest total being Hythe M.B. 3. In Essex 14 cases were notified (Clacton U.D. 3) and in Devon 16 (Plymouth C.B. 4, Exmouth U.D. 4, Newton Abbot R.D. 3). The 18 cases in London were spread over 12 boroughs (Wandsworth 4). In Middlesex 19 cases were reported (Hendon M.B. 4, Willesden M.B. 3), and in Warwickshire 11 (Birmingham C.B. 6, Coventry C.B. 2).

Of the 13 cases in Northern Ireland, 7 were reported from Belfast C.B.

Week Ending September 7

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 272, whooping-cough 1,013, diphtheria 1, measles 2,073, acute pneumonia 206, dysentery 220, paratyphoid fever 12, typhoid fever 6.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the years 1948-56 are shown thus - - - -, the figures for 1957 thus —. Except for the curves showing notifications in 1957, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

The fall in the incidence of infectious diseases continued during the week ending August 31 in England and Wales. The falls in the notifications included 1,262 for measles, from 4,267 to 3,005, 97 for whooping-cough, from 1,107 to 1,010, 70 for food-poisoning, from 336 to 266, 63 for dysentery, from 287 to 224, and 56 for acute poliomyelitis, from 363 to 307.

The incidence of measles declined throughout the country; the largest fall was 104 in Southampton County, from 247 to 143, and the only rise of any size was 48 in Dorsetshire, from 72 to 120. The largest fall in the number of notifications of whooping-cough was 43 in Essex, from 80 to 37. The notifications of scarlet fever numbered 245, being 10 fewer than in the preceding week, and only small variations were reported in the local returns. 6 cases of diphtheria, the same number as in the preceding week, were notified; 2 cases were notified in Lancashire, Liverpool C.B., and in Northumberland, Gosforth U.D.

The largest outbreak of paratyphoid fever was 3 cases in Hertfordshire, Rickmansworth U.D.

The number of notifications of dysentery was the lowest for almost three years. The largest returns were Lancashire 53, Yorkshire West Riding 35 (Leeds C.B. 14), and Leicestershire 19 (Wigston U.D. 13).

The largest outbreak of food-poisoning was 43 cases in Surrey, Carshalton U.D.

Influenza

Outbreaks of virus influenza have been reported from many parts of England and Wales, especially in the north-

west and from the East and West Ridings of Yorkshire. Laboratory tests have now shown that the Asian virus is widespread.

Vaccine against Asian influenza is being manufactured at the Wright-Fleming Institute, St. Mary's Hospital, London, and the Government is expected to purchase most of it. It is proposing to buy enough to offer vaccination to doctors and other workers specially exposed to infection. The vaccine is not yet on sale in the pharmacists' shops, and it seems unlikely to be so for several weeks.

Medical News

Changes at Ministry of Health.—Owing to Mr. DENNIS VOSPER's unexpectedly prolonged illness and his need for a thorough convalescence, the Prime Minister has been compelled to accept his resignation and appoint a new Minister of Health. Mr. Vosper succeeded Mr. R. H. TURTON at the Ministry of Health only seven months ago. The new

(Camera Press, Ltd.)

Minister is Mr. DEREK WALKER-SMITH, Q.C., whose appointment was announced on Tuesday. Mr. Walker-Smith comes to the Ministry from the Board of Trade, where since January he has been Minister of State, after two years as Parliamentary Secretary; before this he had been chairman of the "1922 Committee" for four years. He was chairman of the Conservative national advisory committee on local government from 1954 until January, 1956. Mr. J. K. VAUGHAN-MORGAN, who in his capacity as Parliamentary Secretary has been holding the fort at the Ministry of Health since Mr. Vosper became ill, has been promoted to the vacancy left by Mr. Walker-Smith: he becomes Minister of State at the Board of Trade. The new Parliamentary Secretary to the Ministry of Health is Mr. R. H. M. THOMPSON, Vice-Chamberlain of the Royal Household since 1956 and formerly a Lord Commissioner of the Treasury. Mr. Walker-Smith, whose portrait is reproduced here, is 47. He has been Member of Parliament for the Hertford Division since 1945 (Hertford East since 1955), and is the younger son of Sir Jonah Walker-Smith, a former Conservative M.P. and Director of Housing at the Ministry of Health in the 1920s. Educated at Rossall, Mr. Walker-Smith went to Christ Church, Oxford, as a history scholar, where he gained a "First." He entered the Middle Temple as a Harmsworth scholar in 1931, and was called to the Bar in 1934, taking silk in 1955. He joined the Territorial Army in the 1930s, was subsequently commissioned, attended the Staff College, and held various staff appointments during the second world war. In the 1945-51 Parliaments Mr. Walker-Smith took an active part in opposition, particularly in matters relating to Housing and Local Government. He has made many appearances on radio and television. In 1954 he attended the Conference of the Commonwealth Parliamentary Association at Nairobi, and toured parts of East, Central, and South Africa. Mr. Walker-Smith is married and has a son and two daughters. Mr. Thompson, the new Parliamentary Secretary, is 44; he has represented a Croydon constituency since 1950 (first West Croydon and now South Croydon).

Educated at Malvern, he was until 1939 in business in the Far East. He served in the R.N.V.R. from 1940 to 1946, rising from the rank of ordinary seaman to lieutenant-commander. On entering Parliament, he became an assistant Whip in 1952, a Lord Commissioner of the Treasury in 1954, and was appointed Vice-Chamberlain to the Royal Household last year.

W.H.O. Committee on Fluoridation.—"The effectiveness, safety, and practicability of fluoridation as a means of preventing dental caries is now established," states a W.H.O. expert committee on the subject in a press release this month. This opinion is based, it is stated, on a review of fluoridation programmes in 17 countries. According to the committee, there was remarkable uniformity in the results of these programmes: the prevalence of caries in the permanent teeth of children was decreased by some 60%. The only ill effect noted from areas with a naturally high fluoride content in the water was mottling of the teeth. The committee was under the chairmanship of Professor INGVE ERICSSON, associate professor of cardiology at the Royal School of Dentistry, Stockholm. Dr. JEAN FORRESTER, senior dental officer of the Ministry of Health, was one of the rapporteurs.

R.A.F. Appointment.—Air Commodore J. HILL has been appointed principal medical officer, Home Command, with the acting rank of Air Vice-Marshal. The appointment is from October 22. He is at present principal medical officer at Technical Training Command.

Wellcome Foundation.—Dr. FRED WRIGLEY has been appointed to the board of the Wellcome Foundation Ltd. as sales director.

COMING EVENTS

National Smoke Abatement Society.—Annual conference, Hastings, October 2-4. Details from the secretary of the Society, Palace Chambers, Bridge Street, London, S.W.1.

Course in Gastroenterology.—March 10-18, 1958, at Western General Hospital, Edinburgh; arranged by the Edinburgh Postgraduate Board for Medicine. For details see advertisement on p. 44 of this issue.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Tuesday, September 24

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Edridge Green Lecture by Professor George Wald: Molecular Basis of Vision.
WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Dr. J. N. Milnes: Neurological demonstration.

Thursday, September 26

COLLEGE OF GENERAL PRACTITIONERS: NORTHERN HOME COUNTIES FACULTY.—At University College Hospital Medical School, 8 p.m., First Annual Pfizer Lecture by Lady Isobel Barnett: Why Don't We Live to be a Hundred?
FOUNTAIN HOSPITAL.—5.30 p.m., Professor R. S. Illingworth and Dr. Ruth Griffiths: Early Diagnosis of Mental Deficiency.
HILL END HOSPITAL MEDICAL SOCIETY.—8.45 p.m., Dr. P. M. F. Bishop: Endocrine Therapy.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Professor J. F. Silva (Colombo): Old Dislocations of the Elbow.

Friday, September 27

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. J. Smart: clinical demonstration.
INSTITUTE OF PSYCHIATRY.—3 p.m., public lecture by Professor Leo Kanner (Johns Hopkins University): Sources and Results of Perfectionism in Child Rearing.

Saturday, September 28

ASSOCIATION OF CLINICAL BIOCHEMISTS.—At Royal College of Surgeons of England, 9.30 a.m., scientific meeting with Association of Clinical Pathologists. 5 p.m., annual general meeting.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Blatchley.—On September 7, 1957, to Barbara, wife of Dr. W. R. Blatchley, of 29, Birchall Avenue, Matson, Glos., a brother for Christopher and Alison.
Lamble.—On August 26, 1957, at the Nuttall Memorial Hospital, Jamaica, British West Indies, to Pamela (formerly Rothnie), wife of Dr. Ronald Somerville Lambie, a sister for Penelope—Jane Fraser.

DEATHS

Barlow.—On August 24, 1957, at his home, Foxhill, Porthcurnow, Cornwall, Albert Malcolm Barlow, M.R.C.S., L.R.C.P.
Williamson.—On August 18, 1957, Alexander Dewar Williamson, M.B., F.R.C.S.Ed., D.O.M.S., aged 52.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Effect of Adoption on Fertility

Q.—It is a commonly held belief that the adoption of a child by a hitherto barren couple is often followed by the wife becoming pregnant. Are there any statistics to support this belief?

A.—Although it is commonly believed, even by adoption societies, that the adoption of a child by a hitherto childless couple is often followed by the wife becoming pregnant, there are no statistics showing that this occurs more often than would be due to chance. Many relatively infertile women bear their first and often only child some years after marriage, when they have ceased to be hopeful of conceiving. But nowadays women are seldom resigned to wait for this chance, and often, if they have not had a child after a few years of marriage, prefer to adopt one, in order to enjoy parenthood while they are still young. A number of these women will have a child of their own soon afterwards.

If there has been some difficulty in the consummation of the marriage it is of course possible that the mutual happiness derived from caring for an infant might remove feelings of sexual guilt and inferiority, and then impregnation might occur because of improved sexual relations. But adoption societies would be against placing a child with any couple whose sexual life at the time of the placement was known to be unsatisfactory; there is too much risk of such a couple eventually drifting apart, separating, or seeking a divorce.

Grease-gun Injuries

Q.—What is the best treatment for puncture wounds from a grease-gun where grease is injected into the tissues? We have had three recent cases where grease was injected into a thumb or finger.

A.—In Britain grease-gun injuries are very uncommon. One hospital, with a yearly turn-over of 55,000 injuries of all types, sees no more than one a year, and industrial medical officers in the same city attached to large motor manufacturers using these tools extensively report an incidence of only one such injury every ten years. Clearly, therefore, users of this tool must go out of their way to injure themselves by placing their finger or thumb directly over the nipple and turning on the power. Typically the entry wound through the skin is minute, but the tissue damage underneath may be extensive. It is the explosive force of the gun—particularly the powered gun with a bullet-end nozzle used in high-pressure types of greasing—that does the damage. The grease itself may be a relatively inert foreign body.

The wound can be classified as of the "untidy" type. Although the punctured skin wound is a clean one the subcutaneous tissues are damaged over a wide area. Treatment should follow the general principles governing an "untidy" wound. Operation should be carried out in a bloodless field and under local analgesia (without adrenaline). Since almost all such injuries affect the fingers or the hand, either a finger or a pneumatic arm tourniquet is easily applied. The skin incision should cover the puncture wound and be along the crease lines or other well-described safe areas where the skin of the hand is relatively immobile. If such an area does not cover the entry wound then the incision should be of the "Z" pattern. All obvious grease should be removed and all badly damaged and dead tissue excised. As in all hand surgery, the principle of minimum excision of skin and tissue should be observed: stained but viable tissue can safely be left. After careful wound toilet, apposition of the tissues

and closure of the wound should, if possible, be achieved by a pressure dressing of gauze, cotton-wool, and crêpe bandage; sutures and buried ligatures should be avoided. The hand should be immobilized in a position of function and elevated by the use of a sling until the wound is healed. The intact skin of a greaser's hand is usually contaminated by a very wide variety of pathogenic organisms, and these are driven into tissues whose viability has been reduced by the force of the injury. Therefore the surgical cleansing of these wounds is of extreme importance. This is the main defence against subsequent infection, but cleansing should be supplemented by the usual precautions against tetanus. Penicillin therapy is also advised to prevent streptococcal or staphylococcal infection.

Infectivity of Infectious Hepatitis

Q.—(1) For how long does a case of infective hepatitis remain infectious? If there are relapses are these also infectious, and, if so, is the intervening non-icteric period also? (2) What steps should be taken to limit the risks of spreading the infection among the patient's attendants and others?

A.—(1) The stools are considered to be infectious for about three weeks from the onset of illness. A very small number of transmission experiments on volunteers, using faecal material and blood from adult patients who had persistent symptoms suggestive of chronic hepatitis, gave negative results. On the other hand, two young children living in a nursery where the disease was endemic were said to be excreting the virus in their stools 5 and 16 months respectively after the onset of their illness. It is unlikely that there will be any further exact information on the infectiousness of patients with chronic or relapsing hepatitis until the causative virus has been isolated in the laboratory.

(2) Although the conclusions from epidemiological studies in the pre-1939 period favoured spread from the upper respiratory tract as the common mode of infection, the experimental work with volunteers since that time supports the theory that the faecal-oral route is the main mode of spread. Thus the steps to be taken to limit the risk of spread are those usually applied to the enteric fevers—for example, personal cleanliness, safe disposal of excreta, prevention of contamination of food, water, and milk supplies, etc. The chain of contact and spread is very often through schoolchildren, and these should be given particular instruction in personal hygiene.

Gamma globulin may be given to protect pregnant women or other contacts who are in poor health.

Physiological Basis of Leucotomy

Q.—What is the physiological basis of the frontal leucotomy operation? It has been suggested that emotional disorders in the human may be associated with an abnormal reverberation mechanism between the thalamus and cortex. In the intact subject cortico-thalamic fibres inhibit thalamic activity and prevent thalamic sensations from occupying consciousness to any great extent. If the activity of these fibres is impaired surgically, should not this lead to increased awareness of thalamic sensation on the part of the patient and hence to exaggeration of his emotional disturbance?

A.—The mode of action of the various psychosurgical procedures which have now been employed—cortical excisions, leucotomy, and destruction of the dorsomedial nucleus of the thalamus—is not fully understood.

To many the cerebral cortex still represents the anatomical substratum of the highest level of nervous function, and that of the frontal lobes the peak achievement of man's evolution, removal of these lobes interfering with will, inhibitory power, foresight, and initiative.

Sensory stimuli are relayed from the thalamus to the appropriate area of the neopallium and then spread over associative fibres, awakening memories and arousing responses conditioned by past experience. Eventually on the

basis of this the impulses are gathered in and channelled to the cortical area which will effect the appropriate motor response. Simultaneously the stimuli are relayed from the thalamus to the older portion of the cerebral cortex (archi- and meso-cortex), sometimes called the visceral brain, where the emotional response to the particular variety of sensation is elaborated, and through connexions between these regions and the hypothalamus the visceral and vascular changes characteristic of the particular emotion are produced. Through thalamo-frontal and other connexions the emotional accompaniment of the stimulus influences intellectual activities—the influence of the older portions of the cerebral cortex on behaviour being thus effected through the neocortex.

Leucotomy reduces the impact of discharges from lower levels (thalamus and visceral brain) upon the neocortex, so that intellectual processes are freed to a greater or less degree from excessive emotional accompaniments. The lower centres (visceral brain) thus influence behaviour through the higher levels (neocortex), and when separated from these higher levels, in which is centred the neural basis of conscious behaviour, they lose their ability to affect this behaviour. It may be added that in fact the operation of leucotomy does produce a bleaching of emotional response.

Oestrogen Therapy in Prostatic Cancer and Ageing

Q.—Has acceleration of the ageing process in man been noted following the prolonged administration of stilboestrol for carcinoma of prostate?

A.—There is no reliable clinical method of measuring biological (as distinct from chronological) age in man; in addition, changes due to ageing may not affect all organs and tissues simultaneously. Consequently it is difficult to assess whether there is any acceleration of the ageing process in men treated with stilboestrol, or to decide whether the changes which do occur are similar to those which accompany ageing. There is, however, some experimental work which suggests that prolonged stilboestrol treatment may accelerate ageing of the prostate, kidney,¹ and adrenal² in some species of animal.

Tingling of Lips and Tongue

Q.—A woman of 50 has consulted me several times during the past year because of tingling, numbness, and burning of the tongue and buccal aspect of the lips. The condition is made worse by certain foods, such as fruit and spices. She has worn artificial dentures for a few years, but leaving them out for a few weeks has produced no improvement. Clinical examination of the mouth and tongue shows no abnormality, and her blood count is normal. She has not consented to have a fractional test meal, but hydrochloric acid given with her food has produced no improvement. Various treatments have been tried, including injections of the vitamin-B group and cyanocobalamin topically and systemically, without helping the symptom. She is otherwise a healthy woman, apart from mild symptoms due to the menopause. I would be grateful for any suggestions about cause and treatment.

A.—Disturbances of taste and unpleasant sensations in the mouth, lips, and tongue in the absence of physical signs are often difficult to explain and to treat. They are on a par with pruritic sensations in other parts of the body and in this patient may well be related to the menopause. For this reason small doses of one of the oestrogens might be tried. It is unlikely that the symptoms are due to achlorhydria, but the gastric secretion could be tested indirectly by using one of the methods of tubeless gastric analysis or by estimating the excretion of uropepsinogen in the urine.

Painting or spraying the tongue and lips with a solution of hydrocortisone would be worth a trial, and in addition phenobarbitone could be given as a sedative.

Climate and the Chronic Bronchitis

Q.—What atmospheric, climatic, and geological conditions are most favourable to patients who get recurrent attacks of bronchitis? Which parts of Britain are most nearly ideal for these patients?

A.—The question rather implies a knowledge of the aetiology of recurrent bronchitis which, unfortunately, we do not yet possess. There seems little doubt that upper respiratory tract infection, atmospheric pollution, and cigarette smoking may all be important factors. Thus, living away from industrial towns and "smog" in countryside psychologically conducive to a happy and mentally full life in which tobacco plays an unimportant part, seems sound common sense. The southern parts of Britain on the whole enable more days to be spent out of doors, but the writer would not put that factor higher than a country area anywhere where the patient's friends or interests are found. For those who believe in the finer points of climate as a therapeutic agent, the different factors have been discussed and summarized by Sir Adolphe Abrahams.¹

NOTES AND COMMENTS

Fibrous Cavertitis.—Dr. F. PARKES WEBER (London, N.W.1) writes: In connexion with your remarks on Peyronie's disease ("Any Questions?" August 31, p. 535), I think there can be no doubt that, though appearing in middle age, it is of naevoid atavistic origin and allied to the os penis in some animals.¹ It may well be connected with a "fibroblastic constitution" showing itself by keloid scarring of small wounds and tendency to excessive fibrous transformation of syphilitic and tuberculous lesions in the lungs, liver, and other viscera and skin in certain individuals. I frequently saw an elderly man in the hospital out-patient department who had the condition of a so-called "fibrous cavertitis" associated with little fibroid lesions on the legs, which I regarded as the result of fibrous transformation of small syphilitic lesions—subcutaneous fibroid syphilomata.² There was a past history of syphilis.

RECENT ADVANCES IN HAEMORRHAGE AND SHOCK*

BY

A. RUSCOE CLARKE, M.B.E., F.R.C.S.

Surgeon, Birmingham Accident Hospital

I wish to say, first, that it is a privilege to be asked to address this Conference of Surgeons of the St. John Ambulance Brigade. In tendering my thanks for the opportunity I would like to acknowledge my debt to my research associates and clinical colleagues at the Birmingham Accident Hospital. This is important, for these observations would not have been possible without the existence of an independent unit attempting to focus the potential of modern medicine and scientific research on the treatment and study of patients suffering from the effects of injury.

In the past I have been critical of inadequacies in the teaching of first aid, and in particular of many of the first-aid textbooks. A year ago I opened a discussion at a meeting of industrial medical officers and nurses with some sharp comments on first-aid orthodoxy. I tried to be provocative, and it is perhaps due to that attempt that I have been invited to give this address.

Meanwhile I have delved more deeply into the historical origins of ideas which many of us now consider to be out of date. I had not previously appreciated the weight of medical scientific authority which lay behind the treatment of "shock" by artificial heating, hot sweet tea, and rubbing the limbs. The argument is presented in theory and practice in the Medical Research Committee's green book on "Wound Shock and Haemorrhage" based on observations during the first world war of a team of workers which included such historic names as Cannon (1919) and Cowell (1919).

It is true that Blalock (1940) had developed the theory that shock was due to loss of fluid from the circulation, but a new stimulus was needed to shift the balance from the approach which Cannon had so ably presented.

Problem of Blood Loss in Shock

The old attitude is illustrated by Cannon when he poses the question of "the problem of the lost blood in shock." Everyone knew that shock was often associated with bleeding. It was widely known that studies of plasma volume showed that conditions of severe collapse following injury were associated with a severe fall in blood volume and at times an even greater disappearance of red cells, but for many years no reliance was placed on the evidence. Measurements of plasma volume were considered to be unreliable when it was assumed that plasma-like fluid was leaking from the circulation in shock and that this leak was not confined to the site of injury. Furthermore, it was almost univer-

sally assumed that the observed haemorrhage could not possibly account for the disappearance of blood. It was therefore argued that the missing blood must still be inside the circulation, not measurable by blood-volume techniques because it was no longer circulating. Evidence was produced to show that it *could not* be in the arteries and *was not* in the veins—therefore it *must* be in the capillaries.

In the light of our present knowledge we believe this to have been a fundamental error—but a very good case was made out. In certain clinical states which follow injury, with and without severe infection, particularly when death is imminent, the capillaries lose their tone and a patient can bleed to death into the capillary bed in spite of transfusion. The mistake was to conclude that at an earlier stage the fall in circulatory blood volume was due to capillary stasis. The objective of treatment was to mobilize the missing blood back into effective circulation: hence the heat and the friction.

It was known that patients with moderate injuries could partially restore their own blood volume by absorption of fluid from outside the circulation. When this process was slow or ineffective it was assumed, sometimes correctly, that the patient's fluid reserves were deficient. In any case, it appeared to be sometimes possible to increase the blood volume more rapidly by forcing fluids. In addition, severe states of shock were associated with acidosis, which was made worse by anaesthesia. Hence the hot sweet tea—hot as a "stimulant," sweet to provide glucose to combat acidosis, wet to provide fluid. Originally it was laced with alkalis, but these seem to have been left out during the years that followed.

A further fallacy underlies the older approach: we now know that, except in burns, in the occasional crush injury, and in abdominal injuries with peritonitis, the fluid lost from the circulation in the overwhelming majority of injuries is whole blood. For a time, and even well on into the period of the second world war, the emphasis was on the need to restore the blood volume when it was low. We are convinced to-day that this was only a second-best objective even when effective, and that the restoration of red cells can be almost as important as the restoration of total circulating volume.

Blood Banks and Transfusions

I shall return to the story of the missing blood, but first I must stress the fact that the older observations contained almost all the evidence, although the basic

*Based on a lecture given to the St. John Ambulance Brigade Surgeons' Conference, Harrogate, on May 4, 1957.

conception here presented did not receive any wide acceptance until the emergence of the modern blood bank with the possibility of transfusing large quantities of stored blood.

During the first world war transfusion was used in very small quantities. A litre (2 pints) was a large transfusion. It was the experience of the transformation effected by transfusion of much larger quantities of blood to patients with severe injuries that established the need for drastic revision of theory and the reassessment of old therapeutic practices. Blood banks were established in Moscow and Chicago by the early 'thirties. Durán-Jordá (1939) organized a modern transfusion service for the casualties in Barcelona during the Spanish Civil War. Blood banks were being developed in Britain during 1938 and 1939. The experience of the second world war led to their establishment as a normal part of our Health Service.

With stored blood available, transfusion came into its own. Early transfusion of large quantities of blood gave results that were clearly a major advance on all previous experience. Further investigations showed that the blood-volume methods were more reliable than had been suspected. New knowledge of blood groups and new techniques of cross-matching reduced the danger from incompatible transfusions. New methods of preparation and storage reduced other transfusion hazards, and blood can be stored for longer periods.

British, American, and Canadian research teams came to similar conclusions during the 1939-45 war, and by 1946 it was possible for some authorities to suggest that traumatic shock was nothing more than the effect of loss of blood or other fluid from the circulation. This was an over-simplification, but the new thinking required for the treatment of injuries at all stages must be based on the accumulating evidence that *the most important single factor underlying states of shock and leading to early death following injury is loss of whole blood by bleeding.*

Assessment of Extent of Bleeding

The most important clinical and research study which emerged from the second world war is the Grant and Reeve (1951) classic "Observations on the General Effects of Injury in Man," based on a study of 120 patients in England during the air raids and a further 110 patients seen in forward areas in Italy in 1944 and 1945. These authors emphasized the extent of haemorrhage and the role of early rapid transfusion, especially in "large" and "very large" wounds. They elaborated the possibility, particularly in limb injuries, of assessing the extent of blood loss from the nature of the injury. They concluded that the word "shock" was misleading and that existing theories were inadequate.

Observations at the Birmingham Accident Hospital (Clarke, 1952; Clarke, Topley, and Flear, 1955; Clarke and Fisher, 1956) have confirmed those of Grant and Reeve. They are particularly important, because we have been dealing with civilian casualties and have been in a position to carry out very much longer follow-up studies. The last 15 years, moreover, have seen the development of new methods for the determination of blood volume, using red cells labelled with radiophosphorus or radiochromium. These methods are not only more accurate than the plasma-volume techniques but they measure the red-cell loss directly. The radiochromium technique labels the red cells more permanently, so that their subsequent fate can be studied. In a large proportion of patients the life-span of transfused cells is similar to that of the patients' own erythrocytes. The fact that we now have a variety of techniques has meant that

we can cross-check one against the other and determine the blood volume at more frequent intervals. We are now satisfied that blood-volume studies carried out in the acute phase of injury and even during states of clinical shock can provide important information on the depletion of blood volume and the extent to which this is due to loss of whole blood. Compared with Grant and Reeve we would pay less attention to the blood pressure when it is normal and have had a greater experience in studying the effects of more adequate transfusions.

The first theoretical issue that we have been up against is the controversial question of "where all the blood goes to." From repeated blood-volume studies we have been able to show that when seriously injured patients are resuscitated by transfusion to clinical states resembling normality this change has never been associated with any apparent return of missing red cells. This alone might not be considered decisive, so we have concentrated attention on measuring or assessing the actual extent of bleeding.

We soon became aware that blood was missing from the circulation just as frequently in major closed fractures as it was in open wounds. The disappearance of blood appeared to be proportional to the extent of injury, and particularly to the size of the swelling. We therefore measured the amount of swelling in injured limbs soon after injury. The order of swelling frequently corresponds to the amount of blood missing from the circulation. From these measurements and a variety of clinical observations we are now in a position to make a more accurate clinical diagnosis, not only of the extent of blood loss already present but of that which is likely to occur later. The fact that swellings of a given order with recognizable surface appearance can conceal such extensive blood loss can be vividly illustrated by attempting to reconstruct such swellings, for which purpose we have used measured volumes of surgical felt (Clarke *et al.*, 1955; Clarke and Fisher, 1956).

In addition to investigating blood loss in closed fractures, we have studied blood loss from open wounds. During surgery, bleeding can be measured by swab-weighing. Bleeding between admission and surgery can be measured by collecting the blood in a "polythene" bag wrapped round the limb. Bleeding at the place of injury, on clothes, on stretchers, and on the floor is difficult to measure, but we have toned up our capacity to estimate such loss by photographing known amounts of blood distributed in clinically relevant forms. In addition photographs and clinical observations of a wide range of injuries have been correlated with blood volume and laboratory studies.

During the last four to five years we have carried out repeated studies of blood volume on over 100 patients suffering from non-thermal injuries, many of whom have had very detailed clinical and laboratory investigation.

Our general observations have been further confirmed by reports from the American research team in Korea (Prentice *et al.*, 1954). They had large quantities of blood available and were able to resuscitate patients with such severe injuries that they would certainly not have survived at an earlier period of history. Although some of these observers speculated on the fate of the blood lost, it is now generally agreed that frank haemorrhage from the surface or into the tissues is enough to explain the loss of blood and that there is no fundamental mystery. *We are now convinced that the blood loss observed in traumatic shock is simply due to haemorrhage—to loss of whole blood, including red cells, irretrievably from the circulation as a result of direct injury to blood vessels and not due to pooling or stasis in the capillaries.*

Indications for Transfusion

The recognition that blood loss following injury has in the past been repeatedly underestimated has led not just to a policy of giving larger transfusions earlier and with greater speed, but to a careful attempt to establish a more accurate approach to transfusion indications at various stages. At

the same time we have had an opportunity to review other methods of treatment in the light of the effects of transfusion.

We are now convinced that any patient who has lost more than 2-4 pints (1-2 litres) of blood, even when this has taken place slowly and when no early surgery is required, warrants consideration for blood replacement by transfusion. When such a patient has to be submitted to surgery and anaesthesia, or when further bleeding is likely to occur into dressings or into the injured part, transfusion is more definitely indicated. In the presence of more severe blood loss, large transfusions are indicated at an early stage, and in very severe injuries we are using transfusions which frequently exceed the patient's total blood volume.

As a result of our experience with larger primary transfusions we are convinced that blood replacement plays a vital part not only in the treatment and prevention of "shock" but in allowing more adequate primary surgery and in influencing the whole pattern of illness following injury so that convalescence is greatly shortened. We have carried out detailed haematological and biochemical studies which begin to suggest how undertransfusion can lead to illness, and to suggest how adequate transfusion to its reversal or cure. At a later stage transfusion is invaluable in the treatment of infected wounds. Adequate primary transfusion plays a part in the prevention of wound infection and delayed healing.

In summary, blood transfusion is indicated when blood loss has occurred after injury: (1) for the treatment of established traumatic shock; (2) for the prevention of shock and other complications of a low blood volume and red-cell mass; (3) for the facilitation of adequate primary surgical repair, whether this be life-saving, for the arrest of haemorrhage or the prevention of infection, or merely to limit disability following injury to various tissues from bone to skin; and (4) for the prevention of many features of the later illness of trauma.

Dangers of Delay

Our attitude to transfusions as the primary weapon in the prevention and treatment of complications of injury has altered our point of view on the timing of other methods of treatment. When transfusion is not indicated or possible, and in the presence of injuries that do not require surgery, a policy of expectancy may be in order. It may be justifiable to wait during the course of establishing a detailed diagnosis or for accurate cross-matching so that transfusion can be safe. In moderate injuries there is rarely any indication for delay before the patient is transferred to expert medical care. In more severe injuries even without overt shock, a policy of delay without the facilities for diagnosis and transfusion is dangerous. Even when the patient appears fit, processes are taking place in connexion with moderate or severe injuries that tend towards deterioration rather than recovery. A large proportion of injured patients will begin their recovery only when transfusion and surgery have been carried out. Time is not on our side until a detailed diagnosis and assessment has been made and treatment planned and begun.

During recent years we have had considerable experience of the result of delay in transferring patients from outlying hospitals. Our experience corroborates the observations of Grant and Reeve. Patients with moderate and severe injuries do not benefit by an hour's rest which is associated with an hour's delay in carrying out effective treatment. When it was imagined that the fall of blood volume was not due to actual loss of blood one can appreciate the focusing of attention on rest. The patients that recovered did so because they were likely to improve anyway, but too many did not recover at all. A patient who has lost 25-40% of his blood volume from bleeding to the outside or into the tissues, even if he looks fairly fit, is in grave danger of major complications, particularly renal failure, if his blood volume is allowed to remain low for two to three hours. Some of our most successful experiences with severe injuries have been with patients transferred very early, or, when this has been

impossible, when the surgical team has been transported to the patient.

I remember in particular a boy of 18 injured in the Sutton Coldfield train smash. Both legs were torn to shreds from the lower thigh downwards and he had a fractured pelvis which required abdominal exploration to exclude a lesion of the gut. He was put straight in an ambulance at the site of the incident and reached the Birmingham Accident Hospital, 15 miles away, about 45 minutes later. He was in a state of profound haemorrhagic shock, but with the aid of transfusion of 11 bottles of blood, equal to his total blood volume, he survived early bilateral amputation and abdominal exploration and proceeded to make an uneventful recovery. Half an hour's delay without full transfusion might well have been fatal.

Some Traditions

The next orthodoxy which I wish to discuss is the tradition of hot sweet tea. Except when a very long delay is inevitable before full medical attention can be reached, the amount of good that can be done by giving oral fluid is negligible. The real objection to ill-advised administration of fluids or solids to injured patients is the risk that this may lead to vomiting under anaesthesia, one of the common causes of anaesthetic disaster in patients requiring emergency operations. When transfusion is needed, fluids by mouth are unnecessary. Quite apart from abdominal injuries any patient with an injury that might conceivably require surgical treatment under anaesthesia, and this includes many minor wounds and fractures, should have nothing by mouth whatever until a medical decision has been taken that no early operation is necessary. The only exception is that patients likely to be longer than two to three hours before reaching hospital may be given sips of water to allay their thirst. I remember the full operation of the older policy during my first few days in a casualty clearing station in North Africa. The hot sweet tea was given by the reception staff followed by large white tablets to prevent infection, and milk chocolate by the padres. The result was so dramatic that the routine was soon altered. Hot sweet tea is required only for patients who have not been significantly injured. Friction is not indicated at all and smelling-salts should be relegated to the Victorian drama.

More complex is the question of the use of heat in the treatment of the injured. It is perhaps logical from a lay point of view to heat anyone who feels cold. In fact, a patient who is cold and pale from a shut-down of the surface blood supply has insulated himself against heat loss. If he is shivering he is creating heat. The patient whose skin feels cold to the touch and who complains of feeling cold may have a raised internal temperature. The patient who is cold because he has lost a moderate amount of blood will warm up spontaneously unless exposed to the elements. Heating the surface of a patient who has lost a moderate amount of blood may open up the blood supply to the skin and side-track blood from circulation through more essential organs. The patient who is shocked or in a state of lowered consciousness following a head injury is liable to be burnt by the use of hot cradles or hot-water bottles even when the latter are supposed to be applied outside blankets. Finally, the skin appearance and temperature are valuable clues to the state of the circulation in the body as a whole and of an injured limb in particular. The use of heat confuses the evidence. In general there is no place whatever for hot-water bottles or hot cradles in the treatment of injured patients. The more serious the injury the less need there is for blankets. Blankets should be used for (1) the comfort of the patient with a minor injury, and (2) in cold weather for the protection of the patient with moderate injuries.

The head-down position is valuable when the pulse is thin or absent and it appears that consciousness has been interfered with as a result of severe blood loss. It is necessary only in severe conditions.

Splintage is important but needs to be simple. When a patient is to be transported a short distance and will reach hospital within half an hour of injury, it is not justified to take 20 minutes to apply a Thomas splint when tying the legs together will do just as much good.

Morphine and allied drugs are sometimes of value in the presence of pain, distress, and major anxiety. In general, however, the more severe injuries do not give rise to great pain except on movement of injured parts. Such drugs must never be used as treatment for "shock." Large doses of morphine, particularly when repeated subcutaneously in the presence of a sluggish circulation, are dangerous.

Shock: A Complex of Reactions

The main lesson I would suggest from the point of view of first aid is that there is *no treatment for shock* as such, and that in this country rapid evacuation to hospital is the decisive objective. Before concluding with some concrete proposals on the formulation of first-aid principles in this connexion I would like to deal further with the theoretical question of the nature of the complex of reactions commonly known as "shock." The best early description I can find is that of the famous sixteenth-century French surgeon Ambroise Paré. It appears in Johnson's translation as "sowning":

"Sowning is a sodain and pertinacious defect of all powers, but especially the vital; in this the patients lie without motion and sense, so that the Ancients thought that it differed from death only in continuance of time. The cause of sowning which happens to those that are wounded is *bleeding*, which causeth a dissipation of the spirits: or *fear*, which causeth a sodain and joint retirement of the spirits to the heart. . . . Also sowning happens by a putrid and venenate vapour, carried to the heart by the arteries, and to the brain by the nerves; by which you may gather, that all sowning happens by three causes. The first is, by dissipation of the spirits and native heat, as in great bleeding. And then by the oppression of these spirits by obstruction, or compression, as in fear or tumult. . . . Lastly, by corruption, as in bodies filled with humours, and in poisonous wounds. The signs of sowning are paleness, a dewy and sodain sweat arising, the failing of the pulse, a sodain falling of the body upon the ground without sense and motion, a coldness possessing the whole body, so that the patient may seem rather dead, than alive. For many of these who fall into a sown die unless they have present help."

Since Paré's day there has been a continuing battle between the advocates of the three main theories—that shock is due to haemorrhage, nervous action, or toxins. To deal with the last category first, it is true that a state indistinguishable from the shock we are talking about can result from severe infection following injury, particularly from gas gangrene or peritonitis. Even in these conditions there is probably some blood loss and widespread extravasation of fluid. A low blood volume plays a major part in the clinical condition, which can frequently be reversed by a combination of chemotherapy, surgery, and intravenous transfusion of blood or other fluids. In the terminal stages it is perhaps true to say that the capillary bed is paralysed by toxins whose full nature has yet to be elucidated. From the point of view of first aid such conditions are unlikely to develop within four hours of injury, and the answer is still rapid evacuation to hospital.

We are left with the effects of haemorrhage and loss of fluid from the circulation and with the effects of reflex nervous action. In the absence of significant local or general injury, a transient state of collapse, with pale, cold extremities, a feeble pulse which may be slow, a very low blood pressure, nausea, vomiting, sweating, and loss of consciousness, may result from reflex nervous action resulting in redistribution of blood within the circulation. In the presence of bleeding this response may be of value to the patient in that the blood pressure falls and arrest of bleeding is facilitated (Edholm, 1952; Barcroft, 1957). But the responses can happen without any bleeding at all from the fright of the injury and the events associated with it. from a

needle-prick, the sight of blood, or even the sight of a needle-prick in a film or on television. The thought of blood is almost enough in some people to induce this type of faint or vasovagal attack. The blackout may be of secondary benefit to the patient in that the full impact of unpleasant events is obliterated from consciousness.

It may be possible that we are dealing here with a basic unconditioned type of reflex response to a falling blood volume which in the course of evolution and conditioning can now be fired off in man by a variety of stimuli not infrequently associated with haemorrhage. Such responses may possibly acquire new significance in the course of this evolutionary emergence. The primitive "fight or flight" response of Cannon (1923) may not be the only basic pattern of primary response to injury. Cowell's (1919) "primary shock" may vary greatly in its prognostic significance, but is a clinical state that still happens and requires explanation. The stimulating hypothesis of Slome and O'Shaughnessy (1938) that the primary reaction was due to fluid loss and the secondary collapse had its nervous component, warrants renewed consideration at a higher level of complexity and in the light of further evidence from the human subject now that we can measure the degree of oligæmia.

The real difficulty is that it is often clinically impossible to distinguish this reaction from true haemorrhagic shock, and that this type of response may be the first overt reaction of the organism to a serious injury with severe bleeding.

The shock reactions which result from bleeding or loss of fluid may in the first place be precisely similar to the classical neurogenic response, but may pass over to another type of circulatory response. This is characterized by constriction of blood vessels tending to keep the blood pressure raised as opposed to the dilatation of deep blood vessels especially in muscles, which has been demonstrated in the first type of response. All the patterns of redistribution of the circulation which can follow soon after injury are operated through the nervous system by reflex action, so that once there is significant injury of any kind it is no longer a question of this or that type of shock—it is a question of a particular pattern of nervous reaction fired off by particular combinations of causative factors, of which haemorrhage is likely to be the most important. The nervous response determines the reaction of the circulatory system.

While some of the early patterns of so-called circulatory failure following injury are essentially beneficial to the organism, the continued operation of the underlying processes, especially when associated with further bleeding, may change their fundamental character for the worse without obvious external change. The continued operation of a beneficial type of response beyond a given period of time may lead to dangerous complications. This is particularly so when the shock reaction involves vasoconstriction. The blood pressure may be maintained, but the blood flow through essential organs can be so reduced that their subsequent failure is inevitable. Partial resuscitation may produce an apparent improvement, but the patient dies from interference with the functions of such essential organs as the kidney, liver, heart, lungs, and brain.

A considerable amount of recent medical research and literature has focused attention on the endocrine glands, particularly the suprarenal cortex and the pituitary. These organs undoubtedly play a major part in producing the total reaction of the patient, but their activity is intimately linked with that of the nervous system, and theories which attempt to attribute the whole "stress reaction" (Selye, 1950) to action of these glands are, to say the least, one-sided.

A further new concept has emerged in recent years. It is suggested that following injury or other severe disease the patient may be suffering chiefly from harmful excessive reactions which can be modified by transforming the total reactivity of the organism. This can be done by cooling or by the use of such drugs as chlorpromazine and the "lytic cocktail" or by these combined with cooling (Laborit, 1952; Laborit and Huguenard, 1954). The whole question is

complex, and I think it fair to say that at present there is not enough evidence to warrant the use of cooling or hibernation in the treatment of severe injuries, with the possible exception of certain head injuries. Further elucidation of the detailed responses of the organism to injury may allow us to replace heating by cooling as a definitive approach to treatment, but this belongs to the future.

Suggestions for Teaching of First Aid

To return to the point from which we started, the teaching of first aid and the content of the first-aid textbooks. The full report of Grant and Reeve did not appear until 1951, six years after their research had been completed. It is then hardly fair to criticize the fact that the last edition of the *St. John First Aid to the Injured*, which was revised in 1950, reflects a position intermediate between the teachings derived from the first world war and those which are now in process of emerging from more recent clinical and research observations.

The time is now ripe for the incorporation of these advances and their implications into the teaching of first aid, and with this in mind I shall conclude with suggestions for the section on "Shock" in the *St. John* textbook for consideration by those responsible for its revision.

SHOCK

Shock is a state of collapse following injury or disease. It is characterized essentially by changes in the circulatory system. Its severity varies with the nature and extent of injury. It may develop early or late. It is a common cause of death following major injury. Prompt efficient hospital treatment is frequently of the utmost importance.

The most important cause of shock is loss of blood or other fluid from the circulation. In most injuries other than burns, severe shock within a few hours of injury is due to bleeding to the outside or into tissues or body cavities.

TYPES OF SHOCK

There are two types of early shock following injury which may be clinically indistinguishable. The one may follow the other with or without an interval. Nerve shock is a reflex nervous response not necessarily associated with any reduction in the volume of circulating blood. The other type of shock is associated with a reduced blood volume from bleeding or other fluid loss. In addition, any patient with a moderate or severe injury must be regarded as in a state of latent or concealed shock. The blood volume is reduced with little evident disturbance of the circulation. Obvious clinical shock can be precipitated by movement, further bleeding, emotional stimuli, surgery, and anaesthesia, or may develop with the passage of time.

Toxic shock may complicate the development of infection following severe injuries to the limbs or trunk. It is rarely of significance within four hours of injury and requires immediate transfer to hospital.

NERVE SHOCK

All forms of shock involve reflex nervous action, but it is possible to distinguish a type of early nerve shock associated with minor injury which results from purely nervous or psychological factors.

Signs and Symptoms.—These may range from a faint or "vasovagal" attack with little evident circulatory change except a slow pulse accompanying transient loss of consciousness to a state of severe collapse with extreme pallor, coldness of extremities, a feeble pulse which may be undetectable, sweating, vomiting, and unconsciousness.

Course.—In the absence of serious injury or bleeding this condition will pass off within a few seconds or minutes. In the presence of significant injury and bleeding it may pass imperceptibly into a state of severe shock or may recur following movement or further bleeding. It can be diagnosed with confidence only when recovery is rapid and it is clear that the injury is trivial.

Treatment.—Lay the patient flat on the floor, stretcher, or couch. Reassure when conscious. Examine for evidence of significant injury. Cover with a blanket but do not heat. If recovery does not take place rapidly, medical care must be obtained urgently or the patient sent to hospital. When the

patient is conscious and it is clear that no operation will be necessary, he may be given a drink of tea or whatever other drink is available or preferred.

LATENT SHOCK

The majority of patients with more than trivial injuries are liable to develop some form of shock. This may appear to be due to pain or movement, but is always more likely in the presence of blood loss. The extent of bleeding distinguishes certain types of injury and makes them more likely to develop late collapse or a persisting state of shock.

A patient with a single fracture of the femur can lose 20-30% of the blood volume (2-4 pints) into the thigh without a wound. A patient with a fracture of the pelvis can lose much more. In compound fractures of the tibia and fibula 15-20% of the total blood can be lost. In multiple injuries each individual injury contributes its quota of bleeding. The risk of collapse depends on the amount and rapidity of such bleeding.

The patient with suspected major fractures, severe wounds, multiple minor injuries, or significant trunk injuries can lose enough blood to cause severe dangerous shock. For a time the patient can compensate for the blood loss, but his situation becomes more critical with the passage of time unless the blood volume is restored to a near normal level by transfusion. When surgery is urgently necessary the risk increases with every delay.

Signs and Symptoms.—Patients with latent or compensated shock may be pale with cold extremities, they may be warm and pink. They may have a rapid or slow pulse, a raised or lowered blood pressure. They may be anxious and in pain or listless and semi-stuporous. They may be thirsty, sweating, or vomiting, or *apparently perfectly fit*. The severity of this condition depends on (1) the extent of blood or fluid loss, (2) the extent and nature of the injury, and (3) the time that has elapsed since injury.

Treatment.—(1) Move as little as possible, and that gently but swiftly. Wounds must be bandaged and bleeding controlled. Major fractures must be splinted in the simplest way consistent with efficiency and speed. (2) Give nothing by mouth to any patient who may require an operation later unless there is an unavoidable delay of several hours before reaching hospital. (3) The patient may be covered with a blanket, but in warm weather care must be taken not to increase sweating. Hot-water bottles and hot cradles are dangerous. The unconscious patient requires no heat by way of first-aid treatment. (4) *Evacuate to hospital as quickly as possible.*

ESTABLISHED SHOCK

This is characterized by extreme pallor and coldness of the extremities, sometimes an ashen-grey colour, a feeble pulse which may be very rapid. The blood pressure is low and may be unobtainable. This dangerous condition may be associated with obvious major injuries, but is none the less dangerous when the injuries are deep and blood loss is not evident.

Treatment.—There is no first-aid treatment for shock. When the journey to hospital is likely to be short—for example, less than 45 minutes—transfer immediately to hospital with the minimum of movement except transfer to a stretcher. It is unwise to delay for as much as five minutes for any form of first-aid treatment, except for (1) severe wound bleeding, (2) a sucking chest wound, (3) obstruction to the respiratory passages, or (4) failure of respiration. In any case delay may be fatal. Heat is not needed. Friction is contraindicated. Rapid, firm bandaging of injured limbs may limit further blood loss. The minimum of effective splintage is required. Morphine is valuable for severe pain, but requires the presence of a doctor. The stretcher should be tilted so that the level of the head is lower than the rest of the body. When rapid evacuation is impossible, careful splintage is of great importance, and fluids may be given if the patient is conscious and not vomiting. Overheating is dangerous.

Such patients may recover only with major transfusion and surgery. The severity of the apparent state of collapse makes such treatment a matter of grave urgency.

Conclusion

Finally I must refer briefly to two matters of great importance. Firstly, what are the dangers of blood transfusion? With a 24-hour laboratory service and a well-organized transfusion service the risks of transfusion need be no greater than the risks of anaesthesia for a minor operation in the hands of a trained anaesthetist. Infinitely greater harm is done to-day by inadequate transfusion. There remain

dangers from transfusion at the wrong time and the wrong speed, and we are concerned with learning how the judgment necessary to reduce these risks can be acquired and taught.

The second question is that of supplies. In some parts of the world there are difficulties, but in Britain there are big reserves of voluntary donors yet untapped. The difficulties are organizational. If blood is needed it can be obtained. As for cost: what is it worth to save a life or a hundred lives? Certainly with full modern resuscitation we can do more than save lives—particularly when our injured patients get to hospital quickly. Modern transfusion allows the latest developments in plastic and orthopaedic surgery to be applied at an earlier stage. The lessons we have learnt at the Birmingham Accident Hospital must be shared more widely and especially with our first-line allies—the first-aid workers—so well typified by the thousands who have been trained by the surgeons of the St. John Ambulance Brigade.

Summary

Traditional teaching on the first-aid treatment of "shock" is criticized. The older practices are traced to their theoretical origin in observations based on the experience of the first world war.

First-aid teaching needs to be revised on the basis of a recognition of the role of blood transfusion. This in turn must be based on an understanding of the extent of blood loss. Further evidence has been produced to show that blood loss is as important in civilian injuries as in battle casualties. Modern transfusion has been made possible by the development of blood banks. Modern techniques for the investigation of blood volume have helped the development of clinical aids to the assessment of blood loss and transfusion indications.

An appreciation of the role of transfusion in the prevention and treatment of shock requires reconsideration of the need for early diagnosis and treatment, with early transfer to hospital as a basis of first aid for moderate and major injuries. Fluids by mouth are rarely indicated in first aid. The disadvantages of heat treatment are discussed.

The significance of "primary shock" is discussed, and it is suggested that many forms of early circulatory change following injury are not necessarily harmful unless associated with loss of blood or other fluid from the circulation.

Suggestions are made for revision of the section on "Shock" in the St. John manual *First Aid to the Injured*.

Brief reference is made to the dangers of transfusion and the possibilities of obtaining adequate supplies of stored blood.

SYSTEMIC LUPUS ERYTHEMATOSUS*

BY

LESLIE C. HILL, M.D., F.R.C.P.

Physician, Royal United Hospital, Bath

Arthritis and Arthralgia

Joint involvement was the commonest clinical feature in this series. Of 49 patients, 45 showed joint symptoms at some time. In 28 the first evidence of systemic lupus was a clinical picture indistinguishable from rheumatoid arthritis; a further 10 began their illness with vague joint symptoms, often monarticular or asymmetrical.

TABLE V.—Incidence of Clinical Features in 49 Cases			
Albuminuria ..	38	Splenomegaly ..	14
Rheumatoid arthritis ..	34	Adenopathy ..	12
Secondary infection ..	28	Arthralgia or atypical arthritis ..	7
Respiratory ..	11	Raynaud's phenomenon ..	7
Other ..	17	Pericarditis ..	4
Rash ..	24	Hypertension ..	4
Nervous system ..	23	Gastro-intestinal ..	3
Psychiatric ..	13	Myalgia and vague pains ..	3
Epilepsy ..	5	Blood dyscrasia ..	2
Neuropathy ..	5	Alopecia ..	2
Pleurisy ± fluid ..	19		
Hepatomegaly ..	16		

The high incidence of arthropathy (Table V) in these cases might reasonably be thought to reflect a special interest in the rheumatic diseases; it is in fact little greater than that reported by many workers who have not this special interest. Harvey *et al.* (1944), for example, record arthritis or arthralgia in 95 of 105 cases; in 66 one or other was the presenting symptom. Similar figures were reported by Dubois (1956), 90%, Jessar *et al.* (1953), 77%, and Shearn and Pirofsky (1952), 85%.

Joint symptoms fall broadly into three main types—arthralgia, migratory polyarthritis, and chronic arthritis of the rheumatoid type.

Arthralgia and Myalgia

The aching pain in the muscles or around the joints is usually described as "fibrositis"; it may be migratory and accompanied by transient swelling and tenderness over a few joints. This muscular pain and tenderness is occasionally the predominating symptom, as in the following case.

Case 1.—A woman of 37 first noted stiffness, swelling, and slight pain in her fingers eight months before admission to hospital, followed in two months by tenderness of the thigh and upper arm muscles. Later, all her muscles became so tender and painful on movement that a diagnosis of dermatomyositis was considered. The facial rash and L.E. cells, however, suggested the true diagnosis, which was confirmed at necropsy two weeks later.

In my experience, arthralgia or myalgia as a first symptom seems to be of unfavourable significance. Of 10 patients presenting in this way, three died within two and a half years, two were in very precarious health about two years after the onset, and three others were only kept in partial remission by steroid therapy. Some of Kersley's (1951) cases of senile myalgia may belong to this group. He described a syndrome of muscle pain with systemic reaction in elderly patients, predominantly women. Their symptoms were unusually persistent and refractory to conservative therapy but responded promptly to cortisone. Bagratuni (1956) has reported a similar series.

Migratory Polyarthritis

This is easily confused with rheumatic fever, especially as it seems to occur mainly in younger patients. The incomplete response to salicylates may suggest the diagnosis.

*The second of two Lumleian Lectures (abridged) delivered before the Royal College of Physicians of London on April 2 and 4, 1957. The first lecture appeared in last week's issue (p. 655).

A girl of 11 developed painful swelling of her ankles. Ten days later she had swollen painful knees, pleuritic pain, and fever. On admission the joint swelling and pain had disappeared, but nodules were felt over the occiput and iliac crests and there were raised red nodules on the fingers. Pleural and pericardial friction developed and she was treated with penicillin and aspirin. Two days later an erythematous rash appeared on her face and arms with later a further attack of fever, pleurisy, and jaundice. In three weeks she was well again and remained fit, except for Raynaud's phenomenon and stiffness in the legs, for nine months. She then developed simultaneously swelling of the knees and a sore throat and was given sulphonamides; there followed on the next day a rash, fever, glands, and nodules. She again improved spontaneously. L.E. cells have never been found in this child, but a continuously raised sedimentation rate with a leucopenia makes the diagnosis probable. (She has recently been in hospital again with a short-lived pericarditis.)

Chronic Arthritis of the Rheumatoid Type

The arthritis of systemic lupus can exhibit features which are unusual in typical rheumatoid arthritis. Joint involvement may be asymmetrical and show rapid spontaneous variations; on the whole, destructive changes and deformity are less in evidence. I cannot agree with Keil's (1937) statement that ulnar deviation never occurs in systemic lupus. I have seen it often. On the other hand, I have never seen the absorptive changes of arthritis mutilans. Many cases, however, are indistinguishable from rheumatoid arthritis until severe constitutional disturbances suggest the more serious disease.

Arthritis of the rheumatoid type rarely seems to develop when some other manifestation has been the presenting feature. Of the 10 patients whose illnesses began without any joint symptoms, only 2 developed rheumatoid changes, and these were mild and atypical; a chronic discoid rash was the presenting feature in both cases. If we accept the thesis that features such as severe constitutional upset, serositis, or a neurological disorder are evidence of the malignant phase of the disease and that this malignant phase is limited in duration, it may well be that patients who pass rapidly into the malignant phase do not survive long enough to develop chronic arthritis unless their disease is well controlled by steroids or antimalarials. Clearly this is not the whole explanation. Of the seven patients not presenting with either joint symptoms or a rash, two died in less than three years, three were maintained precariously on steroids, one was doing well on mepacrine, and one has achieved a spontaneous remission.

The problem of deciding when the diagnosis of a patient with arthropathy should be changed from rheumatoid disease to systemic lupus is a difficult one. At the moment my decision rests on the clinical assessment, and I am not prepared to be browbeaten into making the diagnosis on the basis of an unexplained laboratory phenomenon. In general, the more serious diagnosis must be considered when a patient with rheumatoid arthritis shows severe constitutional features or goes rapidly downhill, or, again, if the sedimentation rate remains high (over 60 mm. in 1 hour) when the joints have passed into a stage of remission. Other suspicious features include chronic leg ulceration, a false-positive test for syphilis, or the involvement of other systems. The significance of the L.E. cell phenomenon in rheumatoid arthritis becomes more controversial since Kievits *et al.* (1956) reported it in 17% of nearly 500 cases. Their patients with positive L.E. cells had more rapid sedimentation rates, a higher incidence of splenomegaly, respiratory and renal disease, anaemia, and false-positive Wassermann reactions than other cases of rheumatoid arthritis. It may be that these cases are examples of a prolonged benign phase of the disease.

So far no comparable survey has been reported in this country, but the L.E. cell test is now almost a routine in severe cases with constitutional symptoms. Even in this selected group, positive tests are rare—certainly less than 17%—and I am not prepared to believe that 1 in 6 of rheumatoid patients is a candidate for systemic lupus. It is difficult to avoid the impression that standards of technique and interpretation vary from centre to centre.

Skin

The scrupulous and graphic description of the rash by Hebra and Kaposi (1875) has never been surpassed and should be read in the original. The distribution of the lesions can be best appreciated by quoting Kaposi's (1872) concluding remarks, "I have seen lupus erythematosus everywhere on the body surface."

There are, however, some distinguishing features. Characteristically, the rash occurs as a group of discoid lesions occupying a butterfly wing pattern on the cheeks (Fig. 8). Another more widespread erythematous type commonly affects the V area of the neck and other exposed parts, and varies from a mild blush to a violent erythema with oedema and even vesicular and bullous eruptions. Any form of the rash may occur at any point in the disease. Less common features are the elongated telangiectases, usually on the nail-folds, and intense purplish erythema around the nail-beds, which may progress to ulceration and scarring (Fig. 9). After mepacrine treatment,

FIG. 8.—Lupus erythematosus occurring as a group of discoid lesions of butterfly-wing pattern on the face.

FIG. 9.—Showing the intense purplish erythema around the nail-beds.

lichenoid changes have been described which can be very disfiguring. One of my patients (Case 49) unfortunately shows these blemishes.

The relationship of chronic discoid to systemic lupus is still controversial. Careful investigation of patients with apparently uncomplicated discoid lupus has tended to support such a relationship by revealing laboratory abnormalities common to both. Wilson and Jordon (1950) considered every case to be the cutaneous expression of a generalized disease; their evidence is unconvincing. They have, however, received support from Dubois and Martel (1956). Cohen and Cadman (1953) drew attention to the many gradations between the chronic discoid lesion without evidence of generalized spread and the acute systemic disease with no skin changes. Systemic spread seems more likely when the rash has extended below the chin. In contrast, R. Warin (1957, personal communication), who has carefully followed 48 patients with chronic discoid lupus (33 women and 15

men) for three years or more in Bristol, found only two cases of frank generalization, both following a course of penicillin for intercurrent infection.

A rash was the first symptom in four of our cases. It was followed after intervals of from six months to two years by other evidence of the disease. The rash in these patients did not differ from other examples of discoid lupus which remained confined to the skin. For practical purposes, therefore, systemic spread must be recognized as a hazard of discoid lupus, though probably quite a small one. A lupus rash was present at some time in 24 of our 49 cases.

Renal Lesions

Involvement of the kidneys is a most serious feature, and uraemia is one of the two main causes of death. Renal involvement commonly takes the form of a nephrosis which is unremarkable, except that, as in amyloidosis, the serum cholesterol is usually not raised. Hypertension is rare. The urinary sediment is in no way specific. It is important to appreciate that the mild albuminuria which may occur in the early stages, and even be accompanied by a deposit of red cells and a few granular or hyaline casts, can be merely a temporary febrile phenomenon.

Many workers, notably Stickney and Keith (1940), Dubois (1953), and Harvey *et al.* (1954), have emphasized the frequent discrepancy between the clinical picture and the necropsy findings. Joske (1956) and Muehrcke *et al.* (1956), using renal biopsy, confirm this lack of correlation and stress the frequent occurrence of renal damage without corresponding clinical evidence of nephritis. They also show that renal lesions can arise and progress during steroid therapy and that they are usually irreversible. Dubois (1956) has suggested that very large doses of steroids may favourably influence renal pathology, but this is not the general opinion.

In our series albuminuria occurred at some time in 37 cases. Impaired renal function was found in 10 out of 15 patients tested.

Lungs and Pleura

Terminal bronchopneumonia is of course common, but intrinsic lung involvement is less well documented. Osler (1895) mentioned "protracted pneumonia" among the visceral changes. Since then pulmonary lesions of all types have been described, notably by Foldes (1946), Israel (1953), Harvey *et al.* (1954), and Ellman (1956). They may cause dyspnoea to dominate the clinical picture and have to be distinguished from the secondary pyogenic infections which are so frequent in the terminal stages.

Pleuritic pain is a prominent and frequently early symptom. It has a way of persisting and can be very distressing. The pleurisy is usually dry; when an effusion occurs it tends to be small. L.E. cells have been found in both pleural and pericardial effusions. Abundant coarse and sticky rales are commonly heard at the bases, where they tend to be associated with x-ray appearances of plate-like atelectasis with elevation and fixation of the diaphragm on one or both sides. Ellman and Cudkowiec (1954) and Ellman (1956) have described similar changes in association with rheumatoid arthritis.

Whereas the pleural changes are variable, tend to respond to treatment, and rarely give rise to anxiety, little regression can be expected in the lungs.

Clinical evidence of pleurisy, with or without effusion, was present in 19 of our cases; in one it was the presenting feature. Gould and Davies (1955) found x-ray signs of pleural thickening in 74 of their 100 cases, and ill-defined lung infiltration or linear plaques in 50. Massive effusions were rare.

Central Nervous System

The central nervous system is frequently implicated and no part is immune. Neurological and psychiatric symptoms may be severe and are usually intractable. More than a

quarter of the 100 cases of S.L.E. recently reviewed by Clark and Bailey (1956) revealed evidence of involvement of the nervous system. Among the mental symptoms were anxiety, depression, personality changes, mental deterioration, and hallucinations. Of the neurological symptoms, convulsions were by far the commonest; others included diplopia, hemiplegia, polyneuritis, and subarachnoid haemorrhage.

The highest incidence of fits, 35%, is recorded by Dubois (1953). While a long history of epilepsy may usher in the disease, fits are more commonly associated with acute exacerbations and are ominous signs, though they may respond to steroid treatment.

Case 34.—A 13-year-old boy was admitted to hospital with fever and central chest pain. Pericarditis was diagnosed. He was treated with salicylates and improved. Ten months later he relapsed, had an epileptiform convulsion, and remained semi-conscious for two months. L.E. cells were found. Following intravenous hydrocortisone, transfusion, and antibiotics, he slowly improved, though the passage was stormy and interrupted by pleurisy with effusion. He is now maintained precariously in a "Cushingoid" state on a large dose of prednisone, and has had no more fits.

Nervous symptoms were present in 23 of our cases. In 13 there were psychotic features, notably severe depression. Five patients had convulsions and five some form of neuropathy.

From these considerations we learn two valuable lessons. Firstly, mental and neurological disturbances, arising without obvious cause in a woman between 20 and 40, require the estimation of the sedimentation rate and, if it is raised, for further investigation bearing on systemic lupus. Secondly, such symptoms must be recognized as part of the natural history of the disease and not be mistakenly attributed to steroid therapy.

Hepatic Involvement

Clinical evidence of important damage to the liver is rare. Nevertheless, it is probably the site of pathological change in a considerable proportion of cases; hepatomegaly occurs in about one case in three in most series, and our figures, 16 cases in 49, agree with this.

Joske and King (1955) refer to these changes as "hepatic lupus"; in contrast they, and Mackay *et al.* (1956), reported a small series which they labelled "lupoid hepatitis." These patients had symptoms and signs of active chronic hepatitis, usually of viral origin but occasionally alcoholic, but with additional features which included a rash, arthralgia, nephropathy, haemolytic anaemia, high sedimentation rate, leucopenia, the presence of L.E. cells, and response to cortisone. Biopsy, performed in two cases, showed infiltration by lymphocytes, plasma cells, and histiocytes, and one case exhibited active nodular regeneration and fibrosis. The clinical and laboratory changes in these seven patients compare closely with another series reported by Bearn *et al.* (1956); 23 of their 26 patients were young women, with an average age of 15. They emphasized the frequency of arthralgia, which is uncommon in cirrhosis following hepatitis, and the striking response to cortisone therapy.

The clinical course and response to steroids of these cases is reminiscent of the so-called "choleangiolitic hepatitis" described by Watson and Hoffbauer (1946), in which prolonged hepatitis was associated with regurgitant jaundice. The absence of evidence of hepatocellular dysfunction. The authors postulated increased permeability of the finest bile radicles permitting regurgitation of fluid and bile pigments into the intercellular spaces. The response to corticotrophin might depend upon a capacity to decrease bile capillary permeability in the same way that it decreases blood capillary permeability.

It is possible that this "lupoid hepatitis" is another manifestation of the benign phase of systemic lupus, this time in a vital organ. The features described by Joske and King as "hepatic lupus" seem, however, to be entirely non-specific and might occur in the course of any grave illness with fever and poor nutrition.

Gastro-intestinal Manifestations

Brown *et al.* (1957) have reminded us that systemic lupus can affect the gut, and they support Osler's (1895) emphasis on this aspect of the disease. They report gastro-intestinal symptoms in 32 out of 87 proved cases. In the main, the symptoms were non-specific and of minor importance, but five cases had features of small-gut obstruction. This was due to localized ileus of the duodenum and upper jejunum. It is important to recognize such cases, since they respond to a conservative regimen of rest, frequent small feeds, and antacids, if necessary with steroids to control the underlying disease. Surgical intervention is contraindicated. Whether the ileus is neurogenic, from involvement of the autonomic nervous system, or due to vascular changes with consequent ischaemia is uncertain.

Ocular Changes

Ocular changes are a recognized feature of systemic lupus, and Semon and Wolff (1933) were the first to describe histological findings. Clifton and Greer (1955), in an excellent paper, recorded the ophthalmoscopic and pathological appearances in two fatal cases, both malignant in type, and I have their permission to reproduce one of the fundus paintings (Fig. 10).

FIG. 10.—Ocular changes. Reproduction of a fundus painting of Clifton and Greer, 1955, by permission.

Retinal changes are rare, except in the acute and particularly the terminal phases. They consist of "cotton-wool" lesions—the cytooid bodies—mild papilloedema, and small superficial haemorrhages. The cytooid bodies vary in size and lie along the course of arteries or veins. In sections they appear as spherical or pyriform eosinophilic structures with a deep red core. They have a high mucopolysaccharide content. They have been regarded as nerve fibres swollen by immersion in oedema fluid, but both Maumenee (1952) and Clifton and Greer (1955) favour an exudative origin. They are not specific, occurring also in hypertensive retinopathy, and in diabetic retinopathy accompanied by hypertension. Their presence when hypertension is absent is, however, highly suggestive of systemic lupus.

Treatment

The problems of treatment are many and difficult. We are confronted with a disease whose natural history is unpredictable and whose phases are often sudden and unexpected. Management, indeed, tends to be paradoxical: a Gladstonian air of expectancy may well be more rewarding

than the most energetic use of powerful hormones, possessing potentialities for great evil as well as great good.

Although we do not know how to avoid the disease, we have become aware of aggravating factors. As early as 1896 Bowen noted that sunlight was harmful. Most of Tumulty and Harvey's (1949) 32 cases were sensitive to light; one patient, indeed, had the typical butterfly eruption in 12 successive summers before symptoms of the generalized disease supervened. We must beware of lightly advising ultra-violet light for rheumatoid patients. Hutchinson, noticing the ill effects of cold on the extremities, was observing Raynaud's phenomenon.

Many drugs have been impugned. In some, the evidence is tenuous; so often in retrospect it seems that the drug had been given at the time of the first manifestation of the visceral disease. Against others I find that a *prima facie* case has been made. These include sulphonamides, hydrallazine hydrochloride, and probably thiouracil. In considering sulphonamides we are confronted by two divergent views. Earlier reports, notably by Ingels (1938) and Barber (1941), favoured their use in chronic cases, and even in acute cases (Anderson, 1938; Hopkins, 1941) good results occasionally followed. More recently, exactly the opposite view is taken (Probert, 1940; Von Fischer, 1947) and sulphonamides are roundly condemned. The fact that the introduction of sulphonamides provided the first means of dealing with the septic complications may explain the early successes. More reliable antibiotics now replace them.

The sulphonamides are photosensitizing agents, as those who have experience of the tropics well know. I have been unable to discover any work bearing on the relevance of this action, but it seems to offer a possible line of research.

Gold (1951) has carefully reviewed sulphonamide intolerance, pointing out that the increased incidence of systemic lupus and of other paraneoplastic diseases followed chronologically the advent of these drugs, but too much must not be inferred from this observation. I avoid sulphonamides in the acute phase and advise great care in using them on patients with chronic discoid lupus or rheumatoid arthritis.

Hydrallazine hydrochloride ("apresoline") has been shown to produce clinical pictures indistinguishable from rheumatoid arthritis, and, if continued, from systemic lupus. Dunstan *et al.* (1954) found this lupus syndrome in 13 of 139 hypertensive patients treated with hydrallazine hydrochloride as the sole hypotensive agent. Eleven of the 13 showed excellent control of their blood pressure. Relatively large doses for long periods seem to be required to produce these syndromes. However, critical perusal of many of the cases reported suggests that they had symptoms consistent with the early stages of the disease before the drug was given. Nevertheless, we must use it with caution. This point is illustrated by Case 46.

Case 46.—A woman of 45 was admitted to hospital for severe Raynaud's phenomenon, which she had had from the age of 18. She was found to have unexplained enlargement of the liver and spleen and a leucopenia. Hydrallazine hydrochloride, 50 mg. t.d.s., relieved her circulatory symptoms and she remained on it for two years, when she suddenly developed fever, joint pain and swelling, and a lupus rash; L.E. cells were found. The symptoms slowly subsided when the drug was stopped, only to flare up severely after a test dose of 50 mg. A week later she died, and necropsy showed a segmental pneumonia, collapse of the bases, mitral stenosis from Libman-Sacks endocarditis, and cirrhosis of the liver.

In 23 of 24 of our patients treated with gold for their presenting arthritis, no time relationship between the treatment and the onset of systemic features was evident. In five, gold was given after L.E. cells had been found, with no ill effect in four. In one case (No. 22) it was stopped after three months because of a generalized dermatitis and haematuria; these then disappeared; five months later a typical lupus rash appeared on the face. Clearly this may have been coincidental.

The grounds for including penicillin among the precipitating agents are much more insecure. Reactions from this

invaluable antibiotic are not uncommon, but how many patients with such reaction have developed systemic lupus? We should not be deterred from using penicillin by reports of the occasional finding of L.E. cells in patients during these reactions, for the significance and specificity of the test are still incompletely established.

It seems likely that these drugs act on occasion as "trigger factors," precipitating a disease to which the patient was already prone.

Conservative Measures

In discussing treatment proper I begin with conservative measures. After a long apprenticeship to the study of rheumatism, I have learned to value these measures above all others and to consider them at every stage of treatment.

In the acute phase of systemic lupus rest in bed is essential, with all possible measures to support general health and morale. But bed rest must not be too protracted. As soon as a remission sets in progressive activity should be introduced. Supervision is important during remissions; we must avoid letting our patients get overtired and stop them from "pressing on" when a less strenuous life is desirable. Equally, we must guard against unnecessary despotism and against an endless succession of follow-up clinics in the hands of zealous but inexperienced doctors.

One of our first duties as physicians is the relief of pain; but we must also avoid the danger of so far suppressing a natural reflex that we inhibit a protective mechanism. Salicylates are invaluable for the rheumatoid pains which Kaposi (1872) graphically described. Where there is the least hint of joint involvement the use of light removable plaster splints is imperative to avoid deformity; they should be combined with physiotherapy, muscle exercises, and active and assisted movements. It is seldom too early to start these. In this "plastic era" I would plead for the continued use of plaster splints; these are strong, light, cheap, ready for use in a matter of hours, and, with change in joint profile, may be happily discarded.

The era of effective treatment of systemic lupus opened in 1940, when Prokoptchouk introduced mepacrine; yet eleven years had to pass before the first report of its use in this country (Page, 1951). Improvement with mepacrine seems to be related to the degree of skin staining, and my own plan is to give 0.3 g. daily until the skin is yellow and then reduce to a maintenance dose of 0.1 g. Repeated courses of from four to six weeks have been very successful. Treatment with mepacrine is empirical. Though it may understandably benefit the skin lesions by reducing light sensitivity (just as it relieves photophobia due to the action of ultra-violet light on the cornea), this can hardly explain its effect upon the internal organs. Serious side-effects are rare. The most important is toxic dermatitis, which occasionally follows prolonged treatment and may result in a disfiguring lichenoid rash. The yellow staining of the skin, personality changes, and, in the early stages, nausea, vomiting, and diarrhoea make up a list of complications, most of which can be overcome with tact and encouragement.

Chloroquine, introduced in 1954 by Prakken and Molhuysen vander Walle, is now preferred by most dermatologists to mepacrine, largely, I fancy, on account of its greater popularity with patients. It seems to be equally effective for the skin lesion, but less satisfactory than mepacrine in its effect upon the systemic features. Dubois (1956) says it is less effective than mepacrine, when used in conjunction with steroids. The side-effects of chloroquine, though rare, are more serious, and include pruritus, diarrhoea, vomiting, greying of the hair, myasthenia, and cycloplegia.

Amodiaquine ("camoquin") has also been used but is less effective, both alone and in combination. It may suit the occasional patient who tolerates other drugs badly. The side-effects are similar to those of chloroquine.

Hormones

Since Hench *et al.* (1949) introduced us to the hormone therapy of rheumatoid disease we have experienced four

phases. Initially there was an immediate and often spectacular relief of symptoms, but within a year the failure of short-term therapy was becoming obvious and we were meeting severe withdrawal symptoms. From 1952 to 1954 we learned the disadvantages of long-term high-dosage therapy and recognized the state of "hypercortisonism." In the last years hormones have been largely abandoned in the long-term treatment of rheumatoid disease.

This melancholy experience has not favoured their use in systemic lupus. But experience is sometimes fallacious. In the malignant phases the adrenocortical hormones may be life-saving; but I agree with Bauer and Ropes (1956) that they should be reserved for the acute stage when death is very close.

While it is unwise to temporize with less potent measures in an extremely ill patient, the automatic use of hormones in milder cases is to be sternly discouraged. The possibility that this may even precipitate the disease is suggested by Slocumb's (1953) finding of L.E. cells in 15 patients with rheumatoid arthritis during withdrawal of the hormone.

When hormone therapy is necessary, enough must be given to suppress the disease; this is generally about 300 mg. of cortisone a day, or its equivalent, but I am prepared to push the dose much higher in order to achieve my objective. The requisite dose must then be continued until a remission is clearly on its way. Only then, when the patient is obviously on the mend, joint and serous membrane pain are lessening, appetite and sleep are returning, and the anaemia is improving, is it wise to cut down the dose. Later, by adding mepacrine or chloroquine, the maintenance dose of steroids can often be brought within safe limits and the disadvantages of hypercortisonism avoided.

The choice of hormone depends on the cardiac and renal status. I do not use corticotrophin, finding its side-effects to outweigh its usefulness. If the patient has salt retention prednisone or prednisolone is preferable, but otherwise these preparations have not seemed any better than cortisone. Indeed, I regard the liability to fluid retention with cortisone as a warning light against overdosage, a warning which we do not get with prednisone.

The response to steroids is variable. Some symptoms, such as the fever, the general malaise, and the joint swellings, respond quickly; the blood dyscrasias, the serous membrane reactions, and the manifestations in the spleen and lymph nodes more slowly; the severe renal, cardiac, and central nervous features respond not at all. The disappearance of a haemic murmur as the anaemia improves, or of a febrile albuminuria as the temperature settles, must not be mistaken for retrogression of the severe cardiac and renal aspects of the disease. Papilloedema and retinal haemorrhages slowly subside, but the cytoid bodies usually remain.

Relapses are common and must be met with a temporary increase in steroid dosage. In over 100 patients whom he followed for five years, Dubois (1956) found a relapse rate of 54%, and considered this an indication for indefinite maintenance therapy.

The problems of hormone treatment are too well known to require repetition. Most of them arise from giving too much drug to the particular patient. Among the disasters are acute psychoses, neurological catastrophes, and unexpected sudden death (Page, 1954). A characteristic feature of hypercortisonism which has interested me has been an increase of weakness, muscle and joint pains, and emotional lability. The pains tend to be generalized and associated with hypersensitivity and hyperalgesia. Increased dosage gives but temporary relief, and is indeed merely a turn in a vicious spiral; aspirin gives little or no relief. The decision to raise or to lower the dose of steroid for a patient whose symptoms have worsened under treatment is one of the most difficult in practice.

Renal involvement in systemic lupus is common and a frequent cause of death. Nitrogen mustard has been advocated for this. I have no personal experience of its use, and indeed find it difficult to understand how such a

toxic substance can have any place at all in treatment. Nevertheless, Dubois (1954) reported some encouraging results in 33 patients to whom he gave a single dose of 20 mg. after suitable sedation, claiming for them a diuresis within two weeks. It might be instructive to try out a control series with sedatives only (particularly if these were antihistamines).

It is amusing, and also a sad reflection on the gullibility of our profession, to read of the reappearance of autohaemotherapy. When I was first in practice it was the up-to-the-minute treatment for boils and blains; now we are asked by Kurnick (1956) to believe that it supplies desoxyribonuclease-inhibitor.

Aetiology

During the early years of the century systemic lupus was thought to be associated with tuberculosis, and this view dominated the literature until in 1933 Keil's detailed analysis finally made it untenable.

Welsh (1948) has tried to impeach the streptococcus, and Moolten and Clark (1952) claim to have isolated a virus, but their work has not been confirmed.

The association of the anaphylactic type of hypersensitivity with certain forms of arteritis has led to speculation regarding its role in the aetiology of systemic lupus. In 1798 Edward Jenner first claimed that infection can so alter the body that its tissues react with increased intensity when they subsequently encounter the same infective agent. This caused so little attention that when Koch, 100 years later, rediscovered this phenomenon, in his studies on reinfection in tuberculosis, his observations were widely regarded as the first of their kind.

Rich (1946-7), in his famous Harvey Lecture, pointed out that there is no correlation between the degree of hypersensitivity and the degree of acquired resistance, that the hypersensitivity reaction does not protect against the spread of infection in the absence of acquired resistance, and that acquired resistance is not dependent upon hypersensitivity reaction for its effective operation. Injury to vascular endothelium leading to increased permeability and necrosis, spasm of smooth muscle, fragmentation of connective-tissue fibres, and alteration of ground substance are accepted features of the serum-sickness type of reaction; they have been reproduced experimentally by Rich in rabbits subjected to protracted anaphylactic reactions; they also figure among the protean manifestations of the connective-tissue diseases. But to explain the whole complex nature of the disease on the basis of anaphylactic sensitivity is much too facile. Hypersensitivity, in the ordinary sense, may be present but often is not. It seems more likely that this disease is associated fundamentally with abnormality in the mechanism of antibody production or of antigen-antibody reaction.

The antibody-forming cells of the reticulo-endothelial system are constantly being brought into contact with protein breakdown products, both from the host's own catabolic activities—for example haemoglobin, plasma protein—and from foreign sources—for example, bacteria. There must be, as Burnet and Fenner (1949) have pointed out, some mechanism whereby the antibody-forming tissues distinguish between foreign protein ("not-self") and their own tissues ("self"), so that only alien protein excites antibody production. The capacity to identify "not-self" seems to develop late in intrauterine life. The earlier embryo does not appear to reject heterologous tissue, and twins of different blood groups can develop without cross-immunization. Any subsequent change in the nature of a body protein, which is liable to encounter reticulo-endothelial tissue, may lead to auto-immunization. "Sedormid" acts in this way by attaching itself to platelets and stimulating the production of antibodies, not against the drug or the platelets alone, but against the sedormid-platelet complex.

It is also possible that the antibody-forming cells could lose their capacity to identify "self"; some such change might conceivably explain the occurrence of haemolytic anaemia in the reticuloses.

Again, connective tissue itself, or the products of its partial breakdown, might under certain circumstances be able to combine with foreign prosthetic groups to form "not-self" antigens. This might account for the precipitating action of certain physical and chemical agents, such, for example, as hydrallazine, sulphonamides, or penicillin.

There is evidence that connective tissue can be made antigenic. Scott and Hill (1956), using fluorescein-tagged antibody, have demonstrated its attachment to the reticulin of the glomerular basement membrane.

Such features as the elevation of gamma-globulin and the reduction of serum complement would fit in with this theory, as also would the tendency for patients to form abnormal globulins of antibody type. On this theory chronic rheumatoid arthritis or discoid lupus of the skin could act by providing connective-tissue breakdown products and presenting them to the reticulo-endothelial system. Whether these breakdown products are recognized as "self" or "not-self" would then depend on the reticulo-endothelial system.

Thus, the syndrome of systemic lupus erythematosus might arise and self-perpetuation follow in three ways:

1. The cells of the reticulo-endothelial system become modified in some way, so that they fail to recognize the normal breakdown products of connective tissue as "self." This could account for acute systemic illness without obvious cause.

2. Normal breakdown products become changed as a result of action by or attachment to a prosthetic group, and are not recognized as "self" by a normal reticulo-endothelial system. This might explain the precipitating effects of sunshine, sulphonamides, penicillin, and hydrallazine.

3. Abnormality in the quantity or nature of breakdown products due to some unknown cause lead to their non-recognition as "self." This might account for the change in state of rheumatoid arthritis, discoid lupus of the skin, and possibly for the cases of lupoid hepatitis.

Conclusion

In this survey I have tried to deal with the problem of systemic lupus in a common-sense way and to tell a little more simply a story that has become confused by the over-technical embellishment of clinical fact. In this I was encouraged by reading an address by Hughlings Jackson (1931) to the Clinical Society of Bath and Bristol. "A man," he said, "as a biologist classifies plants one way in his botanical garden for scientific purposes, but in his common garden arranges them like everybody else in the plan most convenient for practical purposes." It is as the gardener, rather than the biologist, that I have approached this problem, for, in studying and treating systemic lupus, I have become very conscious of the need for some overall synoptic view, such as was evident from the writings of the clinical masters, Kaposi and Osler, and I retain my belief that the clinician has always a prime and constructive part to play in modern medicine. At the same time, I was not tempted to find fact where only fancy played. Even at the cost of disappointing my friends, I was not prepared to delineate the boundary between rheumatoid disease and lupus. In short, I took heed of Lucretius (IV, 816): "Deinde ad opinamur de signis maxuma parvis, ac nos in fraudem induimus frustraminis ipsi." Which, since Latin no longer finds grace at the censor's board, I dare to translate, "I have tried not to base wide opinions on small signs, and so involve myself in the snare of self-deceit."

Of the cases in my own series, 20 were seen and followed up personally; I had access to the other 29 through the kindness of Drs. Barber, Burt, Jarrett, and Pearson. Only cases with characteristic clinical features were included. The diagnosis was established

in 47 cases by the finding of L.E. cells (with necropsy confirmation in seven), in one by typical changes at necropsy, and in one by skin biopsy.

For help in providing clinical material I am particularly indebted to Dr. Stewart Barber, who generously gave me access to his cases. Dr. Hugh Burt and many West Country colleagues, including Professor Bruce Perry, Drs. J. R. Bolton, H. L. Hoffman, D. H. Davies, E. Jarrett, J. E. Pearson, and D. Pugh, constantly put me in touch with interesting clinical material. Dr. Pugh read and kindly criticized the manuscript. Drs. Frederick Kohn and Charles E. Wells were very helpful with the historical sections, and Dr. R. L. Bishton gave advice upon the pathology and provided the sections. Dr. M. R. Jeffrey was a tower of strength at all stages, and in particular I am grateful for his advice on the clinical pathology.

A SERUM FACTOR IN LUPUS ERYTHEMATOSUS WITH AFFINITY FOR TISSUE NUCLEI

BY

E. J. HOLBOROW, M.D.

D. M. WEIR, M.B., Ch.B.

AND

G. D. JOHNSON, F.I.M.L.T.

Special Unit for Juvenile Rheumatism, Canadian Red Cross Memorial Hospital, Taplow, Bucks, England

The L.E. cell phenomenon, first demonstrated by Hargraves *et al.* (1948) in blood from patients with systemic lupus erythematosus, has since received considerable attention. It has been established that the responsible serum factor is present in the gamma-globulin fraction (Lee *et al.*, 1951) and brings about *in vitro* (1) swelling and disintegration of the nuclei of mature polymorphonuclear neutrophils, and (2) phagocytosis of the cell remains by intact granulocytes to form a typical L.E. cell (Rohn and Bond, 1952). Gueft and Laufer (1954), using histochemical techniques, have demonstrated altered nuclear material in the tissues of such patients.

In the present work we have shown that sera giving a positive L.E. cell test contain a globulin factor with affinity for tissue nuclei. These findings are similar to those already briefly reported by Friou (1957) at the 9th International Congress on Rheumatic Diseases.

Method

Tissue and cell preparations were treated with anti-human globulin sera conjugated with fluorescein isocyanate, and examined microscopically using an ultra-violet light source. Sections pretreated with serum giving a positive L.E. cell test (L.E. positive serum) showed apple-green fluorescent areas where the conjugated antiglobulin serum had reacted with fixed globulin derived from the L.E. positive serum.

Preparation of Tissues.—Human tissues were obtained at operation, or as soon as possible after death. Tissues from

stillborn infants, adult post-mortem tissue, and operation tissue all gave concordant results. Small blocks of unfixed tissue from these sources were instantly frozen in test-tubes in solid CO₂ acetone mixture and transferred to a cryostat cabinet kept at -20° C. in which sections were cut on a microtome at 6 μ thickness and mounted on slides. Each section was covered with a few drops of L.E. positive serum and incubated in a moist chamber for 30 minutes at 37° C. Duplicate sections were similarly treated with normal human serum. After incubation the serum was washed off in buffered saline (pH 7.0) and a drop of the fluorescein-conjugated anti-human-globulin serum placed on each section; after 30 minutes sections were again washed, and mounted in buffered glycerine (pH 7.0).

Preparation of White-cell Films.—The clot from fresh group O blood was broken up with a wooden applicator and the admixture of serum and cells centrifuged in a Wintrobe tube at 3,000 r.p.m. for five minutes. Thin films were then made from the buffy coat and treated in the same way as the tissue sections.

Preparation of Conjugates.—Two rabbit anti-human-globulin sera were used: (1) prepared in rabbits injected intravenously with their own red cells previously agglutinated by pooled human serum (Milgrom *et al.*, 1956); (2) Coombs anti-human-globulin serum. These two sera were conjugated with fluorescein isocyanate according to the method of Coons and Kaplan (1950). Before use the conjugates were absorbed with a dried organ powder prepared from rabbit liver to remove non-specific staining of tissues.

Test Sera.—Three sera giving positive L.E. cell tests were used for pretreatment of tissue sections on white-cell films. Two of these sera were obtained from patients with systemic lupus erythematosus, and the third from a severe and ultimately fatal case of rheumatoid arthritis. Results with all three sera were similar. A number of normal human sera were used as controls.

Examination of Preparations.—Mounted preparations were examined microscopically, using a 250-watt high-pressure mercury-vapour lamp as the source of ultra-violet light. Visible light was absorbed by Wood's filter, and either a quartz condenser or a dark-ground condenser was used. Better definition was obtained with the dark-ground condenser, particularly with higher-power objectives.

Results

Tissues examined were skin, heart muscle, kidney, thyroid, and spleen. Fig. 1 shows a section of kidney which was pretreated with normal serum and then with fluorescent anti-globulin. Another section of the same kidney treated with serum positive in the L.E. cell test, and then with fluorescent anti-globulin, shows specific "staining" of the cell nuclei (Fig. 2). In all tissues examined exposure of the section to "L.E.-cell-test-positive" sera resulted in marked specific fluorescence of the nuclei on subsequent staining with the anti-globulin conjugate. This was never found when normal sera were used to treat the section. The appearance is best shown in tissues containing epithelial cells where the arrangement of nuclei is in orderly patterns of tubules, acini, or strata (Figs. 3 and 4), but was clearly present in every tissue examined. The specificity of staining by the anti-globulin conjugate was confirmed by showing that its ability to stain tissue treated with L.E. positive serum was blocked by pretreatment with unconjugated anti-globulin serum but not by normal serum.

Both the conjugates described above gave similar results, varying only in intensity of fluorescence; some preparations showed brighter fluorescence with one than with the other, but no qualitative difference was observed.

Fig. 5 shows a buffy-coat preparation pretreated with L.E. positive serum and then stained with fluorescent conjugate. The white-cell nuclei fluoresce brightly and specifically. In control films pretreated with normal serum the white-cell nuclei appear as unstained spaces against faint non-specific staining of the cytoplasm. Some granulocytes, possibly eosinophils, show bright non-specific staining of cytoplasmic granules, which serves to emphasize the lack of nuclear staining (Fig. 6).

Positive results were obtained only when sections were cut and treated on the same day. Sections kept for several days before treatment, even when refrigerated, gave variable or negative results.

Discussion

This work shows the presence in the three L.E. positive sera examined of a factor with an affinity for tissue-cell nuclei. This factor was not present in normal sera tested.

Fig. 1.—Kidney cortex. Section pretreated with normal serum, then treated with fluorescent anti-globulin. No nuclear staining. ($\times 160$.)

Fig. 2.—Section from same tissue block as Fig. 1. Pretreatment with L.E. positive serum results in specific staining of nuclei on treating with fluorescent conjugate. ($\times 160$.)

Fig. 3.—Thyroid gland from neonatal death; section pretreated with normal serum. No nuclear staining on treatment with anti-globulin conjugate. ($\times 160$.)

Fig. 4.—Same tissue as Fig. 3: section pretreated with L.E. positive serum. Bright nuclear staining on treatment with conjugate. ($\times 160$.)

Fig. 5.—Group O blood film, unfixed. Pretreated with L.E. positive serum, then stained with conjugate. Leucocyte nuclei fluoresce brightly. ($\times 480$.)

Previous work has shown that a gamma-globulin fraction is responsible for the L.E. cell phenomenon of Hargraves, a part of which involves alteration of the nuclear material of white cells. This suggests that the L.E. cell factor is of an antibody nature, and the present demonstration in tissue-cell

FIG. 6.—Non-specific fluorescence of cytoplasmic granules in certain leucocytes (? eosinophils). Unfixed blood film pre-treated with normal serum, then stained with conjugate. Nuclei remain non-fluorescent. ($\times 480$.)

of the white cells in an L.E. cell preparation. It thus seems very likely that the "L.E. factor" active against leucocytes is also the factor reacting with the tissue-cell nuclei reported here.

Further work may show whether the existence in lupus erythematosus of an immunological mechanism involving tissue-cell nuclei can account for the presence of altered nuclear material in this disease.

We wish to acknowledge the help of Dr. E. G. L. Bywaters, who read the manuscript, and Dr. S. Leibowitz, who was associated with the initial stage of this work.

VIRUS HEPATITIS WITH FEATURES OF PROLONGED BILE RETENTION

BY

STANLEY SHALDON, M.B., M.R.C.P.
Late House-Physician, Hammersmith Hospital

AND

SHEILA SHERLOCK, M.D., F.R.C.P.
M.R.C.P.Ed.

Physician and Lecturer, Department of Medicine,
Postgraduate Medical School of London, W.12

Atypical manifestations of infectious diseases are difficult to recognize when the causative agent cannot be identified. In epidemics their recognition is facilitated, but sporadic cases are always diagnostic problems. "Virus" hepatitis is a well-recognized clinico-pathological entity, although the causative virus still eludes us. Eppinger (1937) recognized that, in addition to a hepatocellular variety, infective jaundice might take a "cholagogic" form which was characterized by more prolonged, deeper icterus, clinical features of obstructive jaundice, and histologically a liver showing periportal cellular infiltration and bile stasis with little evidence of hepatocellular injury. Watson and Hoffbauer (1946) described the cases of eight patients who were exposed to hepatitis and whose illness began as a typical acute hepatitis, but who showed a prolonged course with features of

obstructive jaundice, and they introduced the term "cholangiolitic hepatitis" for such cases. This complication of acute hepatitis has subsequently been described by others (Saint, 1952; Lipschutz and Capson, 1955; Johnson and Doenges, 1956).

It is the purpose of this paper to review 12 cases of acute "virus" hepatitis showing features of prolonged bile retention, with particular reference to the difficulty in diagnosis, to the management, and to the prognosis.

Clinical Features (Table I)

The seven female and five male patients were aged 13 to 59 years (mean 40 years). Two had been in contact with hepatitis during the preceding two months and two had received blood transfusions three months previously. In the others the jaundice occurred sporadically. The onset was always acute with anorexia, malaise, nausea, and vomiting, and smokers developed a distaste for tobacco. Pain in the liver area was unusual. Following the acute prodromata, jaundice appeared and deepened progressively. After about three weeks pruritus was noted, lasting about three weeks, and two patients showed a generalized maculopapular rash which lasted two to three weeks. The liver was enlarged in seven patients, but tender in only three; in two patients the spleen was palpable. The urine showed bile pigment, and an initial urobilinogen excess was soon followed by absence of urobilinogen. Stools became acholic, but as the disease continued pigment was usually noted from time to time.

After the first three to four weeks the patients felt well, were afebrile, gained weight, and the spleen and liver could no longer be felt. Jaundice, however, deepened and lasted 8 to 29 weeks, with a mean of 13 weeks. In three patients the possibility of extrahepatic biliary obstruction was so strong that exploratory laparotomy was performed, but no bile-duct obstruction could be found. These patients made slow post-operative recoveries, one having a transient episode of liver failure with ascites and impending hepatic coma. All the patients made an eventual complete clinical recovery. In seven patients a cholecystogram or intravenous cholangiogram was performed, and this was normal. The patients have been followed up for one month to six years, no relapses or clinical progression to chronic liver disease being noted.

Biochemical Features (Table II)

The peak serum bilirubin level was reached within eight weeks, and averaged 17 mg. per 100 ml., with a range of 6.6 to 27 mg. per 100 ml.; it then fell fairly sharply and steadily but did not fall below 2 mg. per 100 ml. until about the thirteenth week. The urobilinogen returned to the urine about the eighth week with a range of 4 to 18 weeks. The serum alkaline phosphatase level was raised above 30 units per 100 ml. in only three patients, but showed a tendency to increase with the serum bilirubin level and fell some time after the serum bilirubin level was normal; in two patients it was still raised after one year. Serial changes in serum cholesterol values were not remarkable, but three patients showed an elevation at the onset and one rose later. The serum albumin concentration was not significantly altered. There was a tendency to hyperglobulinaemia, with a proportionate increase in the α_2 - and β -globulin fractions (Fig. 1), which eventually returned to normal. During the first six to eight weeks the flocculation tests were positive in eight patients but became

FIG. 1.—Case 6. Electrophoretic pattern of the serum proteins, showing an increase in the α_2 - and β -globulin fractions. Serial changes in serum cholesterol values were not remarkable, but three patients showed an elevation at the onset and one rose later. The serum albumin concentration was not significantly altered. There was a tendency to hyperglobulinaemia, with a proportionate increase in the α_2 - and β -globulin fractions (Fig. 1), which eventually returned to normal. During the first six to eight weeks the flocculation tests were positive in eight patients but became

negative in six of these as the disease progressed and the α_2 - and β -globulins rose. The other patients showed negative seroflocculation tests throughout.

Haematological Features.—The leucocyte count was normal and the erythrocyte sedimentation rate was raised in only three patients. There was no significant anaemia.

Hepatic Histology (Table III)

Sixteen liver biopsies were obtained from 10 patients—3 at the time of operation and 13 by the needle method. The first biopsy was performed 5 to 17 weeks (mean 8 weeks) from the onset. Varying degrees of bile retention, parenchymatous damage, and portal zone infiltrations were constant.

Bile retention was shown by bile thrombi, bile staining of liver cells, and swelling of Kupffer cells with bile pig-

ment. This change was absent only in two biopsies taken late in the illness. Bile necroses or laking were not seen, and the distribution of the bile thrombi was not predominantly zonal. Bile-duct proliferation was not prominent.

In the three operation biopsies and in one needle biopsy centrilobular necrosis was definite and too conspicuous for simple extrahepatic biliary obstruction. In these patients the picture was easily recognized as that of virus hepatitis. A second needle biopsy from Case 11 eight weeks post-operatively showed a marked increase in hepatocellular necrosis, and this coincided with an episode of liver failure. One year later, however, the liver biopsy appearances were normal. In the remaining six patients the evidence of hepatocellular damage was less obvious. However, all six showed definite centrilobular eosinophilic change in the cyto-

plasm of the liver cells, indicative of damage, and ancillary evidence of hepatocellular necrosis was given by pyknosis of nuclei and multinucleated liver cells.

Portal zone infiltrations, predominantly mononuclear, were always present. The reticulin pattern of the liver was normal.

Patient 7 was an obese man and showed fatty change in the liver cells in both biopsies; this was an atypical feature.

Case 6

A schoolboy aged 13. In November, 1955, three school-fellows developed infective hepatitis, and six weeks later, on December 31, the patient complained of headache, malaise, loss of appetite, nausea, and generalized weakness. On January 9, 1956, he was noticed to be jaundiced, with pale stools and dark urine. The appetite returned and he felt very well. On January 16 itching was noted, and, in spite of bed rest and a high carbohydrate diet, the jaundice deepened and the pruritus continued; he lost 14 lb. (6.4 kg.) in weight.

He was admitted to Hammersmith Hospital on April 17, not acutely ill but deeply icteric with many scratch marks. The liver was enlarged 2 cm. below the right costal margin, firm, smooth, and non-tender. The spleen was palpable. The stools were pale, and urine contained bile pigment but no urobilinogen. He was kept in bed without specific therapy. Urobilinogen appeared in the urine two days after admission, and during the next month the jaundice gradually subsided. Itching disappeared spontaneously three weeks after its onset. An aspiration needle biopsy of the liver performed five months after the beginning of the illness (May 15, 1956) showed residual bile thrombi with centrilobular multinucleated liver cells compatible with a healing hepatitis. He was discharged from hospital, having gained 6 lb. (2.7 kg.) in weight and having a normal serum bilirubin level. Eight months later he had gained a further 14 lb. (6.4 kg.), grown 2 in. (5 cm.), and was a well-developed boy. The liver was no longer palpable and there were no stigmata of chronic liver disease.

Comment.—Six weeks after contact with epidemic jaundice a typical onset of hepatitis was followed by prolonged icterus of obstructive type lasting five months, with final excellent recovery.

Case 11

A draughtsman aged 21. In June, 1955, while on holiday, he felt tired and ill, lost his appetite, and had nausea and occasional vomiting. Three days later the urine became dark and the motions loose and pale, and two days afterwards the eyes and skin were yellow and there was gener-

alized itching and a widespread rash. As the jaundice deepened he felt better, pruritus being the only symptom. After three weeks the jaundice was still intense and he was admitted to hospital, where he was found to be deeply icteric with a palpable spleen. The skin showed excoriations and a maculo-papular rash. Liver-function tests in July, 1955, showed: serum bilirubin, 19 mg. per 100 ml.; alkaline phosphatase, 16 King-Armstrong units per 100 ml.; serum albumin, 4 g.; serum globulin, 3.6 g.; thymol turbidity, 9 units. The urine contained bilirubin and no urobilinogen. X-ray examination of the abdomen revealed no calculi, and the Paul-Bunnell test was negative. The patient was kept in bed with a low-fat diet and the pruritus and rash cleared. However, after four weeks the jaundice had not altered significantly and the seroflocculation tests were now negative. The original diagnosis of infective hepatitis was revised, and an exploratory laparotomy was performed on July 27, eight weeks after the onset of jaundice. Apart from an enlarged spleen, no abnormality was found. A liver biopsy showed appearances consistent with a healing hepatitis (Table III).

Post-operatively the jaundice deepened and he developed ascites and ankle oedema. The ascites cleared quickly on dietary salt restriction and mercurial diuretics, but as the jaundice persisted he was referred to Hammersmith Hospital in September, 12 weeks after the onset. He was mildly icteric, with a palpable spleen but no other stigmata of chronic liver disease. A second aspiration needle biopsy performed two months after the first showed evidence of recent acute centrilobular necrosis with increase in reticulin, a few bile thrombi, and conspicuous portal zone cellular infiltration with some fibrosis; progression to cirrhosis seemed possible. During the next two weeks the jaundice cleared and he was discharged from hospital. In August, 1956, he was readmitted for assessment. He felt perfectly well and was leading a normal life. The spleen was no longer palpable, biochemical tests were virtually normal (Table II), and an intravenous cholangiogram showed a normal biliary system. Aspiration liver biopsy revealed normal liver structure.

Comment.—In this patient hepatitis started acutely but was followed by a prolonged phase of biliary retention. Following laparotomy, liver function deteriorated, ascites developed, and the liver lesion progressed. Ultimate recovery, however, was complete.

Case 12

A buyer aged 45. In November, 1956, following a car accident, he received blood and pooled plasma intravenously. In January, 1957, anorexia, nausea, malaise, loss of desire to smoke, with some fever, were followed several days later by dark urine and the eyes became yellow. On January 16, 10 days after the onset, he was admitted to Hammersmith Hospital. He was an ill-looking, moderately icteric man with marked fetor hepaticus and a tender liver edge just palpable. Biochemical tests showed: serum bilirubin, 6.1 mg.; albumin, 3.9 g.; globulin, 3.6 g. ($\alpha_2\beta$ pattern); thymol turbidity, 6.5 units; zinc sulphate, 4 units; alkaline phosphatase, 37 units; cholesterol, 239 mg. per 100 ml. A diagnosis of serum hepatitis was made and he was treated with bed rest, glucose drinks, and a light diet. His appetite improved and he felt generally better, but jaundice deepened and two weeks after admission there was generalized itching. Six weeks after the onset he felt well, although his serum

FIG. 2.—Case 12. Effect of corticotrophin and prednisolone therapy on the serum bilirubin level.

bilirubin level had risen to 21 mg. per 100 ml. and the urine still contained no urobilinogen.

Diagnosis

The exclusion of extrahepatic or surgical jaundice is essential, as laparotomy seems to affect the prognosis adversely. The history is all-important. In an epidemic, little difficulty should be experienced in the initial diagnosis, which should not be changed because jaundice is prolonged. In sporadic cases the diagnostic difficulty increases. However, the prodromal symptoms followed by the acute development of jaundice with recovery of appetite and well-being are typical of hepatitis. If, as was usual in this series, the patient is first seen several weeks after the onset of jaundice and after other medical opinions have been taken, the history can be misleading. Biochemical tests may not be helpful, although the occasional positive flocculation test, with hyper-gammaglobulinaemia and the frequent low serum alkaline phosphatase values, may support the diagnosis of hepatitis.

Intravenous and oral visualization of the biliary system is of no value, as the liver is unable to excrete the contrast media in the presence of jaundice. Plain x-ray examination of the abdomen may reveal opacities in the right upper quadrant, but undue emphasis should not be placed on their diagnostic value. A chest x-ray examination is routine, and further investigations may include a barium meal and stool testing for occult blood.

Aspiration liver biopsy is indicated when the clinical diagnosis cannot be made with certainty. In our series evidence of hepatitis was present in every case, and the criteria for diagnosis are well described by Gall and Braunstein (1955) as focal necrosis with eosinophilic hyaline bodies replacing liver-cell cytoplasm, ballooning of liver cells with ground-glass cytoplasm, nuclear vesicularity, and intralobular clusters of lymphocytes. They suggest that these lesions show no essential differences from typical hepatitis, but may be obscured by the additional features of biliary retention.

Certain drugs, especially chlorpromazine, methyltestosterone, and organic arsenicals, may occasionally produce jaundice characterized by bile retention without extrahepatic biliary obstruction. The clinical course, biochemical findings, and hepatic histological changes may closely mimic virus hepatitis with predominant bile retention, and the history of taking the drug is essential for diagnosis.

Primary biliary cirrhosis should present no diagnostic difficulty. The onset, usually in a middle-aged woman, is gradual, with pruritus and jaundice; hepatosplenomegaly is constant. The hepatic histology shows a proliferative portal zone lesion.

The subacute form of virus hepatitis may provide diagnostic difficulties. This patient, however, is predominantly suffering from failure of liver-cell function and feels and looks ill. Jaundice is rarely deep and waxes and wanes. Vascular spiders develop and the spleen is enlarged. The serum gamma-globulin level is always very high and the flocculation tests are strongly positive.

Occasionally diagnostic doubt continues, and it is then our policy to wait for a minimum of six weeks before considering surgical intervention. The intervening period is occupied by daily clinical assessment, weekly serum biochemical tests, and daily observation of the urine and stools. Liver biopsy is then performed, and if doubt still exists surgical exploration is undertaken. Little is lost by delaying operation in extrahepatic obstruction, but surgery may kill the patient with infective hepatitis.

Discussion

The mechanism of biliary retention without obstruction to extrahepatic bile ducts is uncertain and the site of the obstruction still unknown. It has been suggested that the abnormality is located in the cholangiole, the hypothetical connexion of the intralobular bile canaliculus with the bile duct in the portal tract. This might be a mechanical stricture by portal zone infiltrations or a change in membrane permeability causing bile pigment to increase in

FIG. 3.—Case 12. Jaundiced for 51 days. Aspiration liver biopsy 1, showing centrilobular necrosis and giant liver cells with Kupfer-cell increase and many very dark bile thrombi. (Stained Best's carmine. $\times 92$.)

FIG. 4.—Case 12. Jaundiced for 81 days. Aspiration liver biopsy 2, showing residual portal zone cellularity and scarring and slight centrilobular rarefaction. The zonal architecture is preserved. (Stained Best's carmine. $\times 66$.)

corticotrophin therapy this biopsy did not differ from other comparable cases in the series, although perhaps the infiltration in the portal zones was less. The corticotrophin was now replaced by prednisolone, 10 mg. twice daily. Three weeks later there was no jaundice and his liver was no longer palpable. A second aspiration needle biopsy showed portal tract fibrosis with a few bile thrombi and several centrilobular eosinophilic granules (Fig. 4). This picture, with residual scarring, was comparable with our other serial biopsies on patients who had not received steroid therapy. The prednisolone was reduced to 5 mg. twice daily for one week and then discontinued. When seen on April 8 he felt perfectly well and was returning to work. Biochemical tests on liver function were normal (Table II).

Comment.—In this patient serum hepatitis was followed by a prolonged period of biliary retention. Steroid therapy induced an abrupt clinical relief of the biliary retention but did not seem to influence the sequence of histological changes in the liver.

concentration in the secreted bile at this site. The bile thrombi could therefore be the result of resorption of bile from change in membrane permeability rather than the actual cause of the jaundice by obstructing canaliculi. In the present state of knowledge, as the site of the lesion and the mechanism of the jaundice are still uncertain, it is unwise to call this condition "cholangiolitic hepatitis," and it is better described generally as hepatitis with features of prolonged bile retention.

The prognosis of our patients has been uniformly excellent, with complete clinical recovery and restitution of a normal liver histologically. This has been the opinion of others (Lipschutz and Capson, 1955; Johnson and Doenges, 1956), although their follow-up periods have been less than two months and they attribute remission to the use of steroids. Watson and Hoffbauer (1946) postulated the development in this type of patient of a cholangiolitic cirrhosis which they likened to primary biliary cirrhosis. Liver-cell damage, however, is so minimal and the essential zonal architecture of the liver so undisturbed that progression to biliary cirrhosis would be unexpected. The picture of primary biliary cirrhosis (Ahrens *et al.*, 1950; Sherlock, 1955) develops insidiously without acute prodromata and should not cause confusion. It is particularly important as regards prognosis to differentiate hepatitis with prolonged bile retention with a good prognosis from subacute virus hepatitis in which the zonal architecture of the liver is destroyed and which progresses to a post-necrotic or portal cirrhosis.

The value of biochemical tests in the differential diagnosis is limited, for identical results may be obtained whether the biliary retention is of intrahepatic or extrahepatic origin. Popper and Szanto (1956) found no essential difference in the biochemical features of intrahepatic and extrahepatic cholestasis, both being characterized by pale stools, absent or reduced urinary urobilinogen, and raised serum bilirubin, alkaline phosphatase, and cholesterol levels. In the present series, in the first six weeks of the illness flocculation tests were often positive, but with the increase of bile retention these reverted to normal. Negative flocculation tests should not exclude viral hepatitis as the cause of jaundice, particularly when the patient is first seen at a late stage of the disease.

Corticotrophin administration for four days has been advocated for the differential diagnosis of jaundice, the fall in icteric index in acute hepatitis contrasting with extrahepatic obstructive jaundice in which there is little change (Solem, 1957). A great decrease in serum bilirubin values strongly suggests hepatogenous jaundice, although there is much overlap and the usefulness of the method has been questioned (Chalmers *et al.*, 1956). In our Case 12 corticotrophin administration was followed by a dramatic fall in serum bilirubin values and the duration from peak to normal serum bilirubin values was the shortest in the series. Serial liver biopsies while on corticotrophin and prednisolone therapy, however, showed changes comparable with others in the series and the development of minimal portal zone scarring was not prevented. These hormones have a place in the treatment of virus hepatitis with prolonged biliary retention, as they shorten the period of jaundice and enable the patient to return to activity sooner. The sequence of events in the liver, however, is probably unaltered and steroids serve only as a convenient "whitewash." Relapses are likely if steroids are withdrawn too soon, and treatment should be given until the serum bilirubin level is normal and continued well into convalescence.

Summary

Twelve patients with virus hepatitis experienced an acute onset and then showed prolonged jaundice of obstructive type. Biochemical findings were often of little differential diagnostic value. In 10 patients liver biopsy showed histological evidence of hepatitis with additional bile-pigment retention. Three patients who

underwent laparotomy recovered very slowly. The prognosis in all the patients was excellent.

The differential diagnosis and the place of corticotrophin and prednisolone treatment are discussed.

AGRANULOCYTOSIS ASSOCIATED WITH INFECTIVE HEPATITIS

BY

F. E. DISCHE, M.D., M.R.C.P.

Late Junior Assistant Pathologist, Department of Pathology,
University of Cambridge

AND

J. R. GOLDING, B.M., M.R.C.P.

Late House-Physician, Addenbrooke's Hospital, Cambridge

The haematological changes in infective hepatitis are characterized by an early leucopenia, affecting neutrophils and lymphocytes, followed by a relative lymphocytosis and a return to normal by the end of the second week (Havens, 1948). The degree of leucopenia varies, the lowest count recorded by Thewlis and Middleton (1925) being 1,200 per c.mm. (47% neutrophils). Severe degrees of granulopenia appear to be rare, and the only reference to agranulocytosis accompanying possible infective hepatitis we have been able to find is a case report by Sabrazès and Saric (1935): since, however, the jaundice in their patient, a young woman, was preceded by diarrhoea and vomiting of one month's duration, the exact nature of the illness is open to speculation; the patient recovered completely.

In view of the apparent rarity of the association, we describe here a case of infective hepatitis complicated by fatal agranulocytosis.

Case Report

The patient, an undergraduate aged 22, was admitted to Addenbrooke's Hospital on April 29, 1955. Eight weeks previously he had become ill with depression, frontal headache, and fever, and when his doctor was consulted two weeks later jaundice and a dark urine were noted.

After a fortnight's rest in bed he felt improved, but developed a painful pharyngitis which responded well to treatment with penicillin lozenges. Two weeks before admission he returned to Cambridge for the beginning of term; he was now only slightly jaundiced. However, severe fatigue soon prevented work and games, and marked jaundice recurred, with clay-coloured stools and a slight aching pain below the right costal margin. He had lost in all 21 lb. (9.5 kg.) in weight. His previous health had always been good, apart from an attack of jaundice at the age of 7 years. He had had no injections in the recent past, and there was no suggestion of exposure to potentially toxic drugs or chemicals.

On clinical examination the patient was icteric and his liver was moderately enlarged and tender; the urine contained large amounts of bile pigment. There was generalized slight lymph-node enlargement, but no other abnormal physical sign. Blood investigations showed: haemoglobin, 10.9 g. per 100 ml.; total leucocyte count, 3,500 per c.mm. (47% neutrophils, 0.5% eosinophils, 48.5% lymphocytes, 4% monocytes); serum bilirubin, 6.3 mg. per 100 ml. The thymol turbidity test was normal, but the serum alkaline phosphatase was raised (14.7 Bodansky units per 100 ml.).

At first he was afebrile and, although ill and drowsy, had a good appetite. By May 6 the liver was smaller and the jaundice less, but he complained of a sore throat; the fauces appeared hyperaemic, with pus on the right tonsil, but a culture was negative for haemolytic streptococci. Thereafter the temperature gradually rose to 103° F. (39.4° C.). On May 9 the leucocyte count was 2,000 per c.mm. with only 1% neutrophils. At this stage the serum proteins totalled 6.1 g. per 100 ml., with a normal electrophoretic pattern, and the thymol turbidity test remained negative; the Paul-Bunnell test was negative. All subsequent leucocyte counts, taken on and after May 10, varied between 250 and 150 per c.mm., and neutrophils were completely absent, all the cells being lymphocytes. The haemoglobin level varied between 8.7 and 9 g. per 100 ml., with normochromia, normocytosis, anisocytosis, and poikilocytosis of the red cells, and platelets totalled 170,000 per c.mm. The sternal marrow was very hypocellular, with fair numbers of megakaryocyte fragments but scanty normoblasts and leucocytes, the latter chiefly lymphocytes and myeloblasts with very occasional later granulocytes.

Treatment for the agranulocytosis consisted of penicillin and, later, streptomycin injections, and of corticotrophin gel and pyridoxine, but swallowing became extremely painful and his general condition deteriorated. The jaundice seemed to diminish, but he lapsed into terminal coma and died on May 15.

At no time was a "flapping" tremor or the fetor hepaticus noted. Apart from the drugs already mentioned, the patient received during his time in hospital only magnesium trisilicate and a single capsule of pentobarbitone sodium, 1½ gr. (0.1 g.).

Necropsy Report

The body was that of a thin, jaundiced young man. The liver was firm, khaki-coloured, and moderately enlarged (weight 2,200 g.), with a slightly uneven surface showing wrinkled depressions in places; at three widely separated sites small superficial areas of liver tissue were light yellow and evidently necrotic. On section variable broadening of the portal tracts was seen and at places some wider grey-pink zones, but there was no obvious nodular hyperplasia of the parenchyma. The Prussian-blue test for iron was strongly positive. The gall-bladder and bile ducts appeared normal.

Histologically, a lobular pattern was still recognizable, but the lobules varied in size and shape, and the central veins were often eccentric, while in some parts regenerative nodules without central veins were present. The liver cells were large, with slight fatty change, and there were some bile "thrombi." Most of the portal tracts were widened, incorporating proliferated bile ducts, a moderate lymphocytic and plasma-cell infiltration, and numerous thin-walled blood vessels. The sublobular veins showed an endophlebitis. Here and there completely destroyed lobules were represented only by collapsed stroma surrounded by a ring of proliferated bile ductules (Fig. 1). There was extensive, probably agonal, centrilobular necrosis in the yellow areas, with no inflammatory infiltration.

The bone marrow of the sternum and vertebrae was pale and brownish, and haemopoietic marrow was present in the upper femur. Histologically the marrow was hypocellular (Fig. 2), with only scanty myeloid cells, mainly of the eosinophil series with rare neutrophils. Normoblasts, however, were relatively abundant in all stages of development, especially early forms, some of which were abnormal and

resembled plasma cells; there was an increase of true plasma cells and lymphocytes, while megakaryocytes were present in about normal numbers.

The spleen was moderately enlarged and congested (weight 405 g.). Microscopically, hyperplasia of reticulum cells was present, mainly in small foci in the pulp. The

FIG. 1.—Severely damaged area of liver, showing remnants of lobules, devoid of liver cells and outlined by proliferated bile ducts, on left, and surviving parenchyma on right. (H. and E. ×30.)

FIG. 2.—Bone marrow from vertebral body. Clumps of normoblasts predominate. (Barrett's stain. ×90.)

pulp contained occasional neutrophils, but phagocytosis was confined to a few red cells; there was some haemosiderin deposition.

The soft palate and pharynx, the lower oesophagus, and the respiratory passages were covered by a thick layer of shaggy, easily scraped-off, yellow exudate and the mucosa was necrotic but with a relatively slight inflammatory reaction, including very few neutrophils; bacteria were extremely numerous, and a fungal mycelium was present, in greatest quantity in the oesophagus. The lungs had a mottled red colour with large, yellow, necrotic bronchopneumonic foci in which the inflammatory reaction was mainly mononuclear with a small minority of neutrophils. Cultures from various sites grew predominantly *Staphylococcus pyogenes* (penicillin- and streptomycin-resistant) and also coliform bacilli, haemolytic streptococci, and *Candida albicans*.

Apart from some small haemorrhages in the pericardium and upper ileum and conspicuous reactive changes in the upper abdominal lymph nodes, there were no important changes in other organs.

Discussion

The clinical picture—a febrile illness followed by jaundice, with a relapsing course—is strongly suggestive of virus hepatitis. The necropsy and histological findings are those of liver scarring and regeneration following parenchymal cell loss, and are compatible with a viral aetiology (Lucké, 1944). A toxic origin would appear to be excluded by the negative history, and it therefore seems reasonable to regard the case as one of subacute infective hepatitis; homologous serum jaundice may give rise to identical pathological changes, but there was no story of an appropriate injection or transfusion. The changes in blood, bone marrow, and other organs leave no doubt that a severe agranulocytosis developed and was responsible for the fatal outcome. It remains to consider the possible cause of the agranulocytosis.

Drug toxicity can be excluded, for none of the drugs which are commonly responsible was administered. Barbiturates have only rarely been thought to cause granulopenia, and the single dose of pentobarbitone given can hardly be held to blame.

Overaction of the spleen is unlikely to have been present, for evidence of increased sequestration and phagocytosis of leucocytes in this organ (von Haam and Awmy, 1948) is lacking; in addition, hypoplasia of the marrow is exceptional in hypersplenism. A pre-existing chronic hypoplastic neutropenia (Spaet and Dameshek, 1952) can be ruled out on account of the satisfactory past history.

The possibility of hepatic failure must be taken into account: Sherlock (1955) refers to a patient with cirrhosis in whom polymorphs were absent from the blood, returning as liver function improved. Our patient was drowsy, but in the absence of supporting evidence severe liver failure must be regarded as improbable.

Finally, a relationship with infection has to be considered. A similar question arises also with certain other fevers, including measles, mumps, and influenza (Whitby and Britton, 1953), in which agranulocytosis occurs as a rare complication; in each of these diseases, in common with hepatitis, a neutropenia is common in the ordinary course of the illness. Two possibilities suggest themselves: that the hepatitis virus alone may have caused the agranulocytosis, with secondary infection as a result, or that the secondary infection itself may have played some causative role. Robertson (1949) has emphasized the importance of infection in aggravating the granulopenia when marrow depression is due to drugs; he also refers to a case of glandular fever with moderate neutropenia, in which a streptococcal throat infection led to a severe drop in neutrophils, with prompt improvement after the start of penicillin treatment. In the present instance the first alternative cannot be excluded, but we suggest that the second offers a more attractive explanation—secondary infection occurring when marrow function was already depressed as a result of the virus disease, and in turn precipitating severe leucopenia. The failure of antibiotic treatment, which is usually so effective, can be attributed to the antibiotic-resistant staphylococci in the lesions, and it seems likely that these organisms were there from the earliest stages.

Summary

A case is reported of fatal agranulocytosis developing late in the course of severe hepatitis, thought to have been of viral origin. The agranulocytosis cannot be attributed to drugs, and a relationship with hypersplenism is improbable, while the presence of severe hepatic failure seems unlikely; it is suggested that it may have resulted from secondary infection occurring at a time when marrow function was already depressed as a result of the virus disease.

We are indebted to Dr. L. B. Cole and Dr. A. M. Barrett for advice and permission to publish, and to Dr. N. F. C. Gowing, Dr. F. Dudley Hart, Dr. K. Weinbren, and Dr. J. L. Stafford for helpful criticism. Mr. G. Spurgeon prepared the histological sections and Dr. A. D. Morgan and Dr. Peter Hansell the photomicrographs.

GLOSSOPHARYNGEAL BREATHING ITS VALUE IN RESPIRATORY MUSCLE PARALYSIS OF POLIOMYELITIS

BY

W. HOWLETT KELLEHER, M.D., D.P.H.
Physician Superintendent

AND

R. K. PARIDA, M.B., B.S., M.S., D.T.M.&H.
Registrar
Western Hospital, London

In 1951 Dail, in the U.S.A., described the mechanism of this interesting and, for the human, abnormal form of breathing as observed in a series of 15 patients. A further report by Dail, Affeldt, and Collier (1955) brought the number under observation up to 100 with a correspondingly enhanced experience and comment. Our purpose is to bring to the notice of those faced with the problem of the respiratory muscle defect in the post-acute and chronic stages of poliomyelitis the experiences of the American observers, and also to describe the results of the attainment of this aid to breathing in a few of the patients in the respiratory unit of this hospital.

Description of the Technique

Glossopharyngeal breathing was so named by Dail because of the anatomical structures which take part in the process. It has also aptly been called "gulping" and "frog-breathing" because of its similarity to the breathing mechanism of amphibians. It has been stated that the method has been used by divers to allow for longer periods of submersion and may have been spontaneously developed by some poliomyelitis patients and used for years without recognition. Dail (1951) quotes the case of a patient whom he had observed to be using his mouth and throat in what appeared to be a swallowing action, but which further observations showed to be a gulping of air trapped by the pharynx and then forced through the larynx. It was later shown that each gulp could trap from 30–60 ml. of air and that from 10–20 or more of such gulps constituted a single inspiration. Breathing could continue in this fashion for minutes or hours.

In an excellent manual of instruction for glossopharyngeal breathing (G.P.B.) prepared by Dail, Zumwalt, and Adkins (1955) a description of the mechanism, based on observations and studies of more than 100 patients and 50 normal persons who had learned the technique, is summarized as follows: "There is a stroke-like action of the tongue together with constricting action of the pharynx pumping air through the larynx. The air accumulates step-like in the lungs. Each full 'inspiration' consists normally of about 10 or more such strokes, at the end of which air is released from the lungs in a manner similar to ordinary expiration."

Each stroke is regarded as a cycle consisting of four distinct steps. These steps are illustrated and described in the accompanying illustration. We are indebted to the authors and to the editors of the *Journal of the American Medical Association* for permission to reproduce it here.

Steps taken during one "stroke" of glossopharyngeal breathing. Step 1: a mouthful and throatful of air is taken, depressing the tongue, jaw, and larynx to get maximum volume. Step 2: the lips are closed and the soft palate raised to trap the air. Step 3: the jaw, floor of the mouth, and larynx are raised. This, together with progressive motion of tongue, forces air through the opened larynx. Step 4: after as much air as possible is forced through the larynx, it is closed and the air is retained in the lungs until the cycle is reinitiated.

Application of the Technique

There are now many patients in this country who, as a result of poliomyelitis, have reduced breathing capacity. The reduction is not infrequently almost complete failure, but in most cases, even in those who have achieved only partial release from mechanical assistance, there is sufficient recovery to allow of continued existence in reasonable comfort. Where normal breathing-muscles are inadequate much of the ventilation is carried out by the accessory muscles, such as the sternocleidomastoids and platysmata, and in some cases also by the abdominal muscles, which may have escaped damage. A considerable degree of stability and absence of distress are achieved in these chronic patients even when their efforts produce small tidal exchanges and a vital capacity in many cases of less than 700 ml. (about one-fifth of normal) in the adult—in some, indeed, as low as 300 ml. However, where existence is largely dependent on such accessory muscle groups the patient must be helped by mechanical means when he becomes tired or when he needs to sleep. In many cases he can be released from mechanical aid only for brief periods daily.

While it is for those in the severely limited class that G.P.B. may be particularly useful as an aid to partial release from mechanical aids, Dail and his associates (1955) have pointed out that complete dependence on the respirator is not the only indication for its use but that G.P.B. has also a most useful application in increasing the amount of time free from the machine. In addition, it appears to have a most useful function in those who, though they no longer require a respirator, have nevertheless inadequate capacity for forceful coughing and are therefore subject to lung complications such as atelectasis.

Capacity to Learn Glossopharyngeal Breathing

The technique may be acquired spontaneously, as, for example, in efforts to remain free from the respirator, and indeed one of our patients (Case 4) developed it in this way. Another of our patients found that in efforts to increase spirometer readings she gulped extra air (Case 3). Dail and his associates (1955) state that, while some patients have

learned the technique in one lesson, others required many lessons covering a period of several months. Having acquired it, however, it was found that in the majority several weeks of practice were required to achieve improvement both in the effectiveness of the "gulp"—that is, an increase in the quantity of air trapped in the stroke—and in the endurance for continuation of G.P.B. over lengthening periods of time. These observers also stated that for the new pupil three months should usually be allowed for learning and developing G.P.B.

In Dail's series of 100 cases, G.P.B. was learned at widely varying stages of recovery following on the onset of the disease, the earliest being at two months and the latest four years after onset. Two of our cases have exceeded the latter figure, having been paralysed more than five and seven years respectively (Cases 2 and 6). Therefore the duration of paralysis, however long, does not appear to be a limiting factor in the attainment of G.P.B.; although in our small series it has appeared to us that the younger patients may be expected to have less difficulty in acquiring G.P.B. and in a shorter period than older ones. The youngest in Dail's series was 4 years old and the oldest a man of 47, and it was found that relatively few children learned the technique. About one-quarter of his 100 patients learned the method without appreciable help from others, 5 developed it spontaneously, 15 were taught by other patients, and 55 were instructed by hospital staff.

Uses of Glossopharyngeal Breathing

Dail, Affeldt, and Collier (1955) stated that benefit from use of the method cannot be claimed unless there is evidence of increase in vital capacity, and, furthermore, that the capacity to remain free from mechanical aid by the use of G.P.B. should be at least five times that without it. They mention three classes of patients who were subjects of study based on their functional disability: (a) those who were unable to be free from mechanical aids for any appreciable time without G.P.B.; (b) those who used it as an aid to spontaneous breathing and would otherwise be fatigued; and (c) respiratory cripples who used it as an aid to chest-stretching and coughing.

The volume of air propelled by each stroke in Dail's groups was measured as averaging nearly 60 ml., and he and his colleagues estimated that effective use of the method required a stroke volume equal to approximately 1% of the predicted normal vital capacity in patients with very severe respiratory defect.

Case 1 in our series (see Table) is an excellent example of almost complete dependence on G.P.B., while Case 3 fits into the category of those who use it to supplement their ordinary capacity at intervals. Cases 2, 4, and 5 are examples of those who benefit from it chiefly in the assistance it gives in coughing or chest-stretching. Case 4 uses it also to supplement his efforts when he is under stress—for example, when undergoing active physical exercises for rehabilitation.

Report of Cases

Measurements showing the effects of G.P.B. on the respiratory mechanics of 6 patients are presented in the Table. Case 6 was, however, not available for complete data.

Case 1.—Woman aged 38. The onset of poliomyelitis was in October, 1956. She has been left with almost complete quadriplegia and severe paralysis of the respiratory muscles. She commenced G.P.B. in March, 1957, and the period of freedom from mechanical respiration progressively increased, so that after one month she could remain free of mechanical aid for more than three hours. Now she can remain out of the respirator for as long as 8–10 hours continuously and without obvious fatigue. She has also learned to eat when out of the machine, and while doing so she uses the accessory muscles of respiration. Her normal vital capacity is only 200 ml., but with G.P.B. she can trap up to 1,900 ml. Each phase of maintenance G.P.B. comprises

§ Only two hours after learning the technique.

6-8 gulps, each of approximately 60 ml., giving a tidal volume of 360-480 ml. Her glossopharyngeal breathing rate is about 14 a minute. The acquisition of G.P.B. has greatly simplified the problem of nursing and physiotherapy. She can be taken to the bath, for trips in her wheel-chair, and even for car rides.

Case 2.—Man aged 27. This patient was taught G.P.B. within three days of admission to our unit in August of this year. He has been a chronic respirator case for more than five years, relying almost entirely on accessory muscles and therefore needing a respirator to sleep. His readmission to hospital was precipitated by an ominous reduction in vital capacity to 350 ml. from the usual level of about 800 ml. His vital capacity now is only 550 ml., but after G.P.B. he can blow 1,800 ml. into the spirometer. However, it is expected that with further practice his G.P.B. efficiency will increase. At the moment he traps an average of 40 ml. per gulp.

Case 3.—Young woman aged 19. Admitted to hospital a year ago with very severe paralytic poliomyelitis. Originally treated in cabinet respirator; later weaned through cuirass and rocking bed. She has now been free from mechanical aid for approximately two months. This patient was found to have developed G.P.B. spontaneously and without consciousness of the technique. It appears that she found that in efforts to increase her spirometry readings she gulped air, and this was probably the origin of her ability for G.P.B. Her present vital capacity is only 600 ml. With G.P.B. it totals 1,850 ml., and she uses it for occasional deep breaths—for example, for coughing.

Case 4.—Man aged 30. Has had paralytic poliomyelitis for about 21 months. He developed G.P.B. spontaneously, and with it he can increase his vital capacity of 550 ml. to no less than 3,500 ml. While gulping he produces an audible pumping sound not unlike that of air under compression in a tyre pump. He uses G.P.B. for stretching his chest and coughing, and also to supplement his normal capacity when doing his exercises. He can manage his usual tidal exchange by the use of remnants of ordinary muscles of respiration supplemented by accessory muscles during the day. At night he requires to sleep on a rocking bed.

Case 5.—Man aged 36. Developed poliomyelitis in March, 1957, and needed a cabinet respirator continuously for many weeks. He now has a vital capacity of 800 ml., but needs a rocking bed for sleep. He has been taught G.P.B. during the past fortnight and can now gulp so as to increase his vital capacity to 1,800 ml. His present gulp traps about 25 ml. We expect the efficiency of his G.P.B. to increase with further practice.

Case 6.—Woman aged 23. A chronic respirator patient of seven years' duration requiring the cabinet respirator for the greater part of each 24 hours. While on a visit to London (in her cabinet) she was admitted to our unit for examination and for trial of other breathing apparatus—for example, rocking bed. During the eight hours she was in our unit

she learned the technique of G.P.B. On simple tests before her departure in the late afternoon it was found that her vital capacity was increased from 350 to 700 ml. with G.P.B. Her capacity to count in one breath was increased from 12, using her accessory muscles, to 24 when supplemented with G.P.B. Since her return home she has written to us as follows: "I am now able to do frog-breathing almost imperceptibly apart from the gulping movement in my throat. It has given me so much more confidence to go further away from home and from my iron lung. Last week I made a journey to town by train—about eight miles (12.87 km.)—and spent four hours there before coming back home, which is something I had never ventured to do previously. Also it means I am always able to get sufficient breath to make my voice carry all over the house."

Discussion

Since Dail's original observations further studies on glossopharyngeal breathing have been carried out in many centres in the U.S.A. (Collier, Dail, and Affeldt, 1956; Zumwalt, Adkins, Dail, and Affeldt, 1956; Loeser, 1956; Feigelson, Dickenson, Talner, and Wilson, 1956). The advantages derived by the patient are basically due to his ability to amplify his inspiratory volume unaided by mechanical respirators. Thus he becomes less dependent on machines during waking hours and is assured of a safety factor in case of electrical breakdown or power cuts. The increased volume of air trapped in the lungs also helps the patient to produce a better cough and with it an ability to clear his lungs of secretions. However, the cough mechanism is also dependent on functioning abdominal muscles and diaphragm, and severe involvement of these will diminish the cough effort considerably even though the patient is a good frog-breather (Feigelson et al., 1956). In such patients, however, a good expulsive effort can be produced with the help of an assistant squeezing the lower chest and upper abdomen during the expiratory phase of G.P.B. Efficient frog-breathers can stretch the chest intermittently, and this helps in reducing or preventing rigidity, which alone could seriously interfere with the efficiency of ventilation. Additionally, the deep breathing achieved must be of considerable value in reducing the risk of atelectasis.

In addition to its medical advantages frog-breathing provides considerable social and psychological help to these cripples. It allows them, with certain limitations, to visit their homes, to do shopping, and go for car rides. If the limb paralysis is not severe they may even be able to earn their living, and we are hoping that one of our patients (Case 5) will eventually be able to resume his occupation as a schoolteacher.

There are, however, certain limitations to what G.P.B. can achieve. The patient cannot do it during sleep, and if his unassisted vital capacity is very low and largely or entirely carried out by accessory muscles he will certainly need a respirator for sleeping.

PSYCHOSIS DUE TO ISONIAZID

BY

S. L. O. JACKSON, M.D., M.R.C.P.

Assistant Physician, Uxbridge Chest Clinic

Although it would appear that in the U.S.A. many tracheotomized patients have learned G.P.B., we have not so far succeeded with two patients now on intermittent positive pressure breathing. There are difficulties in preventing leaks from the tracheostome which could be minimized by using suitable plugs as recently developed in the U.S.A. (Dail, personal communication, 1957). These patients, we think, are psychologically ill-adapted also, particularly where they have been for a long time "addicted" to intermittent positive pressure breathing.

A patient cannot eat during frog-breathing. However, one of our patients (Case 1) uses her accessory muscles of respiration while masticating and returns to frog-breathing after she has swallowed. With this combination she can consume an average meal in less than half an hour.

If illness develops, the energy required to perform G.P.B. may be lacking and the patient will require assistance by artificial respiration.

The presence of an irritant—for example, food particles or mucus near the glottis—may cause guarding and temporarily diminished ability for efficient G.P.B. An assistant may be required to help by chest squeezing during expiration to facilitate its dislodgment.

Glossopharyngeal breathing may be regarded as a form of intermittent positive pressure respiration. If the inspiratory phase is prolonged the venous return to the heart is progressively reduced as the intrathoracic pressure rises; thus the cardiac output progressively diminishes, and it has been observed to coincide with a reduction in blood pressure. Most patients complain of lightheadedness for a few seconds after maximal G.P.B., presumably due to transient cerebral anaemia. However, when G.P.B. is carried out to provide maintenance tidal exchange there appears to be no lessening in cardiac output. Dail and his co-workers (Collier et al., 1956) maintain that if the tidal exchange is kept below one litre, provided also that the inspiratory phase is not very prolonged, there is no significant change in cardiac output.

Summary

The usefulness of glossopharyngeal breathing (G.P.B.) in chronic poliomyelitis patients with respiratory paralysis is described. Case reports of six patients from this hospital who have learned the technique are presented and the value of G.P.B. is analysed in each case.

The basic advantage of G.P.B. is the enhanced ability of the patient to increase his vital capacity, which makes him less dependent on respirators and increases his power to cough and stretch his chest. The social and psychological advantages of this type of breathing are stressed.

It can be concluded, without reserve, that G.P.B. is of great value to seriously handicapped patients and that more use of this technique should be made in all centres where post-acute and chronic poliomyelitis patients are cared for.

We wish to record our thanks to the staff and patients of the poliomyelitis unit for their help and co-operation in this study. Our thanks are also due to Mr. E. J. Tunnicliffe, of Electronic and X-ray Applications Ltd., London, for loan of the Monaghan spirometer with which many of the measurements were made.

4	1 week	2.9	"	Schizoid reaction	I.M. nicotinic acid; partial response. I.M. vit. B complex	5 weeks
5	6-8 weeks	3.2	Chronic alcoholism. Oxytetracycline. Chlor-tetracycline	Depression	I.M. nicotinamide; good response	1 week

Case 1

A scaffolder aged 53 was admitted to the ward in July, 1954, with a cavity in the right upper lobe and a positive sputum. He had a long history of basal bronchiectasis with a recent acute episode treated with oxytetracycline. His general condition was, however, good and he was not appreciably toxic. He was given a 60-g. course of daily streptomycin with P.A.S. followed by isoniazid, 200 mg. daily (3.8 g./kg.) with P.A.S. After three months the P.A.S. was replaced by streptomycin owing to some mild gastric upset, but progress was otherwise satisfactory and he was co-operating well. In mid-January he complained of

transient paralysis down the right side and a sensation of butterflies in the stomach. No neurological signs could be elicited, except that reflexes were all very brisk. Thereafter he showed increasing mental change, becoming resentful and argumentative. Hysteria was diagnosed and he was sedated with phenobarbitone. A month later the "paralysis" recurred. The only change in the C.N.S. was that ankle clonus was now present. His mental state had not improved. He remained in a state of tension, constantly complaining about trivialities, and was difficult to manage in the ward.

All chemotherapy was then stopped and over the following six weeks his mental outlook slowly returned to normal. During this period of mental upheaval his cavity had closed and no further chemotherapy was given. He was eventually transferred to a rehabilitation settlement, where he has done well.

Case 2

An aircraft fitter aged 39 developed infiltration in the left upper zone in December, 1954. Sputum was positive for acid-fast bacilli. On admission to the ward his condition was good, he was not toxic, and he appeared normal mentally. From January 3 to March 22, 1955, he received a course of twice-weekly streptomycin with P.A.S. Owing to mild gastro-intestinal disturbances the chemotherapy was then changed to streptomycin, 1 g. three times weekly, and isoniazid, 300 mg. (4.5 mg./kg.) daily. Over the next 10 weeks he became increasingly talkative, until it was quite impossible to nurse him in the general ward and he had to be moved to a side-ward. He was euphoric and had grandiose ideas of his own capabilities and resources. Chemotherapy was stopped on May 26; on June 6, before psychiatric aid was forthcoming, he discharged himself from hospital.

Two weeks later he attended the Chest Clinic and was still talkative, euphoric, and somewhat facetious, though there was also some insight into past events. In spite of his zest for conversation, his expression was noticeably clumsy. There had been continuous and satisfactory regression of his tuberculosis. In another month there was some mental improvement, though he was still talkative and excitable. In August a course of streptomycin and P.A.S. was begun and he remained in bed at home.

In January, 1956, his wife complained about his behaviour. From a quiet disposition prior to his stay in hospital his personality had completely changed and he had taken to asserting himself in demonstrative and sensational ways. On interview he seemed rational, but obviously was still tense and loquacious. It was then decided to try the effect of intramuscular "parentrovite,"* a vitamin B concentrate, and 5 ml. was given twice weekly for three weeks. Within one week there was noticeable improvement, and within two months he was back to his normal quiet and relaxed temperament. Subsequently long courses of streptomycin and P.A.S., and isoniazid and P.A.S., were given, but no relapse was provoked.

Case 3

A tool-grinder aged 37 was admitted to hospital in May, 1955, in a toxic condition with a cavitated lesion in the right upper lobe and strongly positive sputum. After six weeks of streptomycin, 1 g. twice weekly, isoniazid, 200 mg. daily (2.6 g./kg.), and P.A.S., 15 g. daily, his temperature became normal. There had been no sign of mental instability. Chemotherapy was then changed to streptomycin, 1 g. daily, with isoniazid, 200 mg. daily. A few days later he complained that the other patients were whispering about his chest condition and that he feared that they would smother him with a pillow. He took his own discharge from hospital shortly afterwards. Chemotherapy (streptomycin 1 g. four times weekly with isoniazid 200 mg. daily) was restarted at home on June 29, three days after his self-

*Parentrovite: aneurine 250 mg., nicotinamide 160 mg., riboflavin 50 mg., pyridoxine 50 mg., calcium pantothenate 5 mg., ascorbic acid 500 mg.

discharge. On July 5 he attended the Chest Clinic in a highly nervous state, although he himself claimed to be back to normal, and he displayed considerable insight into his previous aberrations.

When seen again a month later he had obviously relapsed into an acute anxiety state. He appeared apprehensive and fidgety and said he had completely lost confidence in himself. There was, however, no recurrence of paranoid delusions. Isoniazid was stopped immediately and replaced by P.A.S., 20 g. daily. In a month he was much improved, and within four months was back to his normal self. Subsequently he received several long courses of streptomycin and P.A.S. (but not isoniazid), was readmitted to hospital, and had a two-stage thoracoplasty without any recurrence of anxiety symptoms.

Case 4

A draughtsman aged 17 was admitted to hospital on October 3, 1955, with a cavity at the right apex which had failed to respond to a three-months course of streptomycin and P.A.S. at home. He had a low-grade temperature, his general condition was good, and mentally he appeared to be a normal and intelligent youth. Streptomycin, 1 g. four times weekly, and P.A.S., 15 g. daily, was continued and he was postured for the apical cavity. On November 15 P.A.S. was replaced by isoniazid, 200 mg. daily (2.9 g./kg.). About a week after the course started an acute confusional state developed. Anxiety was the predominant mood, but he also had complex delusions, including the conviction that he was changing sex. Insight into his condition was only partial. Neurological examination was negative, apart from a generalized increase of tendon reflexes. The C.S.F. showed a slight increase of protein (65 mg.) with slight excess of globulin.

A psychiatrist to whom the patient was known personally considered that his condition was compatible with a toxic psychosis due to drugs. Isoniazid was discontinued soon after the onset of the mental change and from November 25 nicotinamide, 100 mg. three times a day, was given for seven days. Prompt improvement in his mental state occurred, although his behaviour remained a little childish and emotionally overcharged. Towards the end of December delusions recurred, though of a milder character. The C.S.F. was unchanged and there were no fresh neurological signs. Parentrovite, 2 ml. intramuscularly on alternate days, was given over a period of four weeks, and within a week his mental state was completely normal. Chemotherapy (streptomycin and P.A.S.) was restarted in January, 1956, and in spite of repeated courses, which included isoniazid at a later date, and in spite of the ordeal of a major surgical operation (lobectomy) there has been no further mental relapse.

Case 5

A professional man aged 52 had had extensive cavitated disease since 1948 and was an alcoholic. He was nevertheless a good chronic case and was able to carry out his professional duties. The only previous chemotherapy was a three-months course of streptomycin and isoniazid in 1953. He was admitted to a general hospital in August, 1955, with collapse/consolidation of the right lung following fracture of ribs by a fall. There was a partial response to courses of penicillin, oxytetracycline, and chlortetracycline (the latter two antibiotics causing some diarrhoea), but it then became obvious that there was also an exacerbation of the tuberculous disease. Streptomycin, 1 g. daily, and isoniazid, 200 mg. daily (3.2 g./kg.), were started on September 10, but, owing to streptomycin resistance, viomycin, 4 g. weekly, and P.A.S., 15 g. daily, replaced streptomycin on October 6. Isoniazid was continued in spite of partial resistance to the drug.

Over the next four weeks the patient developed increasing mental lethargy and depression, although there was coincident improvement in his temperature and chest x-ray picture. He seemed incapable of helping himself and had to be

fed at every meal. His reaction time was excessively slow and he was grossly disorientated in time. Examination of the C.N.S. was normal except that the reflexes were on the brisk side. Without stopping his drugs intramuscular nicotinamide, 100 mg. daily for seven days and 50 mg. daily for seven days, was started on November 24. The improvement was dramatic and almost immediate, the depression and lethargy disappearing within a week. On discharge three weeks later he was mentally alert and cheerful. A further course of isoniazid was given at a later date without untoward effect, the patient receiving simultaneous vitamin B complex supplement to the diet.

Discussion

The mental changes shown in these cases are all compatible with a toxic psychosis, the precise form of the disorder being dependent on the previous constitutional make-up and personality of the patient. Although direct evidence implicating isoniazid is perhaps not overwhelming in every case, by inference it is strong because of the absence of any previous mental breakdown and because of the similarity to other reported cases.

Deprivation of vitamin B is the generally accepted mechanism involved in both peripheral neuropathy and psychosis due to isoniazid. Biehl and Vilter (1954), investigating peripheral neuritis occurring after high isoniazid dosage, were impressed by the similarity of the picture to that produced by the pyridoxine antagonist desoxyripyridoxine. Moreover, they found that neuropathy did not develop if pyridoxine, 50 mg. daily, was given with the isoniazid. Instead of the theory previously put forward of competitive blocking of pyridoxine by the similar isoniazid molecule, they considered that isoniazid interacted with vitamin B₆ in the tissues to form a pyridoxal isoniazid complex which they found excreted in the urine in large quantities. This was confirmed by Williams and Abdulian (1956), and these authors and Vilter (1955) have drawn attention to the increased excretion of xanthurenic acid in the urine which occurs with pyridoxine deficiency and consequent failure of the enzyme system responsible for tryptophan breakdown, in which pyridoxine plays a part. Vilter claims to have demonstrated this more clearly by giving a 10-g. loading dose of tryptophan and finding a gross excess of xanthurenic acid excretion in such cases.

Other clinical evidence in favour of a simple pyridoxine deficiency is less certain. One of the two cases of peripheral neuropathy described by Jones and Jones (1953) responded to nicotinamide alone, and two of eight cases in alcoholics taking isoniazid reported by Oestreicher *et al.* (1954) failed to improve with pyridoxine. Wood (1955) reported five cases of psychosis and 13 cases of pellagra amongst Bantu, presumably all in poor nutritional state, receiving isoniazid dosage varying from 8 to 12 mg./kg. Three of the psychotics recovered completely with nicotinic acid alone. Three of the pellagra cases also recovered with nicotinic acid alone, but in others improvement was only partial until other B complex vitamins were given. McConnell and Cheetham's (1952) case of pellagra and psychosis occurring in a patient with tuberculous peritonitis in relapse and Zabad's (1953) case of psychosis both responded dramatically to parenteral nicotinic acid. In the series described in this paper Case 5 responded satisfactorily to nicotinamide, Case 4 responded partially to nicotinamide but only completely after vitamin B complex had been given, whilst Case 2 was given vitamin B complex throughout. It is therefore unlikely that isoniazid toxicity can be attributed to one single member of the vitamin B complex, though there is ample confirmation that thiamine plays no part (Jones and Jones, 1953; Wood, 1955).

These problems are perhaps rather academic, and a matter of more practical importance is the question why only certain patients appear to develop C.N.S. toxicity. Biehl and Vilter (1954) give the incidence of peripheral neuropathy as 2-3% amongst those receiving normal dosage (2-3 mg./kg.), a figure which from personal experience

appears to be much too high. It may be worth noting, however, that increase of tendon reflexes occurs in a high proportion of patients receiving isoniazid. It occurred in 13% of M.R.C. (1952) cases, and this may well have been an underestimate. It was a striking finding in at least two of this series and has been noted by many others (Hunter, 1952; Katz *et al.*, 1954; Wood, 1955). Its significance is doubtful, but it has been recorded as an early sign in nicotinic acid deficiency (Brain, 1947), and it is possible that a subclinical deficiency state exists in many more persons than show overt toxic signs.

Dosage, although not a factor in this series—none of the patients having received more than 4.5 mg./kg.—seems undoubtedly of much importance in the published cases of peripheral neuritis. Biehl and Vilter (1954) give an incidence of 40% in patients receiving 20 mg./kg. Wood's cases of psychosis received 7-12 mg./kg. On the whole, the dose relationship appears to be less significant in psychosis than in peripheral neuritis, but it is doubtful if this alone points to any fundamental difference in the mechanism of the two conditions.

Obviously, if vitamin B deficiency is responsible for the toxicity, anything reducing the intake of this vitamin will predispose to a reaction. Malnutrition from various causes, such as extensive tuberculous disease, poverty, and alcoholism, has featured in cases in the literature. In Case 5 in this series the patient was a definite chronic alcoholic, and in Case 1 alcoholism may also have been a factor. With modern chemotherapy, bowel upsets often occur, and P.A.S., for instance, causes diarrhoea, which may be tolerated for long periods by patients and which is bound to upset absorption of essential food factors. Both Cases 1 and 2 had difficulty taking P.A.S. The tetracyclines are known to interfere with the normal bacterial flora of the intestine, and, as intestinal bacteria may be responsible for supplying some of the body's nicotinic acid and pyridoxine, courses of these antibiotics may predispose to isoniazid toxicity. Cases 1 and 5 both received oxytetracycline prior to taking isoniazid. This leaves Cases 3 and 4, in which there was apparently no reason to expect any interference with vitamin absorption; and probably in all the cases, except Case 5, other unknown factors must have been operating.

It is premature to advise giving vitamin B supplements to all patients receiving isoniazid, at any rate in those taking conventional doses, but nervous reactions are probably more common than is realized, and if suspected should be treated promptly. It is particularly important to consider an isoniazid reaction in any patient showing an unexpected and peculiar mental change, especially where there is no past history of mental instability. Perhaps it may also account for some of the reported increase of self-discharges from sanatoria—and two of the present series came to notice for just this reason. Treatment should be given with vitamin B complex, including nicotinamide, pyridoxine, and pantothenate. The dosage should be massive, and, in view of a possible impairment of absorption from the alimentary tract, should be given parenterally. Fortunately, it seems that, once the patient has been saturated with vitamin B complex, further courses of isoniazid can be given with impunity. This was seen in Cases 2, 4, and 5 in this series, and was also observed by Wood (1955) in most of his cases of psychosis and pellagra. No doubt it would be advisable to continue with supplements of vitamin B in the diet.

Summary

Five cases of psychosis are described in patients receiving isoniazid in the usual dosage range of 2-5 mg. per kg. Three of the cases responded completely to vitamin B complex. The role of this substance in the production of the nervous side-effects of isoniazid is discussed.

I should like to thank Dr. J. T. Nicol Roe and the staffs of the Uxbridge Chest Clinic and Mount Pleasant Hospital, Southall, for assistance in preparing this paper. I am also

indebted to the medical staff of Harefield Hospital, to whose sanatorium wards three of the patients were admitted.

TREATMENT OF OPHTHALMIC ZOSTER WITH PREDNISONE

BY

A. BARHAM CARTER, M.D., M.R.C.P.

Physician, Ashford Hospital, Middlesex; Civilian Adviser in Neurology to the War Office

AND

J. E. ROYDS, M.B., M.R.C.P.

Assistant Physician, Ashford Hospital, Middlesex

Herpes zoster affecting the first division of the trigeminal nerve is a severe and painful condition, particularly in elderly patients. In many cases it is complicated by ophthalmic lesions and is often followed by intense neuralgia. There is usually considerable oedema of the face in the early stages, and some of the pain occurring before, during, and after the eruption may be peripheral in origin. It is possible that the cellular reaction to the zoster virus both intraneurally and extraneurally accounts for some of the pain, and, if so, any successful control of this reaction would be useful.

Suppression of cellular reaction by corticosteroid drugs is seen to best advantage in the allergic hypersensitivity states, but it is also known that these drugs can inhibit primary tissue responses to infection, and it was therefore thought justifiable to try their effect on ophthalmic zoster. To avoid sodium and water retention due to treatment, prednisone rather than cortisone was used.

Material and Method of Treatment

Fifteen consecutive cases of herpes ophthalmicus were treated during 1956, eight of them in the Ashford Hospital, Middlesex, and seven in their homes. Details of the treatment are as follows:

Systemic.—(1) Prednisone, 10 mg. six-hourly by mouth for four days, followed by 10 mg. eight-hourly for the next three days. The dose is then reduced by 5 mg. each day until it is discontinued on the fifteenth day. (2) Tetracycline, 250 mg. six-hourly by mouth for seven days. (3) Vitamin-B complex ("becosym"), two tablets three times a day for seven days.

Local.—(1) To the rash, oxytetracycline cream 1% daily. (2) To the eye: atropine 1%, sulphacetamide 30%, hydrocortisone 1%, applied as drops six-hourly for the first week and then according to the condition of the eye.

Results

The results of treatment in these patients, although the follow-up times were short and varied from 18 to 6 months,

were sufficiently satisfactory to consider that the natural history of ophthalmic zoster had been altered for the better. A previous group of 44 cases of zoster, including by chance exactly 15 cases of ophthalmic zoster, had been reported by one of us (Barham Carter, 1951), and this group was thought to be similar enough to act as a reasonable control series.

TABLE I.—Comparison of Control and Treated Groups

	No. of Patients	M.	F.	Average Age	Average Age of Rash on Admission
Control group, 1951 ..	15	8	7	64 years	4.3 days
Treated group, 1956 ..	15	7	8	66 "	4 "

Table I compares the two groups regarding age, sex, and duration of illness before admission to hospital. Both groups were nursed in the same wards of the same hospital under the care of the same physicians. The criteria chosen for comparison were: time of subsidence of oedema; time taken for drying of rash; appearance of fresh lesions; degree of scarring; percentage of ophthalmic complications; and severity and duration of pain, including occurrence of post-herpetic neuralgia. Tables II and III show in detail the results and progress of the two groups.

Subsidence of Oedema.—In the control series the peri-orbital oedema lasted from 8 to 17 days, and in the prednisone series its duration depended entirely on when treatment was begun. In Cases 5 and 13 treatment was started on the second day of the pain and within 24 hours of the rash, and no oedema appeared at all, and in Case 6 prednisone was started on the third day of the rash and the oedema lasted only for five days. In contrast one patient was admitted on the 16th day of her illness and her oedema

Scatter diagram showing relationship between improvement of rash and time of treatment. O = First day of dry rash (15 patients). X = First day free of oedema (13 patients, as Nos. 2 and 5 had no oedema).

persisted until the 24th day. A scatter diagram relating the time from onset of illness to treatment with the time from onset to first day oedema-free shows a steady correlation (see Chart). Two patients are omitted, as they had no oedema on admission to hospital.

Drying of Rash.—A similar relationship was seen between drying of the rash and inception of treatment, and this has been plotted and incorporated in the Chart. An interesting observation was that the rashes were more haemorrhagic than in the control series and pustulation in the early treated cases was minimal.

Appearance of Fresh Lesions.—In the control group fresh vesicular lesions appeared in all the patients admitted within 72 hours of the rash, and continued to appear up to the eighth day of the eruption. In the treated group 10 patients were admitted within 72 to 96 hours of the rash, and no fresh vesicles were seen in any of these patients 24 hours after prednisone had been started.

Degree of Scarring.—It is accepted that in all patients with ophthalmic herpes of any severity scarring is to be expected, and in most cases this will be deep and its extent will be in accordance with the extent of the rash. To us one of the surprising effects of the corticosteroid therapy was the remarkable lack of scarring in those patients treated within four days of onset of rash. There were 10 of these patients, and in seven of them it is now difficult to find scars without close examination, and on superficial inspection the site of the lesion cannot be identified. In the control series nine patients were admitted within four days of the rash, and seven of these are scarred sufficiently to be noticed.

Ophthalmic Complications.—All patients in both groups showed conjunctivitis, and in the treated series six patients had keratitis with some evidence of iridocyclitis. In one of these it was severe enough to require tarsorrhaphy and one patient had a panophthalmitis and lost all vision. This patient was not admitted until the 16th day of her illness,

and the tarsorrhaphy patient was first treated on the seventh day, the rash appearing on the fourth day. In the control group eight patients had keratitis and iridocyclitis; two required tarsorrhaphy and two had corneal scarring sufficient to impair vision severely. No patient became completely blind in the affected eye.

Incidence of Pain and Post-herpetic Neuralgia

Herpetic and pre-herpetic pain is universal in this complaint except in the mildest of cases, and post-herpetic pain is said to occur in 1 patient in 10 (Ritchie Russell, Espir, and Morganstern, 1957). The pain of post-herpetic neuralgia is usually a continuation of severe herpetic pain, often at its maximum in the stage of vesiculation; and Tatlow (1952), in a series of 58 unselected cases, found that 7 out of 29 examined from 5 to 10 years after the illness had severe pain or painful paraesthesiae. Only one case had needed any surgical treatment for the pain, and the rather surprising impression obtained by the author from this series was that the incidence of post-herpetic neuralgia was very small, that it bore no relation to age, and that the patient who continued to have pain after herpes zoster was of the introspective, worrying type. Ritchie Russell *et al.* (1957), however, think that this complication cannot be correlated with the severity of the illness but is much more likely in the elderly—the patients actually being over the age of 60 and often over 70. They also make the point mentioned by Taplow that post-herpetic neuralgia is commoner in those who sit at home doing little but nursing and protecting the sensitive area, and suggest that prevalence in the elderly is correlated more with their inactivity than with their age. Peet (1929) considered post-herpetic neuralgia "exceptional" in his experience, and in a series of trigeminal neuralgia cases found only 3 out of 400 due to this. Similarly, Cushing (1920) and Frazier (1921) considered that this condition produced only 1% of all cases of trigeminal pain.

In our treated series 3 patients out of the 15 still complain of pain. One has mild pricking sensations, one has occasional annoying jabs, and one persistent pain causing some disability eight months after the attack.

In the control series only 10 out of the 15 patients can be traced owing to deaths, and two of these find their pain still annoying six years later, but "think they have got used to it." Taking the two groups together our impression is that a combination of old age, severity of attack, and severity of secondary infection is likely to result in prolongation of herpetic pain into post-herpetic neuralgia. We found little evidence of psychological disorder as a cause, but agree that some elderly patients complain more about pain than others.

Discussion

If it is agreed that any comparison can be made between two such small groups, then it appears that the use of prednisone has only in some respects modified the patient's response to ophthalmic zoster for the better. Disappearance of oedema is quicker, drying of the rash occurs earlier, and scarring is reduced to a minimum. No fresh vesicles appeared once treatment was established, and pain during the course of the illness was less. Treatment seemed to have no effect on the incidence of post-herpetic neuralgia, but, as the incidence of this is low in any case, a much larger series is necessary to draw any conclusions. Moreover, treatment with prednisone seemed to have no effect on the incidence of ophthalmic complications, but there seems to be plenty of evidence that it has a beneficial effect on these when they occur.

Duke-Elder (1951) treated four cases of zoster iridocyclitis with cortisone and found improvement, and Olson *et al.* (1951) had a similar experience with corticotrophin. Poulin (1952) described four cases of ophthalmic herpes treated by corticotrophin and suggested that the ocular complications could be controlled thereby. Doenges (1954), in a series of 15 cases of herpes zoster, treated 11 with cortisone alone, 3 with chloramphenicol, and 1 with no specific drug. His criteria were drying of the rash, occurrence of fresh vesicles, and the relief of pain. Only one of these cases was ophthalmic, and it did well, but the author concluded that the cortisone had not changed the course of the illness. Gelfand (1954) treated five cases, of which two were ophthalmic, with good results, and Marshall (1955) had one excellent result in a severe iridocyclitis and keratitis with local hydrocortisone. Appelmann (1955) treated four cases of ophthalmic zoster with corticotrophin and had good results; and finally an encouraging report comes from Scheie and Alper (1955) of 11 cases of ophthalmic zoster with iridocyclitis treated with cortisone or corticotrophin in which relief of pain was prompt in all, occurring within 24 to 36 hours of treatment. In all these cases the ocular lesions improved, and in none was there any permanent loss of vision. From the literature it appears established that the ocular complications responded to local or systemic corticosteroid drugs, but there is nothing to suggest that these drugs influence the incidence of these complications.

From the present series it is evident that the earlier prednisone is begun the better the result, and it is probably useless to use it after the first 10 days, except locally for the eye. The necessity for continuing treatment after early improvement is shown in Case 6.

Case 6.—A woman aged 68 was admitted to hospital with the story that 11 days before admission she had been talking over the fence to her next-door neighbour, who developed shingles on the following day. Five days later the patient experienced pain in the left forehead, and two days after that a rash appeared. Five days after the pain began she was admitted to hospital with her left eye closed by oedema and with a severe vesicular rash. Prednisone, 10 mg. six-hourly, was given for three days, and on the second day the eye was open, the rash was haemorrhagic, and she was free from pain. Prednisone was reduced gradually to 10 mg. daily by the ninth day of her stay in hospital, but she then complained of severe pain and her forehead looked swollen

and red around the haemorrhagic rash. Full dosage of prednisone was resumed, and was continued for three days; a more gradual withdrawal then followed. The pain disappeared two days after recommencing prednisone, and she was discharged after 30 days. Ten months later she was well.

It would be wrong to suggest that all our cases were severe ones, as zoster differs in its virulence of attack and people differ in their response to infection, but prednisone seemed to abort an attack of zoster in Case 13.

Case 13.—A woman aged 76 was admitted to hospital for investigation of anaemia. On her left-hand side in the next bed was a woman with a right ophthalmic zoster; a week later the patient complained of pain in the left side of her head, and next day developed a left ophthalmic herpes which was immediately treated with prednisone. The vesicles coalesced quickly into a haemorrhagic crusting and pain was minimal by the third day. No fresh vesicles appeared, and although a little discharge was seen from the eye no conjunctivitis occurred. The rash was dry by the fifth day, when all oedema had disappeared; the crusts had completely separated on the eighth day of her illness. She was then entirely free from pain, showed hardly any scarring of the forehead at all, and had no sensory changes. She was re-examined 19 weeks later and had no complaints. There were four small scars of her illness present on the left side of her forehead and no anaesthesia between them. Her corneal response was normal.

The course of this patient's illness differed from the usual pattern in that all stages were telescoped into a much shorter time than usual.

Dangers of Treatment

It is well known that the corticosteroid drugs are not without danger in their use, particularly in elderly patients.

However, by the use of prednisone rather than cortisone, and by restricting the course of the treatment to a fortnight and keeping the dosage relatively low, no complications were encountered. We consider the use of antibiotics essential when using prednisone in these cases, as without them septicaemia might well be a complication of the secondary skin infection. One possible danger is that the treatment might produce a lowering of naturally produced cortisone for a while after the patient's discharge from hospital, so that during this time any further trouble in the damaged eye might produce a severe panophthalmitis. However, this has not occurred in any of our cases, and presumably this danger is largely theoretical.

Summary

Fifteen consecutive patients with ophthalmic zoster have been treated with prednisone and antibiotics. The results of treatment are compared with a similar group treated with prednisone in 1951. No conclusions regarding the efficacy of this treatment can be drawn owing to the small numbers treated, but in the prednisone group oedema was less, drying of the rash quicker, and scarring considerably reduced. Fresh vesicles did not appear after 24 hours of treatment, and herpetic pain was much less.

No effect was found on the incidence of ophthalmic complications or of post-herpetic neuralgia.

MASSIVE HAEMATEMESIS IN A CHILD TREATED WITH PREDNISOLONE

BY

JOHN LORBER, M.D., M.R.C.P.

Reader in Child Health, University of Sheffield; Honorary Consulting Physician, Ash House Hospital School for Rheumatic Fever, Sheffield

It is well known that gastro-duodenal complications not infrequently arise during treatment with corticosteroid compounds. Several cases of perforation and haematemesis have been reported in adults, and the incidence of such complications in patients treated for rheumatoid arthritis is said to be as high as 7.5% (Sandweiss, 1954; Bollet *et al.*, 1955). The purpose of this communication is to record the occurrence of a series of massive haematemeses in a child while receiving prednisolone for the treatment of rheumatic fever.

Case History

The patient, who was born in June, 1942, had her first attack of rheumatic fever in 1953 and was treated at home for five months. She then attended school irregularly for two years, during which period she was not really well and complained of shortness of breath. In October, 1955, pain and swelling of her ankles developed, followed by involvement of several other joints. She was put to bed in March, 1956. At the beginning of April she was seen at another hospital because of dyspnoea and inability to lie flat. Tachycardia and an enlarged heart with loud apical systolic and diastolic murmurs were present, but there was no involvement of the joints at the time. She had pyorrhoea, her sedimentation rate was 40 mm. in one hour (Westergren), and a throat swab grew β -haemolytic streptococci. A radiograph of the chest showed enlargement of the heart. After oral penicillin for three weeks her throat swab was clear of streptococci.

On May 19 she was admitted to the Rheumatic Fever Hospital School at Sheffield with a view to prolonged convalescent care. On admission she was a well-nourished, well-developed girl of nearly 14 years of age. She had a tachycardia with a sleeping pulse rate of 86-96 a minute. Her heart was clinically and radiologically enlarged, and loud systolic and diastolic mitral murmurs were heard. At this stage there was no evidence of an aortic valvular lesion. She had several badly carious teeth and her E.S.R. was 49 mm. in one hour.

Four carious teeth were removed under general anaesthesia and intramuscular penicillin cover, and thereafter 125 mg. of phenoxymethyl penicillin was given twice daily to prevent streptococcal infection. During the next 19 weeks there was evidence of a smouldering rheumatic activity and she was kept in bed. Her E.S.R. was persistently high, varying from 28 to 52 mm. in one hour. During this period a soft aortic diastolic murmur gradually developed, her apical systolic murmur became louder, and there was a systolic thrill.

In view of these developments treatment was started on October 5 with prednisolone and salicylates. Her E.S.R. was 38 mm. Treatment consisted of prednisolone by mouth, 20 mg. three times daily for three days, followed by 10 mg. four times daily for 11 days, three times daily for 14 days, and twice daily for a further 35 days, together with "disprin," 10 gr. (0.65 g.) three times daily, and potassium chloride, 2 g. once daily. Her condition was very good during this period; the apical systolic murmur became less loud, the thrill was no longer palpable, and the apical diastolic murmur became inaudible. Her E.S.R. returned to

normal on the 14th day of treatment, but it rose again three weeks later without any apparent cause.

Nine weeks after the beginning of treatment the E.S.R. rose to 31 mm. and she complained of mild abdominal pain. For fear of masking an acute inflammatory condition—for example, appendicitis—prednisolone treatment was discontinued. No complicating illnesses were found while she was off treatment, and as the pain disappeared but the E.S.R. remained high prednisolone was started again a week later in a dose of 40 mg. daily. Mild abdominal pain returned, but she had no abdominal tenderness or guarding and no fever. Her urine was normal. This slight discomfort continued and her E.S.R. remained high (22-30 mm.) without an apparent cause.

On January 18, 1957, an unexpected major haematemesis occurred. She vomited about 1 pint (570 ml.) of bright red blood. As the haematemesis might have been due to either the prednisolone or the disprin, both these drugs were discontinued. Nevertheless a further major haematemesis occurred two days later, to be followed by seven major haematemeses in the next eight days. Several melaena stools were passed during this period. Almost continuous blood transfusions were given—a total of 17 pints (9.6 litres)—either as whole blood or in the form of packed cells (after the bleeding had been arrested). As the bleeding continued for so long, an emergency gastrectomy was contemplated, but as a last measure the procedure suggested by Brandon (1956) was adopted. The stomach was washed out with normal saline and 15 ml. of 1 in 1,000 dilution of adrenaline was left in it after the washout. The procedure was repeated one hour later, and 4 ml. of "stypven" was left in her stomach along with 5 ml. of adrenaline. Her general condition greatly improved and she had no further haematemesis. Her last melaena stool was passed two days later.

Since then progress has been uneventful so far as her gastric condition is concerned, but her E.S.R. was still 40 mm. in one hour on February 21. A barium-meal examination on March 18 showed no evidence of gastric or duodenal ulcer, and her haemoglobin on that day was 10.5 g. per 100 ml.

Discussion

Haematemesis in children is a rare complication even during prolonged treatment with cortisone or its derivatives. During the past few years we have given cortisone or its derivatives to 80 children with rheumatic fever in the Children's Hospital and Rheumatic Fever Hospital School, and to many others with such conditions as the nephrotic syndrome, adrenocortical hyperplasia, and leukaemia, but we have not encountered gastro-intestinal complications in any other child. In a series of 340 children treated for a variety of conditions Good *et al.* (1957) observed two children, aged 2 years, who developed gastro-intestinal bleeding on the 10th day of treatment for the nephrotic syndrome with metacortisone. Goldberg (1954) reported the occurrence of peptic ulcer in a boy of 6½ on cortisone treatment for the adreno-genital syndrome, and Busby *et al.* (1952) observed a bleeding gastric ulcer in a boy of 12 after he received treatment with corticotrophin and cortisone for rheumatic fever.

It therefore seems that, although these complications are rare in children, it might be of advantage to combine routine antacid treatment with cortisone or prednisolone therapy as suggested by Boland (1956).

I thank Dr. A. C. Blandy, who kindly referred this child for treatment.

Medical Memoranda

Thrombosis of Internal Carotid Artery after Soft-palate Injury

Thrombosis of the carotid vessels in the neck following external injury is well recognized. It may occur with penetrating injuries, and numerous examples of this condition were reported from both world wars (Makins, 1919; Caldwell and Hadden, 1948; Lawrence *et al.*, 1948). It may also occur, though less commonly, with non-penetrating injuries to the neck (Verneuil, 1872; Greco, 1935; Northcroft and Morgan, 1944; Schneider and Lemmen, 1952).

An even less common mechanism is damage to the internal carotid artery, as it lies close to the tonsillar bed, following a penetrating injury of the soft palate. This is particularly likely to happen to small children who fall while carrying pencils or other pointed objects around in their mouths. The first report of such a case was made by Caldwell (1936). His patient, a boy of 16, received a penetrating injury to his soft palate following a fall on to a hedge. After a few hours he became drowsy and dysphasic, and within 10 hours had developed a right hemiplegia. He gradually lapsed into coma and died six days later. At necropsy the left internal carotid artery contained a well-formed thrombus which extended from the cervical portion of the artery into the cranial portion and on into the middle cerebral and Sylvian arteries. The left cerebral hemisphere was softer than the right, and on section a haemorrhagic infarct was found in its central portion.

No further reference was made to this condition until 1956, when Braudo reported three cases, all in children under 5, in which an injury to the soft palate or the faucial pillar was followed after an interval of a few hours to two days by contralateral hemiplegia and other signs of cerebral damage. The children all recovered, but were left with a slight physical disability. Although the diagnosis was not established by angiography, there can be little doubt that the mechanism of the cerebral damage was injury to the adjacent internal carotid artery.

A further case is reported here in which a relatively slight injury to the soft palate resulted in thrombosis of the internal carotid artery. The patient died 30 hours after receiving the injury. This is therefore the second recorded case of death following such an injury.

CASE REPORT

The patient, a previously healthy boy of 1 year 10 months, was brought to the casualty department of Harold Wood Hospital at 3.20 p.m. on May 24, 1956. His foster-mother stated that he had been running about with a blunt unsharpened pencil in his mouth at midday, when he fell and the pencil injured the back of his mouth. He was never unconscious, but he vomited twice, the vomitus containing streaks of fresh blood.

On examination he was fully conscious and showed no signs of shock. There was a small transverse laceration, about 1 cm. in length, of the posterior part of the soft palate on the left.

He was taken to the theatre at 4.45 p.m., for repair of the laceration. Induction of anaesthesia took a considerable time because he vomited, but there was no cyanosis either during the induction or during the operation. The wound in the soft palate was found to involve the mucosa and the muscle, but it had not penetrated the mucosa on the superior surface of the palate. There was no undue haemorrhage from the wound. Repair was carried out with interrupted catgut sutures.

The child took some time to come round from the anaesthetic and had a good deal of inspiratory stridor, which subsided by midnight. At 8.30 next morning he woke up and appeared to be fairly normal. He accepted a drink, but cried a good deal and seemed to be rather restless. He went to sleep after about 30 minutes. At 10.30 a.m. it was found that he could not be roused. He responded to painful stimuli

by restless purposeless movements of his limbs. The left pupil was widely dilated and did not react to light. There was increased tone in the right arm and leg, and the tendon reflexes on that side were exaggerated.

I saw him at 2 p.m. on May 25, 26 hours after his injury. He was unconscious, but responded to painful stimuli by thrashing purposeless movements of his limbs, the right limbs moving less well than the left. He made no sound. There was no neck stiffness and the fundi were normal. The left pupil was widely dilated and showed no reaction to light. The right pupil was small and reacted sluggishly to light. There was no facial asymmetry. The right limbs were held in a position of extension with a marked continuous increase in tone. The tone of the left limbs was normal. The tendon reflexes were all brisk, those on the right side of the body being brisker than those on the left. Both plantar responses were up-going. Painful stimuli were resented more on the left side of the body than on the right. The child showed some inspiratory stridor, but there was no cyanosis. Normal carotid pulsation could be felt on both sides of the neck.

A presumptive diagnosis of thrombosis of the left internal carotid artery following a penetrating injury of the soft palate was made. The child was transferred to Oldchurch Hospital for angiography. On arrival at 3.15 p.m. his condition had deteriorated. He was in deep coma and showed practically no response to painful stimuli. The right pupil was now moderately dilated. The left limbs showed a tendency to be held in rigid extension.

A left carotid angiogram was done within half an hour of admission. This showed complete occlusion of the left internal carotid artery at a point 2 cm. above the bifurcation of the left common carotid artery. The left external carotid artery was patent.

The child's condition continued to deteriorate, and at 5 p.m. spontaneous respiration ceased. Artificial respiration was instituted, but he failed to respond to all resuscitative measures, including intravenous sucrose, and died at 6 p.m.

Post-mortem Examination.—The thrombosis of the internal carotid artery extended upwards from the site of the injury into the whole of the intracranial course of the artery. The middle cerebral, anterior cerebral, and posterior communicating arteries were completely occluded by thrombus. The whole brain was swollen, particularly the left cerebral hemisphere. There was extensive softening of the central part of the left cerebral hemisphere, with involvement of the basal ganglia.

COMMENT

The immediate cause of death in this case was an acute rise of intracranial pressure associated with ischaemic damage to the left cerebral hemisphere. The severity of this damage was related to the wide propagation of the thrombus from the site of injury in the neck to the left half of the circle of Willis and its main branches.

Propagation of thrombus into the cerebral vessels following injury to the carotid vessels in the neck has been frequently observed. Experience in both world wars (Makins, 1919; Caldwell and Hadden, 1948; Lawrence *et al.*, 1948) shows that it is often, though not necessarily, found in fatal gunshot wounds of the neck involving the carotid vessels. It was present in the cases of thrombosis of the carotid vessels due to non-penetrating injuries to the neck described by Verneuil (1872), Greco (1935), Northcroft and Morgan (1944), and Schneider and Lemmen (1952). It was also a feature of the case described by Caldwell (1936), in which thrombosis of the internal carotid artery followed an injury of the soft palate. According to Schorstein (1940) it is not found in subjects who have died following ligation of the carotid vessels in the neck for bleeding intracranial aneurysms.

It must therefore be regarded as a particular and dangerous hazard of traumatic lesions of the carotid vessels in the neck whatever the precise mechanism of injury. It may well be that the favourable outcome of Braudo's three cases was due to the absence of this complication.

It would appear important to recognize the possible dangers associated with the type of injury to the soft palate

described above. Patients who have sustained such an injury should be kept under observation for a few days. At the first sign of any neurological involvement, anticoagulant treatment should be instituted with a view to limiting the spread of the thrombus.

BERNARD FAIRBURN, M.B., F.R.C.S., D.A.,
Consultant Neurosurgeon, Oldchurch Hospital, Romford, Essex.

General Anaesthesia as an Aid to Therapeutic Hypothermia

One of the possible complications of a severe head injury is diffuse cerebral contusion and oedema. This swelling of the intracranial contents produces raised tension and consequent interference with the blood supply of the cerebral tissues, and also leads to compression of the reticular system and other mid-brain structures, with resulting unconsciousness and decerebrate rigidity.

If the patient can be kept alive until cerebral oedema has settled, the prognosis is often excellent, and to this end hypothermia has proved its usefulness (Sedzimir *et al.*, 1955; Rowbotham *et al.*, 1957). At a lower body temperature not only is the volume of the intracranial contents reduced (Rosomoff and Gilbert, 1955) but the cerebral oxygen requirements are lowered as well (Bering *et al.*, 1956). Most patients of this kind can be cooled satisfactorily by surface application of ice-bags, together with chlorpromazine and levorphanol ("dromoran") to control shivering. There are, however, occasional cases in which hypothermia may be life-saving, but which cannot safely be kept cool in this way on account of persistent shivering and violent objection to the presence of ice-bags. It may, in fact, be impossible to bring the temperature down at all. Tachyphylaxis is likely to develop with chlorpromazine, and there is a limit to the safe dose of levorphanol even when levallorphan is used to counteract respiratory depression.

It was shown by Dundee *et al.* (1953) that general anaesthesia alone is no less effective than the "lytic cocktail" in producing hypothermia, and light nitrous oxide anaesthesia was soon being used as an aid to the prevention of shivering (Dundee *et al.*, 1954). Its effectiveness for therapeutic purposes is well illustrated by the following case.

CASE REPORT

The patient, a boy of 12, was transferred to the Liverpool Neurosurgical Unit the day after sustaining a head injury on the road outside his home. He had not been unconscious at the time and had not presented any localizing signs, but he had been bleeding from the right ear and had an obvious fracture of the clavicle. During the day following the injury he had become more drowsy, both plantar responses had become extensor, and he had become spastic in all limbs; the temperature had risen to 101° F. (38.3° C.) and hyperventilation had started.

As soon as he arrived in the neurosurgical unit a right subtemporal decompression was carried out. There were several large fragments of fractured bone, a large subgaleal haematoma, and a small extradural haematoma. The dura was opened widely and contused brain bulged through. While he was still receiving nitrous oxide his temperature was brought down to 90° F. (32.2° C.) with ice-bags and chlorpromazine; but when he was back in bed, without anaesthesia, he shivered violently in spite of repeated chlorpromazine and levorphanol. Two days later he was still in light coma and his chest contained copious secretion. A tracheotomy was performed, preceded by bronchoscopy and suction, and ice was applied again. However, by the same

evening his condition had deteriorated greatly; he was in decerebrate rigidity, the right pupil was widely dilated, and his temperature was 100° F. (37.8° C.) in spite of attempts to induce hypothermia.

The prognosis seemed hopeless, but since it had been fairly easy to produce cooling during the previous anaesthesia it was decided to make a second attempt. As the tracheotomy opening would not admit a tube large enough for a long anaesthesia he was intubated orally with an uncuffed armoured endotracheal tube. Through this, connected to a T-piece arrangement, he was kept asleep for 24 hours with nitrous oxide and oxygen and occasional supplements of ether. With the aid of ice-bags the temperature was brought from 101.4° F. (38.6° C.) to 93° F. (33.9° C.) during the first hour of the anaesthesia, without any shivering; the hypothermia was easily maintained and a steady state was established at a level of 87.5–91° F. (30.8–32.8° C.) for 16 hours.

All spasticity disappeared, and although the patient still responded to painful stimuli the response was no longer extensor but was a purposeful withdrawal. The general condition gave rise to no concern at any time, the systolic blood pressure varied between 90 and 125 mm. Hg, the chest remained dry, with good air entry to all zones, and there was no significant change in the clotting-time or the white-cell count. Spontaneous respiration was permitted throughout.

By the end of the 24 hours the temperature had been allowed to rise to 96° F. (35.6° C.), and as soon as the nitrous oxide was discontinued shivering recommenced. All the previous difficulty in maintaining a steady level of hypothermia was again encountered, and in spite of the tracheotomy being re-established secretion accumulated in the chest within 11 hours. It was a further 12 days before the hypothermia was permanently discontinued and the tracheotomy allowed to close. One month after the injury the patient was moving all limbs, obeying directions, and constructing simple sentences; after a further month he went home. He had a moderate left facial weakness which was improving, and slight weakness of the left arm; his right pupil was still slightly larger than the left. Apart from this he was a normal boy, gaining weight and walking well, and he talked and answered questions extremely intelligently.

COMMENT

The consequences of allowing secretion to accumulate in the chest may have been sufficient to increase the degree of cerebral oedema to a critical level in this borderline case. Without anaesthesia at this stage it would have been impossible to establish an effective hypothermia, and without this the child would have died. There are possible dangers from prolonged inhalation either of nitrous oxide (Lassen *et al.*, 1956) or of 100% oxygen (Comroe and Dripps, 1950), although the effect of hypothermia in this connexion is probably unknown. Perhaps for anaesthesia extending over several days the best, and cheapest, alternative would be a suitable mixture of compressed air and oxygen with minimal ether.

A bronchoscopy was carried out two days after the anaesthesia in this case, and there was no evidence of damage to the larynx or trachea after 24 hours' intubation.

I thank Mr. R. H. Hannah for permission to publish the report of his case, Dr. Doreen Jacobs, who was responsible for most of its management, and Dr. C. G. Lloyd for his assistance.

Reviews

THE ART OF PSYCHOTHERAPY

The Doctor, His Patient, and the Illness. By Michael Balint, M.D. (Pp. 355+x; 40s.) London: Pitman Medical Publishing Co. Ltd. 1957.

Dr. Balint suggests that at least 25% of the patients seen by the general practitioner need psychiatric help. At present he tells us that to obtain psychotherapy for the adult under the National Health Service is nearly as difficult as winning a football pool. The real need can only be met either by a vast increase in the psychiatric services or by teaching the general practitioner how to deal with such problems himself. The book is a stimulating demonstration of the latter course.

It is possible to learn the art of psychotherapy individually by methods of trial and error. It is a hard road and few are bold enough to attempt it. Not everyone has the aptitude for this type of work, but Dr. Balint has shown that it is possible to choose suitable candidates. He has demonstrated that the art can be acquired comparatively easily and safely, and without disruption of everyday practice, by his group method. The seminar takes up two or three hours a week for a year or more—a small price to pay for the acquisition of such a useful skill. Not only does the doctor learn how to tackle the psychiatric problems of his practice, but he learns his own "blind spots" and he is himself likely to undergo "a limited though considerable change in personality." The seminar was liberal in criticism and advice to members describing their cases, but in the long run the therapist himself had to make decisions and deal with his patient accordingly. Remarkable recoveries took place in many patients, who were helped to a much more healthy and mature outlook on life. It might be pointed out that all the psychiatric problems in general practice are not so involved, and the inclusion of a few simpler case records would encourage readers who are interested but reluctant to take the plunge.

The author's style could be improved. It is irritating to the reader to be told no fewer than 12 times in the early chapters, "We will come back to this problem later." All through there are too many cross-references for easy reading. The problem of time for such treatment is a very real one and deserves more attention. These are, however, small criticisms in a book which is full of wisdom. It is a bold attempt at the enrichment of general practice by a consultant who has the interest of both the patient and the general practitioner before him. It is to be hoped that this book will be widely read by general practitioners and psychiatrists, and that the methods initiated at the Tavistock Clinic will be tried in other centres up and down the country, so that doctors outside the Metropolis may have the opportunity to learn the art of psychotherapy.

Clinical Orthopaedics—No. 8. Editor-in-Chief: Anthony F. DePalma. With the assistance of the Associate Editors, the Board of Advisory Editors, and the Board of Corresponding Editors. (Pp. 337+xi; illustrated. Single copies 60s.; subscription price 48s.) Philadelphia and Montreal: J. B. Lippincott Company. London: Pitman Medical Publishing Co. Ltd. 1956.

Charles Goff (Yale), who writes a note on Louis Bauer, a pioneer of American orthopaedics and professor of surgery at St. Louis in 1869, points out that orthopaedic surgery benefits as much as any branch of medicine from research into disorders of a hereditary nature, as endoskeletal systems are more easy to study. This is in an introduction to a number of original monographs on congenital anomalies and mutation rates with clinical and genetic considerations. It is thought that study should continue on the lines that hereditary, embryonic, and intrauterine factors may be concerned in malformations and diseases. There is no com-

mentary linking up the essays, which include the usual subjects of congenital dislocation of the hip, anomalies of hand and foot, and abnormalities of neural arch and lumbar cord.

Winnett Orr reviews the work on heredity as a factor in malignancy and reminds us that there is a "science of the bedside" as well as a "science of the laboratory." In the section of general orthopaedics the comprehensive chapter on haemophilic arthropathy by DePalma and Cotler attracts attention. An anatomical study of the knee by Giorgi and a practical chapter on neurogenic arthritis and arthrodesis of the knee by Wiseman will be read with interest. The motorist comes in for his share of attention in Section III. The crash-impact engineering is studied from several aspects little known to the medical man. A subsequent volume will deal with the psychosomatic mechanical factors in accident prevention. The editor points out that the study of causation and prevention of accidents necessitates consideration of the interactions between host (rider), agent (vehicle), and environment (highway). In this section of the book there is much interesting matter in the engineering problems of the host-agent relation. The volume is illustrated with reproductions from excellent drawings and photographs.

ST. J. D. BUXTON.

VENOMS

Venoms. Papers presented at the 1st international conference on venoms, December, 1954. Edited by Eleanor E. Buckley and Nandor Porjes. (Pp. 467+xii; illustrated. 86s.) Washington: American Association for the Advancement of Science. London: Bailey Bros. and Swinfen Ltd. 1956.

The varied scope of the sixty-one papers presented in this volume reflects the growing interest in a subject concerning which "many intricate problems remain to be solved." The first three papers are introductory and cover the history of the subject as a whole, the nature of the specific problems involved in investigations of snake venom, and a brief but valuable résumé of the toxic marine organisms. Next come accounts of the laboratory examination of venoms of different kinds of fish, toads, insects, spiders, and scorpions. Treatment and the clinical signs and symptoms are dealt with in interesting detail. Of particular interest is an account of the investigation of Brazilian scorpion venom using the electrophoretic technique and a paper evaluating current therapy for sting-ray injury. The method of preparing anti-scorpion serum at the Pasteur Institute, Algiers, is described and stress laid on the good results attendant on its use in North Africa. Nothing is said of the method of distributing the serum in an area notorious for its poor communications, nor is there any reference in this or other papers on scorpion sting to an empirical remedy, emetine hydrochloride, which has found favour recently in Nigeria.

Accounts of the analysis of snake venoms by various techniques and of the treatment of snake bite occupy some two-thirds of the volume, in a series of papers too specific for separate reference in a review. There is general unanimity on the need for care in the use of antivenins and of the need to avoid producing, by treatment, a trauma more serious than that caused by the actual bite. The papers are well documented and the index tested at random was found to be satisfactory. This is a publication that can be recommended with confidence to both research workers and clinicians, and a place should be found for it in medical school libraries.

C. A. BOZMAN.

INSTINCT IN MAN

Instinct in Man in the Light of Recent Work in Comparative Psychology. By Ronald Fletcher, B.A., Ph.D. (Pp. 348. 40s.) London: George Allen and Unwin Ltd. 1957.

The problem of instinct is such an important one in psychology and psychiatry that a good review of the evidence would be most welcome. The present book, alas, does little to fill the gap. It is a Ph.D. thesis with all the traditional faults of such a thesis when made into a book. The emphasis is largely on the examination of topics which have

little meaning to modern experimentalists, and semantic solutions take precedence over detailed factual reorganizations. It needs only a look at the very short bibliography, much of which is devoted to Freud's writings, to see how little in touch the author is with modern work in psychology. Lloyd Morgan is there, but Hebb is not; McDougall is there, but not Hull; Hobhouse, but not Beach. The 1910 *Symposium on Instinct and Intelligence* is quoted, but not the *Nebraska Symposium on Motivation*. It no doubt makes it easier to write a book like this if most of the facts are omitted, but it does not help the reader to gain an appreciation of current issues. To those who wish to have a convenient source book on the state of the field as it was 30 years ago, with particular emphasis on psycho-analytic speculations, this book may be useful. It is difficult to see that it has any other value.

H. J. EYSENCK.

THYROID HORMONES

Ciba Foundation Colloquia on Endocrinology. Volume 10—Regulation and Mode of Action of Thyroid Hormones. Edited for the Ciba Foundation by G. E. W. Wolstenholme, O.B.E., M.A., M.B., B.Ch., and Elaine C. P. Millar, A.H.-W.C. A.R.I.C. (Pp. 311+xii; illustrated. 48s.) London: J. and A. Churchill Ltd. 1957.

This book is a record of a Ciba symposium held in 1956 under the distinguished chairmanship of Mrs. Pitt-Rivers. In few of the subjects discussed was any certainty achieved, and in not many was there unanimity of opinion. Sir Charles Harington in his final summing-up said: "The complexity of the situation grows with the new facts that are revealed; even so far as the nature of the thyroid hormone itself is concerned we are forced into the position that we must think of not one hormone, but of a family of hormones, and a family that grows with alarming speed. When we think of the regulation of the thyroid hormone we find that the simple feed-back mechanism of the mutual thyroid-anterior pituitary control is totally inadequate to account for the regulation process as it must exist in the intact body." The clinician interested in the function of the thyroid will find here no solutions to his problems, but he will, if he is industrious, discover many experimental facts and some speculative notions to correlate with his own observations. The reader's labour would have been somewhat diminished if each contributor had been asked to summarize succinctly his conclusions. One feature of thyroid function to which increasing attention is being paid in the laboratory, as judged by these collected papers, is the nature of the action of the thyroid hormones in the peripheral tissues; but the synthesis of the hormones and the regulation of their production are also fully discussed by many contributors.

D. V. HUBBLE.

PAEDIATRIC SURGERY

Lehrbuch der Kinderchirurgie. By M. Grob. (Pp. 755; illustrated. D.M. 157.) Stuttgart: Georg Thieme Verlag. 1957.

This is the third textbook of paediatric surgery published since the war. After an American book written by Gross and a French one by Duhamel, we now have one from Switzerland written in German. These publications reflect the growing interest in the surgery of childhood. This new book is a volume of some size and in many ways superior to the other two publications; it deals with the whole field of surgery of childhood and covers a wide range of subjects. Apart from abdominal and genito-urinary surgery, large chapters on chest and especially cardiac surgery, plastic surgery, neurosurgery, and orthopaedic surgery are included.

Dr. Grob is obviously a general paediatric surgeon in the truest sense of the word. The fact that in every one of the so-called specialties which he covers he has made original and valuable contributions gives this volume its special interest. During the war years Switzerland was practically cut off from the Western world, and in such a small country this must have produced a certain "insularity" in medical outlook. Nevertheless Dr. Grob shows that he is well

acquainted with current practice and developments in paediatric surgical practice in Anglo-Saxon countries, though he does not mention some well-established procedures—for instance, the Denis Browne operation for hypospadias. These are, however, small faults in an outstanding book which reflects the high standing of the Zurich school of paediatrics and paediatric surgery. The description of the various subjects is masterly, and the treatment is always based on common sense and personal experience. The operative mortality of some of the more severe conditions is perhaps not quite as low as in the Anglo-Saxon countries. This may be due to the relatively slow advances in anaesthesia in Switzerland; the short section on anaesthesia is perhaps the weakest part of the book.

The production is most lavish, which may account for the high price. There is a wealth of excellent illustrations, both drawings and photographs, the large number of colour photographs being of a particularly high standard.

P. P. RICKHAM.

A SURGICAL PIONEER

Macewen of Glasgow: A Recollection of the Chief. By Charles Duguid, M.A., M.B., Ch.B., F.R.F.P.S.(Glas.), F.R.A.C.S. (Pp. 51. 7s. 6d.) Edinburgh and London: Oliver and Boyd. 1957.

On one occasion when his house-surgeon asked Sir William Macewen why he did not write a manual on surgery he replied: "Well, you see, I am not a good collaborator. I should have to write the book myself, and before it was finished the first part would be out of date." Charles Duguid was the house-surgeon who elicited that characteristic reply, which at least proved that Macewen knew one of his own failings. But what an epoch would have been marked if such a textbook had been written, for to all those who have read and studied his writings Macewen was the outstanding surgeon of his generation. These recollections, though very brief, are interesting, but for the most part confirm the known facts about the personality and work of one of the great pioneers of modern surgery.

ZACHARY COPE.

HISTORY OF HYPERTENSION

Classics in Arterial Hypertension. By Arthur Ruskin, M.D., F.A.C.P. (Pp. 358+xxv; illustrated. 72s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1956.

The history of a disease that is the subject of so much research at the present day is certainly fascinating to follow. The book is divided into two parts. First the methods: here we find the descriptions of the early ways in which attempts were made to obtain some figures by which to express the pressures in the arteries. It is curious to note that nearly a century elapsed between the rather crude experiments of Stephen Hales and the mechanical ingenuity of Poiseuille; and three-quarters of that time from him to Korotkoff. How many more years will elapse before the cause or causes of these abnormal figures will be found? The second part deals with the significance of the findings, ending with quotations from the work of Goldblatt. Readers will find it very satisfactory to peruse the work of Bright and Potain. Some of these excerpts appear in other excellent works, such as those of Major, and Willius and Dry; but Poiseuille and George Johnson and Mohamed have not received the attention they deserve from historians. The translations read very well. There are numerous examples of the original illustrations, and some portraits which might have been better done. The work would have been still more interesting if a little more had been included concerning the lives and personalities of the writers, and something of the other matters on which their many-sided genius often threw light.

These writings of the Old Masters of Medicine are worthy of study, and one hopes that other subjects will be dealt with in time, for there are several that seem to be appropriate. Here at any rate is a satisfactory and readable example.

LONDON

SATURDAY SEPTEMBER 28 1957

MÉNIÈRE'S DISEASE

Modern views on the clinical problems of vertigo are based on the well-known studies of the French physician Prosper Ménière.¹ In the disorder which he delineated so clearly a clinically characteristic combination of symptoms—in particular deafness, tinnitus, and vertigo—was shown to occur unaccompanied by any evidence of disease of the central nervous system. Its course was uniformly benign, and it has since come to bear his name—Ménière's disease. His observations led him to attribute the symptoms to a lesion of the labyrinth. This was confirmed, and the morbid anatomy of the lesion was first demonstrated in 1938 by Cairns and Hallpike,² whose histological examination of the temporal bones of two characteristic cases showed a widespread distension of the endolymph spaces of the inner ear. Although its exact mechanism is not yet understood, such distension may be the consequence of overproduction of endolymph, failure of its absorption, or of disordered local metabolism resulting in abnormal metabolic products, with resultant osmotic distortion. Damage to the vestibular end-organs causes paroxysms of vertigo followed by loss of labyrinthine function. At the same time deafness and tinnitus result from the damage to the cochlear end-organs. As stressed by Ménière himself, there is no definite association with any form of organic disease outside the eighth-nerve system.

Occurring in the middle period of life, this essentially benign condition begins with partial and at first unilateral deafness, accompanied by tinnitus. Upon

this background are superimposed the well-known dramatic paroxysms of vertigo with nausea, vomiting, and prostration. The differential diagnosis of Ménière's disease from other organic affections of the eighth-nerve system is often difficult, and has been the subject of a number of recent publications by Hallpike and his associates.³⁻⁵ Thus, vestibular neuronitis, a toxic affection of the vestibular neurones, may be distinguished from it by the absence of deafness; positional vertigo of the benign paroxysmal type by the demonstration of a particular type of nystagmus in a critical head position; and tumours of the eighth cranial nerve by the results of the loudness recruitment test. Other organic disorders which may simulate Ménière's disease are infective disorders of the labyrinth resulting from suppurative otitis media, disseminated sclerosis, or labyrinthine injury after head trauma. A full description of the clinical differentiation of these various disorders has been given by E. A. Carmichael, M. R. Dix, and C. S. Hallpike.⁵

The treatment of Ménière's disease, though based to some extent on the conception, suggested by its morbid anatomy, of an endolymphatic hydrops, is still largely symptomatic. Although the wide variety of treatments available would indicate that there is not yet any specific remedy, the great majority of patients can be rendered sufficiently free of their symptoms to carry on a normal life. In particular, encouragement and reassurance, based on accurate diagnosis that the condition is benign, will calm and comfort the patient. Sedation with barbiturates in varying dosage forms the essential of most treatments. M. Atkinson⁶ has suggested that Ménière's disease arises from increased capillary permeability, and divides his cases into two main types on the basis of reaction to the intradermal injection of histamine. Those considered sensitive to histamine (primary vasodilator type) were treated by slow desensitization, with subcutaneous injections of histamine; those patients insensitive to histamine (primary vasoconstrictor type) were given 50 mg. of nicotinic acid by intramuscular injection, or larger doses orally as a vasodilator. Other workers have failed to confirm the value of histamine as an aid to diagnosis, and found a good response to treatment with either histamine or nicotinic acid. S. H. Mygind and D. Dederding⁷ combat the hydrops of the inner ear by encouraging fluid loss from the body and limiting fluid intake. A. C. Furstenberg and colleagues⁸ maintain that the attacks of vertigo are due to retention of sodium whatever the state of body hydration, and successfully treated their cases by excluding sodium in all forms from their diet without restriction of fluid intake. Antihistamines have been given with varying results to treat a supposed underlying allergic basis for the condition.

The final state in this disease, not often reached, is total destruction of the end-organs of balance and hearing. Central compensation occurs after destruction of the vestibular end-organs, and the ability to balance is thus restored. Attempts to hasten the selective destruction of the vestibular end-organs while preserving cochlear function have been made. M. Arslan⁹ uses an ultrasonic generator to destroy the vestibular end-organs only. H. F. C. Schuknecht¹⁰ attempts the bilateral destruction of vestibular end-organs in cases of bilateral disease by means of the toxic action of streptomycin. The danger of this method is that the vestibulo-cerebellar connexions may be damaged, with resultant intractable ataxia. Control must be exercised by frequent caloric tests, and even so the method is not free from danger. Schuknecht has also attempted the unilateral selective destruction of the vestibular end-organs, with sparing of cochlear function, by intratympanic injection of streptomycin.

For the most part the surgical treatment of Ménière's disease has been aimed at destruction of the entire inner ear, and is thus usually reserved for cases in which little or no useful hearing remains. The most reliable method of accomplishing it is by labyrinthectomy. The method advocated by T. E. Cawthorne¹¹ is to open the lateral semicircular canal, and to remove the membranous canal. Absolute alcohol may be injected to destroy any residual nerve endings. Transtympanic labyrinthotomy is performed by Schuknecht.¹⁰ Complete deafness of the treated ear results, but unfortunately tinnitus is not affected. Intracranial section of the vestibular division of the auditory nerve has been advocated by W. E. Dandy.¹² Vertigo may thus be relieved, but the disease process is unaffected, and the hearing usually deteriorates subsequently. E. R. Garnett, Passe and J. S. Seymour¹³ suggested that, if vasoconstriction was a major factor in the production of Ménière's disease, relief could be expected by depriving the inner ear of its sympathetic nerve supply. Dix¹⁴ recently reviewed five cases operated upon by Passe, who had carried out upper dorsal sympathectomy up to five years previously. Vertigo was improved in all, but one relapsed. Attempts to produce similar results by injection of local anaesthetic into the stellate ganglion are not uniformly successful, nor free of danger. Recent surveys of the results of sympathectomy by other workers^{15 16} suggest that this method may be of value in alleviating the attacks of vertigo.

In short, the accurate diagnosis of Ménière's disease is not always easy, especially in atypical cases. In these a detailed neuro-otological examination is usually advisable, with a full battery of modern tests of cochlear and vestibular function including the loudness recruitment and caloric tests, supplemented on

occasions by a neurological examination. Investigations of this kind are best carried out in special hospital clinics. Once the diagnosis is established, treatment usually begins with a reassurance of the benign character of the disorder. Thereafter sedation with phenobarbitone is usually prescribed, with restriction of fluid intake to 2-3 pints daily and elimination of salt from the diet. Advice is given to ensure that these patients do not work or live in surroundings where sudden vertigo might endanger them. The majority of cases so treated remain free of vertigo for long periods to an extent greater than may be expected by the natural remissions of the disease. When vertigo persists but hearing is good, dorsal sympathectomy, as advocated by Passe, may have its place. When hearing is poor and vertigo troublesome, labyrinthine destruction is advised in unilateral disease. No certain means of controlling tinnitus is yet available. Heavy sedation may be necessary, and in extreme cases prefrontal leucotomy may have to be considered.

PSYCHIATRISTS DISCUSS SCHIZOPHRENIA

The second International Congress for Psychiatry, held at Zurich from September 1 to 7 under the presidency of Professor Manfred Bleuler, was attended by more than 2,000 psychiatrists. The discussions were almost exclusively devoted to the schizophrenias, the most sinister and mysterious group of mental disorders. They had been brilliantly described by Eugen Bleuler, of Zurich, who was born 100 years ago. Had he been present he would certainly have been impressed by the diverse approaches of present-day psychiatrists towards the elucidation of this problem. But he would no doubt have been deeply disappointed that psychiatry seems no nearer to an understanding of the aetiology and to a rational treatment of schizophrenia to-day than it appeared to be when he published his famous monograph. None of his basic assumptions about this group of mental disorders can be regarded as finally established. To many it is even doubtful whether it is a disease in the accepted clinical sense or an unsuccessful and devious kind of adaptation.

Among the trends which could be discerned at the congress, one of the most striking was the tendency to concentrate less on the disease schizophrenia and more on the schizophrenic as a person and fellow-being. Many Continental psychiatrists, notably L. Binswanger and E. Minkowski, have for some time concerned themselves with the study of the world in which the schizophrenic lives. Their orientation is based on phenomenology and existential analysis, and they are aiming at a medical anthropology derived from the philosophies of Husserl,

Heidegger, Bergson, and Sartre. Although this approach contributes to the understanding of the mental outlook of psychotic patients it appears to many psychiatrists unpromising clinically and sterile so far as the study of aetiology is concerned. It nevertheless has exerted a great fascination on a large section of German and French psychiatrists, who are using their languages with skill and imagination in their efforts to put into words their patients' peculiar experiences and moods. Much of their vocabulary has been borrowed from the writings of their favourite philosophers. Compared with the past enthusiasm of the psychiatric nosologists and the biologically orientated psycho-analysts, existential analysis appears rather detached and academical, although its advocates have found it helpful in psychotherapy. Whether this approach is a throw-back to a period when psychiatry was dominated by philosophy, or whether it will act as a healthy corrective against a purely physiological orientation, it is too early to say.

Psychiatric history was conjured up by the personal appearance at Zurich of some well-known figures. E. Stransky, now an octogenarian, claimed his place in the evolution of the concept of schizophrenia with his old vigour. C. G. Jung had a crowded auditorium when he was present at the reading of his paper by his grandson, a young assistant at the Burghölzli, where he himself had started his career. Jung restated his views on the emergence of archaic forms of association, which he regarded as signs of a profound disturbance of the biological foundations of the personality. He had been greatly impressed by two findings of experimental psychiatry—that is, the drug-produced psychoses, and the emergence of archetypal thought contents in hallucinations produced by electrical stimulation of the brain stem. He hoped that "cerebral localization of the archetypes" would some day become possible. As to the aetiology of schizophrenia, Jung expressed himself in a most interesting though somewhat obscure way. He thought that an excessive strength of affect seriously impaired the complexes by producing a toxin acting around them. As a result, the processes of association became archaic. He boldly disregarded the tenet that the psychic should not be described in physical terms. He was careful to point out that his thesis of a primarily psychogenic origin of schizophrenia with secondary toxic effects probably applied only to mild and latent cases such as he had been treating in his consulting practice. In his view specific methods were unimportant in the psychological treatment of schizophrenia, but knowledge of mythology and primitive psychology was essential.

Another reassertion of an orthodox position persistently held over several decades came from K. Kleist, who presented his neurological interpretation of schizophrenic symptoms with a conviction and

charm which would have warmed the heart of his teacher Wernicke. E. Kretschmer, still the most catholic of Continental psychiatrists, advocated a policy of discrimination and open-mindedness on therapy, which should be somatic or psychotherapeutic according to the requirements of the individual case.

Classification was discussed at length on conventional lines, and there was a noticeable tendency to narrow the Bleulerian concept of schizophrenia, which to many appeared too wide and clinically unwieldy. Many papers were read on the treatment of schizophrenia. The tranquillizing drugs were generally agreed to be of value in severe schizophrenic behaviour disorders. In many American hospitals they have ousted insulin-coma therapy and leucotomy. However, most experienced clinicians warned against abandoning established treatments prematurely. Leucotomy had proved strikingly successful in the treatment of the so-called pseudo-neurotic forms of schizophrenia, according to reports coming from the New York State hospitals. There were several contributions from psycho-analysts, who discussed the value of their method in the treatment of certain types of schizophrenic patients. It was also interesting to learn that systematic psychotherapy on psycho-analytical lines was given to many schizophrenics at the Burghölzli.

The importance of social factors in the aetiology and prognosis of schizophrenia was ably presented by the team of workers from Yale University, while recent studies into hereditary factors were reported from New York and from Scandinavian countries. There was a strong British contingent which took a very active part in almost all sections of the congress, especially those concerned with social, clinical, and experimental aspects. Careful observations made in the social treatment and rehabilitation of schizophrenics had demonstrated that these patients were more adaptable than was generally accepted. Many interesting biochemical studies were reported, but there was no unanimity on whether the changes found were primary or secondary. Experimental psychoses were discussed exhaustively, although their direct relevance to schizophrenia was not generally accepted. Reports on the production of transient schizophrenia-like states by injections of serum from schizophrenics aroused interest, and will no doubt encourage others to carry out similar experiments.

The most remarkable feature of the Zurich congress was the absence of dogmatism and the willingness of the participants to tolerate and even to take a genuine interest in other approaches and methods which not so long ago they would have thought to be incompatible with their own. In this new climate of co-operation and synthesis lies the hope of psychiatry.

INFLUENZA EPIDEMIC

The most unusual features so far of the influenza epidemic are the season at which it has come and the ages of the few patients reported to have died of it. The great infectivity of the Asian virus in a world population lacking antibodies against it no doubt accounts for its rapid spread here at a season when the incidence is normally low. The notable feature of the deaths that have been attributed to it is the relatively high proportions of schoolchildren and middle-aged adults. The very young and the very old seem not to be succumbing in the proportions that past experience would suggest as usual. The case fatality rate is evidently exceedingly low, at least at present, and reports of the disease from abroad do not suggest that a high rate is to be expected. In its progress across the country the disease has occasionally received such publicity as might be the envy of an invading army from Mars. But many doctors will agree with the general practitioners whose letters appear at p. 763 that, if exaggerated, this can do more harm than good.

Reports of the disease¹⁻⁵ have not disclosed any particularly unusual signs or symptoms. The first of these reports, from Malaya,¹ was written partly by a general practitioner, so that symptoms of milder cases not admitted to hospital receive due emphasis. The authors of the report stated that "recovery is usual by the fourth day," experience which the medical officer of Aden confirms.³ They mentioned thirst as being an early symptom, followed in 6-12 hours by sore throat. In contrast, a high incidence of sore throat was not noted in a report from Kuwait,² though it was described as characteristic—red, dry, and mat in another from the same area.³ The familiar aches and pains, malaise, and shivering that make the influenza victim a miserable object seem to be as common in this outbreak as in others. In Holland antibodies to the Asian strain have been found in people aged 80 to 90, suggesting a possible if somewhat remote virological relationship with an epidemic that spread from Asia in 1889-90.³

Of two deaths reported at Kuwait,⁵ middle-aged Indian men, one was considered to be due to secondary bronchopneumonia and the other to primary influenzal pneumonia with pleural effusion. Some cases of secondary bronchopneumonia in Great Britain are considered to be due to a staphylococcus, and the possibility is being investigated of an association between secondary bronchopneumonia and skin infection in the patient or members of his family. Treatment on the normal lines seems to be effectual, for few complications are reported. As to a preventive vaccine, not enough is likely to be available to stem the tide of infection, though selected groups of people, including doctors, are being or soon will be offered it. A vaccine can give only incomplete

protection, perhaps about 30-40% if the results of the Medical Research Council's studies of other influenza vaccines may be taken as a guide,⁶ though a protection of about 70% has been attained under the restricted conditions of the U.S. armed forces.⁷ At present there seems no reason to depart from the view expressed in these columns recently that, so long as the Asian influenza remains mild, vaccination of the general population is unnecessary and perhaps unwise.⁸ Indeed, immunization is still an experimental procedure.⁹

With each batch of vaccine being distributed by the Ministry of Health will go a pamphlet giving technical details, including information on possible reactions and contraindications. Tried out on civilian and military volunteers, the vaccine has not been found to cause serious reactions; some cases of sore arm have been noted, and slight malaise for 24 hours. About 3-4% of subjects have also experienced headache and slight pyrexia. Contraindications include a history of epilepsy, allergic diseases, and sensitivity to egg.

Since influenza is not a notifiable disease, the medical officer of health is specially dependent on the willing help of his medical colleagues in general practice and hospitals for the running of an efficient intelligence service during an epidemic. In accordance with previous practice,¹⁰ the medical officer of health usually asks certain general practitioners to act as "spotters" and keep him informed of the first signs of an outbreak, but he will welcome information from general practitioners not so designated. In addition, local officers of the Ministry of Pensions and National Insurance are informing medical officers of health when sickness benefit claims either increase by 30% over the figure for the previous week or are double the average weekly figure for the period April 4 to December 4, 1956. These measures should help to give some idea of how the disease spreads through the country, and they show that at present it is mainly in the northern half of England and South Wales. The incidence of cases cannot be known. The spread of infection has been very rapid in eastern countries, and, if it runs true to form here, may almost have subsided by the turn of the year. A second outbreak, caused by one of the older virus strains, might then appear in what we have come to regard as the true influenza season.

WASP STINGS

We have learnt a good deal in recent years about stings. Nettle stings owe their effects to the presence of histamine, acetylcholine, and hydroxytryptamine in them.¹⁻³ Thus the nettle produces its effects by injecting substances present in man's own body. A much more serious matter is the wasp, for the effects of its sting last for several days and are occasionally fatal; two deaths are reported in our medico-legal column at page 771 this week.

In 1949 F. C. MacIntosh and W. D. M. Paton⁴ described a new class of compounds called "histamine liberators." Histamine is liberated in anaphylaxis, and anaphylaxis was discovered during a study of extracts of the stinging tentacles of sea anemones. Therefore in 1954 R. Jaques and M. Schachter⁵ investigated sea

anemones to see if they contained a histamine liberator in their tentacles, since when applied to man these tentacles cause cutaneous reactions. They found that an extract of tentacles did in fact release histamine when injected into the fluid perfusing the skin of the cat, and having made this observation they wondered whether the venom of the wasp might also possess similar activity.

In their first paper on wasp venom⁶ they showed not that it released histamine but that it contained both histamine and hydroxytryptamine, and a third substance which they did not identify. (Some samples of wasp venom contained a histamine liberator and also hyaluronidase.) The average weight of the venom sac together with glands was 0.8 mg., and the average histamine content was 3.2 µg. as determined by quantitative pharmacological tests. This is a large amount. Both histamine and hydroxytryptamine were identified by paper chromatography. Schachter and E. M. Thain⁷ then examined the third and more important constituent present in large quantity, which they called kinin. It appeared to be a polypeptide, a highly potent substance which produced a characteristic delayed contraction of the isolated guinea-pig ileum and a fall of blood pressure in the cat and the rabbit. Recently D. J. Holdstock, A. P. Mathias, and Schachter⁸ have purified kinin and shown that it is exceedingly effective in enhancing capillary permeability. They gave intradermal injections to guinea-pigs and rabbits, followed by intravenous injection of a dye, pontamine blue. Kinin was ten times more effective than histamine in causing increased permeability to the dye in the guinea-pig, and 100 times more effective in the rabbit. Like other polypeptides kinin caused cutaneous pain when it was applied to the base of a blister according to the method of D. Armstrong and colleagues.⁹ In these respects kinin was similar to kallidin, a substance released from the globulin fraction of serum by an enzyme kallikrein present in human saliva, and also similar to bradykinin, which is released from serum by an enzyme in the venom of the snake *Bothrops jararaca*. Thus we see that human saliva has similarities to snake venom and to wasp venom. It is therefore interesting to note that in 1260 Barthelmy de Glanville said that the saliva of the young man has a secret corrupting power, "for if a man is wounded and you put saliva in the wound it corrupts the blood. This is why archers moisten their arrowheads with saliva, for they are more harmful to their enemies." The main damage inflicted by the wasp sting, the oedema of which may persist for two or three days, seems then to be due to the polypeptide kinin. The occasional deaths which are caused, however, are probably not due to kinin but are rather anaphylactic, and arise because of earlier sensitization to wasp venom.

THE BRITISH NATIONAL FORMULARY

It is now eight years since the first edition of the now familiar *National Formulary* appeared. Fathered by the B.M.A. and the Pharmaceutical Society of Great Britain, with the co-operation of the Departments of Health and the Service Departments, this enterprise occupies an established place in medical practice, providing doctors and pharmacists with a selection of formulae and preparations comprehensive enough to meet all the ordinary needs of general medicine. Though the *N.F.* was in many respects the direct successor of the *National War Formulary*, the Joint Formulary Committee set up in 1946 to prepare the first volume was faced with a far more onerous task than that which faced those who prepared the *N.W.F.*, largely because the imminence of the National Health Service foreshadowed a big switch from private to Health Service prescribing. The committee, therefore, submitted their ideas for comment to a large number of bodies representing the medical and pharmaceutical professions before they finally committed themselves to print.

The fifth edition of the *Formulary*¹ was published in August and comes into operation on November 1. The customary title of *National Formulary* has now been discarded for that of *British National Formulary* because, it is said, there was evidence of some confusion of the old name with that of the *National Formulary, U.S.A.*, which is a book of standards. In the latest edition some of the older and familiar prescriptions have had to give place to new. On the other hand, the committee has kept to its policy of retaining preparations or formulae still being widely used or frequently prescribed even if their justification on pharmacological grounds is open to dispute. The *B.N.F.* does not hold itself out to be a textbook, and the committee is right to cater for the practitioner's natural conservatism in prescribing, which certainly springs as much from a fund of practical experience as it does from habit.

The Joint Formulary Committee this year has embarked on a new venture, foreshadowed in the preface to the 1955 *N.F.*, in the shape of an alternative addition² to the *B.N.F.* in which the preparations are grouped according to their pharmacological use instead of alphabetically, and in which English titles replace Latin. After making inquiries the committee believed that there would be a demand for the new volume, particularly from hospitals for teaching purposes. In general the contents of the alternative edition are the same as that of the main edition and the formulae are identical. Each group of drugs is preceded when practicable by a short account of the actions and uses of the preparations which follow, and these descriptive monographs replace the prescribers' notes, although in some cases they are the same. The alternative edition will not be distributed free of charge by the Departments of Health to doctors in the National Health Service as has been done with the main edition, and what demand

¹ *British National Formulary 1957*. B.M.A. and Pharmaceutical Society of Great Britain, London. Price 6s. 6d.

there will be for it remains to be seen. One thing that the grouping of formulae in the alternative edition clearly shows is the large number of preparations in the *B.N.F.* that have a similar pharmacological action.

CANCELLOUS STRIP GRAFTING

An innovation in the technique of bone-grafting for non-union and for delayed union of fractures seems likely to be generally adopted. The use of massive cortical grafts is declining. The recent vogue for grafting stored homogenous bone, which never attained more than a limited popularity in Britain, is passing, at least so far as the treatment of fractures is concerned. Techniques employing the grafting of calf bone have not been accepted outside the Continent of Europe.

Cancellous "strip" grafting, in which the grafts are prepared as flat strips cut from the crest of the ilium, promises to become the standard method in treating indolent fractures. The technique is simple, and, since it employs only spongy bone, has a better physiological basis, because the revascularization and reossification of spongy bone is a much more rapid process than is the incorporation of massive portions of cortex. This new technique appears to have been adopted in many centres simultaneously, mainly as an application of the ideas put forward by D. B. Phemister.¹ The subject was discussed at the spring meeting of the British Orthopaedic Association last May. J. N. Wilson described its application in 22 cases. As with other techniques, the most satisfactory results are obtained in delayed union rather than in established non-union. If the fracture under treatment is stable, by reason either of firm fibrous union or of previous metallic internal fixation, all that is necessary is to refresh the cortex above and below the level of fracture, and to apply strips of iliac cancellous bone to the bared surfaces. External splintage is essential. If the fracture is unstable or badly displaced it must be "taken to pieces," reduced, fixed with a plate and screws or with an intramedullary nail, and the cortex refreshed and grafted similarly.

There is nothing new in reliance upon grafts of cancellous bone rather than upon cortex. W. E. Gallie in 1931² and H. Matti in 1932³ demonstrated the greater osteogenetic powers of grafted cancellous bone, and cancellous "chip" grafts have been widely used ever since, both for slow union of fractures and in operations for intra-articular arthrodesis. Strip grafting has the advantages over chip grafting that a larger bone-producing area is produced and that it is often possible to leave the fracture itself undisturbed.

Strip grafting alone, even reinforced with internal fixation, is seldom adequate for the treatment of non-union with considerable gap between the fragments. In such cases the method combining the use of a block of cancellous bone with internal fixation, as advocated by E. A. Nicoll,⁴ is an advance over previous techniques. If, however, bone has not been lost and there is no gap

between the fragments, cancellous strip grafting is so simple and so certain that it should be employed early, as soon as it becomes apparent that a fracture of the shaft of an adult bone is not healing properly and is likely to present the problem of delayed union. Some orthopaedic surgeons would go further, advocating the use of this method as a primary procedure in comminuted fractures or in fractures inflicted by major violence in which, for any reason, open reduction and internal fixation are to be employed.

RENAL CALCULI IN SEVERE PARALYSIS

A dangerous complication for the severely paralysed patient is the development of renal calculus. It is apt to occur because the calcium balance is disturbed. In the normal subject osteoblastic and osteoclastic activity are about equal, but in the patient with severe paralysis the balance is upset. The stress that muscles exert on bone is a stimulus to osteoblastic activity, and in the severely paralysed patient it is missing. In consequence, osteoclastic activity continues, but osteoblastic activity is diminished. Calcium is therefore lost from the bones, and the excess is excreted in the urine. In severe cases of acute poliomyelitis the calcium balance becomes negative early in the paralytic stage of the disease, and becomes increasingly so until it reaches a plateau after about five weeks. Loss of calcium continues at this level for some months, and equilibrium is not again attained for about seven months.¹ During this period the hypercalciuria may be sufficient to cause a calculus to form; this is more likely to occur if the urine becomes alkaline owing to urinary infection, excessive artificial respiration, or ingested alkali.

When sodium phytate is taken by mouth it forms the insoluble calcium phytate, and prevents the calcium being absorbed from the alimentary tract. P. R. Vagelos and P. H. Henneman² have recently investigated the effect of this substance on the urinary excretion of calcium in severely paralysed patients. Their nine patients were quadriplegic owing to poliomyelitis and had hypercalciuria. They were given two courses of sodium phytate, the first lasting about six weeks, the second about four weeks. In five of the nine patients the urinary excretion of calcium fell appreciably during treatment, and the decrease in hypercalciuria suggests that sodium phytate deserves further trial in the prevention of renal calculi in these patients. The dosage has to be restricted lest it cause diarrhoea.

The measures commonly recommended to prevent the formation of renal calculi are a generous fluid intake, avoidance of urinary infection, especially by scrupulous sterility in catheterization, and frequent changes of posture. The last does not affect calcium metabolism,³ but may be useful in preventing stagnation of urine in the renal pelvis. These measures, important though they are, have not solved the problem, and further progress may depend on reducing the amount of calcium in the diet or making it unavailable by giving sodium phytate.

SYMPOSIUM ON NUCLEAR SEX

[FROM A SPECIAL CORRESPONDENT]

Since the original observation of Barr and his colleagues in 1949 there have been many reports on the morphological sex difference in the nuclei of cells from males and females. The difference is a characteristic chromatin mass in the nucleus (chromatin positive) in the female, and is most conveniently seen in the epithelial cells of the skin or buccal mucosa and the neutrophils of the blood. Study of these cells has thrown light on the problems of development and classification of some of the intersex states, but there remains much confusion, particularly in nomenclature. An important point still in dispute is whether these chromatin masses actually represent, as seems probable, the chromatin associated with the XX chromosomes or whether they are merely a sex characteristic.

In an attempt to clarify some of these problems a symposium was organized by a committee consisting of Dr. W. M. Davidson and Dr. D. Robertson Smith (secretary; King's College Hospital), Dr. P. Bishop and Dr. P. E. Polani (Guy's Hospital), Professor L. S. Penrose (University College, London), Dr. G. I. M. Swyer (U.C.H., London), Dr. B. Lennox (Glasgow), and Professor M. L. Barr (London, Canada). Interested representatives were invited from many fields, including clinical medicine, endocrinology, pathology, biochemistry, cytology, anatomy, physiology, psychology, and genetics. King's College Hospital Medical School provided the facilities for the meetings, which were held on September 6 and 7, and the Wellcome Trustees made a grant towards the expenses. The 65 participants came from Britain, Canada, the United States, France, Germany, Austria, Denmark, Switzerland, Portugal, Italy, and Israel.

Sexing the Intersexes

The first session was a technical discussion on the cytological and genetic aspects of nuclear sex. The present report, however, is confined to the papers of more immediate clinical interest. These were in the second session, for which Dr. P. Bishop was chairman, and were concerned with the application of nuclear sexing to the study of intersexes and related states. Several papers dealt with the interesting problem of Klinefelter's syndrome, a specific type of "male" hypogonadism often associated with gynaecomastia.

Dr. MATHILDE DANON and Dr. LEO SACHS (Rehovoth, Israel) reviewed the results of nuclear sexing intersex patients. Most intersexes appeared to have a genetic basis. The female phenotype might develop with XX or XY genetical constitution, and perhaps XO or XX/XO. The male phenotype with testes might have an XX constitution as in Klinefelter's syndrome, and, as Dr. D. J. P. Ashley later showed, the female phenotype with ovaries could have an XY constitution. There was still no satisfactory explanation of these cases of complete sex reversal, but the male and female pseudohermaphrodites with gonads conforming to the nuclear sex could be understood on the basis of the findings of experimental endocrinology in the embryo.

Dr. A. PRADER and Dr. R. E. SIEBENMANN (Zurich) described a new syndrome of congenital insufficiency with lipid adrenal hyperplasia and female genitalia in boys. They postulated that it was due to a hereditary enzymatic failure at a very early stage of steroid synthesis in the adrenal and Leydig cells leading to adrenal and testicular insufficiency.

Professor CLAUS OVERZIER (Mainz) in a clinical and experimental classification of the intersexes referred particularly to the very rare cases of true agonadism. The three cases described were genetically male and had no extra-genital deformities. They had to be distinguished from cases of Turner's syndrome, in which gonadal remains might be found.

Dr. ELIOT SLATER (London) had analysed the mean age of the mother at the birth of the patient, number of

sibs, position in sibships, and birth order in four groups of sex deviants: male homosexuals, exhibitionists, transvestites, and female homosexuals. Only in the group of male homosexuals was there any significant variation: they tended to be born late in sibships and to older mothers. Dr. C. N. ARMSTRONG (Newcastle upon Tyne) presented a detailed account of a case of male transvestism with male nuclear sex, and, although the aetiology of this type of case is obscure, a constitutional factor with a genetic basis was suggested. These cases were very difficult to manage.

Klinefelter's Syndrome and Infertility

Dr. W. M. DAVIDSON and Dr. D. ROBERTSON SMITH (London) discussed Klinefelter's syndrome. Although the cases were genetically female, the frequency of the characteristic chromatin "drumsticks" in the neutrophils was low. This unexpected finding might have some bearing on the causation of the condition, or it might be akin to the low frequency found in a small number of normal females.

Dr. B. LENNOX, Dr. M. A. FERGUSON SMITH, Dr. W. S. MACK, and Dr. J. S. S. STEWART (Glasgow), from their experience of cases attending a male subfertility clinic, considered Klinefelter's syndrome to be an important cause of infertility. In addition to the chromatin-positive cases (female nuclear sex) they recognized a chromatin-negative form (male nuclear sex), the testes in the two groups differing in histological appearance. Dr. R. SIEBENMANN (Zurich) also discussed the histological appearances of the gonads in Klinefelter's syndrome, and stressed their constancy in the cases with female nuclear sex compared with the very varying picture in the male cases. The Glasgow workers, with Miss M. IZATT, then reported their investigation of the incidence of sterility in the families of the chromatin-positive and their chromatin-negative cases of Klinefelter's syndrome and their investigation of the blood groups of these cases. They suggested that both types are hereditary, the defect in the chromatin-positive cases being transmitted by the fathers and that in the chromatin-negative by the mothers. During the discussion, however, some doubt was expressed about the existence of the chromatin-negative form of the syndrome.

Dr. P. BISHOP, Dr. M. A. FERGUSON SMITH, Dr. B. LENNOX, Dr. P. E. POLANI, and Dr. J. S. S. STEWART were studying the colour vision in cases of Klinefelter's syndrome. Although the numbers were small, the absence of any defects tended to confirm the femaleness of chromatin-positive cases.

Dr. D. J. B. ASHLEY (Liverpool) reported the first case of sex reversal showing the presence of ovaries in an individual of male nuclear sex—that is, the complete analogue of Klinefelter's syndrome. The presence of testicular tissue had been excluded so far as was practicable.

Nuclear Sexing of Tumours

The final session, with Professor MURRAY L. BARR (London, Canada) in the chair, was devoted to the application of nuclear sexing to the study of tumours. Dr. LOIS MYERS (London) described a detailed study of the nuclear sex of a large number of teratomas and commented on the curious variability of the nuclear sex of teratomas in the male. Dr. A. S. TAVARES (Oporto, Portugal) also discussed exceptions to the identity of the nuclear chromatin of the host and tumour in undifferentiated carcinomata and teratomas. Dr. N. B. ATKIN (London), who had used squash preparations to study chromatin patterns in human tumours, thought the variability of the sex chromatin in tumours from females was related to variations in the chromosome complement.

Social events associated with the symposium included a reception by the Ciba Foundation, a luncheon provided by the board of governors of King's College Hospital, and a dinner given by the dean and council of King's College Hospital Medical School, at which Professor ROBERT PLATT, P.R.C.P., Mr. L. R. BROSTER, and Professor JOST (Paris) spoke.

MEDICAL RESEARCH IN THE BRITISH CARIBBEAN

Last April in Trinidad the Standing Advisory Committee for Medical Research in the British Caribbean held its second annual scientific meeting.* These two-day meetings bring together research workers from the various West Indian islands and territories, provide a forum for the discussion of their work, and allow others to learn the trends of medical research in this area, the proceedings and many of the papers being published in full in the *West Indian Medical Journal*. This year "Communicable Diseases of the Caribbean" was the topic. The meeting was held on April 6 and 7 under the joint chairmanship of Professor A. C. FRAZER, professor of pharmacology at Birmingham, and Professor G. W. PICKERING, Regius professor of medicine at Oxford. Here we summarize a selection from the 29 papers that were presented.

Parasitic Diseases

Dr. C. ROMITI compared the incidence of post-operative malaria in British Guiana before and after the intensive antimalarial campaign which was begun there in 1947 and has resulted in the extermination of the disease from the coastal plain. Between 1924 and 1947 a total of 14,027 patients were operated upon, of whom 3,445 had had malaria previously; 13.5% of the latter developed malaria post-operatively, but none of the 10,582 non-malarial subjects did so. Since the 1947 antimalarial campaign, 14,120 operations had been performed on the same class of patient and only five cases of post-operative malaria had been noted.

Dr. W. ADAMS (British Guiana) reported the results of a study of the night blood of 30,000 working-class persons, including children, living in the unsewered suburbs of Georgetown and along the coastlands. One blood film per person was examined and microfilariae were found in 11.4% of cases. East Indians showed a lower incidence than the Negroes and those of mixed race, and in all races the incidence was low in the first decade of life. There was clinical elephantiasis in 3.3% of the total series. The mosquito vector—*Culex fatigans*—showed a preference for water contaminated by sewage; it abounded in the pit latrines which became flooded in rainy weather.

Two cases of rhinosporidiosis—infection of the nasal mucosa and cheek by *Rhinosporidium seberi*—were reported by Dr. R. REESAL (Trinidad). This infection has not previously been recognized in Trinidad.

Viral Studies

Dr. R. LEWTHWAITE (Colonial Office) opened a session on viruses by reviewing work on this subject being carried out in Entebbe, Lagos, and Kuala Lumpur. He stressed the newly recognized Arbor viruses, the occurrence of cross-immunity between viruses, and the difficulties in their isolation and identification. Workers from the Trinidad Regional Virus Laboratory then described some of their researches. Dr. T. H. G. AITKEN said that 71 strains of virus had been isolated from Trinidad mosquitoes, of which 22 represented yellow fever, 7 Ilheus, 3 St. Louis virus, and 39 had still to be identified. Dr. C. R. ANDERSON discussed the St. Louis encephalitis virus. It had been found in mosquitoes and in a fledgling bird in Trinidad, but no human cases had so far been encountered, although some individuals showed serological evidence of immunity. Dr. W. G. DOWNS gave preliminary details of a serum survey of inhabitants of Grenada, which suggested that dengue had been prevalent in the coastal towns and villages, and also the possible presence of Ilheus and St. Louis viruses. Experimental work on Mayaro virus in the mouse was reported by Dr. J. D. ARNEAUD (Trinidad).

*For an account of the first meeting, see *British Medical Journal*, 1956, 1, 1359.

Dr. L. V. BUTCHER, of the Trinidad Veterinary Service, reviewed the present status of paralytic rabies in Trinidad. The last human death was in 1937, but among cattle there had been sporadic deaths until 1954, when the disease assumed epizootic proportions in South Trinidad. The disease was transmitted by the bat, and the present programme of control was directed towards the immunization of livestock with a live attenuated avianized virus vaccine, rather than destruction of the bats.

Tuberculosis and Other Conditions

Dr. R. A. S. CORY (Jamaica) reported on the immediate results of treatment in 200 consecutive patients admitted with sputum-positive tuberculosis, 60% of whom had far-advanced disease. Rest, drugs, and surgery were combined as required. In the final analysis 81% left hospital with a good prognosis, the disease having become arrested, or apparently arrested. The incidence and clinical effects of abnormal haemoglobins in Jamaica were discussed and illustrated by Dr. J. MACIVER and Dr. L. N. WENT (University College of the West Indies). Sick-cell disease was common in Jamaica. Among antenatal subjects the sick-cell trait had been found in 9.5% and the haemoglobin-C trait in 3.9%. Cooley's anaemia and sick-cell-thalassaemia disease had also been discovered in the population.

Dr. G. H. GENTLE (Trinidad) described their attempts at the Caribbean Medical Centre to separate yaws from syphilis as the cause of positive serological findings in asymptomatic cases. Leptospirosis in Jamaica was reported by Dr. L. S. GRANT and Dr. G. BRAS (University College of the West Indies). This condition was first recognized there four years ago, and 35 cases had since been confirmed. A new type of leptospira had also been isolated.

MEDICAL DEFENCE UNION

The annual meeting of the Medical Defence Union was held at the Union's offices in Tavistock House South on September 17. In his presidential address Dr. S. COCHRANE SHANKS forecast an increase in the members' subscription and also referred to the case of Dr. Bodkin Adams—"perhaps the most dramatic case of this year"—as it fell outside the period of the annual report.

President's Address

In presenting the report, Dr. COCHRANE SHANKS said that the membership of the M.D.U. was now over 45,000. More and more members were seeking advice and guidance, their requests ranging from simple questions on professional practice to complicated legal problems. An increase in the annual subscription, still £2, seemed inevitable. Of recent years there had been a mounting flood of claims against doctors for negligence; and although the number of cases referred to the solicitors had been about the same as the previous year (just under 300), the work in the office was increasing and the sums for damages or the settlement claims tended always to rise. There had been a deficit of £445 in the year covered by the report (1956-7), and it seemed certain that the coming year would show a larger debit balance.

The president then referred to the case of Dr. Bodkin Adams. He would like to offer just one comment. "I doubt if it would be possible to find—or even invent," said Dr. Cochrane Shanks, "a better recommendation for belonging to a defence society than this case." A doctor was suddenly faced with the gravest charge that could be made against a medical man, that of murdering a patient. In return for a subscription of £2 a year, they had successfully defended him at a cost of many thousands of pounds, and enabled him to leave the Court acquitted of that dreadful charge. Had ever £2 per annum been better spent?

The council of the Union, said the president in conclusion, was engaged in making proposals for the amendment of the disciplinary procedure under the Medical Act, 1956. These

proposals, which were designed to safeguard those brought before the disciplinary committee of the General Medical Council, would be considered by the joint co-ordinating committee of the three medical defence societies.

Annual Report

The council's report for the year 1956-7 discusses, as is customary, a number of medico-legal matters of interest to the profession. These include: the propriety of submitting reports of accidents in hospital to lay persons; the implications of last year's amending regulations on a doctor's responsibility for his deputy and on the restriction of the right of complaint against a doctor or dentist; alleged breaches of the "terms of service"; appeals against the findings of medical service committees; professional secrecy; theft of belongings from residents' quarters in hospitals; the rights of industrial medical officers regarding the ownership of their medical records; and the management of those who wish to alter the registration of their sex.

Correspondence

Halothane

SIR,—When I received my first supply of halothane it seemed to me that, if the drug was going to be widely used, the closed-circuit method was obviously the one of choice, owing to its high cost to hospitals—£10 5s. per 250 ml. From reading the publications on the drug several points stand out.

(1) Most of the clinical experience has been carried out with the highly expensive semi-open circuit, which is akin to using cyclopropane in the same way. Surely no hospital management committee will tolerate such expense. (2) Much has been said about the drug being used in specially calibrated machines, but the figures of percentages appear to have been the result of samples taken from machines and not from the tracheas of patients as those in my report (*Journal*, August 10, p. 331). Also, it is obvious that as soon as the patient is forcibly inflated the concentration in his trachea and blood bears no relation to that being delivered by the machine. Hence a dangerous atmosphere of false security is being created. I know that modern anaesthetists delight in talking about percentages, but take little heed of them during their conduction of anaesthetics, and rely, as always, on their clinical knowledge and skill. Why, when all other inhalation anaesthetics are administered satisfactorily from present uncalibrated machines, should halothane, by no means the most deadly of them, suddenly become unsafe to use in these machines? Is this another "anti-static band wagon," or a prolongation of the principles in the use of trichlorethylene by midwives? (3) I am very reluctant to accept some of the forthright statements in the report of the Medical Research Council (*Journal*, August 31, p. 479), based on only 245 cases over a period of 18 months and between four teaching hospitals, and wholeheartedly agree with the closing words of Dr. M. Johnstone's letter (*Journal*, September 14, p. 641). I cannot find the logic in their argument that the closed circuit was not used because of the possibility of a rapidly mounting halothane vapour concentration, except that, of course, it will mount rapidly if forcible inflation is used. Surely this comment should also condemn the known successful use of ether and cyclopropane in the closed circuit.

In my opinion there are certain rules for using any method. When using halothane in the closed circuit, forcible inflation of the patient's lungs should not be employed when the vaporizer is in circuit. In answer to Dr. F. L. Robertshaw (*Journal*, August 31, p. 526), the percentages were estimated by a gas-interference refractometer from samples taken by means of a bronchial catheter after at least 20 minutes of anaesthesia at each setting of the control,

proving conclusively that the percentage of halothane remains constant as long as physiological breathing takes place. I cannot agree with the conclusions nor the conditions of the laboratory experiment reported by Dr. Brennan and his colleagues.¹ It is not my experience, for instance, to see a patient on a fully closed circuit with a flow of only 500 ml. of O₂ breathing at anything approaching 500 ml. sixteen times a minute. Further, the all-important notch 1 and 2 figures were not given, and laboratory test figures vary greatly from those taken during an operation. The other rule is that D-tubocurarine is not used, abnormal blood loss is replaced before the patient is returned to the ward, and any tachypnoea is countered by 25 mg. to 50 mg. of pethidine.

Finally, it is my contention that those who have condemned the fully closed circuit method have done so on supposition not backed by experience.—I am, etc.,

Coventry.

H. REX MARRETT.

Hospital Confinement

SIR,—May I ask Dr. John Frampton (*Journal*, September 14, p. 644), through you, why he assumes no doctor is to condone the practice of episiotomy and subsequent suture in the home? "Condone" does not indeed seem the right word. I don't see any reason why episiotomy and suture, or suture of a tear, should not be performed in the home. It seems to me a simple and safe enough procedure, and I have not had trouble in a single case. Moreover, though I have not kept statistics, I have the certain impression that the incidence of such cases during home confinements is much lower than the 50% Dr. Frampton quotes. I speak from an experience of more than seventeen years in this suburban, semi-rural practice, where I attend an average of well over sixty confinements a year, the overwhelming majority of them in the patient's home and only a few in a maternity home. From this experience, I fully agree with Dr. M. G. Smith (*Journal*, August 17, p. 414), Dr. H. D. Forbes Fraser (*Journal*, July 20, p. 159), and others in advocating home confinements in any case in which there is no definite contraindication. The fact that a woman is a primipara is, according to my experience, certainly no such contraindication.—I am, etc.,

Gillingham, Kent.

K. F. M. POLE.

SIR,—The very point raised in Dr. John Frampton's letter (*Journal*, September 14, p. 644)—namely, the high incidence of perineal repairs in primiparae—supports the argument in favour of home confinement.

In spite of poor light and wound exposure, apparently inadequate asepsis, and other mechanical difficulties of the operator, I have never yet come across a case of broken-down perineum in over 200 home confinements. The repairs invariably heal by first intention. While obstetric house-surgeon, I have been dismayed at the relatively high rate of perineal breakdowns in hospital. I have discussed this with colleagues and midwives in this area, which has a very high birth rate indeed and in which "normal" primiparae are not booked for hospital confinement, and they share my experience. It may be that our technique as house-officers was deficient or that the bacterial flora in the home is less virulent, but the fact remains that home confinement appears to be safer, at least in respect of sound healing of the cut or lacerated perineum.—I am, etc.,

Stevenage, Herts.

J. O. NEWMAN.

Asian Influenza in Manchester

SIR,—Dr. D. W. A. McCreadie (*Journal*, September 21, p. 684), in his memorandum about influenza in Kuwait, reports few cases of inflamed tonsils. This is also true of adults in Manchester, but not of children who still have them. But all cases show some degree of pharyngitis. I

think the explanation is that a large fraction of the adult population no longer has tonsils to get inflamed. The proportion with a gastric upset at some stage in the illness seems much nearer 30% than the 6% vomiting in Kuwait, but many, I think, suffer from nausea because of taking too many aspirins and various proprietary remedies in efforts to ward off influenza.

The real danger seems to me that a large part of the public now has in its keeping small amounts of various medicaments, from cough medicine to sulphonamides and oral penicillins, which have been given to patients with "bronchial" symptoms because of the publicity given in the press to deaths from bronchopneumonia and because of a medical officer of health being quoted as advising the calling of a doctor to all cases of influenza. As soon as the patients feel better many stop their drugs and give them to new "victims" of the influenza because doctors are no longer available quickly and the demand for visits goes up with headlines enumerating the number of "flu deaths." This may lead to drug resistance in the ordinary throat germs—resistance which till now has plagued hospitals more than G.P.s—making the G.P.'s choice of sulphonamide or antibiotic harder this winter, making the use of the more expensive newer antibiotics essential, and sending the drug bill up even higher next year.—I am, etc.,

Manchester, 16.

S. SHUBSACHS.

Influenza Publicity

SIR,—My partners and I feel very strongly that it is time the B.M.A. took urgent steps to counteract the ridiculous and hysterical exaggerated publicity given in the daily press and magazines to the present epidemic of Asian 'flu. Although so far there have been no cases of Asian 'flu recognized as such in this neighbourhood, patients have already started sending urgently on most inadequate grounds. One woman in the best of health had obeyed instructions given her in a woman's magazine and had sent urgently because she felt hot. I gather that even television has been used to encourage patients to send for their doctor at once if they think they are starting 'flu. It is difficult to imagine any more efficient way of encouraging unnecessary calls.—I am, etc.,

West Malling, Kent.

G. E. R. HAMILTON.

SIR,—I wish to protest against the highly sensational reports of the national press about the present influenza epidemic. Patients get worried unnecessarily and so do their doctors. A statement by the B.M.A. declaring that the influenza epidemic, whether Asian or 48-hour 'flu, is highly contagious but quite harmless, without evidence of serious complications, might help. Perhaps the press could instead devote their pages to the publication of names and addresses of victims of carcinoma of lung, with the average number of cigarettes smoked.—I am, etc.,

Nottingham.

G. FIELDING.

Caudal Analgesia

SIR,—Once again another article is published supporting the use of caudal analgesia in obstetrics (Dr. G. Trevor Johnson, *Journal*, August 17, p. 386), but surely it is time that the myth of its associated technical difficulties and complications was exploded.

The technique described by Hingson and Edwards¹ is well known, and most people familiar with extradural analgesia will acknowledge that in approximately 25% of subjects the sacral hiatus is difficult or impossible to locate. Why not, therefore, in such cases perform a lumbar extradural puncture with a Tuohy needle at the level of the first and second lumbar spines, and pass a vinyl plastic 442 T catheter into the extradural space? This method is easier to perform than that employing the sacral hiatus. In fact, anyone capable of making a lumbar puncture methodically should be able to give an extradural injection. This different site

further away from the anal cleft should also help to rest the minds of those worried over the chance of the puncture site being soiled, if, indeed, they are not already consoled by the work of Hanley and Malone,² who had no case of infection in their series of 2,000 cases.—I am, etc.,

M. BRIAN COMERFORD.

Jersey, C.I.

Listerial Meningitis

SIR,—As the cases of Listerial meningitis mentioned in your article (*Journal*, July 27, p. 188) and subsequent correspondence were in infants, I feel that it might be of interest to draw attention to what I believe to have been a similar infection in a girl 10½ years of age. This girl was admitted to Waddon Hospital on May 30, 1957, as a suspected case of poliomyelitis. She had typical acute meningeal symptoms which had commenced on the previous day, with temperature of 102° F. (38.9° C.). She was an extremely thin child, had an irritable cough and cyanotic tinge, and looked more ill than is usual for non-paralytic poliomyelitis. The upper part of the left ear-drum was inflamed.

Lumbar puncture gave a turbid fluid containing 612 leucocytes per c.mm. (94% polymorphs and 6% lymphocytes), 90 mg. protein and 62 mg. sugar per 100 ml. No organisms were seen on the Gram or Z.N. stained deposit, but culture on a blood-agar plate produced a profuse growth of diphtheroid morphology. The organism was shown to be penicillin-sensitive, and the patient was successfully treated by daily intrathecal injections of penicillin for five days and oral phenoxymethyl penicillin for 12 days. Subsequent C.S.F. specimens, collected daily at the time of intrathecal injections, showed a continuous and rapid fall in both cell and protein content, thus further confirming that the meningitis was a septic rather than a poliovirus infection. Also, attempted culture of poliomyelitis virus from the faeces failed.

I had hoped to get the diphtheroid-like organism which grew from the C.S.F. further investigated, but the culture was unfortunately discarded after being sent to another laboratory. I have failed to find any record of meningitis due to a true diphtheroid, and therefore feel that the organism was most probably *Listeria monocytogenes*.—I am, etc.,

Croydon.

J. J. LINEHAN.

Toxic Effects of Meprobamate

SIR,—Dr. David L. Miller (*Journal*, August 3, p. 300) and Dr. Helen Wagstaff (*Journal*, August 17, p. 414) have each reported a case of a toxic rash due to meprobamate. I should like to describe a similar one.

A man of 58 was under treatment for a mild anxiety state associated with many organic disabilities. About two hours after taking the second dose of 400 mg. of meprobamate on September 7, 1956, he suddenly developed a rash associated with pruritus which was so intense that he had to leave an important religious service. At first the rash was a generalized, bright erythematous one, more severe on the trunk and pelvic regions. A few hours later large blisters appeared on the right elbow and thigh. The following morning antihistamine therapy was started with chlorpheniramine ("piron") but without relief; later hydrocortisone ointment, applied locally, was effective in relieving the pruritus. Although no more meprobamate was taken after the onset the rash persisted for a fortnight. After three more weeks a patch skin test, done with pure meprobamate kindly supplied by I.C.I. (Pharmaceuticals) Ltd., was negative. A further two weeks later, after a dose of 200 mg., a similar rash appeared, persisting for about 10 days in the groins and genital area, where a little hyperkeratosis developed. He had not taken meprobamate before, but in the previous year he suffered the typical skin lesion associated with carbromal.

The features of interest in this case, which is similar to those already reported, are that the rash followed the second dose with no previous administration, the persistence of the rash for a fortnight, the negative patch test, and the recurrence of the rash after only 200 mg., proving the causal relationship of the drug to the rash.

In spite of limited use of meprobamate I have treated also a patient who rapidly developed severe diarrhoea which ceased on withdrawal and recurred when the drug was restarted, and another who developed a state of "drunkenness," with difficulty in walking and in keeping her eyes open. Other toxic reactions have been described; thus Scott, Grimshaw, and Molony¹ drew attention to hypotensive episodes; Friedman and Marmelat² described cases of paradoxical excitement, of palsy of the extraocular muscles as well as those with skin lesions.

The Council on Drugs of the American Medical Association³ has discussed recently the potential hazards of meprobamate: the hypersensitivity reactions, similar to the cases described by your correspondents, with also non-thrombocytopenic purpura; the acute intoxications, as a result of suicidal attempts, which have not been fatal, although alarming central depression has occurred with coma, shallow respiration, muscular weakness, hypotension, and even complete vasomotor and respiratory collapse (see also Heberden and Cooper⁴). In some instances the drug has proved to be habit-forming, and withdrawal symptoms of convulsion and psychic disturbances have occurred; on the other hand no blood dyscrasia has yet been reported. The Council stresses that the number of reactions to meprobamate is unknown but is probably small.

In view of these toxic reactions meprobamate should be used with caution, but its ultimate place in medicine will depend upon further studies of its sedative or tranquillizing action, such as those of Raymond⁵ and his colleagues at St. George's Hospital, who showed that it is of no more value than a placebo, and those of West and da Fonseca⁶ at St. Thomas's Hospital, who found no significant difference between meprobamate and sodium amylobarbitone.—I am, etc.,

London, W.C.1.

Congenital Malaria

SIR,—Dr. K. J. Atkins's letter (*Journal*, August 3, p. 300) on the frequency of congenital malaria in Calabar (Nigeria) is of interest. Nevertheless it is difficult to reconcile his conclusions with the general consensus of opinion of workers from tropical Africa.

The problem of congenital malaria was comprehensively reviewed by Covell,¹ who quoted several large series of observations from Sierra Leone, Kenya, Belgian Congo, and Nigeria totalling 5,324 deliveries with 16 congenital infections (0.03%). Thus it appears that transplacental transmission of malaria from the mother to the child is very rare in the indigenous population possessing a substantial degree of tolerance to the parasite. This is all the more remarkable since malaria infections of the placenta are very common (up to 50–74%) in African women. In our own series from Lagos² 22% of all placentae from 567 deliveries were heavily infected with *P. falciparum*, but only one newborn baby had malaria parasites in the peripheral blood, and even this case was not absolutely certain, as it was not examined within the same period as the others.

In assessing the incidence of true congenital malaria (meaning by this a transplacental infection of the newborn, confirmed within 24 hours after birth by finding parasites in the peripheral blood) the frequent heavy infections of the maternal side of the placenta may be a source of error. In

contradistinction to the African population, congenital malaria of non-immunes is not uncommon and may be a very real hazard to any baby born from an expatriate mother unprotected by antimalarial drugs. Naturally the administration of prophylactic drugs to expectant mothers, particularly during the last two months of pregnancy, cannot be but beneficial in every case, irrespective of the degree of tolerance of the individual concerned.—I am, etc.,

Selsdon, Surrey.

Homoeopathy

SIR,—Sir Henry Dale's mention of homoeopathy in his Gideon Delaune Lecture on medicinal treatment (*Journal*, August 24, p. 423) repeats an ancient misconception and will mislead many doctors who know nothing of the subject. The essence of homoeopathy is the simile principle, and good homoeopathy can be, and is, practised with doses of drugs which are well short of the astronomical dilutions mentioned by the late Professor Clark and referred to by Sir Henry. A fairer reference to homoeopathy was made by Sir William Osler in his farewell address, entitled "Unity, Peace and Concord," to the medical profession in the United States, from which I quote the following.

It is not as if our homoeopathic brothers are asleep; far from it, they are awake—many of them at any rate—to the importance of the scientific study of disease, and all of them must realize the anomaly of their position. It is distressing to think that so many good men live isolated, in a measure, from the great body of the profession. The original grievous mistake was a ours—to quarrel with our brothers over infinitesimals was most unwise and stupid thing to do. That we quarrel with them now is solely on account of the old Shibboleth under which they practise. Homoeopathy is as inconsistent with the new medicine as is the old-fashioned poly-pharmacy, to the destruction of which it contributed so much. The rent in the robe of Aesculapius, wider in this country than elsewhere, could be repaired by mutual concessions—on the one hand by the abandonment of special designations, and on the other by the intelligent toleration of therapeutical vagaries which in all ages have beset the profession, but which have been mere flies on the wheels of progress.

It is a matter for regret that so many eminent teachers of medicine to-day dismiss homoeopathy with some scoffing remark at infinitesimal doses, because those who have learned to use the method find it a valuable addition to their medicinal armamentarium. To get students and young doctors to look into the subject is extremely difficult, because their minds have been already closed to it by the *ipse dixit* of high authority.—I am, etc.,

Glasgow, C.3.

T. D. ROSS.

Stove-in Chest Injuries

SIR,—I was most interested in the case of stove-in chest injury reported by Mr. L. Henry (*Journal*, August 10, p. 339) and in the subsequent correspondence. Stove-in injuries of the chest are not rare, but in the nature of things it happens that cases may be admitted as emergencies to any general hospital in the country. When A. F. Grant and I reviewed the problem¹ we felt that open reduction and fixation by wiring, after the method described by Coleman and Coleman, was a logical one which could be applied without fear by surgeons who were not especially trained in thoracic methods. Subsequent experience has tended to confirm this view, but as the injuries produced by a crushing accident are of infinite variety there is certainly sometimes a need both for pericostal traction and for tracheotomy.

If I may be permitted one or two further comments, it seems to me that pericostal traction has the disadvantage that it may have to be continued for two or more weeks, before sufficient stability of the chest wall has been obtained, and published case reports show that it is sometimes difficult to obtain satisfactory reduction of the deformity. Instability

of the sternum, in my experience, is a less important cause of paradoxical movement than the associated rib or costal cartilage fractures, and I believe that it is usually better to obtain fixation of the ribs rather than of the sternum. I would think that plating of the sternum is rather likely to cause trouble in the future because of the thinness of the overlying skin. The chief advantages of an open surgical approach, as Grant and I tried to show,¹ are (1) it is relatively simple; (2) it gives an almost perfect anatomical and functional result, so that early mobilization is possible if other injuries permit; (3) it is possible to deal effectively with the pneumothorax or haemo-pneumothorax which so commonly accompanies the rib injury.

The question of timing of operation is important; it should be done as early as possible so as to forestall the "wet-lung" state. We think that shock is less of a contraindication to operation than it appears at first. It can usually be corrected by blood transfusion and by dealing with the anoxia which is caused by the paradoxical movement and which seems to aggravate shock very markedly. The early commencement of positive-pressure anaesthesia—if need be for some hours before operation—may be life-saving in these difficult circumstances.

In conclusion, I agree very much with Mr. A. W. Fowler and Mr. J. E. Jacques (*Journal*, September 7, p. 592) when they say that stabilization of the loosened portion of chest wall is the prime object of treatment. Tracheotomy may be, as Mr. J. A. Rhind remarks (*Journal*, August 24, p. 470), dramatically beneficial, but to suggest that it is the only treatment necessary seems to me to overstate the indications for its use. I think that Mr. Henry is to be congratulated on his success in an otherwise hopeless case.—I am, etc.,

Liverpool, 1.

B. J. BICKFORD.

REFERENCES

- 1 Bickford, B. J., and Grant, A. F., *Ann. roy. Coll. Surg. Engl.*, 1956, 19, 371.
- 2 Coleman, F. P., and Coleman, C. L., *Surg. Gynec. Obstet.*, 1950, 90, 129.

SIR,—One would agree with Mr. A. W. Fowler (*Journal*, September 7, p. 592) that it is gratifying to note the increasing interest being shown in the treatment of stove-in chest, which one hopes will lead to a decrease in the high mortality associated with this injury. His assertion, however, that tracheotomy is merely a symptomatic treatment, complementary to stabilization of the chest wall, and should be performed only when the patient has developed a wet lung, is to disregard the underlying physiological principles.

Briefly I would say that tracheotomy diminishes resistance to air flow, and also reduces dead-space, thereby increasing the effective pulmonary ventilation. The result is a marked decrease in the paradoxical movement, eliminating any need for operative fixation of, or traction to, the chest wall. The tracheo-bronchial tree can also be easily aspirated via the tracheotomy tube as frequently as may be necessary, causing little disturbance to the patient, and if the tracheotomy has been performed sufficiently early this will prevent the formation of the wet lung.

The dangers of tracheotomy as suggested by Mr. Fowler relate to cases where the tracheotomy must remain for months or years because of lesions of the nervous system, as in the article to which he refers.¹ A simple aseptic technique can easily be developed by the nursing staff, under supervision, for the few days during which the tracheotomy is required in the stove-in chest injury.

I have attempted to review elsewhere² the whole of the literature relating to this subject, together with a description of cases treated by tracheotomy. More recently Gueukdjian³ has also reported the use of this method. Tracheotomy is a simple, quick, safe, and effective method of treating the stove-in chest as opposed to the discomforts and dangers associated with any form of fixation of the chest wall.—I am, etc.,

Leeds, 9.

Malignant Change Following Herpes Simplex

SIR,—In his very interesting article on malignant change following herpes simplex (*Journal*, September 14, p. 615), Dr. R. Wyburn-Mason writes: "The pathological changes of herpes simplex or zoster and herpetiform lesions are those of an inflammation with oedema between the epidermal cells, and there is nothing specific about the changes."

I would like to point out that the histological changes in herpes simplex vesicles are distinctive and diagnostic. Acanthosis is followed by a disintegration of the structure of the spinal layer due to loss of prickles of the individual cell, and fluid from the underlying inflamed corium passes into the "dilapidated" epidermis to produce an intra-epidermal vesicle. Many epidermal cells also undergo "ballooning degeneration" leading to the formation of mono- and multinucleated "balloon cells." The nuclei of many cells show centrally placed eosinophil bodies (Lip-schütz) and margination of chromatin. The vesicles are due to the action of herpes simplex virus. Similar changes take place in zoster and varicella.—I am, etc.,

London, W.C.2.

HENRY HABER.

Sensitization to Tulle Gras Dressing

SIR,—I entirely agree with the opinions expressed by Dr. C. M. Ridley (*Journal*, May 25, p. 1224) and Dr. W. M. Jordan (*Journal*, September 7, p. 591) regarding sensitization to tulle gras. Looking through my records I found eight similar cases, all patients with hypostatic eczema whose legs had become inflamed after the use of tulle gras dressings. In every case patch tests were positive to balsam of Peru in paraffin molle flav. and negative to the base alone. Apart from its pleasant aromatic smell, balsam of Peru has little value. Its limited antiseptic properties do not make tulle gras a suitable dressing for infected cases, whereas petroleum jelly gauze alone is a safe and suitable application for clean ulcers.—I am, etc.,

London, W.1.

HAROLD WILSON.

Blood Group Chimeras: Transplacental Bleeding

SIR,—Dr. C. C. Bowley and Mr. I. Dunsford (*Journal*, August 17, p. 408), referring to transplacental bleeding, state that, as far as they are aware, haemorrhage from mother to foetus has not been recognized. It should be pointed out that, although spontaneous recognition of this has not to my knowledge been reported, there are already several experimental studies of the problem. Naeslund and his colleagues,^{1,2,3} in three separate studies, transfused elliptocytes and erythrocytes tagged with ³²P and ⁵⁹Fe into women near term, and Mengert *et al.*⁴ similarly used sickle-cell trait blood and cells tagged with ⁵⁹Fe, and examined the infants' blood at birth for the presence of the particular cells transfused to the mother. The radioactive studies did not give a definite answer, but the morphological studies, particularly those using blood of the sickle-cell trait, supported the idea that erythrocytes in small numbers had crossed the placental barrier from mother to foetus. With these experiments in mind I examined the cord blood of a child born of a mother with asymptomatic hereditary elliptocytosis, but found no elliptocytes among the foetal cells. Of course, had elliptocytes been present, one would have had to wait and see whether the few elliptocytes at birth eventually disappeared, thus confirming bleeding from the mother, or whether they increased in number, thus indicating inheritance of the trait. Similar data might be sought in pregnant women with the sickle-cell trait.

As to the factors controlling flow through any placental defect, the pressure gradient between foetal and maternal circulations must obviously be of prime importance. It should therefore be remembered that in the resting uterus the pressure within the foetal villous vessels is some 30 to 40 mm. Hg, while in the maternal intervillous lake it is less than 10 mm. Hg.⁵ Thus the speculation that the

volume of blood flowing from mother to foetus might be similar to that in the reverse direction would appear unlikely during pregnancy. One must admit, however, that during labour these tensions are altered. In a case of severe prolonged transplacental bleeding from the foetus, which I investigated in co-operation with Dr. Frances S. Graham, Dr. Marion C. Miller, and Dr. C. Cameron,⁶ more than 5% of the cells in the mother's circulation were of foetal origin, whereas no maternal cells were detectable in the infant.

The proof of transplacental bleeding from the foetus is mainly in the realm of the serologist, but it should not be forgotten that the detection of the severe case lies first with those clinically responsible for the newborn infant, for it is neonatal pallor which is the paramount sign of such an event. The detection of an excess of alkali-resistant haemoglobin in the maternal blood has also been used as a sign of such bleeding, both supported by agglutination tests⁷ and alone,^{8,9} but it is well known that this has pitfalls, should be interpreted with caution, and should preferably be combined with serology. As for morphological signs in the maternal blood, normoblasts may occasionally be foetal in origin and erythrophagocytosis may indicate the presence of incompatible foetal cells,¹⁰ though this sign is more frequently associated with the presence of a haemolytic process affecting the maternal erythrocytes.^{10, 11, 12}—I am, etc.,

Dundee.

Smoking and Lung Cancer

SIR,—I find the mental processes of my profession fascinating, but rather puzzling. Not long ago a condition was well known in which statistics showed that cancer often occurred at the site of contact with certain products of combustion. No one at that time suggested that we should search for a genotype or a psychological imbalance which should predispose both to cancer and to the adoption of the profession of chimney-sweeping. We have now several long and carefully analysed series of observations on experimental animals of the species concerned, all pointing to the conclusion that smoking in a similar way can cause cancer. Would one of those who object to this conclusion state what other kind of evidence they consider should be sought?—I am, etc.,

London, W.1.

DENIS BROWNE.

Tabulating Data

SIR,—I read Dr. C. N. Smyth and Mr. M. N. Bainbridge's paper (*Journal*, September 14, p. 619) with considerable interest, having found, in the course of writing a thesis some years ago, that an "A.A. mileage chart" system of tabulating data similar to that which they describe was the best solution to the problem of presenting and analysing a large accumulation of data on sweat gland tumours. I used, however, a method of detecting the significant elements of the table which, though at basis similar to that published, is I think rather easier for the non-statistician to follow and certainly leads to a less confusing table.

The primary use of such a table is the detection of unexpected associations between pairs of factors. This is

most directly done by calculating for each entry in the table an "expected" figure—i.e., that which would be expected if the association between the two factors was purely random (the figure is $(N_a \times N_b)/N$, to use Smyth and Bainbridge's notation: its calculation is, of course, laborious for a long table, but not much more so than the calculation of two percentages for each number). By writing the expected figure in brackets against the actual figure one can then see at once which actual figures are too high or too low. Significance of results is assessed by the fourfold table method: after a few trials it soon became obvious what order of difference is likely to prove significant, and only borderline cases need to be worked out in detail. Such a table, with the significant differences starred, comes to life very rapidly. Smyth and Bainbridge's table is twice the size, and involves a great deal of cross reference from one side to the other. Its only major advantage seems to be the presentation of percentages for all figures, but as most of these are non-significant findings few of them are likely to be used.—I am, etc.,

Glasgow.

B. LENNOX.

Merchant Shipping Medical Scales

SIR,—In view of the fact that in less than two years I shall have completed my first fifty years at sea (about two of these as a part-time seaman prior to qualifying in medicine), perhaps you will allow me to comment on one or two points in Dr. S. D. Karve's letter on the above subject (*Journal*, August 31, p. 527). Fifty years is a long time to be at sea. In fact it is a long time to be anywhere. Dr. Karve has been a month at sea, and I doubt whether that is long enough to enable one to give a worth-while opinion on some of the matters he discusses. Just the same, I think it is a good thing for us to hear the views of a newcomer from time to time.

No one among the doctors serving at sea would perhaps claim that the selection of medicines and surgical equipment could not be improved upon, but at least the error is for the most part in the positive direction. There are drugs and instruments I have not yet found a use for, but I would not go out of my way to interfere with anyone else's right to use them. Though I have no responsibility for the present choice of equipment, I can imagine the difficulties which have to be faced by those who have to draw up the scales of medicines carried. Dr. Karve speaks of a lack of planning. I do not like this word "planning," but perhaps in time a little better integration could be achieved without infringing on the rights of interested parties. As regards dispensing in rough weather, this is at most a slight inconvenience that any ship surgeon learns to get round. In these days many of one's patients are already saturated with tablets of various kinds and even antibiotics before they seek advice at all, and I do not think the answer is more and more tablets. A much more important difficulty in heavy seas is in carrying out leucocyte counts, but even this can be overcome, and I would rather be isolated at sea without a good deal of my medical equipment than without my microscope, which I have carried with me since my earliest days at sea.

I believe few doctors with any real experience of sea life would agree with Dr. Karve's assessment of the dangers of operating at sea. No one, of course, should be encouraged to operate at sea merely to demonstrate his ability to carry out a major operation. This is where a steamship company may score by retaining a staff of experienced ship surgeons. As a rule the ship surgeon who is confident of his ability to operate if things appear to be going wrong will stay his hand until it is absolutely necessary to interfere. I have myself carried out about thirty major operations at sea, one or two of those without any assistance, but the majority of them in liners with up-to-date hospital quarters and a trained nursing staff. As far as I know, only three of these cases failed to make a complete recovery. Nearly forty years ago I had to open up a skull with boring instruments supplied by the chief engineer and without any assistance. There was no evidence whatever of what Dr. Karve describes as "an act

amounting to murder." On the contrary, the man returned to duty the following voyage, having in the meantime been exhibited to medical students at Liverpool as an example of how to act in such an emergency.

Dr. Karve's estimate of what can be expected from or achieved by a ship surgeon even in a small ship is, I am sure, too low. In any case, only the doctor on the spot is in a position to say what should be done with a particular case of serious illness. He has certain obligations to the company paying him, as well as to the patient, and an experienced ship surgeon will study the interests of both. In general, I think personnel is of more importance than matériel at sea, though of course a certain minimum must be set to the latter. A permanent ship surgeon familiar with the conditions at sea and used to improvisations has obvious advantages over a temporary ship surgeon, provided that he has kept up to date in his work. No one has more opportunities and time for this than the permanent ship surgeon. Personally, by reason of my attendance at medical schools and hospitals for the past half-century, I have never quite lost the feeling of still being a medical student. I am grateful to Dr. Karve for bringing up so many interesting points.—I am, etc.,

Rustington, Sussex.

A. GARDNER.

G.P. Responsibility in Gynaecology

SIR,—I would like to comment upon the article on general practitioner responsibility in gynaecology by Mr. J. K. Russell and his colleagues (*Journal*, September 7, p. 558). A combined field study by G.P.s and consultants on this important subject is, I think, a very good idea. The comment made that standard textbooks fail to tell the student just how much responsibility he can reasonably take in general practice is, I think, accurate. It is a constant problem to the family doctor in this, as in all other branches of medicine, to know when to treat a patient himself and when to ask for an expert opinion. By and large rural patients prefer to stick to their own doctor, and those in industrial towns will think of the hospital more readily in the event of illness. Having embarked on treatment the family doctor needs experience and clinical acumen in knowing when to resort to a consultant. The patient must have the best treatment and management available. On the other hand, it is to my mind most unsatisfactory for a doctor who has been trained for six years and then had practical experience as a resident in hospital if he is not to shoulder some responsibility on his own.

May I now refer to some of the ailments discussed in the article? I think the one absolute indication in gynaecology for obtaining specialist aid is post-menopausal bleeding. For other cases of abnormal bleeding the doctor can only use his own judgment in obtaining further aid. In my opinion cases needing hormone therapy are best supervised by the consultant, and many too many cases of abortion, both threatened and inevitable, reach valuable hospital beds. In contrast to the opinion expressed by the authors I think that the family doctor is eminently suitable to investigate and treat patients with vaginal discharge and pruritus vulvae. Some cases will best be treated by surgical measures, and these are the ones that the G.P. should recognize and refer to the gynaecologist. He should know that discharge is a symptom of malignancy.

Too little stress is laid upon contraceptive advice in the student's training. It is essential to be able to give this. The subject should be raised in two situations: (1) at a woman's post-natal examination; and (2) to a couple where it is considered there have been too many children born too often. Careful explanations will be required to ignorant or distrustful patients. The authors do not define infertility. I think that if no conception has occurred after at least two years where normal married relations have existed, the couple will have to seek specialist aid. A family doctor should be able to run his own ring clinic for cases of prolapse if he so desires. A woman will wear a pessary for her prolapse if operative (curative) repair is contraindicated or

if, after careful explanations, she would rather not undergo these repairs. Thus I cannot agree that "they ought all to be referred for a gynaecological opinion."

The perfect G.P. knows something of the subject and he has some grasp of his own limitations. This article has made me think, though I disagree with much of its substance. The G.P. should not be thought of as being only a source of reassurance, sedatives, and analgesics, or regarded as a mere signpost to out-patients. He can take some responsibilities.—I am, etc.,

Saffron Walden, Essex.

J. D. C. COOK.

SIR,—I would like to make some comments concerning the article by Mr. J. K. Russell and his colleagues (*Journal*, September 7, p. 558). I believe practitioners have different capabilities, and one interested in gynaecology may treat non-operative conditions as well as the specialist. Because of this it would be difficult and burdensome to the student to attempt to define the sphere of the practitioner and specialist at an undergraduate level. If the subject is well taught the problem will solve itself as the practitioner realizes his own ability. The case of vaginal discharge treated in the Royal Victoria Infirmary merely reflects the inability of one particular practitioner to examine a gynaecological patient. This is not a sound argument for the referral of all these cases to a specialist.—I am, etc.,

Sidcup, Kent.

EDWIN C. WOOD.

Insufficiency of Internal Cervical Os

SIR,—The references given in the interesting letter by Dr. H. E. Reiss (*Journal*, August 24, p. 469) are all dated 1948 onwards, but it is not scientific to ignore my priority. The *C.B.C. Bulletin*, No. 2, was published in 1930 and reported a number of clinical cases recorded by myself of "Coital Interlocking: A Physiological Discovery." This is reprinted and is still obtainable from the Constructive Birth Control Society at 108, Whitfield Street, London, W.1.—I am, etc.,

London, W.1.

MARIE C. STOPES.

Selection of Medical Students

SIR,—In your annotation, entitled "The Student Looks at the Curriculum," in your educational number (*Journal*, September 7, p. 568) you quote, "Students are in general satisfied with the methods by which they are selected." It would have been more to the point if the rejected candidates for medical schools had been asked if they were satisfied with the methods by which they were rejected.

The number of candidates for medical schools far exceeds the number of places they have to offer. The usual method of selection is to ask candidates to fill in a simple questionnaire which asks his name, nationality, age, schooling, and hobbies. They then appear in front of a board of selectors varying from one to six people. On the basis of a ten-minute interview the selectors decide whom to accept. How does the ten-minute interview work? Are the selectors influenced by good looks or height? Is it true that an ability to play group ball games is an advantage? Are the accepted candidates more intelligent than the rejected ones? I would suggest that a study be made of the accepted and rejected candidates to see in what ways they differ. The qualities that are essential for passing the final M.B. examination are an ability to acquire and retain knowledge, and an ability to elicit and correlate facts. It would seem desirable to find out which of the candidates have these in greatest measure, and give them some preference.

In my opinion, the present technique for selecting medical students is a poor one. It is based on emotion rather than reason. It is important to improve this technique; for the simplest and cheapest way of improving the health of the country is to improve the quality of the medical student.—I am, etc.,

Salford, 8.

R. N. EBBING.

Obituary

OLIVER ST. JOHN GOGARTY, M.D., F.R.C.S.I.

Dr. Oliver St. John Gogarty died in hospital in New York on September 22, aged 79. During an era when Dublin glittered even more brightly than usual with an array of literary and artistic talent, Dr. Gogarty made his own very personal mark as a wit, scholar, surgeon, friend of poets and politicians, and finally as a poet, writer, and politician himself.

Oliver St. John Gogarty was born in Dublin on August 17, 1878, and educated at Stonyhurst College and at Trinity College, Dublin, where for four years in succession he was gold medallist in English verse. Graduating M.B., B.Ch., B.A.O. in 1907, he proceeded to the M.D. in the same year, and three years later became a Fellow of the Royal College of Surgeons of Ireland. He chose to specialize in diseases of the ear, nose, and throat, and at one time had consulting rooms in the Harley Street area as well as in Dublin. In 1914 he was honorary secretary of the Section of Laryngology, Rhinology, and Otology at the Annual Meeting of the B.M.A., and in the same year he published a paper in this *Journal* on "Latent Empyemata of the Nasal Accessory Sinuses." Among the hospital appointments he held were those of visiting surgeon and laryngologist to the Meath Hospital and County Dublin Infirmary and laryngologist and rhinologist to the Richmond Hospital, of which he was also a governor. He was honorary professor of anatomy for the Royal Hibernian Academy. During the busiest years of his professional life he had a very large practice.

In his young days Gogarty was a keen and successful athlete, being particularly fond of bicycle racing, as readers of *Tumbling in the Hay* will remember. Though he had a passionate love for Ireland, Gogarty was never an Anglophobe and he opposed the Sinn Féin uprising in 1921. Kidnapped one night by irregulars, he escaped by diving into the Liffey: an outcome of this was his book of lyrical poems, *An Offering of Swans*, published in 1924. In 1922 he became a Senator of the Irish Free State and remained one until the Free State Senate came to an end in 1936.

A notable member of Dublin society, Gogarty was a friend of W. B. Yeats, James Stephens, George Russell ("Æ"), James Joyce, George Moore, Arthur Griffith, and many others. Yeats encouraged him to write poetry, and, in fact, included some of his poems in the *Oxford Book of Modern Verse*. Gogarty figured as Buck Mulligan in *Ulysses*. Of this he said: "I am the only figure in *Ulysses* who swims, shaves, washes his neck, and brushes his teeth."

Gogarty's best-known book, *As I Was Going Down Sackville Street*, was published in 1937. One result of this was a libel action, which the author lost, £900 damages being awarded against him. *Tumbling in the Hay* (1939) contained the highly entertaining reminiscences of his student days: in the classic tradition of all such picaresque medical narrative—from Smollett to Richard Gordon—it possessed a somewhat Rabelaisian flavour. In 1940 Gogarty went to live in the United States, and there he wrote several novels and many short stories, and, in 1954, another book of memoirs, *It Isn't this Time of Year at All*. Besides writing for his living, Gogarty lectured extensively while in the United States, and in 1953 the Poetry Society of America awarded him its gold medal for his services to poetry.

Dr. Gogarty married Martha, daughter of Bernard Duane, in 1906. She survives him, together with two sons and a daughter.

HUGH MacLEAN, M.D., D.Sc., F.R.C.P., M.Sc.
Dr. Hugh MacLean, formerly professor of medicine in the University of London and director of the clinical medical unit at St. Thomas's Hospital, died at Northampton on September 18, aged 78.

Hugh MacLean was born at Kincardine, in Ross-shire, on April 23, 1879. At the University of Aberdeen, where he was a medical student, he came under the notice of the professor of physiology, Dr. T. A. McWilliam, who was an associate of Sir James Mackenzie. From an early stage in his career, therefore, MacLean was encouraged to concentrate on the physiological aspects of clinical medicine, and this was to bear fruit later in the results of his own research. Graduating M.B., Ch.B. in 1903, he proceeded M.D., with highest honours, in the following year. After working at Aberdeen as lecturer in physiological chemistry he was appointed to a similar post in Liverpool, where he took the degree of M.Sc. in 1910. Two years later he took the D.Sc. of London University. MacLean's first post in London was that of senior assistant in the biochemical department at the Lister Institute of Preventive Medicine. One result of his work there was a short book, *Lecithin and Allied Substances*, published in 1918. Shortly before the first world war he was appointed chemical pathologist at St. Thomas's Hospital. During the war he served with the R.A.M.C. in France. Nephritis was a relatively common disease among the troops, and, with O. L. V. de Wesselow, MacLean carried out a thorough investigation of renal efficiency tests. In 1919, after his return to St. Thomas's, he published a monograph on *Albuminuria and War Nephritis among British Troops in France*. In the same year he was appointed consulting physician to the Ministry of Pensions. MacLean's reputation as a thorough and lucid teacher and a clinical research worker of great ability was now established, and in 1920 he became professor of medicine at St. Thomas's and director of the medical unit at the hospital. In the same year he published (*British Journal of Experimental Pathology*, 1920, 1, 53), in collaboration with Professor de Wesselow, a famous paper on a new test for renal efficiency—the urea concentration test.

In 1922 MacLean was admitted M.R.C.P., and was elected to the Fellowship. He gave the Oliver-Sharpey lectures at the College in 1926 on "Carbohydrate Metabolism in Health and Disease." Diabetes was one of the diseases on which he was an authority, and he devised his own method for the estimation of blood sugar. He wrote a number of monographs for a special series on "Modern Methods," and among the subjects he chose to review were renal disease, diabetes, and digestion and gastric disease. In 1923 he was president of the section of pathology and bacteriology at the Annual Meeting of the B.M.A., and a few years later he served on the Association's Postgraduate Committee. He examined in medicine for London University.

MacLean did much for St. Thomas's, where, incidentally, he helped to develop the clinic system. In 1923 he was instrumental in obtaining the funds which, with the help of Sir William Dunn's generosity, made possible the establishment of the Dunn Laboratory at the hospital. During a visit to the U.S.A. in 1924 he saw Dr. Richard Pearce, of the Rockefeller Foundation, the trustees of which made a gift of £15,000 in 1925 towards the cost of the building of the medical unit at St. Thomas's. In 1929 MacLean visited Australia and fulfilled his many engagements there with characteristic energy.

In 1931 MacLean had to resign his appointments because of ill-health, but he continued to practise off and on, and wrote occasional articles for medical journals. For relaxation he played golf and fished. He was a first-class shot, and shooting was a favourite recreation. He married a distinguished member of the staff of the Lister Institute, Dr. Ida Smedley, who died in 1944. They had two children, a son and a daughter.

FERRIS N. SMITH, M.D., F.A.C.S.
Dr. Ferris Smith, an American plastic surgeon of international renown, died at Grand Rapids, Michigan, on September 18, aged 73.

Ferris N. Smith was born at Pontiac, Michigan, and studied medicine at the University of Michigan, where he graduated M.D. in 1910. After a short period of practice

in Ann Arbor he settled in 1913 in Grand Rapids, where he was surgeon to the Blodgett Memorial Hospital. Ferris Smith came to London during the first world war and gave his invaluable help to those who were then developing the treatment of war injuries by plastic and reconstructive surgery. After holding a commission in the R.A.M.C. he returned to the U.S.A. and became one of the founders of the specialty of plastic surgery in North America.

We are indebted to Sir HAROLD GILLIES for the following appreciation: Ferris Smith came to our first plastic hospital, The Queen's, Froggnal, Sidcup, soon after it was built in August, 1917. As an American surgeon *au fait* with the plastic work of that country and brimming over with enthusiasm and charm, it was easy for him to slip on to our surgical staff. He was given the honorary rank of captain, R.A.M.C. Heavy and many jaw and face injuries, literally thousands of them, were awaiting the solution of the problems of their restoration. Many revolutionary methods of repair were at that time going through trials and tribulations, and Ferris's judgment and sound common sense were a great asset in the solid foundation of our specialty.

It can be said with pride that the plastic surgery of today, here and in the U.S.A., indeed in the world, is largely based on the principles worked out by the mixed band of surgeons of which Ferris Smith stood out as a notable contributor. On return to the U.S.A. at the end of the first world war he brought home so many new experiences and so much clinical material in records that his writings and lectures won general commendation: so much so that with the aid of Vilray Blair, Eastman Sheehan, and others a veritable wave of plastic surgery started in the U.S.A. Our surgeons were often invited over for demonstrations and lectures to further the good cause. On such a visit one of the chief joys was to stay with Ferris and his wife Florence at Grand Rapids. Sad indeed to relate that, while nursing the unconscious Ferris at his lakeside home at Elk Rapids, Florence herself, a few weeks ago, dropped dead of a coronary thrombosis.

Of his many publications, not only does his book *Plastic and Reconstructive Surgery* (1950) stand as a lasting monument to his technical work, but he will also be remembered for his efforts in support of the American societies of plastic surgery, and above all in the establishment of the American Board of Plastic Surgery, whose chief function is to set and maintain a high standard of plastic surgery.

One of my hopes was that Ferris would live to read and enjoy my own recent book, which contained many references and tributes to his work. Alas, the autographed presentation copy lies unopened by his bedside. Ferris was a very forceful character: a fast driver himself, he hated being passed by another car, and jibbed quite a bit if crossed in argument about the relative merits of methods, surgeons, or political beliefs. It would be a long evening ahead if the subject turned to politics, about which Florence also had strong views. But both were ever eager to help any friend, and their pushful influence had much to do with my own career, for which I pay glad tribute. This delightful couple had no children, but a special message of sympathy goes out to his devoted secretary Miss Kay Richard.

HERBERT CAIGER, M.B., F.R.C.S., D.O.

Mr. Herbert Caiger, formerly ophthalmic surgeon to the Wharnccliffe Pensions Hospitals, Sheffield, died at Banstead, Surrey, on September 18, aged 91.

Herbert Caiger was born on August 12, 1866, at Lee, in Kent. From University College School he went on to University College Hospital, qualifying in 1890 and graduating M.B. of London University two years later. After holding the post of house-surgeon at University College Hospital he took the F.R.C.S. in 1891 and spent two years as a house-surgeon at the Royal London Ophthalmic Hospital.

In 1894 Mr. Caiger went out to South Africa and first practised at Jacobstaal, O.F.S., and then for 17 years at Burgersdorp, Cape Province. He won a well-deserved

reputation as a physician, published his clinical observations in a number of papers, and in 1912 was elected president of the section of medicine at the annual medical congress held in South Africa. Returning to England in 1914, he took the Diploma in Ophthalmology at Oxford and went into practice in Sheffield as an ophthalmic surgeon.

During the first world war Mr. Caiger was visiting civil surgeon attached to the Wharnccliffe War Hospital, Sheffield, and after the war he published a paper reporting the results of 700 ophthalmic examinations of ophthalmic pensioners. A very active supporter of the B.M.A., of which he was a member for 63 years, he was chairman of the Sheffield Division in 1921, and served on a number of the Association's committees—including the Committee on Miners' Nystagmus. He was vice-president of the Section of Ophthalmology at the Annual Meeting in 1928. He had a profound faith in Christianity and in recent years had drawn the attention of his colleagues to the significance of St. Luke's Day in a number of letters to this *Journal*. In 1922 he contributed a long, thoughtful, and helpful letter to this *Journal* on the subject of the radical prevention of venereal disease: this he wrote from the point of view of a "moral idealist."

Mr. Caiger retired in 1943, and had been living in Banstead for the past ten years or so. At the time of his death he had been a Fellow of the Royal College of Surgeons for over 66 years and then was among the most senior of the Fellows.

Dr. H. BROWN writes: To many of his former colleagues and personal friends in Sheffield the death of Mr. Herbert Caiger recalls happy memories. I had known him since he came to Sheffield as an ophthalmic surgeon, after a period of practice in South Africa, and can speak especially of his long and active interest in the British Medical Association. When invited, in 1921, to become chairman of the Sheffield Division, Mr. Caiger protested, as one would expect, that he had not been long enough in the city to deserve the honour, and that there were others who should come before him. The members, however, thought otherwise, and found in him a very active and able chairman. At the A.R.M. Caiger was a familiar and popular figure, representing the Division eleven times between 1921 and 1939; while for many years he was a most helpful and stimulating member of the borough council and of the divisional executive. Though Mr. Caiger's general political outlook led at times to disagreement with B.M.A. policy, he would always loyally support decisions once arrived at. A deeply religious man, he was a devout Churchman, and as a preacher he often occupied local pulpits. His generosity was outstanding, and for many acts of kindness he will be remembered with gratitude. To me it has been a privilege to know Herbert Caiger well, and to have enjoyed his friendship.

VERA NORRIS, Ph.D., M.B., Ch.B.

Dr. Vera Norris, who died on September 16 at the age of 37, had already achieved a reputation for her work in medical statistics before illness began to curtail her activities four years ago.

From Mary Datchelor School Vera Norris went on to study medicine at the University of St. Andrews, where she graduated M.B., Ch.B. in 1944. After house appointments at the Dundee Royal Infirmary she served in the Indian Army Medical Corps between 1945 and 1947. Returning to England, she went to Birmingham University with a Hailey Stewart Research Fellowship, and received her training in medical statistics under Professor Lancelot Hogben, F.R.S. From 1949 to 1951 she was senior statistical officer to the Birmingham Regional Hospital Board and lecturer in medical statistics at Birmingham University, which awarded her the degree of Ph.D. Her stay in Birmingham covered a period of change in the health services occasioned by the National Health Service Act of 1948, and she made important contributions to the statistical planning for the region, publishing an article on the subject in this *Journal*.

In 1951 Dr. Norris joined the Institute of Psychiatry at the Maudsley Hospital as lecturer in Professor Aubrey Lewis's department, and began to devote herself almost exclusively to problems of mental health. The results of her main investigation will shortly appear as No. 6 in the Maudsley Monograph Series, with the title of *Mental Illness in London*. She collaborated with her clinical colleagues in a number of studies on the outcome in schizophrenia and the senile psychoses and the length of stay in hospital of patients with these disorders. She was a valued member of the Registrar-General's Statistical Committee.

Vera Norris was plentifully endowed with the rare capacity for clear thinking, which manifested itself throughout her work. Moreover, she had energy, the ability to go straight for her main goal, and the power of lucid and forthright expression. She never lost sight of the people about whom she collected statistics, and her strong sense of social justice provided inspiration for the work she did. When she knew that time was against her, she moved with her husband, Dr. Donald Mackay, and their small son to the hospital in Inverness to which he had been appointed in order to devote herself to the tasks of a wife and a mother. But she found herself unable to neglect her professional interest entirely and assisted the regional board there in its statistical work until she was unable to carry on any longer.

Those who have known Vera Norris at various periods of her life will probably prefer to recall her best as a gay and vivacious member of an Army mess in India, where her humour, honesty of purpose, and candour without malice earned her lifelong friends—as was to happen over and over again wherever she moved in the course of her work.

—D. L. D.

JAMES MACKINNON, D.S.O., M.B., Ch.B.

Dr. James Mackinnon, who practised in Sheffield for many years, died on September 8 at the age of 80. Although he had retired from practice for some years, his influence remained a powerful force among his colleagues.

James Mackinnon was born in Glasgow on October 26, 1876, and was educated at Allan Glenn's School and Glasgow University, graduating M.B., Ch.B. in 1900. As an undergraduate he represented the university in swimming, and his team were the champions in the inter-university aquatic sports in 1899. He became a house-physician and later a house-surgeon at the Victoria Infirmary in Glasgow, and was then resident physician at the Leith Fever Hospital. He started in private practice as an assistant in West Hartlepool, but moved to Sheffield in 1903, first as an assistant to the late Dr. Longbottom in the Pitsmoor district of the city, with whom he later entered into partnership, ultimately succeeding to the practice. He very soon impressed his forceful personality and high ideals on his medical colleagues. His erect figure and handsome mien made him conspicuous in any company. He was an excellent clinician, and often it was the consultant who learnt something when meeting him at a case, rather than the reverse. It was also always very obvious that his patients had the most implicit faith in any advice he gave them, and he never spared himself on their behalf.

In 1912 he joined a local field ambulance as an officer in the Territorial Army, and, as in everything he undertook, immediately began to make himself as efficient as possible. He went to France in March, 1915, as the second in command of the 1/3 West Riding Field Ambulance, which was one of the three attached to the 49th Division. Later in the year he was given the command with the rank of lieutenant-colonel, and remained as such until March 1, 1918, when he was appointed A.D.M.S. to the 66th Division. On August 14, 1916, he was awarded the D.S.O. for an outstanding contribution to the improvement of camp sanitation. The first world war was static for many months, and the 1/3 West Riding Field Ambulance remained stationary, four miles behind the front line, for nearly a year. In addition to the usual work of establishing first-aid posts, the

evacuation of sick and wounded, and supplying regimental medical officers when necessary, the ambulance had to establish a field hospital for the admission and treatment of cases of scabies. Several hundreds of these men might need a few days' treatment, at any one time, before being returned to their units. The disposal of excreta and the supply and maintenance of a sufficient and efficient supply of hot water for baths became a very urgent problem, which Mackinnon solved by constructing an incinerator serving both purposes. When an Old Comrades' Association was formed in connexion with the local R.A.M.C. Territorial units in Sheffield, he was elected president. The association met for an annual dinner every year since, except during the second world war, and the president missed only one dinner.

As a soldier and also in civilian life, James Mackinnon was a stern disciplinarian, and, being a born leader, would not tolerate slackness. He saw clearly, and, unlike the politician with his eye fixed on the next election, had the statesman's vision of the effect which any action might have on the next generation. His sincerity, integrity, moderation, and tolerance of the other man's point of view was such that he was elected chairman of the local medical and panel committee from 1924 until the National Health Service was inaugurated in 1948. He had been chairman of the Sheffield Division of the British Medical Association and also chairman of a National Service Medical Board from 1939 to 1952. The leader of almost every deputation from the British Medical Association when interviewing the local authority, he could be relied upon to put the medical case before the meeting with moderation and effect. His wisdom, breadth of vision, and willingness to sacrifice himself for the Association were manifest throughout his working years. Men trusted him. Two of his professional colleagues and neighbours write: "We have known him for thirty years as a friend and fellow practitioner. As newcomers to practice in the locality we still treasure the memory of a warm welcome and the generous hospitality we received from him and his charming, gifted wife. His honesty and sincerity were always manifest in his readiness to help young practitioners in their difficulties. The ideals he followed in his own practice and the standard he set himself were an inspiration to all."

In spite of his professional work, Jimmy Mackinnon managed to lead an athletic open-air life almost to the end, and he had no use for the man who did not play to win. He was a founder member of the Sheffield Medical Golfing Society—in fact the idea originated with him. A keen curler, he was skip of the rink of the Sheffield Curling Club, which takes part in national competitions. For seven years he was president of the Caledonian Society of Sheffield. He held strongly to the Presbyterian faith and was a deacon of his church. It can be truly said: he knew himself, he knew men, he knew his God, and lived his religion. We in Sheffield have been fortunate in having James Mackinnon working among us since 1903. Like a true leader he multiplied his life by developing young men to follow in his footsteps. To them he always gave recognition and generous credit for their achievement. To his wife and family we extend the deepest and most sincere sympathy in their bereavement.—J. A., J. C., J. M. P.

OSCAR OLBRICH, Ph.D., F.R.C.P.Ed.

The obituary of Dr. Oscar Olbrich was printed in the *Journal* of September 14 (p. 648).

W. H. L. writes: I did not become closely associated with Oscar Olbrich until 1950, when, knowing nothing of geriatrics and only a little of the man, I had the good fortune to become his registrar. I did not know then that I was to work with him for the next four years. It was typical of him that, aged 50 and a newcomer to the land, he should take on a classic, chronic provincial institution and know that within five years he would make it into a hospital for people of pensionable age and over, with standards of diagnosis and treatment comparable to any teaching hospital. This, I think, was his greatest work.

He was blessed with a glorious sense of humour and of the ridiculous and a genuine love and understanding of mankind: he could extract from the most unlikely human material the best that was in them plus something else. As a teacher he was outstanding, and many people owe their "Memberships" to him.

He was a dominating personality, liking above all to set people thinking and to provoke discussion. His intellectual restlessness and impatience with anything or anyone he considered mistaken or artificial often prompted him into making remarks or asking questions regardless of the social circumstances. In the ensuing confusion he would remain apparently unembarrassed, and "the cap" generally fitted well. Such a man, of course, is at times awkward company for the ordinary run of people, and his motives were sometimes misunderstood. He was a most tolerant man capable of the greatest kindness and sympathy: he never refused to give help when it was needed and would go to enormous lengths.

Sir CHARLES READ, P.R.C.O.G., M.B., F.R.C.S.
F.R.C.S.Ed., F.R.A.C.S.

The obituary of Sir Charles Read was printed in the *Journal* of August 31 (p. 529).

W. R. writes: Sir Charles Read succeeded Bright Banister at the Northwood, Pinner and District Hospital in 1932, and began a long and happy association with that hospital. He got through twice as much work as the average surgeon with half the toil. Like his brain, his work was swift and accurate. It has been said that the best way to find out about a surgeon's quality and character is to ask his house-surgeons. They will usually be devastatingly frank. I think a better method is to inquire among the body of men who send the surgeon their cases: they are surely more mature and critical assessors. No man showed more attention and kindness to the doctors who brought him their work. Read entered at once into a partnership with the doctor, which is an art in itself not given to many. All of us who worked with him at Northwood for so many years will remember the reports he sent us about our cases, his prodigious memory, and his punctuality. If ever problems arose with patients, Charles Read was always ready to meet a further opinion—perhaps the best and most generous quality of all, but he had so many fine qualities that it is difficult to single them out. He made many friends everywhere, and I am sure no lasting enemies. When the great Treves died over thirty years ago, Thomas Hardy wrote words that apply to Sir Charles Read to-day:

"A marvellous deftness called you forth—to do
Much that was due.
Good. You have returned. And all is well."

Medico-Legal

DEATHS FROM WASP STINGS

Two recent cases of death by misadventure in consequence of a wasp sting have come before the coroners' courts. On September 13 an inquest was held at Guildford on a married woman of 56 who was said to have died from shock after being stung by a wasp. The woman's husband said that he had been twice stung before and each time had had a fainting turn. Dr. David Haler, pathologist, said the sting had penetrated a superficial vein in the woman's arm. She had been sensitized by the previous stings and she had died from severe shock in response to this one. The second case was of a married woman aged 52, and she died within five minutes of being stung. Her husband said that she was stung in the third finger of her left hand. She had been stung previously, and on that occasion she fainted twice and was ill for several days. Dr. M. Symons, pathologist, said death was due to anaphylactic shock and it was possible that the sting had pierced a vein.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending September 7 (No. 36) and corresponding week 1956.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES in Countries and London	1957					1956				
	Eng. & Wales	London	Scotland	N. Ireland	Eire	Eng. & Wales	London	Scotland	N. Ireland	Eire

* Measles not notifiable in Scotland, whence returns are approximate.

† Includes primary and influenza pneumonia.

§ Includes puerperal pyrexia.

Vital Statistics

Influenza

Deaths from influenza in the great towns in the week ending September 14 were as follows, with the figures for the previous week in parentheses: England and Wales 47 (8), Scotland 1 (0), Northern Ireland 0 (0), and Eire 0 (0). Towns with more than one death from influenza were as follows: Sheffield 7, Burnley 4, Birmingham 3, Dudley 2, West Bromwich 2, and London 3.

The regional distribution of deaths from all causes, influenza, pneumonia, and bronchitis in the 160 great towns for the week ending September 14 was as follows:

Region	All Causes	Influenza	Pneumonia	Bronchitis
Northern	291	4	15	8
E. and W. Ridings	618	14	50	19
North-western	829	14	65	50
North Midland	287	3	9	8
Midland	454	7	13	18
Eastern	226	1	9	7
London and S.E. (including Greater London)	1,530	4	68	43
Southern	195	0	5	1
South-western	228	0	10	3
Wales	143	0	7	4

The age distribution of the 47 deaths in England and Wales was as follows: under 1, 1; 1-4, 1; 5-14, 8; 15-24, 3; 25-34, 1; 35-44, 3; 45-54, 6; 55-64, 8; 65-74, 12; 75 and over, 4.

Notifications of pneumonia in England and Wales for the week ending September 14 showed an increase of 127 over the previous week. In the 160 great towns, during the same period, pneumonia notifications increased by 85, pneumonia deaths by 68, influenza deaths by 39, and bronchitis deaths by 30. Weekly new claims on Ministry of Pensions and National Insurance rose by 32,171 to 168,341.

Poliomyelitis

The incidence of poliomyelitis again sharply declined. Notifications (uncorrected) in England and Wales in the week ending September 14 were as follows, with the figures for the previous week in parentheses: paralytic 116 (158), non-paralytic 84 (121), total 200 (279). Total cases in Scotland were 13 (12), Northern Ireland 18 (13), and Eire 6 (4).

In Yorkshire West Riding 16 cases were notified (Leeds C.B. 10). The outbreak in Kent continued with 15 cases (Broadstairs and St. Peter's U.D. 2, Sevenoaks R.D. 2), while in Essex 14 cases were notified (Southend on Sea C.B. 2, Harlow U.D. 2, Thurrock U.D. 2). In Lincs (Lincoln C.B. 3), and in Warwickshire 6 cases (Birmingham C.B. 3). The 15 cases in London were spread over 10 boroughs, none with more than 2 cases.

Of the 18 cases in Northern Ireland, 6 were notified from Belfast C.B. and 5 from County Antrim.

Week Ending September 14

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 323, whooping-cough 771, diphtheria 2, measles 1,237, acute pneumonia 333, dysentery 213, paratyphoid fever 15, typhoid fever 4. There were 47 deaths from influenza in the 160 great towns, as compared with 8 the previous week.

Infectious Diseases

With the exception of measles only small changes occurred in the trends of the notifications of infectious diseases in England and Wales during the week ending September 7. The largest falls were 932 for measles, from 3,005 to 2,073, 43 for food-poisoning, from 266 to 223, and 28 for acute poliomyelitis, from 307 to 279; the largest rises were 27 for scarlet fever, 245 to 272, and 22 for acute pneumonia, from 184 to 206.

The largest declines in the incidence of measles were 116 in Yorkshire West Riding, from 263 to 147, 71 in Dorsetshire, from 120 to 49, 68 in Leicestershire, from 163 to 95, and 64 in Somersetshire, from 109 to 45. Only small fluctuations were reported in the local trends of scarlet fever. 1,013 cases of whooping-cough were notified, being 3 more than in the preceding week. The largest variation in the local returns of whooping-cough was an increase of 34 in Yorkshire West Riding from 41 to 75; this rise was mainly due to an outbreak of 21 cases in Thorne R.D. Only 1 case of diphtheria was notified compared with 6 in the preceding week.

The notifications of dysentery numbered 220, 4 fewer than in the preceding week. The chief centres of infection were Lancashire 51 (Liverpool C.B. 15), Yorkshire West Riding 49 (Leeds C.B. 25), and London 28.

Of the 7 cases of diphtheria notified in Scotland, 5 were reported from Glasgow.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the years 1948-56 are shown thus ———, the figures for 1957 thus ———. Except for the curves showing notifications in 1957, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Medical News

American Report on Common Cold Vaccine.—The *New York Times* of September 19 quotes Dr. WINSTON H. PRICE, Ph.D., of Johns Hopkins University, as claiming that he has developed "the first successful vaccine against a major common cold virus." Dr. Price's appointment is given as director of the division of medical ecology at the University's School of Hygiene and Public Health. The same issue of the *New York Times* contains a three-column scientific paper on the preparation and trial of the vaccine. This paper is stated to be "the text of the article written by Dr. Winston H. Price for the September issue of the *Proceedings of the National Academy of Sciences*." The vaccine—a killed one—was made from a "common-cold" virus isolated by Dr. Price and named J.H. virus (after Johns Hopkins), which proved able to grow in tissue culture. The vaccine trial was controlled and blind. An upper respiratory infection attacked a group of 100 children, living under the same roof, some five weeks after their second inoculation. J.H. virus was recovered from two cases, but not streptococci, adenoviruses, Coxsackie or influenza viruses. Three of the 50 children who had had the vaccine developed respiratory symptoms, compared with 23 of the 50 controls; 20 of the children with symptoms showed a rise in antibody titre to the J.H. virus. The virus is being studied in Britain at the Medical Research Council's common cold research unit. Work on it began there about three months ago.

New Surgical Block at Guy's.—We illustrate on this page an artist's impression of the new surgical block at Guy's Hospital, for which the building contract was signed this week. Clearing of the site, to the east of the hospital, is already well forward, and building is expected to begin very shortly. The new block will have eleven stories. On the lower ground floor, there will be a deep-x-ray department and a central sterilizing department for the whole hospital; on the ground floor the hospital's main casualty department

[By permission of Guy's Hospital Gazette]

with four theatres; on the first floor eight main operating theatres, cystoscopy and plaster theatres, and a clinical lecture theatre; on the second floor, office, laboratory, teaching, and some residents' accommodation; on the third to the ninth floors there will be wards providing 378 beds. The new block is the first major step in the rebuilding of Guy's. The block will take about three years to complete and its overall cost is put at over £2.25 million. The architect is Mr. A. S. GRAY, F.R.I.B.A.; Mr. PAUL G. BURT, of Chicago, is associate consulting architect to the board of governors. The latter was appointed because the height of the block—"the first semi-skyscraper hospital to be built in this country"—presented special problems. A full account of the new block is given in the September 14 issue of *Guy's Hospital Gazette*.

Oliver Bird Trust.—In July, 1957, a charitable fund was established with the title of the Oliver Bird Trust, the trustees being Mrs. M. A. PYKE, The Hon. Mrs. BURRELL,

and Dr. A. S. PARKES, F.R.S. The Trust has as its object the advancement of knowledge of methods of fertility control with special reference to the promotion and provision of facilities for tests and clinical trials of systemic methods of contraception as they become available, and in the meantime for the improvement of locally acting-spermicides. The office of the Trust is at 64, Sloane Street, London, S.W.1 (tel.: Sloane 0451). Immediate steps being taken by the trustees include:

(1) The offer in each of the next five years of an Oliver Bird prize for laboratory or clinical work bearing on the control of conception. The prize will consist of a cash award of not less than £250 and the Oliver Bird medal for the year. The first prize will be offered for award early in 1958, and application should be made not later than December 31, 1957. An announcement to this effect and a statement of the conditions of the award is being widely distributed.

(2) The arrangement annually of two Oliver Bird lectures: (a) A "background" lecture, given with the aim of promoting in medical and scientific circles recognition of the importance of investigating fertility control; (b) a "technical" lecture, to be sponsored by the Society for the Study of Fertility, dealing with the scientific aspects of the technical problem.

The first of the technical lectures will be given on November 6 by Dr. T. MANN, F.R.S., on "The Biochemical Basis of Spermicidal Activity."

(3) The setting up of a Council for the Investigation of Fertility Control, which will work in conjunction with the Family Planning Association and will be responsible for organizing tests and clinical trials in this country and elsewhere.

Chartered Society of Physiotherapy.—The annual congress dinner of the Chartered Society of Physiotherapy took place at the Park Lane Hotel, London, on September 19, with the president of the Chartered Society, Sir CECIL WAKELEY, Bt., in the chair. The principal guest was Dame ENID RUSSELL-SMITH, deputy secretary, Ministry of Health, who proposed the toast of the Chartered Society and its founders. Dame Enid, though pleading ignorance of her subject, showed much insight into the affairs of the profession of physiotherapy and stressed that one of the significant things in its history was that it began on an admirably ethical foundation. Dilating on the present need for the team to take on responsibilities that once belonged to the individual, Dame Enid told her audience that their place in the health team was a most valuable one. The vice-chairman of the council of the Chartered Society, Miss SYBIL M. EVANS, responded. Physiotherapy, she said, was the oldest of the ancillary professions and the Chartered Society now had 15,000 members in all parts of the world on its roll. She expressed alarm, however, that because of the present grave shortage of teachers standards could not be maintained. Sir CECIL WAKELEY welcomed the many distinguished guests present, on whose behalf Lieutenant-General Sir ALEXANDER DRUMMOND, Director General, Army Medical Services, replied. In doing so he emphasized the importance of physiotherapy in the armed Forces.

New Members of the Medical Research Council.—The Committee of the Privy Council for Medical Research, after consultation with the Medical Research Council and with the President of the Royal Society, have appointed Professor A. A. MILES, professor of experimental pathology in the University of London and Director of the Lister Institute of Preventive Medicine, and Professor C. H. STUART-HARRIS, Sir George Franklin professor of medicine in the University of Sheffield, to be members of the Medical Research Council.

Army Medical Advisory Board.—The War Office announces that Professor JOHN BRUCE, Regius professor of clinical surgery at Edinburgh, has been appointed a member of the Army Medical Advisory Board. The composition of the Board is now as follows: *president*, Lieutenant-General Sir ALEXANDER DRUMMOND; *chairman*, Lord MORAN; *members*, Dr. E. R. BOLAND, Sir ARTHUR PORRITT, Dr. E. R. CULLINAN, and Professor JOHN BRUCE; *secretary*, Colonel D. M. AHERN.

COMING EVENTS

Proteins.—The Nutrition Society will hold a symposium on the "Nutritive Value of Proteins" at the Royal Free Hospital School of Medicine on October 12. Full details from Miss D. F. Hollingsworth, c/o Ministry of Agriculture, Great Westminster House, Horseferry Road, London, S.W.1.

British Association of Physical Medicine.—1958 annual meeting, April 25 and 26, 1958, at Royal Free Hospital, Gray's Inn Road, London, W.C.1. Members wishing to read a paper or show a film should submit the title (and in the case of papers an abstract) by November 30, 1957, to the secretary of the association, 45, Lincoln's Inn Fields, London, W.C.2.

Sheffield University Medical Faculty.—Dr. T. F. Fox will give the opening sessional address at 5.0 p.m. on October 10 in the Firth Hall of the University. His subject will be "Pride and Prejudice."

Royal Free Hospital School of Medicine.—Mr. JUSTICE LLOYD-JACOB will give the inaugural address at 3 p.m. on October 4 at the Senate House, London University.

"The Needs of the Mentally Sick—A Challenge to Youth."—Conference on mental nursing as a career, arranged by the National Association for Mental Health, October 17, at York. Open to the public; details from the secretary of the association, 39, Queen Anne Street, London, W.1.

Faculty of Radiologists.—Provincial meeting, Liverpool, October 5. Details from the secretary, Faculty of Radiologists, 45, Lincoln's Inn Fields, London, W.C.2.

Middlesex Hospital Medical School.—"Refresher Course" for old Middlesex men October 4-6, annual dinner October 4. Details from the secretary of the School.

Medical Protection Society.—Annual meeting, October 2, at 3 p.m. at Victory House, Leicester Square, London, W.C.2.

"Scientific Basis of Medicine."—Inaugural lecture of the British Postgraduate Medical Federation will be given on October 17 at 5.30 p.m. by Dr. JULIAN HUXLEY, F.R.S., at the Senate House, London, W.C.1. Dr. Huxley's subject will be "Some Biological Aspects of Cancer."

Microbiological Techniques.—Demonstration by the Microbiology Group of the Society of Chemical Industry at 5.30 p.m., October 18, at Borough Polytechnic, Borough Road, London, S.E.1. Details from Mr. W. W. REID, Research Department, Carreras Ltd., 221, Stanhope Street, London, N.W.1.

Psychiatric Films from France.—October 17 at 6.30 p.m. at the Mezzanine Cinema, Shell Mex House, Strand, London, W.C.2. Films shown by courtesy of the Scientific Bureau of the French Embassy, under the auspices of the medical committee of the Scientific Film Association and the education committee of the Royal Medico-Psychiatric Association. Admission free, no ticket.

Electrical Techniques in Medicine and Biology.—Tenth annual congress, November 6-8, at Boston, Mass. Details from Dr. C. BERKLEY, R.C.A. Laboratories, Princeton, New Jersey, U.S.A.

Welsh National School of Medicine.—Two postgraduate courses for general practitioners: "Cardiovascular Diseases," October 28 to 30; "Paediatrics," October 31 to November 2. Further information from the secretary of the School, 34, Newport Road, Cardiff.

Wessex Rahere Club.—The autumn dinner will take place at the Lansdown Grove Hotel, Lansdown, Bath, on October 26. Membership of the club is open to all Bart's graduates practising in the West Country. Further details from Mr. A. Daunt Bateman, 11, The Circus, Bath, Somerset.

Morison Lecture.—Dr. W. RITCHIE RUSSELL will deliver the Morison Lecture on October 24 at 5 p.m., at the Royal College of Physicians, 9, Queen Street, Edinburgh, 2. His subject will be "The Physiology of Learning."

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked •. Application should be made first to the institution concerned.

Tuesday, October 2

LONDON UNIVERSITY.—At Westminster Medical School (Meyerstein Lecture Theatre), 5.30 p.m. Professor E. M. Papper (Columbia University): Circulatory Complications of Improper Respiration during General Anaesthesia.

NORTHAMPTON MEDICAL SOCIETY.—At Northampton General Hospital, 8 for 8.30 p.m., Presidential Address by Mr. W. Charles Gledhill: Scope of Modern Surgery in the Treatment of Deafness.

UNIVERSITY COLLEGE HOSPITAL: DEPARTMENT OF BIOCHEMISTRY.—At Physiology Theatre, Gower Street, W.C., 5 p.m., public lecture by Professor M. Heidelberger (U.S.A.): Chemistry of Proteins and Carbohydrates in Relation to Immunological Specificity.

WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Mr. G. C. Knight: Intracranial Abscess.

Wednesday, October 3

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. W. Riddell: Role of Fungus in Dermatology.

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Mr. N. R. Barrett: Pulmonary Hydatid Disease.

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—5.30 p.m., Dr. H. Haber: Precancerous Conditions of Skin and Mucous Membrane.

INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Mr. J. D. Fergusson: Prostatic Cancer.

MIDLAND MEDICAL SOCIETY.—At Birmingham Medical Institute, 8.15 p.m., Sir Ian Fraser: Recent Medical Visit to Soviet Russia (illustrated).

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Professor N. F. MacLagan: Place of Chemical Pathology in Medicine.

YORKSHIRE SOCIETY OF ANAESTHETISTS.—At General Infirmary at Leeds, 8.30 p.m., Mr. G. A. Hay, M.Sc.: Electronics in Anaesthesia.

Thursday, October 3

FACULTY OF HOMOEOPATHY.—5 p.m., Dr. F. H. Bodman: Some Observations on the Treatment of Neurosis in Children.

LONDON JEWISH HOSPITAL MEDICAL SOCIETY.—At Medical Society of London, 8.30 p.m., Presidential Address by Dr. Samuel Sacks: The Bible in Art.

NUFFIELD ORTHOPAEDIC CENTRE.—At Wingfield-Morris Orthopaedic Hospital, 8.30 p.m., Dr. J. Risser: Concepts of Scoliosis.

ROSS INSTITUTE INDUSTRIAL ADVISORY COMMITTEE.—At Council Chamber, Rubber Growers' Association, 19, Fenchurch Street, E.C., 2.15 p.m., Dr. O. J. S. Macdonald: Present-day Health Problems on Plantations (with special reference to housing).

ROYAL SOCIETY OF HEALTH.—At St. John Hall, Westway Road, Weymouth, 10.30 a.m., Dr. Katharine Williams: Public Health Aspects of Atomic Energy. Dr. D. A. Ogden: A New Approach in the Treatment of Delinquents.

ST. MARY'S HOSPITAL MEDICAL SCHOOL (WRIGHT-FLEMING INSTITUTE THEATRE).—5 p.m., Professor E. Kerpel-Fronius (University of Pecs): Metabolic Aspects of Infantile Malnutrition.

•SOCIETY OF CHEMICAL INDUSTRY: FOOD GROUP AND ASSOCIATION OF PUBLIC ANALYSTS.—At Royal Society of Medicine (Thursday, October 3, 10 a.m., and Friday, October 4, 9.30 a.m.), Symposium: Quality Control of Food.

Friday, October 4

•INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. S. C. Gold: clinical demonstration.

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. J. Smart: clinical demonstration.

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—3.30 p.m., clinical discussion for general practitioners by Dr. C. H. Edwards: Neuralgias and Headaches.

KING'S COLLEGE HOSPITAL MEDICAL SCHOOL.—At Medical School Lecture Theatre, 4.30 p.m., 10th Thomas Percy Legg Memorial Lecture by Sir Cecil Wakeley, Bt.: Some Aspects of External Herniae.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—10 a.m., Mr. H. H. G. Eastcott: Second Thoughts on Arterial Reconstruction.

WHIPPS CROSS HOSPITAL MEDICAL SOCIETY.—8.30 p.m., Dr. C. Raeburn: Cancer Arising in Scarred Lungs.

Saturday, October 5

NORTH-EAST METROPOLITAN THORACIC SOCIETY.—At Broomfield Hospital, near Chelmsford, joint meeting with East Anglian Thoracic Society, 11 a.m., Mr. G. Flavell: Pulmonary Cysts; 11.45 a.m., Mr. M. Bates: Plastic Procedures to the Bronchus; 2.15 p.m., Dr. C. Van Zwanenberg: A Systematic Search for Tuberculosis; 3 p.m., Dr. L. Capper: Treatment of Tuberculous Neck Glands.

NORTH OF ENGLAND OTOLARYNGOLOGICAL SOCIETY.—At York County Hospital, 2 p.m., annual meeting.

Sunday, October 6

UNIVERSITY COLLEGE HOSPITAL.—At Hospital for Tropical Diseases, 10.15 a.m., lecture-demonstration for general practitioners by consultant staff of the Hospital for Tropical Diseases: Tropical Diseases Likely to be seen in General Practice in the British Isles.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Castle.—On September 2, 1957, at Duke of York Home, Bradford, Yorks, to Drs. Joan (formerly Ingham) and John Castle, a son—Graham John Henry.

Hamilton.—On September 15, 1957, at the Garrett Anderson Maternity Home, to Dr. Margaret Hamilton, F.F.A.R.C.S., wife of Albert Lerse, a daughter.

Maclure.—On September 6, 1957, in Lincoln, to Dr. Nancy Maclure, J.P. (formerly Macfarlane), wife of Dr. W. Alastair Maclure, a daughter.

DEATHS

Harvey.—On September 22, 1957, at the Military Hospital, Colchester, Essex, George Alfred Duncan Harvey, C.B., C.M.G., L.R.C.P.S.I. & L.M., Major-General, late R.A.M.C., retired, of Crastons, Boxed, Colchester, aged 74.

Hillman.—On August 29, 1957, at Guy's Hospital, London, S.E., Leslie Michael Hillman, M.R.C.S., L.R.C.P.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Prophylactic Gargling

Q.—What value has gargling in the prevention of respiratory infections such as colds, streptococcal throats, and influenza? Is indiscriminate gargling harmful or likely to reduce local resistance to infection?

A.—I know of no evidence that gargling has any effect in preventing throat infection; trials have been made of the preventing throat infection; trials have been made of the use of lozenges containing sulphonamides or penicillin, and it is generally agreed that they are useless in preventing or treating infection. I doubt whether gargling is, in any ordinary circumstances, likely to do harm.

Prolonged Penicillin Prophylaxis

Q.—Quite often, as in cases of chronic bronchitis, the specialist advice is intensive penicillin followed by a much smaller prophylactic dose over a period of weeks. Surely this must result in the development of resistant strains of micro-organisms?

A.—One of several unique properties possessed by penicillin is that, generally, bacteria do not acquire resistance to it as they may with most other antibiotics. Resistance in staphylococci is the result not of adaptation but of selection, the few originally rare resistant strains having come to predominate following the elimination of sensitive ones. A common cause of chronic bronchitis is the pneumococcus. Jones and Finland¹ have recently compared the sensitivity to antibiotics of present-day strains of this organism with strains isolated in 1949, and report no change in sensitivity to penicillin. It is perfectly logical to use full doses to eliminate an infection and small ones to prevent recurrence. It is of course desirable to know that the first stage of treatment had the desired effect.

"Shock" after Immunization

Q.—When immunizing large numbers of schoolchildren there is generally an occasional child who becomes pale, sweats, feels ill and nauseated, and has a thready pulse. Is this anaphylactic or psychological shock? Is it advisable to administer adrenaline to such children? They seem to recover in an hour or so. The antigens used have been diphtheria toxoid-antitoxin floccules (T.A.F.), diphtheria-diphtheria toxoid-antitoxin floccules (D.P.P.), and diphtheria alum-precipitated toxoid (A.P.T.). My last case was with T.A.F.

A.—In some cases the symptoms described may be allergic, in others psychological. As the cause in an individual case may be difficult to determine, it is probably wise to administer adrenaline if there is any anxiety. This drug and a syringe should always be in readiness for immediate use whenever any injection of a biological product is given. Although T.A.F. is one of the mildest prophylactics, it has been known to cause trouble from anaphylaxis in rare instances: it contains a small amount of horse serum, to which a person may have become sensitized. In the M.R.C. Report on vaccination against whooping-cough¹ a very few children were said to be pale and limp between screaming attacks in the evening of the day of injection. These minor episodes were not confined to any one of the three injections of the vaccine. In over 30,000 vaccinated children there was no definite evidence that convulsions or encephalopathy was directly related to pertussis vaccination. Moreover, precautions were taken to exclude children with a personal or

family history of convulsions, epilepsy, etc., or a recent history of an infectious fever or smallpox vaccination. Perhaps some of the symptoms mentioned in the question were analogous to those observed in younger children in these official trials. A psychological element predominates in the brief period of collapse after an injection occasionally noted in members of some families. The attitude of the mother, teacher, or nurse may be an important determining factor.

X-ray Epilation

Q.—Can exposure to x rays produce a form of epilation resembling that seen in alopecia areata, including the typical "exclamation-mark" hairs? What is the usual picture after x-ray therapy?

A.—X-ray epilation after a full dose of x rays affects the whole irradiated area and does not produce the patchiness which generally characterizes alopecia areata. In the latter disorder baldness is usually complete within the affected areas, which are sharply defined. However, in some cases of x-ray epilation where the dose of x rays has been rather less than full the epilation may be patchy, while a few cases of alopecia areata are relatively diffuse and do not show the usual sharp outline. For this reason the two disorders may be difficult to distinguish.

"Exclamation-mark" stumps are probably not seen in any disorder other than alopecia areata. The hair-fall after exposure to x rays is from the root, and stumps are not formed. While, therefore, the distribution of baldness after x rays may resemble that seen in some cases of alopecia areata, the presence of "exclamation-mark" stumps is probably pathognomonic of alopecia areata.

Recurrent Dislocation of the Shoulder and Occupation

Q.—Are any figures available on the incidence of recurrent dislocation of the shoulder in foundry workers? Could the condition be regarded as an occupational injury? What movements are specially apt to produce the initial dislocation, and is a previous injury to the joint a prerequisite for dislocation by the patient's own muscular efforts?

A.—There are no figures of any value on the incidence of recurrent dislocation of the shoulder in different occupations. Present evidence suggests very clearly, however, that recurrent dislocation of the shoulder is not an occupational injury. It appears likely that any shoulder dislocation can become recurrent if the capsule is detached from the front of the glenoid cavity of the scapula and if, being detached, it fails to reattach itself and to heal properly. This failure of the capsule to reattach itself may perhaps be associated with minor congenital anomalies of the shoulder. There is no convincing evidence that it is due to any particular method of producing the initial dislocation.

Apart from pathological dislocations such as occur in neuropathic arthropathy of the shoulder-joint, it is true to say that a previous injury is a prerequisite for dislocation of the shoulder by the patient's own muscular efforts.

Tropical Travel for Infants

Q.—Is there any undue risk in taking a month-old baby from England to East Africa by sea? Will its temperature control mechanism be able to cope with the high temperatures likely to be encountered on the journey? What precautions are recommended?

A.—There is no special reason why a month-old baby should not manage the journey by sea from England to East Africa. The temperature control of a normal full-term baby at 4 weeks will be adequate to deal with the temperatures likely to be met, although the partial lack of the ability to sweat at that age might lead to serious trouble if there were a sudden failure of the air-conditioning or electric-fan system on board ship. This, however, is the sort of unlikely eventuality which cannot be guarded against.

older strains of influenza A. It seems most unlikely that vaccines prepared from such older strains will protect against the Far East virus.

Composition of Virus Vaccines

The human serological response to an influenza antigen is quite different from that obtained in animals. This was clearly shown by Davenport and co-authors (1953), whose doctrine of "original antigenic sin" arose out of the discovery that the antibodies found in persons of different ages is a spectrum made up of different components. Briefly, the older persons in the community possess sera richest in antibodies against the antigens of viruses which infected them in their youth. Children's sera are devoid of antibodies against antigens not experienced during their lifetime. This finding has been confirmed with sera from Great Britain (Davenport *et al.*, 1955), and so has the further discovery that a particular virus vaccine tends to enhance the antibodies found in the serum before immunization as well as to produce a response against its own antigenic component (Davenport and Hennessy, 1956; Jensen, 1957; Report of the M.R.C. Committee on Clinical Trials, 1957). The measurement of the serological effect of a particular vaccine is therefore a complicated affair and requires observations on persons of different ages. Meanwhile there is reasonable agreement that a vaccine must be prepared so as to produce antibodies against the virus likely to be encountered in the field. American opinion favours the use of a polyvalent vaccine containing old as well as recent virus strains. The British view is that a good monovalent vaccine will, because of the recall phenomenon, produce an enhancement of older antibodies and will also engender antibodies to the strain contained in the vaccine. These arguments concerning the merits of monovalent and polyvalent vaccine can be settled only by comparison of their relative protection in the field.

A second important matter connected with the antibody response to a vaccine has arisen from the development of vaccines containing adjuvant materials and existing as a water-in-oil emulsion. The simple virus vaccine suspended in formalized saline produces its maximum effect within two weeks, and the antibodies then slowly return to their previous level during the next year. Vaccines containing the virus adsorbed on to aluminium phosphate have been used in Great Britain chiefly because they do not cause such severe general or febrile reactions as do the ones with a similar virus content containing saline alone. Again the antibody response reaches a peak two to four weeks after inoculation and then slowly wanes during the next year. Vaccines emulsified in mineral oil by the aid of emulsifiers such as "arlacel" (Salk *et al.*, 1952) produce a slower rise in antibodies, but the peak, which is reached three months after inoculation, is much higher. A small amount of virus antigen amounting to one-tenth or even one-twentieth of that used in saline vaccine will, because of the adjuvant property of the emulsions, produce an excellent antibody response, which falls off more slowly than after saline vaccines. Unfortunately, although adjuvant vaccines appear to be ideal from the standpoint of economy of virus content and prolongation of the antibody response, they suffer from a serious disadvantage. Both in the U.S.A. and in this country occasional persons inoculated with emulsified vaccine have developed severe local reactions. The latter are really chemical abscesses, but they may require surgical intervention, and though relatively infrequent (0.1 to 1% of inoculated persons) they constitute a serious bar to the wider use of such vaccines. For the present it appears that we have to be content with the less potent but safer formalized saline vaccines.

Living virus vaccines can only be mentioned briefly. If it became possible to develop an attenuated virus strain with an inability to cause clinical reactions there would be much to be said for a trial of the degree of protection produced in the field. Russian workers are reported to have tested such vaccines and to have found that protection is induced with certain selected virus strains. We have no experience

of the use of such a vaccine, but some basic preliminary work is being carried out (Isaacs and Roden, 1956), and we must await developments.

Evidence from Field Trials of Influenza Virus Vaccines

Field trials are the only way to test the relative protective effect of different vaccines and to establish a relationship between the potency of the vaccine in the laboratory and its clinical effect.

Field trials are governed by four important principles. Firstly, the selection of the population with a view to anticipating as high an attack rate as possible; secondly, control of the vaccine under test by a method free from bias; thirdly, avoidance of untoward reactions; and, fourthly, adequate ascertainment of clinical illnesses in both test and control populations subsequent to inoculation. In the U.S.A., Servicemen have been studied in this way by the Commission on Influenza for a number of years. But such groups are particularly liable to outbreaks of acute respiratory disease or febrile catarrh, which has its highest incidence in recruits and is due in part to infection by the adenoviruses. As clinical resemblances exist between influenza and febrile catarrh, it is necessary to rely upon laboratory evidence for proof that the illnesses at any one time are due to the influenza viruses. Such laboratory evidence confirmatory of influenza is harder to obtain in persons vaccinated against influenza than in inoculated persons (McDonald and Andrews, 1955), so that it is probable that a laboratory assessment will tend to bias the results in favour of the vaccine. Whether this is responsible in fact for the relatively good results reported by the U.S. Commission on Influenza cannot be stated for certain, but even these results have shown wide variation (Table I, after Francis, 1955).

TABLE I.—U.S. Influenza Vaccine Trials (Commission on Influenza)

Epidemic	Population	No.	% Attack Rate	Protection Ratio	Diagnosis
A (1943)	Controls	5,776	7.06	3.6	Clinical
	Vaccinated	5,806	1.96		
B (1945)	Controls	2,150	11.21	12.9	"
	Vaccinated	1,150	0.87		
A (1947)	Controls	7,615	8.09	1.1	"
	Vaccinated	10,328	7.19		
A (1950)	Controls	2,082	3.7	3.1	Serological
	Vaccinated	670	1.2		
A (1951)	Controls	5,228	2.01	4.0	"
	Vaccinated	2,596	0.5		
B (1952)	Controls	430	19.32	2.7	"
	Vaccinated	207	7.24		
A (1953)	Controls	5,527	5.7	6.0	"
	Vaccinated	5,994	0.95		

Modified after Francis (1955).

The problem of ascertainment of illness amongst the ordinary population is not a simple one. All sorts of illnesses are labelled influenza, and there are always cases of acute respiratory disease occurring endemically in the population. Furthermore, direct laboratory study of particular persons in the general population is difficult to organize. In Britain a compromise arrangement has been to use a clinical record of illnesses subsequent to inoculation which is kept by the family doctor and by medical officers working in industry. A parallel spotting scheme for evidence of influenza, and organized by the Public Health Laboratory Service, has given the times when the viruses could be detected in the community. In practice this method has worked better than might be expected. There is no doubt that we have obtained precise information of the period of time when the respective influenza viruses have been active in the community. We also have a record in simple diagnostic terms of illnesses causing at least two days' absence from work and diagnosed as clinical influenza, other respiratory disease, and non-respiratory illness. Only the attacks labelled clinical influenza have shown any reduction in the vaccinated compared with the control groups. But the incidence of such influenza over a three-

months period of observation has never been higher in the control population than 5%. At times of such minor prevalence of influenza, a dilution of the latter by the inclusion of other diagnostically confusing illness seems inevitable. So that, on the whole, it has been surprising that a reduction of illness has been demonstrated at all (Table II). Yet

TABLE II.—British Influenza Vaccine Trials

Epidemic	Population	No.	Vaccine	% Attack Rate	Protection Ratio	Diagnosis
(1) A (1953)	Industry, Services, nurses, students	6,370 6,340	B A	4.9 3.0	1.63	Clinical

though vaccination in 1953 and in 1956 lowered the attack rate only by 30 to 40%, the effect was statistically significant. In contrast, a single trial in 1956 at a boys' school, where the attack rate of influenza A in the uninoculated boys was 20%, showed a ratio of protection closely similar to that found by the U.S. Commission (Hawkins, Hatch, and McDonald, 1956). Perhaps part of the disappointment afforded by the M.R.C. field trials may thus be blamed on nature, but some at least is undoubtedly due to our poor methods of measurement of protection.

The Future Prospect

In view of what has thus far been accomplished, it is obviously unrealistic to visualize the control of influenza with immunizing agents such as those at present available. "Control" is a word which implies ability to curtail spread as well as to limit manifestations of the infectious process. The present era may indeed be the first phase in our gropings towards control of influenza, and so we must continue to experiment with different sorts of vaccines and also with field trials.

So far as the present threat of Asian influenza is concerned, it must be obvious that in the short time available we can do little but prepare for as good a field trial of protection by formalized egg vaccine as can be devised. Such a trial must be preceded by tests of the antibody-forming power of an inactivated vaccine made from the Asian virus. As the latter has certain unusual properties, it is clear that we cannot be sure that the facts gathered about vaccine made from older viruses will necessarily hold good for the future.

THE NATURE OF CANCER ANAEMIA AND ITS BEARING ON THE IMMUNOLOGICAL THEORY OF CANCER

BY

H. N. GREEN, M.D., M.Sc.

Professor of Experimental Pathology and Director of Cancer Research, Leeds and Sheffield Universities

JUNE WAKEFIELD, B.Sc.

Research Assistant, Cancer Research Unit, Sheffield University

AND

G. LITTLEWOOD, A.I.M.L.T.

Chief Technician

From the Department of Experimental Pathology and Cancer Research, School of Medicine, Leeds University, and the Cancer Research Unit, Sheffield University

A preliminary account of this work has already been reported (Green, 1957b) in a general survey of the immunological theory of cancer (Green, 1954). This ascribes the neoplastic change to loss of tissue-specific antigen(s). An important part of these investigations was to study the nature of tumour haemolysins and haemagglutinins and determine the response of many kinds of experimental tumours to the parenteral or intratumoral injection of foreign and autologous red cells. Some of these results have been reported (Green, 1957b), and a more detailed account will appear in a separate publication. Here we present the results of tests on the blood of cancer patients and discuss them in the light that these and other findings throw on the immunological theory in general.

This theory implied that an immune reaction of the tumour to certain cells of the host was a possibility. If so, the anaemia of cancer, often so prominent a feature at some stage of human and experimental cancer, might be due to an "auto-antibody" produced by the tumour mass. Such an antibody, if coating the red cell, might be detected by the use of specific antiglobulin sera. Accordingly direct Coombs tests were made on the blood of cancer patients, but only very occasionally was a positive result obtained at a titre positive with sensitized Rh+ cells. However, on using much lower dilutions of antisera it was found in many cases that the speed of agglutination was much greater than that of the red cells of normal subjects. While this work was in progress it was becoming evident (see Discussion) that the anaemia of human cancer was not primarily a by-product of haemorrhage, infection, malnutrition, etc., but a true haemolytic anaemia induced by an agent of unknown origin. In terms of the immunological theory this suggested that the tumour itself could on occasion react against cells of the host possessing an antigen which the tumour cells lacked. Such a possibility made the occurrence of what seemed a relatively feeble antibody coating the red cell a matter of great practical and theoretical interest.

Methods

Direct Coombs Test.—This is performed in the standard way (Dunsford and Bowley, 1955), mixing 1 drop of 50% packed cells and 1 drop of diluted antiglobulin serum on an

opal tile. Much lower dilutions are used than are needed to elicit a full positive test with sensitized Rh+ cells. A serum with an Rh titre of 1:80 was tested at 1:10, 1:20, 1:40, and of 1:200 at 1:20, 1:40, 1:80. Higher dilutions were made if needed. Two sources of antiserum (Burroughs Wellcome, and a goat anti-human-globulin serum supplied by Mr. I. Dunsford) were available. Three controls, test cells and saline, Rh+-sensitized cells (O) and non-sensitized normal cells (from laboratory staff) are set up. After standing one minute at room temperature the tile is gently rocked and readings are made over a period of five minutes. Scoring of agglutination is made roughly as follows: ++, immediate; +, complete within two minutes; ±, agglutination occurring definitely at an earlier period than the control non-sensitized cells. It should be noted that normal control cells often agglutinated in five minutes or more, probably due to an anti-species agglutinin effective at low serum dilutions. If the test was positive (++ or +) it was repeated using serum dilutions up to the maximum giving a ++ reaction with sensitized cells.

Indirect Coombs Test.—Two tubes containing 6 drops of test serum mixed with 2 drops of a 50% suspension of once-washed normal O Rh+ cells are incubated, one at 37° C. and one at 4° C., for 1½ hours. The cells are tested for sensitization as above.

Elution of "Antibody."—Heavy suspensions of cells are washed (×3) in ice-cooled saline and placed in a Kahn tube to about a third of its depth. A similar quantity of saline is added and the mixture agitated in a 56° C. water-bath for seven minutes. The cells are sedimented rapidly in a centrifuge containing water at 56° C. in the buckets. The eluate is removed and immediately tested with once-washed normal Rh+ O cells. Half the eluate plus 2 drops of 50% suspension of the cells is incubated at 37° C. and half at 4° C. for 1½ hours. They are then tested for sensitization directly.

TABLE I.—Direct Anti-Human-Globulin Tests on Red Cells of Cancer and Non-cancer Patients

Non-cancer	214	3	29	15	

Results

Direct Tests

There is statistically a highly significant difference between the percentage of positive tests (++ or +) in cancer and non-cancer patients (Table I). Nor can this difference altogether be ascribed to a large preponderance of groups with a high incidence of positive tests. If we omit two such groups (Table II), advanced cancer and tumours of the

TABLE II.—Incidence of Positive Antiglobulin tests in Various Groups of Patients

Group	No.	No. Positive (++ to +) Tests	% Positive	Significance of Difference P

(7) Non-cancer patients	214	32	15	<0.001

reticulo-endothelial (R.E.) system, a significant difference between cancer and non-cancer cases still remains. It is clear, however, that the greater the cancer mass the more likely is the test to be positive. The advanced cases included all those in which there was a known metastatic focus, local or remote. Obviously the overlap is considerable, for, on this basis, some cases classified as "not advanced" would in fact be so. All but one of the eight Leeds cases labelled carcinomatosis gave a positive test (usually ++). When, in Sheffield, a surgeon was asked to select some widespread cancer cases the incidence of strongly positive tests rose sharply. In this connexion the lower incidence of positives in the Sheffield as compared with the Leeds results may be noted. This is probably associated with the difference in the source of the cases. In Sheffield the majority were ambulant cases from the Radiotherapy Centre, and contained a number, probably considerable, in which the cancer mass, owing to treatment, would be small or non-existent. In Leeds the blood samples were taken in general hospital wards shortly before or after treatment had begun. In the earlier stages of the investigation the Leeds and Sheffield results were much wider apart than they were later (Table I), and at this time the difference in the source of material was more accentuated.

Tumours of the Reticulo-Endothelial System

It will be noted (Table II) that not only advanced cases, but at Leeds the group comprising tumours of the R.E. system, showed a much higher incidence of positives than the cancer group as a whole. This is emphasized if comparison is made with this latter group, from which the advanced cases are removed. Again there is a discrepancy between the Leeds and Sheffield figures, the R.E. tumour group showing no increased incidence in Sheffield, possibly again because there was a preponderance of ambulant cases under treatment in Sheffield. It should be particularly noted, however, that 5 hospitalized cases of multiple myeloma (3, Sheffield; 2, Leeds) all gave positive direct and indirect tests—in 4 so strong as to be reported a frank positive Coombs test.

The high incidence in the R.E. tumours is mainly attributable to the lymphoid tumours, chronic lymphatic leukaemia, and lymphosarcoma. Of 20 such cases in Leeds 16 were positive and a few* gave a frank positive Coombs test—that is, positive at the optimal serum dilution for Rh+ sensitized cells. When these cases are excluded the number of cases in individual tumour groups is too small for exact analysis. The incidence of positives in the 34 Leeds cases of myeloid leukaemia, Hodgkin's, and other reticuloses was 50%, and the figures suggest that chronic myeloid leukaemia may ultimately reveal a somewhat higher, and Hodgkin's disease a distinctly higher, figure than cancer in general—particularly if the advanced cancer cases are omitted.

Other Cancer Groups

The cancer cases in general comprised almost every type of cancer, but the groups were usually too small for discrete analysis. The preponderating group was breast cancer, and of a grand total of 84, 36 (41%) were positive, a proportion very close to the combined total figure (see Table I) for cancer as a whole. Of 34 cases of lung cancer 47% were positive, though the Leeds figure (69%) alone, together with several very strongly positive reactions, suggested that the incidence, possibly because of inadequate treatment, may be higher than average. Otherwise, except for two small groups, skin and testes, which showed a not statistically significant high percentage of positives, the incidence was rather strikingly similar to the common average in all types of cancer. Excluding lymphosarcoma, there were far too few cases of sarcoma to make a comparison with carcinomata possible.

*Any unprecise statement such as this is due to the fact that a record book containing the larger part of the Leeds findings was removed from the laboratory by an unauthorized person and never returned. Fortunately, the results had already been summarized, but not in every detail.

The incidence of positive tests in non-cancer is significantly lower than in cancer patients. This group consisted mainly of surgical operations (hernia, etc.) and surgical cases of infection (appendicitis, etc.). The latter provided the bulk of the positive tests. Of the 29 positives in the Leeds non-cancer group 20 were cases of infection, many suppurative in type.

It is obvious (Table I) that normal subjects rarely give a positive test. These samples were mainly derived from groups of laboratory technicians in the earlier part of the investigation to obtain a rota of normal controls. In later tests only one such blood sample was used as a negative control. It was noted that subjects giving a weak positive (±) test had usually a mild type of infection (for example, acute sinusitis).

TABLE III.—Comparison of Auto- and Iso-antibody Titres in Sera of Cancer and Non-cancer Patients

Case Type	Auto- antibody Titre Higher	No Difference, or Iso-antibody Titre Higher
Reticulo-endothelial tumours	12	6
Advanced cancer	9	4
Other	9	16
Non-cancer	1	21

Indirect Tests

Of 74 cancer patients giving a positive direct test the indirect test was positive in 56, thus showing the presence of circulating antibody in the majority. It is a "cold antibody," for, though sensitization was attempted at 37° C. and 4° C., only at 4° C. was it achieved. Comparison of the titres at which positive cancer and non-cancer sera were active (iso-antibody) with the titres of the direct test (auto-antibody) showed the preponderance of stronger auto-antibodies in the cancer group. This was particularly evident in those cancer groups with the highest incidence of positive tests (see Table III).

Elution of Antibody

In blood samples giving a strong (++) reaction elution of the antibody was successfully achieved in 8 of 15 instances. Here again sensitization was more effective at 4° C., though it could be obtained at room temperature but not at 37° C.

Effects of Transfusion and Irradiation

In only two cases, both giving a strong positive test, was there a distinct possibility of a recent blood transfusion(s) being a factor, but in one of these, in which repeat tests were possible, the reaction had not weakened several weeks after the last transfusion. In five other transfused cases the test was not positive (++ or +). Although this point was overlooked in the early stages there is now ample evidence that positive tests are not usually due to mildly incompatible transfusions.

As to radiotherapy, of the 89 Leeds patients receiving this treatment at the time of blood-sampling the incidence of positives was 51%, a figure differing little from the Leeds average for all cancer patients. The reason for this particular inquiry was that Rosenthal *et al.* (1955) found that in lymphoid tumours x-ray therapy seemed to precipitate the onset of abnormal haemolysis.

Nature of the Antibody

From the above data it seems that we are dealing with a cold incomplete "antibody." Absorption with an equal part of 1:1,000 pure serum gamma-globulin,* which completely removed activity on Rh+ sensitized cells from the antiglobulin serum, left the activity on the many cancer or non-cancer sensitized cells tested intact. Absorption with 1:1,000 human serum or with a mixture of alpha- and beta-serum globulins removed all activity. If the alpha- or beta- (or both) globulin adsorbed on the red cell is an antibody it is related to the type found in auto-immune acquired

*Kindly supplied by Miss McKay, of the Lister Institute.

haemolytic anaemia rather than to the type found in the anaemia of the newborn.

The possibility existed that the cold antibody was anti-H (Dacie, 1955), which is adsorbed from the serum by cooled group O cells, but routine ABO blood grouping showed that the group incidence in positive cases was close to that of the general population. Neither was the cancer-induced antibody adsorbed by the saliva of H-secreters.

Discussion

It is not proposed to cover here all the relevant literature which suggests the existence of haemolytic anaemia in experimental and human cancer (Green, 1957a, 1957b, for further references). There are a few salient points in the development of our approach to the subject that should, however, be emphasized. In the almost inevitable anaemia associated with rapidly growing transplanted tumours, evidence has accumulated that the primary cause is not infection, whose activity bears a linear relationship to the tumour mass. We have shown that the anaemia induced by chemical carcinogenesis is greatly accentuated on the appearance of the tumour and increases progressively until death.

Mrs. Savigear and ourselves have also shown independently that the red cells from 50% of rats bearing either transplanted or chemically induced tumours agglutinate with rabbit anti-rat-globulin serum. No correlation was found between the degree of anaemia and the presence of such a positive test. Nor, it may be noted, was there any direct correlation in the human tests described here. This may possibly be due to varying levels of blood regeneration, for in lymphoid neoplasia Ross *et al.* (1951) and Rosenthal *et al.* (1955) state that evidence of accelerated erythropoiesis may be found. Moreover, the rate of regeneration may very well be modified by such variable factors as an infected tumour, etc.—in other words by factors usually thought to be the direct cause of the anaemia.

The degree of anaemia in man associated with any particular tumour type appears to be related to the size of the tumour mass, but even where the tumour invades the bone marrow the well-known hypothesis that displacement or destruction of blood-forming tissue is the cause cannot be substantiated (Collins and Rose, 1948; Shen and Homburger, 1951). And yet there is no doubt that a significant degree of anaemia occurs in at least half, and accelerated red-cell destruction in all, or nearly all, advanced cases of cancer. It has been clearly demonstrated by the Ashby technique (Brown *et al.*, 1944; Brown, 1950) and the transfusion of isotope-labelled red cells (Ross *et al.*, 1951) that this destruction is sometimes exponential in type and not just an acceleration of the normal disposal mechanism. Moreover, in one particular tumour group, those of the lymphoid system, the evidence is strong that an auto-immune antibody is present in the blood. Not only is there evidence of very great acceleration of red-cell removal (Brown *et al.*, 1951), but the Coombs test is often positive. Rosenthal *et al.* (1955) found it in all of 20 cases of chronic lymphatic leukaemia and 4 of lymphosarcoma, but we have not found the incidence so high, nor did Ross *et al.* (1951). Rosenthal's group found other evidence of haemolytic anaemia such as reticulocytosis, spherocytosis, bilirubinaemia, and hyperplasia of both erythroid and lymphoid bone marrow. No explanation was found, but a review of the literature suggested that some component of the lymphoid system was the source of the antibody. Others have suggested that in auto-immune anaemia in general there is abnormal protein production which stimulates antibody production and that malignant lymphoid tissue provides one example of this (Dacie, 1955; Rappaport and Johnson, 1955).

When the present investigation was started we saw the problem mainly as one possible approach to testing the validity of the immunological theory of cancer (Green, 1954). The idea was that if malignant cells are so because they lack tissue-specific antigen(s), then those derived from cells normally capable of antibody production might well retain that function. The idea was reinforced by the evidence that

neoplastic cells of the R.E. system do retain some functions. Reticulum-cell sarcomas show phagocytosis and reticulin formation (Miller *et al.*, 1952), and multiple myelomata cells produce Bence Jones proteins. Moreover, there is suggestive evidence that malignant lymphoid cells, like the plasma cell, may produce abnormal periodic-Schiff-positive proteins (Rappaport and Johnson, 1955). If antibody is produced by such cells it would be directed against cells containing the antigen they lacked—that is, their normal prototypes and cells developmentally related to them. Tissue identity is almost certain to be defined by a mosaic of antigens, one or more of which will form part of the pattern in other types of cell. When early in the course of the work it was found that red cells from patients with tumours of the R.E. system, particularly lymphoid and reticulum-cell tumours, were giving a high incidence of positive anti-immune globulin tests, it made the idea of an immune response of the tumour to its host not too improbable. When, at a later stage, 5 cases of myelomatosis gave a strong positive reaction (4 Coombs-positive in the accepted sense) the possibility was reinforced, for the plasma cell has now a strong reputation as an antibody producer.

It was, however, now becoming obvious that the red cell from diverse types of cancer, particularly advanced cases, yielded positive results, albeit rarely at so high a serum titre. Ultimately, as we have seen, the difference between the cancer and non-cancer groups became statistically highly significant. It is difficult to believe that two entirely different processes are involved in the anaemia of reticulo-endothelial and other kinds of tumour—particularly since, as already noted, there is ample evidence that haemolytic anaemia of some degree is a common feature of all types of cancer, especially of advanced cases. If the tumour is not the source of the antibody found by us, then this is likely to be the position with lymphoid and plasma-cell tumours also. The usual view that the red-cell antibody may be a response to abnormal proteins formed by R.E. tumours must in that case be extended to cover malignant tumours in general. On the other hand, we have accumulating evidence of antigenic lack in tumour cells (Green, 1957a, 1957b), and there is even some direct evidence of lack in the neoplastic lymphocyte itself (Seligmann *et al.*, 1955). Using the Ouchterlony technique, two antigens were found in the lymphocytes of acute lymphatic leukaemia, compared with three in the normal. Similar evidence of our own for other types of cancer is gradually emerging (see Green, 1957b). Weiler (1956a, 1956b) has demonstrated the absence of organ-specific antigens in experimental liver and kidney tumours. In fact, the evidence, considered as a whole (Green, 1957a, 1957b), strongly favours our view that a malignant cell derived from an antibody-producing cell *would* have no choice by immunological law but to produce antibody against normal cells of its own, and probably related, type—that is, all provided it retained its normal capacity for antibody synthesis. If this does happen, as in theory it must with certain tumours, then the possibility of its happening in all becomes more of a reality. It should be noted that the cold incomplete type of antibody found on the cells and in the serum of some 30–60% of groups of cancer patients is usually a weak one except in certain R.E. tumours and sometimes in advanced cancer. A relatively mild malignant state like chronic lymphatic leukaemia, or a relatively small mass of sarcomatous lymphoid tissue, apparently produces an immune response only equalled by a very large carcinomatous mass. It could be supposed that this is so because lymphoid tissues are either better antibody producers or more closely related antigenically to red cells than other tissues. There is no sound evidence that the normal lymphocyte does produce antibody, but perhaps it is potentially a more efficient producer because it derives from a stem cell capable of differentiating into antibody-forming cells. On the other hand, the plasma cell is most probably an antibody-forming cell and probably retains this property when malignant. The fact that in myeloid and acute leukaemias and Hodgkin's disease there appears to be not much difference in haemolytic antibody formation from cases of advanced cancer in general

suggests that a greater capacity for antibody production, potential or actual, is the possible reason for the greater frequency of positive tests in lymphoid and plasma cell tumours.

The Auto-immune Haemolytic State

If, however, other tissues possess a latent capacity for antibody production when challenged by a tissue containing a specific tissue antigen they do not possess, then malignant cells, if they do lack such antigen(s), might well be the only kind of cell in the body ever to manifest this property. All healthy cells might be neutral to one another as a result of acquired tolerance developed during foetal life. In other words, the essential nature of the malignant state may reveal a property inherent, but never manifest, in normal cells. The mechanism of such an "auto-immune" state may prove to be of quite a different order to the classical reaction to foreign nucleo-proteins (Green, 1957a). If this assumption proves true, a major theoretical difficulty concerning the relation between cancer anaemia and antigen deficiency in the cancer cell would be overcome.

The auto-immune haemolytic state is not yet regarded as a feature of malignancy generally. The prevailing opinion is that only lymphoid tumours, and rarely Hodgkin's disease, can be included amongst the many conditions which may on occasion precipitate it. Such conditions are broadly covered by a few virus diseases like infectious mononucleosis and pneumonia, liver cirrhosis, and "cortisone-responsive" states like lupus erythematosus and rheumatoid arthritis. They are possibly all due to the production of abnormal proteins which function as auto-antigens. An auto-immune state is compatible with other clinical features of many of these diseases. Where a micro-organism is responsible it is likely that some fraction of it unites as a haptene, with tissue protein or polysaccharide, the auto-antigen(s) so produced resembling a red-cell antigen in sufficient degree for the antibody elicited by it to be attracted to this cell. This may not, in minor degree, be an uncommon event, for in our own group of non-cancer cases 15% gave a positive antiglobulin test, though very rarely so strong as in many cancer cases. Such positives were predominantly associated with acute infections. This particular relation may be the result of fortuitous selection of control cases from surgical wards, but it shows that even acute appendicitis fairly frequently produces conditions which temporarily sensitize the red cell to antiglobulin serum.

The autohaemolytic anaemias have been divided into two groups—one with clinical and laboratory evidence of an immune state, and one in which the only evidence of haemolysis is that the survival time of the red cell is reduced. The malignant state, apart from the special tumours mentioned, would, on past evidence, fall into the latter category. It now looks doubtful, however, whether the distinction between, for instance, the anaemia of lymphosarcoma and that of general carcinomatosis is justified. As we have indicated, it may be just a question of the antibody-producing potency of the tissue concerned. Theoretically it would be expected that if malignant growths do produce antibody to host red cells the amount would vary according to its antigenic relationship to the red cell; it might therefore in many cases be nil. Such variations were in fact found in the response to the injections of autologous red cells into a variety of experimental tumours (Green, 1957b). The prototype cell might contain no antigen related to one in the red cell, or, if it did, it might not be lacking in the cancer cell.

This may explain, together with varying capacities for red-cell regeneration, the very different degrees of anaemia in advanced human cancer in which, occasionally, there is no anaemia at all. There was no difference between the average blood (72%) Hb levels of positive and negative cases of the cancer group as a whole; yet there were more cases (21%) of severe anaemia (<50% Hb) in the positive than in the negative group (4%). Tumours of the R.E. system, however, showed a greater average degree (59%) of anaemia in the positive group, and all with severe anaemia gave a positive test. If, then, cases with severe anaemia are excluded,

members of the positive group were on average less anaemic than the negative. One explanation is that up to a critical point the more active the haemolytic process the greater the relative degree of haemopoiesis. In the R.E. group there is also the possibility that blood regeneration is inhibited, which Collins and Rose (1948) have suggested may happen in leukaemia. In terms of the immunological theory, cytotoxicity of blood-forming cells by some tumours of this group might be expected. In our cases there was no evidence that differed greatly as source of antibody, for the numbers of positive tests were fairly equally distributed. The possibility exists, however, that in some cases with increasing malignancy there is a decreasing functional ability to produce antibody.

The lack of individual correlation between the degree of anaemia and the result of the test could also be due to the fact that the antisera used may not be the most sensitive for our purpose. They differed distinctly in potency in that the percentage of positives varied from batch to batch in the apparently comparable groups of cases. In every instance the globulin coating the red cells was of non-gamma-globulin type, whereas the Coombs antiserum is rich in anti-gamma-globulin. Immunization of rabbits with positive cells or their eluates is in progress in the hope that more active antisera will be obtained.

An interesting point was that in more than half the cancer cases, when the comparison was possible, the antibody was more active on autologous than on homologous cells, whereas in non-cancer cases this was rarely so. In tumours of the R.E. system and in advanced cancer this distinction was much more evident. This suggests that the antibody globulin found in cancer serum has a greater affinity for the patient's own red cells, and differs, even if only slightly, from that formed in various other diseases. This would be in line with the hypothesis that in cancer the normal red cell, and in the non-cancer case a modified tissue protein, provides the antigenic stimulus. The antibody in the latter case might well show no autologous specificity.

Structure of the Antibody Globulin

More precise knowledge of the structure of the antibody globulin is being sought by electrophoretic analysis of its cell eluates, but we already have some indication of its nature. In auto-immune haemolytic anaemia the frequency of false-positive Kahn and Wassermann reactions has often been noted. We found a high incidence of such positive reactions, particularly of the Kahn, during experimental carcinogenesis, and some years ago a similar investigation was started in human cancer. This revealed *inter alia* a similar tendency, reflected in a nearly doubled incidence of positive Berger-Kahn reactions (46% of 206) in cancer as compared with non-cancer patients (26% of 441) (see Green, 1957b). At a later date no correlation with positive antiglobulin tests was found. There were, however, indications of a direct correlation with a positive complement fixation test using human tissue phospholipid as antigen, though such positives (14 of 43 tests) were few in number. There are many indications that there are very frequently, both in the sera of animals with cancer and in cancer patients "antibodies," capable of binding with lipid substances. Evidence has been obtained pointing to lipo-proteins with strongly determinant phospholipid groups as important cellular antigens. Moreover, lipo-proteins and phospholipids derived from malignant tissues affect the red cell in ways very similar to those produced by true antibodies. The evidence for all these statements is discussed in detail by Green (1957a, 1957b), and has led to the suggestion that some type of antilipid "antibody" may appear in cancer serum. The speculation is tempting that the antibody globulin detected in the present work is part of a lipo-globulin antibody whose presence may ultimately be detected by other serological tests in which the lipid, and not the globulin, acts as antigen.

If the hypothesis is correct that the cancer itself is the direct cause of red-cell lysis it would seem unlikely that the

effect would be restricted to this cell. In this connexion the possibility has to be remembered that only cells in intimate contact with cancer tissue may provide an efficient antigenic stimulus. Any type of blood cell, provided it has any antigenic similarity to the normal cell from which the cancer derived, could in theory be involved. It is therefore interesting that Mrs. Savigear, working in our laboratory, found that rat-tumour extracts, in addition to their effect on the red cell, also lysed blood leucocytes and splenic lymphocytes and plasma cells. The effect was not given by spleen or liver extracts from the same animal. It was not seen in tumour extracts made just prior to regression in all other tumours of the group—that is, it was manifest only by fully viable cells. On the plasma cell it was much more evident in the transplanted than in the chemically induced tumour, possibly owing to the fact that plasma-cell infiltration in the homologous transplanted tumour is a common phenomenon. If indeed cancer cells are capable of damaging these and related cells *in vivo* it might explain the decline in immunity in general which has frequently been noted in cancer, particularly perhaps in Hodgkin's disease.

Such possibilities indicate that the problem of cancer anaemia, if it proves to be immunological in nature, will have much wider implications both in theory and in practice, in the cancer problem as a whole. It would raise the question of whether many of both the local and the systemic effects of cancer are the result of immune responses on the part of the tumour. In terms of the immunological theory the cancer cell would then be correctly regarded as an aggressive parasite in the sense that it is capable of invading, and perhaps damaging, host tissue because it is, immunologically speaking, a new race of cells. It may possibly prove that not only the anaemia but the general emaciation of cancer is in part due to this immune aggressive reaction of the tumour to the host.

It has long seemed significant to me (H. N. G.) that tumours of the reticulo-endothelial system are particularly prone to produce systemic effects. Not only, as we have seen, are they potent in producing anaemia, which in some types may be the first severe warning of their presence, but they are particularly associated with febrile disturbances and symptoms suggesting the existence of an inflammatory lesion. Fever is observed perhaps more in lymphadenoma (Pel-Ebstein pyrexia), but is not uncommon in any of them. In fact, this disease, like the leukaemias, was long regarded as an inflammatory state both on clinical and on pathological grounds. The pronounced local inflammatory-like changes in Hodgkin's disease may be an expression of an immune reaction of the tumour to host tissue promoted by a cell which, by nature of its origin, is potentially a strong antibody producer. If so, we may have to look at many of the lesser degrees of cellular infiltration in and around cancer tissue in quite a different light from that of the mechanical theories long held.

Validity of the Immunological Theory

The main purpose of this work was to test the validity of the immunological theory (Green, 1954) at a practical level. Direct and indirect evidence in its favour has accumulated greatly since it was first put forward, and more precision has been given to the nature of the antigen(s) lacking in the cancer cell. These, it seems likely, are tissue (organ)-specific antigens with very probably a lipoprotein basis (Green, 1957a, 1957b).

If the suggested mechanism of cancer anaemia proves basically true, then the truth of the theory would be apparent. If another explanation proves true, then of course the theory is not disproved. In fact many immunologists might say that its suggested bearing on cancer anaemia is irrelevant and untenable because it rests on the unproved assumption that many cells, apart from one or more found in lymphoid tissue, have a potential ability to produce antibodies. There exists, however, evidence suggesting the possibility of this happening even in normal tissues. In the experiments of Oakley *et al.* (1949, 1951, 1954, and 1955),

who quote the relevant literature, many tissues, such as breast, uterus, appendix, fat, skin, and striated muscle, were shown to produce antitoxin when challenged with soluble toxin. There was no doubt about the response, but the possibility of invading inflammatory cells as the source of the antibody could not be excluded. Similar interpretative difficulties were found in our own work (Green, 1957b) on tumours. A wide range of spontaneous (animal and human), induced, and transplanted tumours were found to contain haemagglutinins and haemolysins, often more active against cells of the host than other cells. Such properties could be augmented, or specific new ones induced, by challenging certain tumours, particularly by intratumoural injection, with autologous or homologous and heterologous red cells. In this case the response to autologous cells suggested that the cancer cell might be itself producing the anti-cell factors.

Whether this proves true or not, the tumour cell may be, immunologically speaking, in quite a different category to normal cells. As we have seen, in theory it is unique in being the only body cell whose antigenic make-up has altered in postnatal life, and thus immunological tolerance has not, in respect to this alteration, been acquired. If the change in the tumour cell was antigenic gain, then of course some host cells would react against the tumour; if antigenic loss, as seems highly probable, then the tumour could react against the host. In other words malignancy may by its very nature either confer on the cell the property of reacting immunologically or provide an opportunity for this latent power to be demonstrated. It would react only to the challenge of the tissue-specific antigens it had lost. It is possible that the property of reacting to foreign nucleoproteins is a specialized property of normal antibody-producing cells. We have obtained some evidence that tumours do not produce significant amounts of antibody to such antigens. In any case, spontaneous as distinct from transplantable tumours are usually not deficient, to any great degree, in iso-antigens (see Green, 1957a). If antibody is produced by them it would be expected to be directed against membranous and cytoplasmic lipo-proteins. Such ideas accord with the finding that the tumour haemolysins and haemagglutinins belong to this class (Green, 1957b) and suggest where we should search for the precise nature of the antigenic deficiency in the cancer cell.

Conclusion

It is stimulating to realize that more knowledge of the immune mechanism concerned in cancer anaemia may provide a definitive clue to the nature of the antigen(s) lacking in the cancer cell and thus to the fundamental nature of cancer; for it should be noted there is now quite strong evidence that antigenic deficiency is a feature of the cancer cell. The facts presented here, though only a small section of the whole, closely correspond to those predicted by the immunological theory. This indicates that specific antigenic deficiency is not just a pointer to immaturity in the cancer cell, but the cause both of this immaturity and all the properties of the malignant cell.

Finally, it should be made clear that some of the rather dogmatic statements made here cannot be appraised without reading the detailed evidence for the immunological theory of cancer, presented by Green (1957a, 1957b).

Summary

The immunological theory of cancer maintains that the malignant cell profoundly differs from the normal in its antigenic make-up owing to lack of a tissue-specific antigen(s). It was therefore postulated that, because of this antigenic difference, malignant cells, if derived from antibody-producing cells, should be able to produce antibody to the corresponding, and certain antigenically related, normal cells.

This idea was supported by the fact, confirmed here, that certain tumours of the lymphoid system produce an

auto-immune haemolytic state as revealed by a positive Coombs test. It was reinforced by obtaining positive tests in cases of multiple myeloma, a tumour derived from the antibody-forming plasma cell.

Using anti-human-globulin sera at lower dilutions than the standard, it was found that positive tests were not restricted to these special types of cancer.

This modified antiglobulin test was positive in very significantly more (43% of 451) cancer patients than in non-cancer patients (15% of 241). Both the number and strength of positive tests was greater the greater the tumour mass.

If the groups (tumours of lymphoid tissue and advanced cancer in general) which gave the highest percentage of positive tests were excluded, the difference between cancer and non-cancer patients was still highly significant.

The antibody coating the red cell was of the cold, incomplete non-gamma-globulin type, and was found in the serum of many patients giving a positive direct test. It thus resembles that found sometimes in auto-immune haemolytic anaemia in non-cancer patients. Reasons are given for the prediction that it may prove to be a lipo-globulin complex.

It is concluded that the anaemia of cancer in general, and not just of certain lymphoid tumours, is primarily of an auto-immune type.

Both fact and theory point to the tumour, and not the host, as the source of the haemolytic antibody.

It is argued that the production of auto-antibodies is a special and peculiar property of the cancer cell, because not only does it lack certain specific tissue antigens, but, in addition, it has no acquired tolerance to the antigenic incompatibility occasioned by this lack.

These findings were predicted from theory, and thus support the validity of it. If it is found, as the evidence strongly suggests, that cancer cells are immunologically aggressive to the host, it would not only explain the present findings but many other local and systemic effects of cancer. It would also show that the immunological theory of the nature of cancer (Green, 1954, 1955, 1956, 1957a, 1957b) is basically correct.

Warm thanks are due to Mrs. M. Parsons for the laborious task of blood sampling at Leeds and to many members of staff at the General Infirmary and St. James's Hospital, Leeds, and the Radiotherapy Centre at Sheffield. The advice of Mr. I. Dunsford, Scientific Officer, Regional Blood Transfusion Service, Sheffield, proved most helpful.

MALFORMATION OF EARS AS SIGN OF MALFORMATION OF GENITO-URINARY TRACT

BY

D. HILSON, M.B., M.R.C.P., M.R.C.P.Ed.
D.C.H.

Consultant Paediatrician, Oldham, Ashton, Glossop, and Hyde

During the past seven years a number of patients have been encountered with deformities of the external ear associated with congenital abnormalities of the genito-urinary tract. In all of them it was the presence of the deformed ear that drew attention to the possibility of underlying malformation of the genito-urinary tract as an aetiological factor in the clinical picture.

Three newborn infants were seen with the typical facial features of renal agenesis so lucidly described by Potter (1946). She describes the facies thus: "The most striking feature consists of an increased width between the eyes, and the presence of an unusually prominent fold arising at the inner canthus of each eye. The fold sweeps downwards and laterally to form a wide semi-circle under the inferior medial aspect of each orbital space. Other changes which, when combined with the appearance of the eyes, give the face of the infant a resemblance to that of a person of very advanced age—an extreme premature senility as it were—are a flattening and slight broadening of the nose, an unusually preceding chin, and large low-set ears which have proportionately little cartilage" (see Fig. 4). Although two of the three infants seen had ears which conformed to Potter's description, the third had small folded ears, set low, rotated backwards, and a bulbous-edged helix which was sliced or "squared off" across its upper edge (see Fig. 8, lower inset picture). A fourth infant whose facies conformed completely to Potter's description survived.

It has become apparent that malformed ears, particularly if asymmetrical, are quite commonly associated with congenital malformations of the genito-urinary tract with congenital malformations of the genito-urinary tract may often compatible with life. These deformed ears may be large and flabby and resemble Potter's description (suggestive of "Jumbo" or "Dumbo" ears), the ears might be folded over with the helix squared across its upper margin and bulbous, or they might be folded forward to mimic the cockle shell and be quite small, or they might be elfin-shaped. Lesser deformities of the ears are usually associated with marked asymmetry of the two ears.

The genito-urinary tracts in the 23 cases reported below came under suspicion because of the presence of one or more malformed ears, with the exception of Cases 19, 20, and 21, which were the first three encountered and are mentioned above. Cases 22 and 23 were of interest, as the ears resembled those of Cases 19, 20, and 21, but on one side only. At necropsy in both cases the kidney was absent on the same side. This necropsy finding drew attention to the possibility that this complex might be present in surviving patients.

Case Reports: Group A

Group A cases were four in which deformed ears drew attention to the underlying genito-urinary malformations, and in which the family histories revealed a high incidence of malformed ears and/or congenital anomalies of the genito-urinary tract in each of three generations (Table I).

TABLE I.—Group A. Four Children Whose Malformed Renal Tracts Were Suspected Because of Malformed Ears; In Each Case the Father was Unexpectedly Found to Have Deformed Ears, Leading to a Search Into the Familial Incidence

Case No.	Age (in Years) and Sex	Presenting Clinical Picture	Genito-urinary Malformation	Family Members Affected in Generations I, II, and III
1	9 M	Headache, pyrexia, colic, pyuria, grossly deformed bat-ears	Bilateral double ureters	I (1) Grandfather (ears + kidneys) II (2) Father (ears + kidney) III (3) Father's brother (ears + kidney) III (4) Brother (ears + raised blood urea)
2	4 M	Pyrexia, grossly deformed ears	Bilateral double ureters	I (5) Grandmother (ears + kidney) II (6) Father (ears + kidney) II (7) Father's sister (ears + kidney) III (8) Cousin (ears + kidney)
3	Birth M	Moribund newborn infant with typical facies of renal agenesis	No kidneys	I (9) Grandmother (kidney) II (10) Father (ear + hypospadias) III Cousins (11) Absent left kidney (12) Bat-ear + hypospadias (13) " "
4	6 M	Moribund, wide-spread neoplastic disease, deformed left bat-ear	L. cystic kidney	I (14) Grandfather (polycystic kidney) II (15) Father (L. polycystic kidney + ear) II (16) Father's sister (L. polycystic kidney + ear) III (17) Cousin died (cystic kidney) III (18) Brother (L. polycystic kidney)

Case 1

A boy aged 9 years was referred from another hospital, where the cause of a current pyrexia could not be determined. (He was a paratyphoid contact, and the following investigations had proved normal: urinalysis, tuberculin sensitivities, serum agglutinations against salmonella organisms, Wassermann reaction, and stool cultures. Headache, colic, and pyrexia had been persistent. His ears were so ugly and so similar to those infants with renal agenesis that a pyelogram was made. This demonstrated bilateral bifid ureters. His fever was due to an *E. coli* pyelitis. Parental interview disclosed that his father had the identical ear pattern and had been treated for two years for lumbar fibrosis. His urine was found to be infected, and pyelography showed double ureters. Father and son looked very similar; they both had receding chins, and were myopic but highly intelligent. The ears were folded forward at 90 degrees to the head, set low, bulbous, and ugly (similar to those shown in Fig. 2).

FIG. 1.—Family tree of Case 1.

A further family history (Fig. 1) disclosed the following. The paternal grandfather had such ugly ears that he would only be photographed in one profile. He had one kidney removed in adolescence for stones, and he died as a result of an operation to remove stones from the other one. In one paternal uncle with the same ear pattern renal disease was suspected. The youngest of the patient's three brothers, whose ears were similar, had an indeterminate pyelogram, but a blood urea of 55 mg. per 100 ml. The other two brothers had normal ears and pyelograms.

The patterns of abnormality encountered were deficiency of cartilage in large or small flabby ears, folding over of the upper ear, small folded cockle-shell ears, and ears that are "squared off" across the superior margin of the helix with a bulbous thickening of the flat upper edge of the helix. As the children have grown older many of the deformities have become less obvious.

FIG. 11.—Case 17. Large asymmetrical "Dumbo" ears. Absent left kidney. Similar ear formation was noted in Cases 1, 14, 19, 20, and 23 (see text).

Four of the children seen had deformed pinnae and enuresis or pyelitis, but pyelography proved normal. In addition one infant had no external left auditory canal and only a vestigial left pinna; the pyelogram showed bilateral secreting

Only four did not have such anomalies displayed. A further 11 infants who came to necropsy demonstrated this close association, but no case is recalled of an infant coming to necropsy who did not have genito-urinary malformation when he had malformation of the pinnae. Finally, the 18 relatives listed in Table I were investigated for abnormalities of the renal tract because one member of the families had peculiar ears and associated renal anomalies.

Aetiology

Most authors have expressed the view that renal agenesis, absence of one kidney, and double ureter formation are unrelated. Certainly renal agenesis has been thought to be most probably due to some noxious influence occurring at a crucial stage in the development of the foetus, but animal experiments suggest a clear genetic association (Davidson and Ross, 1954). It now appears that, in some cases at least, all these conditions are interrelated and genetically determined, but not sex-linked.

Of the pathological conditions mentioned in this paper, only polycystic disease of the kidney seems to have a well-recognized familial incidence. Madisson (1934) described the case of a mother who gave birth to two infants with renal agenesis, but thought that this was due to mutation causing a defect in the germ plasma. No other case has been found in a search of the literature.

TABLE III.—Group C (Ten Cases)

Case No.	Weight	Estimated Gestation in Weeks	Age at Death	Ear Formation	Genito-urinary Malformation	Other Malformation and Comment
14	3 lb. 10 oz. (1,640 g.)	34	3 days	Very large flabby ears. "Dumbo ears"	Rudimentary penis, hypospadias. No scrotum	
15	4 lb. 5 oz. (1,950 g.)	30	4 hours	Small asymmetric folded ears	Bilateral cystic kidneys	
16	4 lb. 10 oz. (2,100 g.)	37	10 mins.	Small deformed folded ears set low	Minute kidneys, R. smaller than L. Bifid ureters	Anal atresia. Microphthalmos. Omphalocele
17		28	59 hours	Very large flabby "Dumbo ears" set very low (Fig. 11)	Absent left kidney	Oesophageal atresia. Hypoplastic lungs
18	4 lb. 8 oz. (2,040 g.)	25	9 "	Small folded ears. R. much smaller than L. ear. R. ear squared off across top	R. kidney $\frac{1}{2}$ size of L. R. ureter ended blindly in posterior bladder wall. L. ureter had 3 partial stenoses or valves, with intervening dilatations	Hypoplastic atelectatic lung. Very large adrenal glands
19	3 lb. 7 oz. (1,560 g.)	32	5 mins.	Bilateral flabby low-set "Dumbo ears"	No kidneys	Large patent foramen ovale and ductus arteriosus
20	4 lb. 3 oz. (1,900 g.)	40	Stillborn	Bilateral large flabby low-set ears	No kidneys. Small phallus, labia majora. Sex indeterminate	Typical Potter facies
21	3 lb. 10 oz. (1,640 g.)	32	4 hours	Bilateral small ears, low set, asymmetrical	No kidneys or ureters. Male organ formation	Typical facies. Anal atresia
22	7 lb. 11 oz. (3,490 g.)	39	6 days	R. ear small, squared off folded and low set	Absent R. ureter and kidney. L. kidney in pelvis. No urethra. Male	Facies very similar to Potter's infants, but small folded ugly ears
23	3 lb. 13 oz. (1,730 g.)	36	20 hours	Flabby, large R. low-set ear with upper edge squared off	Male. Absent R. kidney. L. kidney in pelvis	Oesophageal atresia. Malrotated gut

renal tissue. However, in the same period three children encountered had normal ears but were found to have double ureters. Large numbers of pyelograms have been made for numerous reasons other than malformed ears, but only in the three cases mentioned has renal tract abnormality been found with normal ear formation.

Eight cases of renal agenesis (not all reported here) were recognized in approximately 18,000 births covering six years. Davidson and Ross (1954) found 5 cases in 368 consecutive necropsies on newborn infants.

Barclay and Baird (1935) examined 500 consecutive pyelograms and found six cases of bifid ureters. Dr. Fawcitt, of Booth Hall Children's Hospital, kindly examined consecutive pyelograms of 50 children and 50 adults and found only one case of a bifid ureter—approximately the same incidence—but this was in a series of cases referred for pyelography because renal tract abnormality had been suspected on clinical grounds (without reference to the ears). This paper reports 19 cases subjected to pyelography because the presence of peculiar ears suggested that the clinical symptoms were associated with anomalies of the renal tract.

Summary

Attention is drawn to the association of deformed ears and congenital malformation of the genito-urinary tract.

The ear deformities are similar to those seen in infants with renal agenesis.

Not all infants who die with renal agenesis have the large flabby ear described by Potter, but other patterns occur and are mentioned.

There seems to be a genetic association between renal agenesis, unilateral absence of one kidney, peculiarity in the formation of the ears, and other malformations of the genito-urinary tracts.

A malformed ear in the presence of enuresis, dysuria, abdominal colic, or other symptom referable to the genito-urinary tract justifies early pyelography.

The familial association of this clinical complex does not appear to be sex-linked.

A number of cases of unilateral bat-ear deformity are described in which the renal tract on the same side as the abnormal ear was affected. This might be coincidental.

Congenital anomalies of the genito-urinary tract occur without associated defects of the ears. In this series this has been in the ratio of 3:41.

Deformity of the ears can occur without deformity of the genito-urinary tract.

Appreciation must be expressed to good-humoured colleagues, secretaries, and clinical photographer Miss Stanley. Particular thanks are due to those allowing me to utilize their material and reports, particularly to the medical staff of the Liverpool Maternity Hospital; to Professor Capon, Drs. Rewell, Parry Jones, Adderley, and Jackson for necropsy reports; to Drs. Fawcitt, Livshin, Taylor, and Walton for radiological findings; to Mr. Grime for Cases 9 and 10; and to Professor W. Gaisford for his invaluable help in the preparation of this paper.

PACHYDERMO-PERIOSTOSIS (IDIOPATHIC OSTEOARTHROPATHY)

BY

J. H. ANGEL, M.B., M.R.C.P.

Medical Registrar, Postgraduate Medical School of London
and Hammersmith Chest Clinic

It has long been recognized by physicians that clubbing of the fingers may occasionally occur in healthy people. In 1935 Touraine, Solente, and Golé pointed out that, in some patients in whom no evidence of intrathoracic or cardiac disease could be found, gross clubbing was associated with enlargement of the extremities, thickening of the skin, particularly over the face, and a perioral reaction in the long bones. They proposed the term "pachydermie plicaturée avec pachy-periostose des extrémités" for the condition. In 1941 Brugsch showed from a study of the literature that a hereditary element was involved. In all, some 50 cases of this syndrome have now been described, mostly in the French literature.

Examples of the condition have been described under many different names—for example, megalis cutis et ossium (Gronberg, 1927), generalized osteophytosis (Freund, 1938), hyperostosis generalisata with pachydermia (Uehlinger, 1941, and most German authors following him). Most recent authors (Vague, 1948; Lièvre *et al.*, 1949; Franceschetti *et al.*, 1950; de Sèze and Jurmand, 1950; Findlay and Oosthuizen, 1951) use the term pachydermo-periostosis, which has the twin merits of brevity and accuracy.

So far as I know, no case has been described in England, and I therefore present three cases in order to draw attention to the syndrome.

Case 1

A single man aged 31 was admitted to University College Hospital on October 28, 1951, because of a sudden attack of pain in the left lower chest associated with "giddiness." The pain cleared up spontaneously over the next few hours. His past history had been eventful. At the age of 4 he had been an in-patient at Great Ormond Street, where he

was treated for swelling of the knees. He also had genu valgum, for which he was in plaster for about 15 months, without improvement. No further details are available about this admission. At the age of 6 he first began to have attacks of loss of consciousness, with or without pain. Since adolescence he had suffered from very heavy sweating, particularly from his hands and feet; at one time he used to rot through a pair of boots every three months. During 1942 and 1943 bilateral cervical and lumbar sympathectomies were carried out. At that time it was noticed that his hands and feet were unusually large. After these operations the attacks of giddiness and pain were reduced in frequency, and the amount of perspiration was greatly diminished. In the subsequent years he developed varicose veins in both legs and suffered from numerous attacks of thrombophlebitis. A number of operations were carried out on his legs; the veins were first tied, and later removed. He still complained of considerable pain in the legs at the time of his admission.

FIG. 1.—Case 1. Note the deep furrows on the face and above the eyebrows.

He thought that his hands and feet had always been large. He did not think that there had been any sudden increase in size at or about puberty. None of his family had large hands or feet.

On examination he was a tall thin man. His face was prematurely aged and was marked by very prominent skin folds on the cheeks and between the brows, and by exaggeration of the normal nasolabial folds (Fig. 1). His nose was large, shiny, and bulbous. The supraorbital ridges were prominent. The skin of the face was thickened and inelastic, and there was considerable sebaceous secretion. There was no thickening of the scalp. Neither the jaw nor the tongue was enlarged. His height was 72 in. (185 cm.); head to pubis 34½ in. (87.5 cm.), pubis to ground 38½ in. (98 cm.). The span of the outstretched arms was 74 in. (188 cm.).

Apart from the facies, the most striking feature was the gross enlargement of the hands and feet. Both wrists

FIG. 2.—Case 1. Enlargement of hands and clubbing of fingers.

and ankles were thickened. The fingers were long and presented a drumstick appearance owing to the clubbing of the distal ends (Fig. 2). The nails were beaked, and curved in all directions, exhibiting the so-called "watchglass" deformity.

There were no clinical abnormalities in the respiratory or cardiovascular system. Examination of the visual fields revealed some concentric diminution, but this was thought to be due to the prominence of the nose and eyebrows. No other abnormality was noted.

Investigations.—Random blood sugar, 80 mg. per 100 ml. Glucose-tolerance curve normal. B.M.R., + 7%. X-ray picture of the skull showed no enlargement of the sella turcica. X-ray picture of the chest revealed no pulmonary lesion. Serum calcium, 10.8 mg. per 100 ml. Serum phosphorus, 2.4 mg. per 100 ml. Serum alkaline phosphatase, 10 units (King-Armstrong). 17-ketosteroid excretion in 24 hours, 10.7 mg. E.C.G. showed normal rhythm and curves. There was no evidence of myocardial infarction.

Striking changes were seen on radiography of the bones. The metacarpals and proximal phalanges were enlarged and chunky, owing to the formation of periosteal new bone (Fig. 3). The terminal phalanges showed no "tufting." Periosteal new bone formation was marked in the tibiae, fibulae, radii, and ulnae (Fig. 4), and present, although less prominent, in the femora and humeri. X-ray examination of the foot showed resorption of the terminal phalanx of the big toe.

No cause was found for the patient's attacks. He was treated symptomatically for the pain in the legs and for his sweating, with some relief.

Case 2

A single man aged 33 attended the out-patient department of Uni-

versity College Hospital in March, 1953, complaining of pain in both knees and ankles. This had been present for five or six years and was getting worse. He had first noticed enlargement of the fingers at the age of 21, shortly after an appendectomy. His only other complaints were of undue sweating of the feet and of impotence.

Clinical examination revealed no abnormality in the chest or cardiovascular system. The hands and feet were enlarged and pigmented, and there was gross clubbing of the fingers and toes. Varicose veins were present on both legs. His ankles and knees were swollen. His forehead was unduly wrinkled and there was some exaggeration of the facial folds. A mild hypospadias was present. The x-ray picture of the chest was normal. Periosteal new bone was found in the radius, ulna, tibia, and fibula on both sides (Figs. 5 and 6). Both femora were also involved, but the humeri had escaped. In places the cortex was thickened and striated.

The W.R. was negative. Serum calcium, 9 mg. per 100 ml. Plasma inorganic phosphorus, 3.3 mg. per 100 ml. Alkaline phosphatase, 5.2 units per 100 ml. (King-Armstrong).

Case 3

A single man aged 36 presented himself at a chest clinic in May, 1956, because he was perspiring heavily at night. Two years previously he had been visiting a friend in another hospital when a passing doctor noticed that his fingers were clubbed and suggested that he ought to have an x-ray examination of his chest. This was quite normal. A second x-ray examination in 1956 was also clear. The patient's only other complaint was of abdominal pain which had been investigated in 1950 and found to be due to a peptic ulcer. His sister is said to have clubbed fingers.

On examination he was a tall thin man. The facies was similar to that of Case 1, although the features were less pronounced (Fig. 7). The naso-labial and cheek folds were deep and the skin was coarse, thickened, and greasy. The hands and feet were large and there was gross clubbing of

the fingers and toes. Flexion and extension of the wrists was limited, but movements of the ankles were normal. The chest and heart were normal and no other abnormality was detected.

X-ray pictures showed a periosteal reaction on the tibiae just above the malleoli and some thickening of the periosteal

FIG. 6.—Case 2. Ankle-joint, showing new bone formation on tibia and fibula.

FIG. 7.—Case 3. Note facial resemblance to Case 1.

the size of the extremities becomes constant. The characteristic clinical changes affect the skin and the bones. There is thickening of the skin over the face, forehead, scalp, and hands and feet. The upper eyelids are often thickened, and the face is drawn into thick folds, so that it appears very lined and creased. The most prominent folds are in the cheeks and on the forehead, and the naso-labial folds are greatly exaggerated (see Figs. 1 and 7). Sometimes the folds are so large that they resemble the gyri of the brain, a condition known as cutis verticis gyrata. The skin is greasy, owing to hypersecretion of the sebaceous glands; this may be associated with acne. The resultant facies, with its prematurely aged appearance, is very characteristic, and indeed the various cases bear a remarkable family likeness to one another. Touraine *et al.* describe it as "un aspect bizarre, à la fois soucieux et endormi." The thickened

attachments of the interosseous ligaments. There was a little periosteal thickening along the medial aspect of the lower end of the right femoral shaft. The tendo achillis was unusually dense in the antero-posterior view of the ankle.

There was no abnormality on the x-ray pictures of the hands and forearms. X-ray examination of the skull showed a normal sella turcica.

The plasma calcium was 11.1 mg. per 100 ml. The W.R. was negative.

Clinical Features

A study of the cases described in the literature and of the reviews by Touraine *et al.* (1935) and Jean Vague (1948) reveals a clear-cut clinical picture. The condition is familial in over a quarter of the recorded cases and affects males predominantly. At about the age of puberty a rapid enlargement of the hands and feet takes place. This is progressive for three or four years, but eventually the rate of advance slows down and

features have on occasion led to a diagnosis of leprosy. Gronberg (1927) states that a patient was refused entry to the United States of America because of this mistaken diagnosis.

The enlargement of the extremities may lead to a diagnosis of acromegaly. Usually only the hands and feet are enlarged, but the forearms, including the wrists and elbows, and the legs up to mid-thigh level may be involved, so that there is swelling of the knees and ankles. The ends of the fingers and toes show "drumstick" enlargement, and the nails are curved and beaked in all planes, thus resembling a watchglass in contour.

The patients are generally not greatly incommoded by the condition. Many complain chiefly of heavy sweating over the hands and feet, and sometimes over the face as well. The sheer size of the hands, feet, and legs may give rise to some clumsiness in their use. The ungainliness of the limbs and the immobile appearance of the face often make the patient timid and withdrawn. If the joints are involved, pain in the limb may be the predominant symptom.

Radiology.—The characteristic bony changes consist of the deposition of periosteal new bone. This has been described in all bones, but is most often seen in the long bones. The articular surface is always spared. The changes are earliest and best seen in the distal third of the leg and forearm. They do not occur over the distal phalanges, but the first two rows of phalanges, as well as the metacarpals and metatarsals, are affected. It is very rare for the carpus, tarsus, vertebrae, or skull to be involved. The new bone is laid down on the surface of the old cortex and gradually becomes fused with it, so that no clear line of demarcation can be made out. The outer surface of the new bone tends to be irregular and spicular (see Fig. 4). The whole cortex is thickened and there is encroachment on the marrow cavity.

Pathology.—Biopsies of the skin have been described. The epidermis is thickened and there is hypertrophy of the sebaceous glands and of the sweat glands. There are no specific changes. Leinwand and Duryee (1943) report a bone biopsy which showed foci of plasma cells in the paraperiosteal tissues. No abnormality of any of the endocrine glands has been found in the cases which have come to necropsy. In particular, the pituitary gland has been found to be macroscopically and microscopically normal.

Discussion

The complete clinical picture which has been described above is not met with in all cases. Incomplete forms of the syndrome in which the pachydermia was more limited, or in which periostosis was slight, were described by Touraine *et al.* (1935). Case 3 is an example of such a form.

It is obvious that this syndrome bears a close resemblance to hypertrophic osteoarthropathy, and differs from it mainly in the absence of a primary lesion. That facial changes do occur in the latter condition is now recognized; they are well illustrated in the publications of Fried (1943), Gilbert-Dreyfus *et al.* (1951), and Semple and McCluskie (1955). The latter also show how the facial changes may clear coincidentally with the removal of the primary lesion, in the same way that the clubbing recedes and the pain disappears. Certain differentiating factors have been described. Osteoarthropathy occurs in older patients (especially since the chief cause is carcinoma of the bronchus), and affects females as well as males; its course is more commonly painful. Radiologically, the new bone is laid down only subperiosteally, and the dividing line from the old cortex can be more easily defined than in pachydermo-periostosis, where the whole bone structure is remodelled and fusion of new bone occurs on the surface of the old cortex.

Nevertheless, the more one reads descriptions of cases of the two syndromes the closer the resemblance becomes. Thus, patients with pachydermo-periostosis may present because of painful joints or limbs. Heavy sweating occurs in both conditions. Many cases have, in fact, been written

up under the title "Idiopathic hypertrophic osteoarthropathy" (Camp and Scanlan, 1948; Fairbank, 1951). The radiological differences which have been described are not constant and may be a result of the difference in the rate of progress of the condition; in hypertrophic pulmonary osteoarthropathy secondary to lung cancer, for example, the process is more acute and there may be insufficient time for the new bone to fuse with the old cortex.

Clubbing of the fingers and hypertrophic osteoarthropathy are usually secondary phenomena, related to such diverse conditions as diseases of the lung (tuberculosis, fibrosis of the lung, emphysema, bronchiectasis, malignant disease of lung and pleura), congenital heart disease, and intestinal disorders, such as multiple polyposis of the colon, ulcerative colitis, steatorrhoea, and cirrhosis of the liver.

The most common single cause is carcinoma of the lung; over a seven-year period Semple and McCluskie (1955) saw no case of osteoarthropathy related to any other condition. Nevertheless, the number of cases of carcinoma of the lung which show clubbing is small and those with hypertrophic pulmonary osteoarthropathy is smaller still. Jack (1952) found three fully developed cases of hypertrophic pulmonary osteoarthropathy in 668 cases of bronchial carcinoma. Wierman *et al.* (1954) reported an incidence of 5% of simple clubbing or osteoarthropathy in 481 resections for malignant lung lesions. In this connexion the family reported by de Sèze and Jurmand (1950) is of great interest. Their patient, a man of 27, presented with a 10-year history of pains in the knees and was found to show the characteristic clinical and radiological picture of pachydermo-periostosis. Investigation of his family revealed that, although his mother and two sisters were quite normal, his father suffered from bronchiectasis and had marked clubbing of the fingers. A brother, who had no chest or other illness, had clubbed fingers to a less degree. De Sèze and Jurmand suggest that the genetic element which is known to be necessary for the development of pachydermo-periostosis may also be the factor determining the development of osteoarthropathy in cases of lung disease. On this hypothesis, all cases of clubbing of the fingers or of osteoarthropathy are familial. Some are idiopathic; others require a lung lesion to bring out the syndrome.

Differential Diagnosis.—Although, as mentioned above, the large hands and feet suggest acromegaly, the normal length of the limbs and the absence of any enlargement of the tongue or jaw differentiate it from that condition. The visual fields are quite normal. Radiologically, the sella turcica is normal in size and shape, and there is no "tufting" of the terminal phalanges. Other conditions which may require differentiation are osteitis deformans and syphilis of the bone. In the former there is asymmetrical involvement of the long bones, as well as involvement of the pelvis, spine, and skull. Pachydermo-periostosis is differentiated from syphilitic periostitis by the absence of history of infection, and of other manifestations of syphilis in the skin and cardiovascular or central nervous systems. The Wassermann reaction is negative.

Prognosis and Treatment.—The prognosis as regards life is excellent, but the effect on function depends on the extent of the process and whether the bones or the skin are chiefly involved. The most-disabled patients are those with joint involvement. Treatment is of little avail in this condition. American authors—for example, Camp and Scanlan (1948)—recommend a change to a hot dry climate. Tarsorrhaphy may be required in those cases in which there is considerable hypertrophy of the eyelids. If sweating is very prominent, sympathectomy will bring about considerable symptomatic improvement.

Aetiology.—Nothing is known about the cause of the condition. A family history has been obtained in over a quarter of the recorded cases, and it seems that inheritance is mediated by a recessive or incomplete dominant gene. Attempts have been made to discover an endocrine cause, but, although in certain cases isolated features suggesting endocrine disorders have been described, they are rare, and biochemical investigation had been consistently negative.

In four cases of the pulmonary type of osteoarthropathy, Fried (1943) noted clinical features of acromegaly such as prognathism and macroglossia. Necropsy revealed enlargement of the pituitary in two cases, and the presence of adenomata in the adrenal cortex and thyroid in two cases. However, no biochemical investigations were undertaken in this series and there is no real evidence for the "dyspituitarism" that Fried invokes as the probable cause of the syndrome.

Summary

Three cases are recorded of a syndrome known as pachydermo-periostosis, in which clubbing of the fingers and toes is associated with enlargement of the extremities and thickening and furrowing of the skin over the face. The characteristic radiological appearances of the bones are described. The differentiation of this syndrome from acromegaly and its relation to hypertrophic pulmonary osteoarthropathy are discussed.

My thanks are due to Professor M. L. Rosenheim and Dr. Peter Stradling for their help and for permission to publish this paper, and to Professor C. E. Dent for his advice.

PAROXYSMAL AURICULAR TACHYCARDIA WITH AURICULO- VENTRICULAR BLOCK

BY

E. FLETCHER, M.D., M.R.C.P.
Physician, Belfast City Hospital

AND

C. F. BRENNAN, M.B., M.R.C.P.I.
Senior Medical Registrar, Belfast City Hospital

Heyl (1932) first drew attention to paroxysmal auricular tachycardia associated with auriculo-ventricular block, leading to disturbance in the ventricular rhythm, arising as a complication of digitalis administration. Lown and Levine (1955) point out the serious nature of this disturbance of the auricular rhythm as a manifestation of digitalis toxicity. It is an example of a rapid heart rate due to this cause (Levine, 1948). The arrhythmia can easily be produced experimentally by the pharmacological action of digitalis on the normal heart, in contrast to the difficulty in producing ventricular arrhythmias (Scherf and Schott, 1953). Fig. 1 illustrates such an experiment. Acetyl strophanthidin was used as the digitalizing agent on account of its extremely rapid action (Lown and Levine, 1955). The drug was administered intravenously to a normal dog (weight 12 lb.;

OCT. 5, 1957

FIG. 1.—Experimental paroxysmal auricular tachycardia with auriculo-ventricular block produced in a normal dog with acetyl strophanthidin. TH=Thoracotomy.

5.4 kg.) anaesthetized with 6 mg. of intravenous pentobarbitone sodium. Paroxysmal auricular tachycardia with auriculo-ventricular block occurred as a terminal complication when 3.2 mg. of acetyl strophanthidin had been given. We describe below four cases of this serious complication of digitalis therapy, with particular reference to diagnosis and treatment.

Case Reports

Case 1.—A man aged 49 was admitted to hospital with intractable congestive heart failure due to coronary artery disease. Prior to admission he had been receiving 0.25 mg. of digoxin thrice daily, and 2 ml. of mersalyl twice weekly for an indefinite period, but he failed to improve. The pulse was rapid and irregular, and he was thought to have uncontrolled auricular fibrillation. Consequently 1 mg. of digoxin was administered orally, and thereafter 0.5 mg. every six hours. Twenty-four hours later his condition was unchanged, and the pulse remained rapid and irregular. An electrocardiogram confirmed the presence of paroxysmal auricular tachycardia with auriculo-ventricular block (Fig. 2). Digitalis was immediately stopped and further diuretic treatment suspended. Potassium chloride, 5 g., was given daily in divided doses by mouth for four days. This restored a slow sinus rhythm, with marked improvement in the patient's condition. One week later the abnormal auricular rhythm recurred, and on this occasion sinus rhythm was effectively restored with procaine amide, 0.5 g. twelve-hourly for four doses.

Case 2.—A woman aged 71 was admitted to hospital with advanced congestive heart failure due to coronary artery disease. She had been receiving digitalis and diuretic treatment for some months previously. The heart rate was rapid and irregular, and she was thought to have uncontrolled auricular fibrillation. Consequently digitalis foliata, 1 gr. (65 mg.) six hourly, was administered. No improvement occurred after three days. An electrocardiogram confirmed

that she had paroxysmal auricular tachycardia with auriculo-ventricular block (Fig. 2). Digitalis was omitted, and 5 g. of potassium chloride was administered orally in divided doses. On the fifth day normal slow sinus rhythm was restored, with improvement in the patient's condition. After further treatment she was discharged ambulant.

Case 3.—A woman aged 83 sustained a fresh myocardial infarction and was treated with 0.25 mg. of digoxin six-hourly until admission five days later with congestive heart failure. An electrocardiogram confirmed that she had paroxysmal auricular tachycardia with auriculo-ventricular block (Fig. 2). Potassium chloride, 5 g., was given orally in divided doses each day. Three days later normal sinus rhythm was restored.

Case 4.—A man aged 50 developed a fresh myocardial infarction, and had been treated with 0.25 mg. of digoxin every six hours for five days before admission to hospital. An electrocardiogram taken just before death confirmed the presence of paroxysmal tachycardia with auriculo-ventricular block, most likely related to digitalis therapy.

Discussion

Paroxysmal auricular tachycardia with auriculo-ventricular block cannot be distinguished from uncontrolled auricular fibrillation on clinical examination. In both conditions the ventricular rate is rapid and irregular. Differentiation is important during the course of digitalis therapy, for whereas

FIG. 2.—Paroxysmal auricular tachycardia with auriculo-ventricular block. Case 1 shows 2:1 block. Reversal to sinus rhythm with potassium treatment is shown in Cases 1 and 2.

increased dosage of digitalis is required for uncontrolled auricular fibrillation, such treatment may be disastrous in the presence of the toxic arrhythmia. Even electrocardiographic analysis may be difficult. Well-defined P waves are helpful, and should be sought in all leads. Oesophageal leads may be necessary (Brown, 1936). Our patients were thought to have auricular fibrillation in the first instance. Cuttings from appropriate leads showing P waves were selected for the figures. An isoelectric interval between successive P waves helps to differentiate paroxysmal auricular tachycardia with auriculo-ventricular block from auricular flutter. Such electrocardiographic diagnoses as "impure flutter" and "impure fibrillation" should be regarded with suspicion, especially if the patient is receiving digitalis. It is doubtful if they have any fundamental meaning, and they may conceal the serious disturbance of auricular rhythm under review. In our cases the auricular rate varied between 195 and 230 a minute.

Our cases were receiving digitalis when they developed paroxysmal auricular tachycardia with auriculo-ventricular block. The response to potassium treatment supports the view that digitalis was the causative agent (Cases 1, 2, and 3; Lown and Levine, 1955). An excessive dose of the drug may cause the arrhythmia, but it is important to realize that it may occur when the heart muscle is sensitized to digitalis by potassium loss (Lown, Salzberg, Enselberg, and Weston, 1951). Thus in intractable heart failure prolonged diuresis may render a therapeutic dose of digitalis a toxic dose, and thereby cause paroxysmal auricular tachycardia with auriculo-ventricular block.

Prompt treatment is essential in paroxysmal auricular tachycardia with auriculo-ventricular block due to digitalis toxicity. The drug, of course, must be stopped, and diuresis, parenteral, and other measures aimed at diminishing the load on the heart must be suspended, to conserve body potassium. Potassium is the specific remedy (Lown and Levine, 1955). In urgent cases it may be given intravenously. We used oral therapy in Cases 1, 2, and 3—5 g. of potassium chloride being given daily in divided doses under continual electrocardiographic control until sinus rhythm was restored. Lown and Levine (1955) note that auriculo-ventricular block is abolished before the ectopic auricular centre is suppressed by potassium. Thus the ventricular rate increases before the sudden restoration of sinus rhythm. Procaine amide is also effective (Case 1). We prefer the intramuscular route, 0.5 g. of the drug twelve-hourly, until sinus rhythm is restored. Two of our cases had fresh myocardial infarction (Cases 3 and 4). One of them recovered with potassium treatment; the other, who received no specific treatment, died. The digitalis treatment of fresh myocardial infarction requires special care with regard to its toxic action causing this serious disturbance of auricular rhythm.

Finally, more rarely, paroxysmal auricular tachycardia with auriculo-ventricular block may occur spontaneously—in the absence of digitalis administration (Lown and Levine, 1955; Friedberg, 1949). It appears to be a benign condition, and, paradoxically, digitalis is the treatment of choice.

Summary

Paroxysmal auricular tachycardia with auriculo-ventricular block is a serious complication of digitalis toxicity that cannot be differentiated clinically from auricular fibrillation. Four cases are described; the importance of diagnosis depends upon the identification of well-defined P waves in any appropriate lead separated by isoelectric intervals.

TWO CASES OF ALKAPTONURIA

BY

A. W. MCKENZIE, M.B., Ch.B.

Late House-Surgeon, the Royal Infirmary, Edinburgh

J. A. OWEN, M.B., B.Sc., Ph.D.

Lecturer in Clinical Chemistry, University of Edinburgh

AND

J. H. ROLLAND RAMSAY, M.B., F.R.F.P.S.

Chest Physician, Industrial Chest Unit,

Bangour Hospital, West Lothian

Alkaptonuria results from an inherited inability to metabolize homogentisic acid, a breakdown product of tyrosine, which undergoes oxidation in alkaline urine to form pigments, giving the urine its characteristic brown or black appearance. The condition is relatively rare; only about 200 cases have been described (Martin *et al.*, 1952). Hogben *et al.* (1932) calculated the incidence of the condition to be about one in ten million.

Apart from constituting an interesting metabolic disorder, alkaptonuria is important in that cases may be misdiagnosed. Thus the presence of a reducing substance (homogentisic acid) in the urine may lead to a diagnosis of diabetes mellitus, whilst the complication of ochronotic arthritis may be diagnosed as some other arthritic condition.

For this reason we are prompted to describe two new and apparently unrelated cases which illustrate diagnostic pitfalls.

Case 1

A 12-year-old schoolgirl was admitted to the professorial surgical wards of the Royal Infirmary, Edinburgh, on May 4, 1956, for the investigation of intermittent attacks of lower abdominal pain. When several months old she had been admitted to another hospital for the investigation of a red coloration of the urine; a diagnosis of pyelonephritis was made, although there is no record of bacteriological examination of the urine or the presence of red cells on microscopy. During the whole of the patient's childhood the mother had often observed brown staining of the diapers and undergarments.

The child was normally developed and no abnormalities were detected on physical examination apart from a generalized brown pigmentation of the skin. Barium-meal and x-ray examination of the skeletal system failed to reveal anything abnormal. The Wassermann and Mantoux reactions were negative. Her urine when freshly voided was acid and usually a normal colour, although occasionally there was a faint red coloration; on standing exposed to the air for several days, however, the urine became alkaline and gradually turned a deep brown colour. Tests for homogentisic acid were positive (see below). Over a seven-day period the excretion of homogentisic acid averaged 2.4 g. in 24 hours.

A diagnosis of alkaptonuria associated with non-specific mesenteric adenitis was made. When seen four months after discharge from hospital she was asymptomatic. A search for other cases of alkaptonuria among relatives was unsuccessful.

Case 2

A coal-miner aged 53 was seen at the Industrial Chest Unit, Bangour Hospital, on July 25, 1956, complaining of breathlessness on exertion. In 1938 he had been admitted to another hospital for the investigation of intermittent lower back pain. At that time there were no abnormalities on physical examination, but an x-ray film of the lumbar

spine was reported as showing "atypical arthritic changes of the spondylitis type with commencing ossification of the ligaments." The urine was noticed to darken on standing and it reduced Benedict's solution. The fasting blood-sugar level was normal. No firm diagnosis was made of the urinary abnormality.

Subsequently he received physiotherapy on several occasions for what was described as osteoarthritis of the spine, shoulders, and knees. Shortly before being seen at Bangour he had attended the out-patient department of another hospital with a pain in the chest which was at first thought to be related to coronary insufficiency. However, his electrocardiogram was normal. His urine was again found to reduce Benedict's solution and to darken on standing: indicanuria was diagnosed.

On admission he was found to be well nourished, with a slight stoop and with mild bronchitis and emphysema. A soft, localized systolic murmur was heard in the mitral area and the B.P. was 200/115. Some diminution of movement was noted in both shoulders and in the lumbar spine. The most striking feature, however, was the presence of two patches of slate-grey pigmentation on the sclera of both eyes to each side of the corneal limbus (Fig. 1). There

FIG. 1.—Eye (Case 2) showing characteristic pigmentation of sclera.

was thickening of the auricular cartilages with a bluish discoloration. The affected cartilages were opaque. X-ray examination of the spine showed the intervertebral disks to be thin and densely calcified (Fig. 2). Calcification was also present in the tendons in relation to the shoulders, pelvis, and knees (Fig. 3). The Kahn reaction was negative.

FIG. 2.—X-ray film of spine (Case 2), showing thinning and calcification of intervertebral disks.

FIG. 3.—X-ray film of pelvis (Case 2), showing calcification of tendons arising from the ischium.

The urine was straw-coloured when voided, but became the colour of nut-brown ale when allowed to stand for two or three days. It never became black even after standing for three weeks. The urine contained a reducing substance which was not fermented by yeast. This was identified as homogentisic acid. The daily excretion of homogentisic acid was measured for two days on a normal hospital diet and was 3.6 g. and 3.8 g. respectively.

Identification of Urinary Homogentisic Acid

Many tests have been described for the detection of homogentisic acid in the urine (Harrison, 1947), but most of the simple tests are not specific.

Colour.—Except rarely in Case 1, the urines were of normal colour when freshly voided. On standing exposed to the air, however, the urines in the course of a few days became dark but not black in colour. While such a finding is of value in arousing a suspicion of alkaptonuria, false-positive results occur; darkening may be observed in urines containing melanogen, indican, urobilinogen, porphyrins, and phenols, including gentisic acid, a metabolic product of salicylates.

Colour on Alkalinization.—Both urines darkened from above downwards on being made alkaline. However, we have observed that urines containing gentisic acid derived from ingested salicylate behave similarly.

Reduction of Copper Salts.—With Benedict's solution the urines gave, on boiling, a black solution with, subsequently, the formation of a yellow precipitate. The urines gave also positive results with "clinitest" but negative results with glucose oxidase tests ("clinitix" and "tes-tape"), which are specific for glucose (Hunt *et al.*, 1956; Tunbridge *et al.*, 1956).

Reduction of Silver Nitrate.—The addition to each urine of an equal volume of silver nitrate solution produced a black precipitate within 10 seconds. Ascorbic acid also reduces silver nitrate; chlorides give a precipitate of silver chloride which turns black slowly on exposure to light.

Reduction of Ammoniacal Silver Nitrate.—The addition to each of the urines of an equal volume of ammoniacal silver nitrate produced an immediate black precipitate. Ascorbic acid and uric acid also reduced ammoniacal silver nitrate in the cold.

Ferric Chloride Test.—In our hands this test gave inconsistent results. Ferric chloride added drop by drop to urine is said to give an evanescent blue colour. However, this reagent gives colours with various other phenolic substances.

Chromatography.—This was performed using the solvent N-butanol, acetic acid, and water (4:1:5 v/v), with ammoniacal silver nitrate as reagent. Homogentisic acid has an R_F of approximately 0.8 in this solvent, and gave an immediate brown or black spot with ammoniacal silver nitrate. Of

normal constituents ascorbic acid ($R_F=0.2$) also gives an immediate brown colour; uric acid ($R_F=0.4$) gives an orange colour slowly, while chloride and other inorganic ions ($R_F=0.1-0.2$) form spots which turn blue on exposure to light. An immediate brown or black spot is also given by gentisic acid ($R_F=0.9$), and other unidentified substances (R_F less than 0.5) present in the urine of patients receiving large doses of salicylates. Neuberger *et al.* (1947), using chromatography, noted, in the urine of a relative of a patient with alkaptonuria, the presence of an unidentified substance which reduced the silver reagent. Fig. 4 shows a chromato-

FIG. 4.—Chromatogram of urines confirming the presence of homogentisic acid.

gram on which has been run urine from both cases along with pure homogentisic acid, homogentisic acid isolated from the urine of Case 1, and gentisic acid. The position of the spots confirmed the presence of homogentisic acid in both urines.

Isolation of Homogentisic Acid.—The acid was isolated from the urine in Case 1; this was carried out according to the method of Neuberger *et al.* (1947). The melting-point of the free acid was found to be 144°C .; Neuberger *et al.* give the result as $144-145^\circ\text{C}$. This melting-point was not depressed by admixture with a pure sample of homogentisic acid.

Discussion

It is not at all surprising that a condition as rare as alkaptonuria should sometimes go undiagnosed. In the past the condition has often been confused with diabetes mellitus (Osler, 1904). In the two cases described here the colour of the urine was the cause of diagnostic errors; in Case 1 the pink colour in the urine led to a diagnosis of pyelonephritis, whilst in Case 2 darkening on standing was attributed to indicanuria. The typical ochronotic arthritis in Case 2 was not recognized and was treated for many years as arthritis of unknown aetiology.

Whilst the diagnosis of the fully developed case presents no serious difficulty, in patients without ochronosis or arthritis the diagnosis is more elusive. The tests for homogentisic acid commonly employed are not entirely reliable,

and Janney (1918) has pointed out that alkaptonuria can be diagnosed with certainty only by the isolation of homogentisic acid from the urine. We suggest that chromatography, which is a more simple procedure than the isolation of homogentisic acid, should be used as a confirmatory test.

Typically, alkaptonuria does not manifest itself, except by the urinary abnormality, until the third decade or later, when ochronosis appears and arthritic changes cause symptoms. The present two cases demonstrate this very well, as the first showed no evidence of ochronosis or arthritis, whilst the second patient developed arthritic symptoms at the age of 35 and had characteristic changes in the sclera and auricular cartilages when seen at the age of 53.

The actual nature of ochronotic pigment is unknown. Chemically it resembles melanin and is believed to be formed from homogentisic acid. The deposition of pigment takes place mainly in cartilage and tendons, and is followed by calcification in these sites; in joints this gives rise to arthritic changes. Pomeranz *et al.* (1941) have described cutaneous pigmentation, and it may be that the skin pigmentation noted in Case 1 was the first manifestation of developing ochronosis. The sclera is often affected. It is of interest that an identical appearance is produced in sclera and cartilage by the prolonged application of phenol (carbolic acid) to wounds (Reid *et al.*, 1908), while a somewhat similar appearance in the eye has been reported in workers engaged in the manufacture of hydroquinone (Anderson, 1947).

The mode of inheritance of the condition has been a subject of dispute. Garrod (1923) thought that transmission was by means of a simple autosomal recessive gene, but Hogben *et al.* (1932), in reviewing the pedigree of 45 alkaptonuric families, found the character to be dominant in three families and recessive in the others. Pieter (1925) has described a case in which inheritance was by means of a Mendelian dominant. Milch (1955) has summed up the position by suggesting that the disease is inherited by a pair of coexistent and incompletely penetrant dominant factors.

Many of the reported cases have occurred as a result of consanguineous marriages. However, in the present cases the parents were not related except by marriage. We have investigated 16 relatives of Case 1 and 8 relatives of Case 2 without finding another case of alkaptonuria, and can therefore add nothing to knowledge on the transmission of the condition.

Summary

Two apparently unrelated cases of alkaptonuria are described.

Tests for the detection of urinary homogentisic acid, including chromatography, are discussed and evaluated.

Attention is drawn to alkaptonuria as a condition to be considered in the investigation of patients with reducing substances in the urine, or with arthritis.

We thank Sir James Learmonth and Dr. C. Kelman Robertson for permission to report Case 1 and Case 2, respectively; Dr. L. H. Easson and Miss E. H. Clark for biochemical investigations in Case 2; and Mr. D. A. Franklin for the photograph, of which Fig. 1 was from a kodachrome original. Professor A. Neuberger kindly supplied a sample of pure homogentisic acid.

IRON-TOLERANCE TESTS IN DIFFERENTIATING BETWEEN HAEMOCHROMATOSIS AND LIVER CIRRHOSIS

BY

LUIGI NAPOLITANO, M.D.

AND

LUDOVICO ANTONIO SCURO, M.D.

From the Institute of Medical Pathology,
University of Rome

The study of the results of the oral and intravenous iron-tolerance tests can help in establishing whether alterations in the metabolism of iron occur in different diseases. Little comparative research has been done on the metabolism of iron in patients with haemochromatosis and liver cirrhosis (Gitlow and Beyers, 1952; Gitlow, Beyers, and Colmore, 1952).

During the course of personal research on haemochromatosis (Napolitano and Scuro, 1954a, 1954b, 1956), it seemed to us worth while studying this problem by simultaneously determining the serum iron, the oral and intravenous iron tolerance, and the serum transferrin in patients suffering from the above-mentioned diseases.

We have also analysed the serum-iron data of Gitlow and Beyers (Napolitano and Scuro, 1956), some of which have proved very useful in differentiating haemochromatosis from liver cirrhosis.

Materials and Methods

Our studies were carried out on 5 patients with haemochromatosis, 12 with liver cirrhosis, and 5 normal subjects as controls. Of the 12 with liver cirrhosis, 7 suffered from Morgagni-Laennec atrophic cirrhosis and 5 had hypertrophic splenomegalic cirrhosis with hyperhaemolysis. In the cirrhotic patients, except Cases 11, 13, 20, and 22, slight anaemia and macrocytosis were present; Case 14 was intensely jaundiced, and subjaundice was present in Cases 11, 12, 13, and 15.

In all subjects the behaviour of serum iron, oral iron, intravenous iron, and serum transferrin has been studied.

The serum iron was calculated according to the method of Bothwell and Mallett (1955), which is based on the lines of the Heilmeyer and Plötnner method and calls for the use of the Beckman spectrophotometer on 520 mμ wavelength.

For the study of the oral iron tolerance 120 mg. of Fe^{++} was administered in the form of ferrous sulphate and vitamin C (three pills of "ferro redoxon"); the serum iron was determined before and 2, 4, 6, and 10 hours after administration of the salt.

In carrying out the intravenous iron tolerance tests 10 mg. of Fe^{++} was injected in the form of ferrous ferro-gluconate with vitamin C; the serum iron was determined before and 5 minutes, 30 minutes, 2 hours, and 3 hours after the intravenous injection of the salt.

The unsaturated serum transferrin (U.I.B.C.) was determined *in vitro* according to the method of Ventura (1952), which is an adaptation of the original technique of Cartwright and Wintrobe, and calls for the use of the Beckman spectrophotometer on 520 mμ wavelength.

In the study of the graphic curve of the intravenous iron-tolerance tests the following data of Gitlow and Beyers were taken into consideration: (1) T.I.B.C.=total iron-binding capacity (specimen drawn five minutes after the injection of iron); (2) INC.=increase from the initial serum iron level

(SeFe) to the T.I.B.C. ($\text{INC.}=\text{T.I.B.C.}-\text{SeFe}$); (3) DEC.=decrease in the serum iron level from the five-minute to the 120-minute specimen ($\text{DEC.}=\text{T.I.B.C.}-120\text{-minute specimen}$); (4) DEC./INC. ratio; (5) SeFe/T.I.B.C. ratio; (6) S.D.I.=addition of the DEC./INC. and SeFe/T.I.B.C. values ($\text{S.D.I.}=\frac{\text{DEC.}}{\text{INC.}}+\frac{\text{SeFe}}{\text{T.I.B.C.}}$).

Results

Our research (see Table and Figs. 1 and 2) gave the following results:

Serum Iron.—The serum iron was constantly high in the patients with haemochromatosis and in those with hypertrophic splenomegalic liver cirrhosis; on the other hand, it was normal or lower than normal in the patients with Morgagni-Laennec atrophic cirrhosis.

Oral Iron-tolerance Tests.—In the cases of haemochromatosis the oral administration of iron did not provoke any significant increase of serum iron, and the graphic curve of the iron-tolerance test showed a clearly level pattern (Fig. 1).

FIG. 1.—Oral iron-tolerance tests with 120 mg. Fe^{++} in patients with haemochromatosis and in patients with (hypertrophic or atrophic) liver cirrhosis.

Also in 10 out of 12 cases of liver cirrhosis these tests gave similar results, with no or very little increase of serum iron. Only in two cirrhotic patients was a moderate increase of serum iron observed (respectively +66% and +80%); it was, however, lower than in the control subjects (Fig. 1).

Intravenous Iron-tolerance Tests.—In the patients with haemochromatosis the increase of serum iron, which is considerable in normal subjects, was very little; it was moderate in only one case. The graphic curve of these tests showed a level pattern (Fig. 2). In the patients with liver (hypertrophic or atrophic) cirrhosis, however, the curve showed a quick increase, but it was lower than in the controls; besides, the serum iron values tended to return to the initial levels more quickly than in the controls (Fig. 2).

Data Drawn from Intravenous Iron-tolerance Test.—From the Table we can observe the following data: (a) T.I.B.C. was normal or slightly reduced both in cases of haemochromatosis and in those of hypertrophic or atrophic liver cirrhosis. (b) INC. was very little in the patients with haemochromatosis and in three out of five patients with hypertrophic hyperhaemolytic liver cirrhosis; it was remarkable in all the patients with atrophic liver cirrhosis. (c) DEC. was variable in all the subjects tested. (d) DEC./INC. (index of response of the body to the intravenous iron charge) was always increased in the patients suffering from haemochromatosis or hypertrophic splenomegalic liver cirrhosis with hyperhaemolysis; it was lower in those suffering from atrophic liver cirrhosis. (e) SeFe/T.I.B.C. (degree of saturation of the serum iron-binding capacity) was always considerably increased in the cases of haemochromatosis or hypertrophic splenomegalic liver cirrhosis with hyperhaemolysis; it was lower in

the cases of atrophic liver cirrhosis. (f) S.D.I. was always higher than 1.35 in those with haemochromatosis and lower than 1.35 in cases of Morgagni-Laennec atrophic cirrhosis. In three out of five patients suffering from hypertrophic hyperhaemolytic liver cirrhosis the behaviour of S.D.I. was the same as in those with haemochromatosis.

Transferrin (Unsaturated Fraction, or U.I.B.C.).—The level of the unsaturated serum iron-binding capacity, or transferrin, was very low in the patients with haemochromatosis. In 7 out of 12 with liver cirrhosis (2 with hypertrophic hyperhaemolytic cirrhosis and 5 with atrophic cirrhosis) it was normal; in the other 5 it was lower than in normal controls.

Discussion

The results are in close agreement with those of Gitlow and Beyers. They show that the study of iron metabolism can supply significant data for the differential diagnosis between haemochromatosis and liver cirrhosis. Three indices derived from breaking down the curve of intravenous iron-tolerance tests are particularly useful from this point of view. They are: (1) DEC./INC., which shows the capacity of response of the body to the intravenous iron charge; (2) SeFe/T.I.B.C., which shows the degree of saturation of the serum iron-binding capacity; (3) S.D.I.—that is, the addition of the two preceding indices (DEC./INC. + SeFe/T.I.B.C.).

In haemochromatosis the values of the first two indices are constantly higher than in normal subjects. In patients with Morgagni-Laennec atrophic cirrhosis they are significantly lower and their levels are not substantially different from the limits registered in normal subjects.

Data from Intravenous Iron-tolerance Test and Transferrin Values in Normal Subjects and in Patients with Haemochromatosis and Liver Cirrhosis

The standard error of the mean was calculated according to the formula $s = \sqrt{\frac{s(y-\bar{y})^2}{n(n-1)}}$.

The t was calculated according to the procedure given in J. H. Burn's *Biological Standardization* (Oxford Univ. Press, London, 1950).

The statistically significant differences of the mean values are printed in italics.

FIG. 2.—Intravenous iron-tolerance tests with 10 mg. Fe++ in patients with haemochromatosis and in patients with (hypertrophic or atrophic) liver cirrhosis.

The third index is generally higher than 1.35 in haemochromatosis and lower than 1.35 in atrophic liver cirrhosis.

The above-mentioned data do not seem to be of value in differentiating haemochromatosis from hypertrophic splenomegalic liver cirrhosis with hyperhaemolysis. In these diseases the values of the indices referred to can be equal. From the Table it will be seen that, except the DEC./INC. ratio, none of the mean values of the indices taken into consideration is statistically different in the two groups of patients. However, other clinical features and laboratory tests are available in this differential diagnosis.

The determination of serum iron alone, of oral iron-tolerance, and of serum transferrin has little diagnostic value in differentiating haemochromatosis from liver cirrhosis.

Serum iron is usually normal or lower than normal in liver cirrhosis, but can often reach very high values in various conditions (acute hepato-cellular damage, hyperhaemolysis, etc.). Also, the oral iron-tolerance test has no significantly differential value; the level pattern of the graphic curve of this test is probably related to an increased

tendency to store iron in the body. This increased iron storage occurs both in haemochromatosis and in liver cirrhosis.

The unsaturated serum transferrin is constantly very low in haemochromatosis. This feature can be observed also in liver cirrhosis, not only in hypertrophic splenomegalic cirrhosis with hyperhaemolysis, but also in atrophic cirrhosis, probably in relation to the usual decrease of plasma β_1 -globulins, to which the transferrin belongs.

Summary

A comparative study has been made of serum iron, of oral and intravenous iron-tolerance, and of unsaturated transferrin (U.I.B.C.) in 5 cases of haemochromatosis, in 12 cases of liver cirrhosis (7 cases of Morgagni-Laennec atrophic cirrhosis, 5 cases of hypertrophic splenomegalic liver cirrhosis with hyperhaemolysis), and in 5 normal controls.

The results obtained prove that the study of iron metabolism can give some significantly differential data between haemochromatosis and liver cirrhosis. Three indices derived from breaking down the graphic curve of intravenous iron-tolerance tests are particularly useful. The first of these (DEC./INC.) expresses the capacity of response to the intravenous iron charge; the second (SeFe/T.I.B.C.) expresses the degree of saturation of serum iron-binding capacity; both are greatly increased in haemochromatosis. Generally such marked increase is absent in atrophic liver cirrhosis, but sometimes values are found to be slightly higher than in normal subjects. The third index (S.D.I.) is obtained by the addition of the two preceding data. S.D.I. is always higher than 1.35 in haemochromatosis and lower than 1.35 in atrophic liver cirrhosis.

The above-mentioned data are of no use in the differential diagnosis between haemochromatosis and hypertrophic splenomegalic liver cirrhosis with hyperhaemolysis.

The determinations alone of serum iron and unsaturated transferrin, and the oral iron-tolerance test, have little value in differentiating haemochromatosis from liver cirrhosis.

The annual conference of the National Smoke Abatement Society was held in Hastings this week (October 2-4). The first three sessions of the conference dealt with air pollution from road vehicles, the administration of the Clean Air Act, 1956, and industry and the Clean Air Act. In his presidential address Dr. R. LESSING, Ph.D., stressed the importance of extensive cleaning of raw coal. He contended that a large proportion of the dust discharged from both industrial and domestic chimneys was due to "natural," removable dust in coal. Dr. Lessing also emphasized the importance of washing coal to remove sulphurous impurities. Papers on air pollution from road vehicles dealt with methods of reducing the amount of sulphur released from diesel fuel and of carbon monoxide from petrol. Mr. G. GRAHAM DON (London School of Hygiene and Tropical Medicine) said that the smoke control area was the backbone of the new attack on air pollution. He considered it more profitable to control a suburban area with mainly domestic chimneys than the centre of an industrial city. He suggested that a "clean air ring," on the "green belt" principle, should be instituted in industrial cities, spreading gradually from the edge towards the centre.

HIGHLY RAISED SERUM VITAMIN B₁₂ LEVELS IN "OBSTRUCTIVE HEPATIC NECROSIS"

BY

Vitamin B₁₂ exists in serum both in a "free" state and "bound" to the alpha-globulin fraction (Pitney *et al.*, 1954). Jones and Mills (1955) reported elevated levels of both free and bound vitamin B₁₂ in viral hepatitis and in Laennec's cirrhosis, whereas values were normal in biliary cirrhosis. Rachmilewitz *et al.* (1956) confirmed these observations and also found an increase in the maximal vitamin-B₁₂-binding capacity of the serum in liver injury, but were not able to correlate high vitamin B₁₂ levels with changes in any particular serum globulin component; they also found normal levels in jaundice due to extrahepatic biliary obstruction.

We record the finding of extremely high levels of bound serum vitamin B₁₂ in a patient with obstructive jaundice and diffuse hepatic necrosis, with return to normal values in the recovery phase. This case represents an example of acute hepatocellular failure with liver coma which may complicate biliary obstruction, particularly in the elderly; we have termed this condition "obstructive hepatic necrosis."

Materials and Methods.—Serial estimations were made of the levels of serum bilirubin, albumin, total globulin, gamma-globulin, and alkaline phosphatase (King-Armstrong units). Cephalin flocculation was read after 24 hours and expressed semiquantitatively as — to + + +. Biochemical methods and biopsy techniques have been previously described (Saint *et al.*, 1953). Serum vitamin B₁₂ levels were estimated by microbiological assay with *Euglena gracilis* as described by Hutner *et al.* (1956). The normal ranges for total and free vitamin B₁₂ are respectively 100–720 µg. and 40–160 µg. per ml. of serum (Mollin and Ross, 1952).

Case Report

A retired man aged 71 was seen on November 3, 1956, with a week's history of pain under the right costal margin, deepening jaundice, and stupor. His previous health had been good apart from two episodes of endogenous depression in 1949 and 1954, and one week of right upper abdominal pain in 1954. Relatives gave the following history. He had suffered from slight indigestion and anorexia for three months; eight days previously he had developed a "squirmy" feeling in the abdomen after eating a pie, followed by bouts of right upper abdominal pain, vomiting, and jaundice. The pain had persisted, the jaundice had deepened, and he had taken no food. He had complained of cold shivers two days before admission, and next day had become mentally confused.

On examination he was deeply jaundiced and stuporous. The liver was slightly enlarged; the gall bladder and spleen

were not palpable. Movements of the limbs were uncoordinated, and there was a coarse tremor of the hands. The haemoglobin value was normal; the white-cell count was 30,000 per c.mm. The results of serial liver-function tests, serum vitamin B₁₂ levels, and other laboratory findings are shown in the Table. It will be noted that initially the usual obstructive pattern of a negative cephalin flocculation associated with an elevated serum alkaline phosphatase is replaced by a pattern suggestive of hepatic necrosis.

The provisional diagnosis was gall-stone obstruction of the common bile duct and cholangitis. In spite of antibiotic and intravenous infusion therapy, his condition deteriorated over the next 24 hours, and laparotomy was undertaken to procure drainage of the biliary system. The common bile duct was completely obstructed by a large gall-stone impacted at the ampulla of Vater. The stone was removed, the common duct was drained, and the patient made a protracted but complete recovery. A biopsy of the liver taken at operation showed the following histological appearances (Fig. 1). A lobular structure was preserved, but there were striking changes in the staining character of the liver cells throughout, involving entire lobules in some areas. The changes varied from cloudy swelling to frank eosinophilic necrosis, particularly in the subcapsular zone. Many areas showed focal polymorph infiltrations and occlusion of portal venules by thrombus. A percutaneous aspiration biopsy of the liver six weeks later merely showed a slight increase in fibrous tissue and lymphocytic infiltration in the portal area. Almost complete repair had taken place (Fig. 2).

Discussion

Raised serum vitamin B₁₂ levels may occur in two disease states. High bound levels are found in chronic myeloid leukaemia (Beard *et al.*, 1954); secondly, data from Lear *et al.* (1954), Jones and Mills (1955), Rachmilewitz *et al.* (1956), and from this unit (unpublished) have shown elevations in acute viral hepatitis and hepatic cirrhosis, and also

FIG. 1.—Operation liver biopsy. Diffuse areas of hepatic necrosis; the surviving cells are staining darkly. (H. and E. ×72.)

FIG. 2.—Percutaneous aspiration biopsy of liver. Regeneration and restitution of hepatic architecture has occurred. (H. and E. ×168.)

an increased urinary excretion of what is apparently free vitamin B₁₂. Rachmilewitz *et al.* (1956) accounted for elevated serum and urine vitamin B₁₂ levels by postulating release from injured liver cells of stored vitamin B₁₂, part presumably becoming bound to alpha-globulin, the remainder being excreted in the urine. A comparable release of enzymes such as oxalacetic glutamic transaminase has been used as an index of hepatic damage (Wroblewski and La Due, 1955); at present serum vitamin B₁₂ assay is too protracted for this purpose. The diffuse hepatic necrosis in the present case would favour this hypothesis, and the gradual fall in serum vitamin B₁₂ level corresponds well to the clinical and biochemical evidence of recovery of the liver.

Release of vitamin B₁₂ as such, however, does not adequately account for serum levels such as 7,040 µg. per ml. which characterized this case. The vitamin-B₁₂-binding capacity of serum, limited to about 1,000 µg. per ml. in normals (Pitney *et al.*, 1954), is considerably raised in hepatitis and cirrhosis (Rachmilewitz *et al.*, 1956).

Thus it seems likely that necrosis results in excessive release from the liver of a binding protein with a high avidity for vitamin B₁₂, which would "mop up" any available vitamin B₁₂ and hold it in the blood stream. The high serum vitamin B₁₂ levels in chronic myeloid leukaemia are similarly accounted for by postulating increased amounts of binding protein, conceivably released from excessive breakdown of granulocytes (Mollin and Ross, 1955); the initial granulocytosis in this case is not considered sufficient to cause these highly elevated levels of vitamin B₁₂. It may be calculated that 7,040 µg. of vitamin B₁₂ per ml. of serum represents a total circulating amount of some 20 µg. Urinary levels of were not obtained in this case, but there is no evidence of renal retention of vitamin B₁₂ in liver disease (Rachmilewitz *et al.*, 1956). Whilst it seems more likely that this amount of vitamin B₁₂ is yielded up by the liver, another possible explanation is that conditions favour uptake from the intestine, where normally a "barrier" exists to absorption to excess vitamin B₁₂ (Baker and Mollin, 1955). Circumstances did not permit the testing of this hypothesis by radioactive vitamin-B₁₂-uptake techniques.

The onset of acute liver necrosis and hepatocellular failure in this patient is noteworthy, for it is rarely acknowledged to be an accompaniment of gall-stone obstruction of the common bile duct. Sherlock (1955) advises that hepatic failure should be diagnosed "rarely, and with caution," in a patient suffering from acute biliary obstruction. Other texts make little or no reference to acute biliary obstruction as a cause of hepatic failure, and undoubtedly some cases have remained unrecognized. A possible example was recently reported (Massachusetts General Hospital, 1956). An elderly man with deep jaundice died after a short illness. Necropsy revealed diffuse hepatic necrosis associated with gall-stone obstruction of the common bile duct. The final diagnosis was "acute fulminant hepatitis with atrophy, probably viral,

? toxic," but the clinical findings and histological appearance of the liver bore a close resemblance to this present case of "obstructive necrosis."

The diagnosis is an important one to make, for the condition represents a remediable form of hepatic failure, and prompt surgical intervention, as in our case, may be life-saving; reliance must be placed on the clinical data alone, for routine liver-function tests may be misleading in the presence of liver necrosis. The high serum vitamin B₁₂ levels in this case are of particular interest in corroborating the clinical and biopsy impression of hepatic failure due to acute widespread liver-cell necrosis.

Summary

Extremely high serum vitamin B₁₂ levels (7,040 µg. per ml.) were obtained in a patient with acute diffuse liver necrosis and hepatic coma. The liver failure was the result of complete obstruction of the common bile duct by a calculus, the condition being termed "obstructive hepatic necrosis." Prompt biliary drainage initiated eventual complete recovery, with return of vitamin B₁₂ levels to normal values.

The interpretation of the extremely high level of circulating vitamin B₁₂ in this case is uncertain. It is known that on occasion excessive amounts of a vitamin-B₁₂-binding protein are released from a damaged liver, and we are inclined to regard this as the most important factor in the present case. The bound vitamin B₁₂ may have been derived in part from the liver and other tissue depots, but an abnormal uptake from the gut is also a possibility.

Dr. W. R. Pitney kindly reviewed this manuscript. We are grateful to Dr. Leon Taft for histological interpretations, and to Dr. Sara Weiden for biochemical analyses. We thank Mr. George Westlake and Dr. E. N. O'Brien for assistance in the management of this patient.

The National Association for Mental Health has produced a booklet containing 50 questions and answers on mental health. This booklet, written mainly for non-medical readers, was produced as a result of two B.B.C. programmes: a television programme "The Hurt Mind," and a radio programme "To Comfort Always." In both these programmes questions on mental health were discussed by a panel of experts. Arising from the broadcasts over 25,000 letters were received from listeners, many enclosing further queries. This booklet is an attempt to answer some of these questions. Included in the booklet is a glossary of some of the terms commonly used in connexion with mental illness. As the number of questions dealt with is small, and the answers brief, a book list is appended as a guide to further reading. The booklet, price 1s. net, is obtainable from the National Association for Mental Health, 39, Queen Anne Street, London, W.1.

ANALGESIC ACTION OF PETHIDINE-LEVALLORPHAN MIXTURES IN MAN

BY

ANDREW HERXHEIMER, M.B., B.S.

Department of Therapeutics, St. Thomas's
Hospital Medical School

AND

CYRIL SANGER, M.B., B.S., F.F.A.R.C.S., D.A.

Lately Department of Anaesthetics, St. Thomas's
Hospital, London

The introduction of specific antagonists to the morphine-like analgesics has suggested the possibility of reducing some of the unwanted actions of these drugs, particularly respiratory depression, without impairing analgesia. The observations described below were made to compare the analgesia produced by pethidine with that produced by pethidine-levallorphan mixtures in normal subjects.

Methods

Table I records experiments done on five normal men, using two methods of assessing analgesia.

TABLE I

Subject	Age (Years)	Ischaemic Pain	Thermal Pain Threshold
S	32	+	+
H	29	+	+
G	20	+	+
Y	20	+	+
A	32	+	+

Preliminary observations on anaesthetized patients showed that 1 mg. of levallorphan can reverse the respiratory depression produced by about 200 mg. of pethidine (Fig. 1). This dose ratio was therefore used as a guide in subsequent tests, although we cannot be sure that it would be the same at the lower dose levels used in conscious normal subjects.

FIG. 1.—Spirometer tracing showing the reversal of pethidine-induced respiratory depression by levallorphan in man. Before operation; thiopenone-nitrous oxide-oxygen anaesthesia.

Ischaemic Pain Experiments

Hewer and Keele (1948) described a method for testing the power of analgesics to relieve experimentally induced pain in ischaemic muscles. We have modified their method slightly in the present experiments.

A sphygmomanometer cuff was applied to the left arm, with the subject lying on a couch. After a preliminary rest of 5–10 minutes the arm was raised to empty the veins, and the cuff rapidly inflated to 200–220 mm. Hg. With the arm resting on a splint, the subject then squeezed the bulb of a Higginson syringe in time with a metronome set at a rate of 90 beats a minute. When a certain number of contractions had been completed the arm was rested. The pain in the arm gradually increased, and all five subjects were trained to assess its intensity on an arbitrary scale (Fig. 2). An ob-

server questioned the subject at irregular intervals of $\frac{1}{2}$ to 1 minute on the intensity of the pain, to conceal from the subject how long the experiment had been going on. When intolerable pain was reached the cuff was deflated and the pain relieved.

Numerous observations were first made on each subject to determine the number of contractions which would produce intolerable pain in about ten minutes after the last contraction. This time was chosen because it was found that there was difficulty in concentrating on the pain, and subjects got bored with experiments lasting longer than

FIG. 2.—A typical pain-intensity/time diagram. Subject G, 52 contractions. Intravenous injection of saline $2\frac{1}{2}$ minutes after last contraction. The pain became intolerable after 13.9 minutes ($=T_{10}$).

about 20 minutes. Most of the experiments were in fact completed within this time. After a suitable number of contractions had been found, one or more preliminary experiments were done giving intravenous injections of pethidine or a pethidine-levallorphan mixture to familiarize the subject with the procedure. After these trial runs four tests were done on each subject, the injections comprising (a) pethidine 22.5 mg., (b) pethidine 22.5 mg. + levallorphan 0.075 mg., (c) pethidine 22.5 mg. + levallorphan 0.15 mg., (d) physiological saline, each in a volume of 3 ml. Preliminary observations had shown that after 15 mg. of pethidine no analgesia could be detected by this method.

The ratios of pethidine to levallorphan in the mixtures were 300:1 and 300:2, bracketing the ratio of 300:1.5 found at a higher dose level in the preliminary experiments. All injections were given intravenously into the right arm $2\frac{1}{2}$ minutes after the last contraction. The subjects did not know which injection they were receiving on any particular occasion. A Latin square design determined the order of the injections in four subjects; in the fifth subject (A) the order was random.

The analgesic effect of the injection was assessed by the time taken to reach intolerable pain.

Pain Threshold Determinations

An apparatus similar to that devised by Hardy, Wolff, and Goodell (1940) was used to measure thermal pricking-pain thresholds on the skin of the forehead. The threshold was measured before and 30, 60, and 90 minutes after the injection. In subjects G and Y the threshold determinations were combined with the ischaemic pain tests described above; in subject A the experiments were done on separate occasions.

Results

Ischaemic Pain Experiments (Table II).—Analysis of the results of the experiments on the first four subjects, which were arranged in a Latin square, showed that the order in which the different injections were given did not affect the results. The figures for the fifth subject (A) were therefore pooled with those from the other four for statistical analysis. In the experiments in which drugs were injected, the mean

TABLE II

Drug	Mean Time Taken to Reach Intolerable Pain (T_{10}) (Minutes)	Standard Error of the Difference Between Any Two Means
(a) Pethidine (22.5 mg.)	13.4	
(b) Pethidine: levallorphan (300 : 1)	15.1	0.83
(c) " " (300 : 2)	14.8	
(d) Saline	11.4	

time taken to reach intolerable pain (T_{10}) was significantly longer than in the control experiments when saline was given. From the means it appears probable that the pethidine-levallorphan mixtures were more effective than pethidine in postponing intolerable pain.

Thermal Pain Threshold.—Thresholds were measured before, and 30, 60, and 90 minutes after the injection. The figures given in Table III are changes in the pricking-pain

TABLE III.—Changes in Thermal Pain Following Administration of Pethidine and Pethidine-Levallorphan Mixtures

Drug	Minutes after Injection		
	30	60	90
(a) Pethidine	+12.5	+5.6	+3.3
(b) Pethidine: levallorphan (300 : 1)	+19.8	+14.1	+10.1
(c) " " (300 : 2)	+13.2	+7.2	+3.7
(d) Saline	-0.3	-0.1	+0.7

threshold expressed as a percentage of the pre-injection threshold. The rise in threshold was greatest after 30 minutes; at 60 and 90 minutes the thresholds were returning towards the pre-injection values.

In the statistical analysis of these results it has been assumed that the random error of the pre-injection threshold measurements was the same as the error of the other measurements. All three drug injections significantly increased the threshold, while saline did not. A difference of more than 5.5 between any two drugs is significant at the 5% level. The mixture containing the smaller amount of levallorphan (b) is thus significantly more effective than pethidine and the other mixture (c).

Discussion

Both methods depend largely on the subject's reaction to pain, as well as on the pain sensation and the physical stimulus provoking it. The ischaemic pain method has the advantage that drugs are tested under conditions close to clinical situations; in practice conscious patients nearly always have a pain before they are given a drug to relieve it. The greater precision of the thermal pain threshold method is offset by its dependence on skin temperature (Whyte, 1951; Jackson, 1952), so that changes in blood flow and sweating caused by the drugs may affect the results. Greater apparent analgesia after one injection compared with another might thus be due to changes in the local blood flow rather than to an action in the brain.

The results show that the two pethidine-levallorphan mixtures relieve ischaemic pain more effectively than does pethidine. The mixtures are also no less effective than pethidine in raising the thermal pain threshold. Lasagna and Beecher (1954) have reported similar results using mixtures of morphine and nalorphine in patients with post-operative pain.

In the thermal pain experiments it was surprising that the mixture containing the smaller dose of levallorphan caused the greatest rise in threshold. If this is a real effect, and not due to chance, it might be explained in several ways. The lower dose of levallorphan might cause vasodilatation and/or sweating, and so raise the threshold, while with the higher dose the antagonism for pethidine becomes manifest. On the other hand, Yim *et al.* (1955) have shown in rabbits that levallorphan is a weak analgesic, and this suggests the possibility that the rise in threshold is due to an analgesic

action which is added to that of pethidine. This might be investigated further by using higher doses of suitable pethidine-levallorphan mixtures, and testing analgesia by a different method.

Costa and Bonnycastle (1955) found that, in rats, levallorphan antagonizes respiratory depression produced by pethidine more than analgesia. Our results show that in man the addition of levallorphan does not necessarily impair the analgesic action of pethidine. Whether the addition of levallorphan is of value in clinical practice can only be decided by a trial in patients under clinical conditions.

Summary

A comparison has been made between the analgesia produced by intravenous injections of (a) pethidine 22.5 mg., (b) pethidine 22.5 mg. + levallorphan 0.075 mg. (dose ratio 300 : 1), (c) pethidine 22.5 mg. + levallorphan 0.15 mg. (dose ratio 300 : 2), and (d) physiological saline solution. The effects of these drugs on ischaemic muscle pain and on the thermal pain threshold were measured.

The pethidine-levallorphan mixtures produced no less analgesia than did pethidine; the mixture containing the smaller amount of levallorphan—(b) above—produced significantly greater analgesia than pethidine. This unexpected result is discussed.

We are grateful to Dr. P. Armitage for statistical advice and for analysing the results, and to Dr. R. S. Stacey for helpful discussion and criticism. The drugs used were supplied by Roche Products Ltd., who also defrayed some of the expenses of the investigation; it was a pleasure to work with Dr. J. F. T. Allison, their Director of Clinical Research at the time the experiments were done.

FATE OF BILE PIGMENT IN CHOLERA

BY

K. C. BASU MALLIK, M.D., Ph.D.

Professor of Pathology

A. MONDOL, M.B., Ch.B.

Officer-in-Charge, Infectious Ward

AND

N. C. GANGULY, M.B., B.S.

Demonstrator of Pathology

Department of Pathology, Nilratan Sircar
Medical College, Calcutta

The rice-water stool of cholera is well known to every student of tropical medicine. It is believed to be due to the absence of bile pigment from the intestine caused by congestion and oedema of the mucous membrane of the biliary tract, and thus to obstruction of the flow of bile to the duodenum (Rogers, 1921). De and Chatterji (1935), on the other hand, suggested that this is brought about by the depression of the secretory function of the liver in cholera. It was felt that these explanations were not satisfactory, since we could not detect any obstruction to the biliary flow at necropsy on cholera patients who died in the stage of purging. We found that gentle pressure on the gall-bladder led to the escape of bile into the duodenum. Investigations were therefore undertaken to ascertain the fate of bile pigment in cholera patients.

Method and Material

Investigations were carried out on 52 cholera patients who were admitted into the infectious diseases ward of Nilratan Sircar Hospital during the epidemic of 1956. *Vibrio cholerae* (47 Inaba strain and 5 Ogawa strain) was isolated from the stools of all these patients. Stools were collected immediately after admission. Ten millilitres of blood was drawn from a vein (in some cases before any saline transfusion was given and in others after saline transfusion; in the latter cases the blood was drawn from the arm opposite to that into which saline was transfused); 2 ml. of it was mixed with oxalate powder to determine the packed cell volume and the erythrocyte count; 0.9 ml. was added to 0.1 ml. of 3.8% sodium citrate solution to measure the plasma haemoglobin. The rest was allowed to clot for the separation of serum to determine the serum bilirubin, for the thymol turbidity test, and to estimate the alkaline phosphatase. As most of the patients were admitted in the stage of anuria a close watch was kept and the first sample of urine was collected.

The serum bilirubin was estimated according to the method of Malloy and Evelyn (1937), the thymol turbidity by Shank and Hoagland's (1946) method, the plasma haemoglobin by Dacie's (1954) method, and the serum alkaline phosphatase by the method of Harrison (1949). The technique of MacLagan (1946) was used to determine the faecal urobilinogen. Urinary urobilinogen was detected by the method of Watson *et al.* (1944).

Result

A summary of our findings is given in the accompanying Table.

Summary of the Findings

	Faecal Urobilinogen (mg./100 ml.)	Serum Bilirubin (mg./100 ml.)	Packed Cell Volume (%)	Plasma Haemoglobin (mg./100 ml.)	Thymol Turbidity Test (Units)	Alkaline Phosphatase (K.A. Units)
On admission	0.08 (52)	0.81 (52)	54 (52)	6.1 (46)	3.5 (40)	8.6 (42)
24 hours later	27.3 (28)	0.58 (28)	45 (28)	3.5 (27)	Not done	Not done
7 days later	135.1 (42)	0.35 (46)	41 (46)	3.1 (42)	" "	" "

Figures in parentheses indicate the number of cases examined.

Faecal Urobilinogen.—The stools of 52 patients were examined soon after admission (usually six to eight hours after onset); 37 had no faecal urobilinogen and in 15 the pigment varied in concentration from 0.07 to 0.52 mg./100 ml. The samples of stool which gave a positive reaction had a yellowish tinge. The test thus appeared to be no more sensitive than could be detected with the naked eye. In most cholera patients the stool does not contain any substance which can react with Ehrlich's reagent. Since we did not perform the petroleum ether extraction of the stool we cannot be sure that the positive reaction with Ehrlich's reagent in the 15 cases was wholly due to faecal urobilinogen and not to some other substance. We do not think that the whole of this Ehrlich reacting substance is something other than urobilinogen, for if it were there is no reason why a similar substance was absent from the stools of the other 37 patients. We are therefore inclined to believe that a part, if not the whole, of this Ehrlich reacting substance is faecal urobilinogen. MacLagan pointed out that "the error introduced by omitting ether extraction is likely to be small" in comparison with other known errors that occur in the estimation of faecal urobilinogen. The pigment reappeared in the stools of all patients within 12 to 24 hours of admission to hospital. The average amount of pigment was 27.3 mg./100 ml. Seven days later this was 135.1 mg./100 g. (stool was formed by this time).

Urinary Urobilinogen.—Since at the time of admission these patients were anuric, the first sample of urine was obtained usually 12 to 24 hours after admission. The urine always gave a positive reaction with Ehrlich's reagent, but

the quantitative estimation was not possible because of the precipitation of albumin with the addition of the reagent, which is acid in reaction. The precipitate caused so much turbidity as to interfere with the colorimetric estimation.

Serum Bilirubin.—The average serum bilirubin of these patients on admission was 0.81 mg./100 ml. Since there was in every case some haemoconcentration, the actual amount when corrected for haemoconcentration was 0.63 mg./100 ml. Although this figure is within the normal range—namely, 0.2 to 0.8 mg./100 ml. (Whitby and Britton, 1953)—it is higher than what we found seven days later (0.35 mg./100 ml.), when there was no haemoconcentration. There is therefore a slight rise of serum bilirubin in cholera patients at the onset of their illness. The direct van den Bergh test was negative in all cases.

Haemoconcentration.—The degree of haemoconcentration on average was 22% as calculated from the P.C.V. on admission (54%) and a week later (41%). The plasma volume was restored to normal within two to four days, and by the seventh day the distribution of the body fluid was normal.

Plasma Haemoglobin.—At the time of admission the plasma haemoglobin was 6.1 mg./100 ml. The actual figure when corrected for haemoconcentration was 4.6 mg./100 ml. There was thus no increase in the plasma haemoglobin concentration of these patients. Seven days later this was 3.1 mg./100 ml.

Thymol Turbidity Test.—The average figure on admission was 3.5 units. This is within the normal range, which is 0 to 4.7 units by this method. There is therefore no evidence of any depression of hepatic function in cholera.

Serum Alkaline Phosphatase.—The average figure found on admission was 8.6 King-Armstrong units per 100 ml. of serum; the maximum was 12 units and the minimum 6 units. In seven cases the blood was collected before any saline transfusion, and in none of these was the figure more than 12 units. This finding, together with the negative direct van den Bergh reaction, is a point against the assumption that there is any obstruction to the flow of bile into the intestine.

Discussion

Faecal urobilinogen was found to be absent from the stools of most cholera patients, though in a small number it was present in a detectable quantity. But we cannot accept the usual explanation that it is due to obstruction of the flow of bile caused by the oedema and congestion of the mucous membrane of the biliary tract, for the following reasons. Firstly, because we could not detect any such obstruction in the cases of cholera which came from necropsy in the stage of purging. Secondly, the normal serum alkaline phosphatase level suggests that the flow of bile from the biliary tract into the duodenum is unhampered. The fact that the direct van den Bergh test was negative in these patients is a further point against this assumption. Indeed, it is difficult to envisage that a pathological process in which there is so much loss of fluid from the small intestine will permit the collection of so much fluid in the wall of the biliary tract as to cause oedematous swelling of the mucosa.

The presence of urinary urobilinogen in the sample of urine collected as soon as the anurial phase passed off indicates that urobilinogen must be present in the gut, for it is well known that urinary urobilinogen arises from the reabsorption of faecal urobilinogen from the gut (Muller, 1892). It is therefore reasonable to believe that bile pigment does flow into the intestine in cholera patients. In our opinion the reason for the failure to detect the pigment in the stool is due either to washing out (a cholera patient passes on an average 8 to 10 pints (4.4 to 5.7 litres) of liquid stool in 24 hours) or to dilution of the stool so that the test is not sensitive enough to detect the infinitesimal amount of this pigment present. Another possibility is that bilirubin is converted into some compound which does not react with Ehrlich's reagent. It is well known that faecal urobilinogen does not account for the whole of the bilirubin formed in the body, as a variable amount of bilirubin is converted into some unknown compound that does not

react with Ehrlich's reagent (Gray, 1953). Spectroscopic examination of cholera stool might show some such compound.

The presence of *E. coli* in the gut is necessary for the conversion of bilirubin into faecal urobilinogen (Baumgartel, 1950). The temporary alteration of the intestinal flora (since the *E. coli* population becomes very meagre in the early stage of cholera) may be responsible for the failure to convert bilirubin into urobilinogen. Thus Sborov *et al.* (1951) found that in patients treated with chlortetracycline urobilinogen disappeared from the stool.

Although it is hazardous to draw any conclusion from a single liver-function test, a normal thymol turbidity test and the absence of an abnormal amount of urobilinogen in the urine of cholera patients suggest that there is probably no gross dysfunction of liver in this disease. This is further supported by the fact that the histological appearance of liver in cholera patients does not show any gross abnormality.

What, then, is the cause of the small rise of serum bilirubin that we observed in these patients in the early stages? Haemolytic mechanism has been suggested in cholera (De *et al.*, 1952, 1954). But our finding of serum bilirubin was within the normal range, and as we could not detect any rise in the plasma haemoglobin level we can definitely exclude the role of haemolysis. In fact, the early enthusiastic papers of the above workers are followed by a more cautious report, where they recorded a much smaller percentage of patients showing signs of haemolysis than what they had found before (De, 1954). The haemoconcentration that occurs in cholera entails a greater osmotic work for the liver cells to pick up bilirubin from the blood for secretion into the bile capillary. This may be the cause of diminished secretion of bile and the slight rise of serum bilirubin concentration that we observed in cholera patients.

Summary

Tests of the stools of cholera patients in the stage of purging showed that in most of them there was no detectable amount of urobilinogen.

The serum alkaline phosphatase level and the thymol turbidity of these patients remain within the normal range.

Evidence is given which suggests that there is no obstruction to the flow of bile into the gut in cholera, and some possible explanations for the absence of faecal urobilinogen in these patients are discussed.

Although there is a slight rise in serum bilirubin in these patients there is no evidence of any haemolysis, nor is there any evidence of the depression of hepatic function.

We are grateful to Principal A. K. Dutta Gupta for permission to use hospital records, and to Professor S. N. Sarkar for his help during these investigations.

Medical Memoranda

Colporrhaphy During the Puerperium

It is well known that secondary repair of unhealed vaginal lacerations during the puerperium is a satisfactory procedure, but the advantages of deliberate formal perineorrhaphy have not attracted attention. In some cases this operation is urgently required, and from the patient's point of view it may be done most conveniently during the puerperium. At such a time the difficult arrangements for supervision of an existing family have been made, and a later visit to hospital will be more difficult to arrange as the family grows larger. The demands of a family are imperious, and most women will tolerate great discomfort for many years rather than forsake their maternal duties for a few weeks. From a national standpoint there is clearly economy of hospital beds and expense if a confinement and operation can be combined at a single admission and without additional days spent in hospital.

PRESENT SERIES

A short account is given of 46 patients upon whom formal perineal repair during the puerperium was practised during the past eight years. Their ages varied from 21 to 44 years, and the operation was done a few days (mostly four or five days) after delivery. In these days of restricted admission to maternity hospitals relatively few multiparae are delivered in hospital. This series is composed almost entirely of women referred for some abnormality to the antenatal and subfertility clinics. The principal reasons for consultation were as follows: (1) Eight women presented with prolapse, with actual protrusion of the cervix or of a rectocele or cystocele early in pregnancy. Pessary support was necessary in five of these cases. (2) Twelve women were referred from the subfertility clinic on account of multiple miscarriages (two to five miscarriages). (3) Sixteen women complained chiefly of urinary incontinence dating from a previous delivery and always worse during pregnancy. The following is a typical example.

Case 1.—A gravida 2, para 1, aged 21, had had her first baby 18 months previously, delivered with forceps. She had had distressing urinary incontinence ever since. After delivery the perineum was seen to be very inadequate, with marked descent of the anterior vaginal wall. Simple posterior colporrhaphy on the fourth day after delivery cured her incontinence. Six weeks after delivery the perineum was sound and the bulge of the anterior vaginal wall was no longer seen.

In 25 cases there was complaint of pelvic discomfort and dragging pain after walking or standing, either alone or associated with other symptoms. In these cases the vulva is usually relaxed and gaping, often after a single confinement. The following example is typical.

Case 2.—A gravida 2, para 1, aged 26, had a very deficient perineum after two normal confinements, with constant backache, and some stress incontinence appeared during pregnancy. A simple posterior colporrhaphy was done on the ninth day after delivery. At post-natal examination seven weeks later she said her backache had gone and bladder control was normal. She added that her whole outlook upon life had improved since her operation; she felt full of energy and her husband had remarked upon her greatly improved temper.

After delivery the perineal tissues are remarkably supple and elastic. At operation dissection is easy, the fascial planes separate cleanly, and the levators can be brought together without tension. Healing proceeds rapidly; patients can get up on the fifth day after operation and should be ready to go home three to four days later—that is, departure from hospital is not delayed. Early ambulation does not seem to interfere with a good final result. No attempt has been made to carry out any elaborate procedure, and anterior colporrhaphy with support of the urethral angle has been performed once only. Nevertheless in 16 cases with marked stress incontinence dating from before the

pregnancy there has been only a single failure to give relief. No complication or difficulty of any kind has been met with.

COMMENT

In watching the progress of these patients, I have felt the results of operation have been almost always much better than I expected. Perhaps this is because so many of the patients were young women, but I believe that another important factor may be the elastic and mobile character of the puerperal tissues. It seems possible that the parts are better able to achieve a natural adjustment when the displacement has not existed for long, and, during the phase of tissue mobility, when there is adequate support by the perineum during involution. I do not mean to suggest that all patients can be dealt with effectively in this manner, and no doubt a more elaborate operation may be needed ultimately in some cases. At the same time, it does seem possible to give much relief, if not permanent cure, by a simple procedure, at a moment in a woman's life when time is of great importance and during a phase that calls for continued effort. There can be no doubt that nearly all these patients would have continued to suffer much discomfort and pain for many years before presenting themselves for operation in the orthodox way. The procedure has given great satisfaction and might be more widely used.

L. G. HIGGINS, F.R.C.S.

Mammary Gland Changes During Chlorpromazine Therapy

Since chlorpromazine hydrochloride ("largactil") has been undergoing widespread trial in the treatment of psychiatric disorders and in the management of the elderly, with promising results, there have been reports in the literature calling attention to certain complications and important side-effects, notably jaundice. There is little doubt that the drug modifies certain endocrine functions, either directly or indirectly. The case described below is, I believe, of considerable interest, in that there were mammary gland changes and unexpected breast development.

CASE REPORT

The patient, a single woman aged 67, has been in a mental hospital most of her life, having been certified in 1908. Perusal of her case notes shows that the illness was of schizophrenic nature. She was childish, emotional, stubborn, and had attacks of excitement, screaming, and sobbing. At times she laughed for no obvious reason, was resistive and troublesome, and could not give a coherent account of herself. Dullness, apathy, and withdrawal from reality were very apparent. This mental state persisted, and by 1932 she was continually muttering to herself, was auditorily hallucinated, and was faulty in bodily habits and hygiene. Her case notes showed that in 1950 she was thought to be deteriorating further. At this stage impulsive behaviour and destructiveness showed themselves. Electric convulsion therapy brought only the most temporary improvement. When she was having a routine mental and physical examination on July 5, 1955, there was little change in her psychiatric condition as described above. The only significant findings on physical examination were a blood pressure of 200/90, a moderate degree of atherosclerosis, and an undernourished appearance. Her breasts were involuted, and she was quite flat-chested. The optic fundi were within normal limits, and no retinopathy was present.

This patient, among 48 other females, was considered suitable for a trial of chlorpromazine therapy, and treatment began on July 6, 1955. With gradual increase over the first few days, she was eventually having a daily total of 150 mg., in tablet form and in three divided doses. This dosage continued for three months, during which time she seemed to tolerate the drug quite well. By October 10 there was considerable mental improvement, and in November the

patient was continuing to have chlorpromazine 25 mg. three times a day as a maintenance dose. She was then clean in habits, tidier in person and appearance, and quieter, and she no longer required sedation. She took an interest in her surroundings and did some knitting. Her conversation was relevant and coherent, although at times it was no more than a shy whisper. Whereas she was previously a problem patient, she became manageable, co-operative, and a willing and helpful ward worker.

During treatment she gained 12 lb. (5.3 kg.) in weight; and the most striking change was marked bust development and increase in size of the breasts—out of all proportion, it is felt, to the weight increase (see illustration). The development was not merely explained by deposition of fat. There was definite growth of mammary gland tissue, and a comparison with the previous picture of atrophic and involuted breasts showed a striking change. Secretion from the nipples was not observed. No oedema was found in this patient, nor was there any sign of congestive or circulatory failure. Uterine haemorrhage did not occur.

COMMENT

Reference to the British literature has failed to reveal a description of the changes of the nature and extent of those described above. Reports by Cohen (1955) and Gäde and Heinrich (1955) note secretion from the mammary gland, either with or without some increase in breast size, during administration of chlorpromazine hydrochloride. The increase in weight found in many of these cases does not seem to be accounted for by water retention, nor is it satisfactorily explained by improvement in the mental state (Elkes and Elkes, 1954). My patient has had weight fluctuations of ± 12 lb. (5.4 kg.) over the past ten years.

Winnik and Tennenbaum (1955) report the occurrence of galactorrhoea in 21 patients treated with chlorpromazine. The ages of these women ranged from 18 to 45 years, and none had previously had any transitory or persistent pathological secretion of milk. In five of these patients the psychosis appeared during the post-partum period, and milk secretion, which had been suppressed by drugs, reappeared during chlorpromazine therapy. In contrast with normal lactation, these authors found that the breasts were not enlarged; the condition was unilateral in six of their series.

The phenomena described lend support to the hypotheses related to the diencephalon, which have been put forward to account for the action of chlorpromazine hydrochloride on the central nervous system. Similar changes have been found in endocrine disturbances, notably the syndrome of Chiari and Frommel, and in some cases of neoplasm of the diencephalo-hypophysial system.

I am indebted to Dr. N. McDiarmid for permission to publish this case, and to Dr. J. Harper, of May and Baker Ltd., for his helpful comments. My thanks are also due to Mr. L. G. Holton for the clinical photograph.

Reviews

SKIN DISEASES

Sequeira's Diseases of the Skin. By John T. Ingram, M.D., F.R.C.P., and Reginald T. Brain, M.D., F.R.C.P. Sixth edition. (Pp. 843+xii; illustrated. £5 5s.) London: J. and A. Churchill Ltd. 1957.

Ten years have elapsed since the fifth edition of this book was published; the senior author, J. H. Sequeira, has died, and as a graceful tribute to his memory the present authors have renamed the work. Much thought has been given to the preparation of the new edition, which will attract, and the merit, as much attention and praise as its predecessor. The book has been completely recast. Although the authors have largely adhered to the aetiological method of presentation, the grouping of diseases has been considerably changed; inevitably this has led to some difficulties, but the rearrangement is on the whole very successful. The size has been increased only by 61 pages—an economy which has been achieved by a reduction in the size of the section on syphilis and the obliteration of the section on pompholyx, and by other less obvious changes. Thus the authors have been able to add much new material without greatly enlarging their work book, and have succeeded admirably in bringing their work up to date and in enhancing its value. There are 46 new text figures; the reproduction of many of the older ones has been greatly improved, and beneficial alterations have been made in the type fonts used for special purposes. The collaboration of R. G. Cochrane, who has written the chapter on leprosy, and the assistance given by five other experts have enhanced the value of the work. The index is adequate. Notable improvements have been made in the sections dealing with the normal skin, vitamin and metabolic disorders, the reticuloses, and viral and rickettsial diseases.

As often happens when a big revision has been undertaken, certain anomalies carried over from previous editions catch the eye of the reviewer and certain new material raises queries in his mind. Thus, when taken in relation to the text the caption of Fig. 14 is odd, but not quite so distressing as the retention of *Mist. quininae et magnesia sulph.* for use in the treatment of lupus erythematosus, pustular acne, rosacea, and pityriasis rosea. Of the new amendments, one wonders if it is satisfactory to include Kyrle's disease among the congenital dyskeratoses because of a possible clinical resemblance between the lesions and those of Darier's disease. Is it justifiable to reduce an excellent description of pompholyx to eight lines within the subject of eczema? Is prurigo gestationes [*sic*] an entity? Would tropical ulcer be better included in some chapter other than that on circulatory disorders? Are x rays correctly to be regarded as latory disorders? These few queries are of minor importance gamma rays? These few queries are of minor importance when considered in relation to the book as a whole, for this sixth edition is outstanding and a credit to all concerned in its production. It can be very warmly recommended to practitioners, and particularly to all who are making a special study of dermatology.

R. M. B. MACKENNA.

ANGRY YOUNG DOCTOR

Angry Young Doctor. By Louis Goldman. (Pp. 114. 5s.) London: Hamish Hamilton. 1957.

This book has already aroused much interest and discussion when it was abstracted recently in a series of weekly articles published in the *Observer*. Its title, *Angry Young Doctor*, is perhaps ill chosen, and, though a somewhat emotional approach has been made to the problems tackled and the opinions expressed, there will be little of its factual content and few of its criticisms with which the great majority of young doctors will not agree. Many will in fact feel that much of it has needed saying for a long time, and the tragedy is that so much of it is unfortunately true and reflects fairly accurately the plight of the junior and

unestablished hospital staff to-day. However, to quote from the text, "the ladder of promotion is slow and so uncertain that the worst service a young man can do himself is to risk being dubbed an 'agitator' or 'malcontent.'" There is certainly no lack of agitation in the pages written by this angry young doctor, and it is probably significant that he, a self-described "itinerant registrar," has now returned to a Dominion far across the seas.

The author sets out clearly and fairly accurately the broad outline of hospital services, administration, and staffing; the duties and remuneration of the various grades of hospital staff; and the nature and functions of the associations, councils, and colleges. He paints a rather too lurid and gloomy picture of the house-officer entitled "Forced Labour," though there is enough truth in it to make one feel uncomfortable to see it in black-and-white. The registrar problem gets rather short measure, and the work of the registrars' group rather less credit than it deserves. The promotion prospects for senior registrars are in fact worse than his rather incomplete information suggests, and more space might fruitfully have been given to this most pressing problem. By saying that, "unfortunately, established practitioners tend to regard the problems of junior hospital staff as transient. The juniors themselves are transient; the problems are not," he strikes deep at the roots of the present troubles, but it is not true to say that no representative organization exists to take up a complaint or a grievance on their behalf, though he is probably correct in his assertion that "no large organization welcomes too much expression of opinion or protest from its younger members." The teaching hospitals are rather unfairly criticized, and in general the second half of the book, which is more personal and less factual, is not so convincing as the first.

There is, however, much food for thought in Dr. Goldman's publication, and its opening paragraph puts into words so clearly what is in the inner hearts of so many that it deserves quotation almost as it stands.

"Running through the hospitals of Britain to-day, invisibly linking doctors from one end of the country to the other, are three closely-woven strands of frustration, fear, and despondency. Highly skilled though these men and women often are, they nevertheless go about their daily tasks in the bitter and frustrating knowledge that the future holds little promise for them in their chosen field of work. Fear of unemployment—and worse, of being unemployable—haunts them. Despondency grows steadily year by year while the authorities continue to discuss their problems without apparently getting closer to a solution."

HAMISH WATSON.

REFLECTIONS ON MEDICINE IN THE U.S.A.

Challenges to Contemporary Medicine. By Alan Gregg. (Pp. 120. 24s.) Columbia University Press. London: Oxford University Press. 1957.

This is a delightful book distilled from the wisdom of a great man, the late Dr. Alan Gregg, who spent a lifetime with the Rockefeller Foundation and in the course of his work obtained unique knowledge of medical practice, education, and research in many countries. It is based on his Bampton Lectures delivered at Columbia University in 1953. Though prepared primarily for an American audience, it has general application to other countries, including Britain.

The contents may be judged by the chapter headings: "How dear is life?"; "What is the meaning of disease?"; "Current factors affecting medicine"; "How are medical education and medical care best paid for?"; and "The natural history of the doctor." Every chapter is thought-provoking: one of the most interesting is the last on how medical students in the United States are chosen. Dr. Gregg thinks that more weight should be given by medical-school admission committees to the character, records, and attitudes of the parents of applicants. A recurring theme is that it is the modern form of fatalism to attribute good health to good luck and to think that the development of disease is a matter

of chance instead of realizing that freedom from disease is often the result of research and its application. Research pays handsome dividends and with, at times, "a bountifulness that is almost intoxicating." But research is like roulette. The "house"—that is, society—will always, in the long run, win. The work on sulphonamide drugs up to and including proof of their efficacy in the treatment of lobar pneumonia cost less than \$150,000. Within three years one life insurance company alone on the west coast of America saved \$3,000,000 because of reduced claims for deaths from pneumonia. (For Gregg's interest in the sulphonamide drugs see Leonard Colebrook on page 302 of this *Journal* for August 3, 1957.)

American teaching hospitals are running into difficulty because those who are insured in the "Blue Cross" or other similar schemes insist on being regarded as private patients and are unwilling to allow themselves to be taught on. Gregg asserts that the best diagnosis is made and the best treatment given in teaching hospitals, and stresses the value to both doctors and patients of the doctor's work being observable and observed by inquiring minds. He remarks that the cost of medical education should be regarded as a normal part of medical care, and that good medical care in the future depends on the quality of medical education now. He advocates the use of prepayment medical insurance funds for medical education. He introduces the term "Great Medicine" to include medical teaching, practice, and research in all its roots and branches.

The book is well produced, but there is a misprint for "brooks" on page 100.

ALLEN DALEY.

THE NATURE OF VIRUSES

Ciba Foundation Symposium on the Nature of Viruses. Edited for the Ciba Foundation by G. E. W. Wolstenholme, O.B.E., M.A., M.B., B.Ch., and Elaine C. P. Millar, A.H.W.C., A.R.I.C. (Pp. 292+xii; illustrated. 42s.) London: J. and A. Churchill Ltd. 1957.

The Ciba Foundation symposium on the biophysics and biochemistry of viruses held in March, 1955, has now appeared in print under a wider title which is more suited to the diverse range of topics included. It contains 17 papers, which mostly summarize work published previously or since the holding of the symposium; the expert will therefore not expect to find much that is new, but the postgraduate student will find that many of the chapters are useful as brief reviews of interesting and important fields in virology, and will be able to appreciate the difficulties facing present work and future progress from a study of the verbatim accounts of the discussions, in which niceties of style and even of grammar, as is customary on these occasions, have gone by the board in the heat of the moment (p. 284: Q. "Is the suggestion that HeLa cells were resistant to polio virus holding up?" A. "This has not materialized for the time being").

The topics range well beyond the medical field and include plant viruses and bacteriophage. The contributions are naturally of varying quality; some of the more significant ones will be briefly noted here, but there is much of interest in the remainder. Crick and Watson point out that in 11 plant and animal viruses for which data are available the total number of amino-acid residues present in the virus particle always greatly exceeds the number of nucleotides, and they discuss the bearing of this observation upon the hypothetical code by which nucleic acid controls the synthesis of specific proteins. Of great interest at the present time is an experimental and theoretical study by Gard on the kinetics of the inactivation of poliomyelitis virus by formaldehyde, in which it is shown that the Salk postulate of a first-order reaction is incorrect, since the rate of inactivation gradually decreases with time, probably on account of the appearance of a chemical change in the virus which renders it less susceptible to the action of formaldehyde. Several papers are devoted to studies of virus genetics, and Bang and Isaacs give some impressive electronmicrographs

of sections of cells infected with influenza and mumps viruses. The proceedings end with a general discussion of muted character in which the protagonists were evidently exhausted by the vigour of their earlier exchanges. The volume is nicely produced with a good index, and merits a rating higher than average in the symposium scale.

D. J. BAUER.

CANCER CONFERENCE

Proceedings of the Third National Cancer Conference, Detroit, Michigan, June 4-6, 1956. Sponsored by the American Cancer Society, Inc., and National Cancer Institute, U.S. Public Health Service. (Pp. 961; illustrated. 72s.) Philadelphia and Montreal: J. B. Lippincott Company. London: Pitman Medical Publishing Co. Ltd. 1957.

The aims of this conference were to promote cancer education, research, and service. Six general lectures—epidemiology as a tool in cancer research, radiation, neoplasia, virus aetiology, chemical effects of growing tumours on the host, factors influencing curability, and measurement of morbidity—are followed by the proceedings of symposia or panel discussions on cancer of different organs or sites—on chemotherapy in cancer, and on end-results in treatment. The editors are to be congratulated on the speed with which these proceedings have been produced. The situation in many of the subjects discussed—for example, the appraisal of endocrine therapy and chemotherapy for specific types of cancer—is a rapidly changing one, and the value of these surveys is much increased by quick publication.

Twenty years ago it was estimated that about 25% of those who developed cancer (except skin cancer) survived for five years. In the period 1947-51, however, there appears to have been an over-all improvement to about 32%. The rise for females (29% to 38%) was greater than that for males (19% to 25%), because lung cancer has a very low survival rate. Encouraging as such progress undoubtedly is, Guyler Hammond believes that the "surest and quickest way to achieve a substantial improvement in cancer cure rates is to pool the resources of a number of institutions for experimental studies." In this way, and by international agreement on stage groupings, sufficient numbers of case-histories should be available for determining which is the best of the several alternative methods of treatment for a particular type of cancer, and thus to raise the general level of therapy to a place where it approaches the very best which can be achieved with present knowledge.

R. J. C. HARRIS.

PSYCHOLOGY AND RELIGION

Psychology, Religion, and Human Need: A Guide for Ministers, Doctors, Teachers, and Social Workers. By W. L. Carrington, M.D. (Pp. 315+xi. 30s.) London: The Epworth Press. 1957.

Its subtitle describes this book as "A Guide for Ministers, Doctors, Teachers, and Social Workers," but in the text it is the pastor or non-medical but specifically Christian "Counsellor" who is addressed, and the basis and purpose of the book are quite definitely evangelical rather than medical. So much is this so that the pastor or "Counsellor" is often, in its pages, advised to refer his "client," sick in body or mind, to his family doctor or to a physician, but no "mirror-image" advice is given to the doctor, teacher, or social worker.

To the pastor or Christian "Counsellor," for whom the author clearly intends it, the book should be useful. There is an informed and balanced account of the principles and schools of modern psychology and of the chief varieties of mental illness, and practical advice on approaching, "counselling," and offering Christian comfort and help to those embarking or embarked on marriage, parents, the old, the sick, the mentally distressed, and alcoholics. The viewpoint is that of a convinced evangelical Christian with medical and psychiatric training and experience who expresses himself clearly and simply. There is a good index.

L. W. BATTEN.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY OCTOBER 5 1957

LORD NUFFIELD

In the last thousand years many men in Great Britain have accumulated enormous wealth, whether from the cultivation or mining of land, from commerce overseas, or manufacture at home. Lord Nuffield is unique in the munificence and artistry with which he has given his wealth away. His eightieth birthday is next Thursday, and members of the medical profession, in offering him their congratulations, acknowledge with gratitude the discerning help he has given to many individuals and institutions. More formal recognition of this help has in the past come from a number of medical bodies, including the B.M.A., of which he was elected an honorary member in 1936.

Though W. R. Morris himself was born in Worcestershire, his family had for many generations lived in Oxfordshire, and they soon moved back to that county. He was educated at Cowley village school, and at the age of 16 was apprenticed to the bicycle trade. On being refused a shilling rise by his employer after nine months, he set up on his own and began making bicycles. There was nothing primitive about these, and they bear a close resemblance to the staid types made to-day. Morris motor-cycles followed the bicycles, and in 1913 appeared the first Morris-Oxford car. It was an 8.9 h.p. two-seater and sold for £165. The consumption of petrol claimed was 35-50 miles per gallon, and a speed of up to 50 miles an hour. All this was against the background of a flourishing garage business, but it was not until after the first world war, during which he made munitions, that Morris began the great industrial expansion that transformed Oxford and Cowley. The 1920's were for motor-cars what would be called in biology a period of rapid evolution. One of the distinguishing marks of such times is a multiplicity of closely related species, and this was evident in the scores of different makes of motor-car on the market. Among these was the Morris-Cowley, which had inherited its bull nose from the pre-war Morris-Oxford. A Morris-Oxford was also made, and soon all sorts of models, including the M.G.s, were on the roads. In 1921 about 3,000 Morris cars were sold; in 1935 the figure was nearly 100,000. Expansion has continued, aided now and then by some elaborate hybridization. In 1939 the

millionth Morris car came off the assembly line—and was auctioned at Guy's Hospital. But long before the firm became large by modern standards Morris began to make his charitable benefactions. One of the earliest, in 1926, was a grant of £10,000 to enable parents to visit their children who were in Borstal institutions, a humane project suggested by the Commissioner of Prisons, the late Sir A. Paterson. As a benefactor his first link with Oxford University was in the same year, when he gave £10,000 to the foundation of a chair in Spanish studies, for he was interested in the idea of Britain's increasing trade with Spanish-speaking countries. His first large medical gifts were made in 1927, to the Coventry and Warwickshire Hospital and the Birmingham General Hospital. It was in 1930 that he began the great series of donations to Oxford University by purchasing the Radcliffe Observatory buildings and grounds, with the object of housing an institute of medical research. The series reached a climax, though far from a conclusion, in 1936 when he gave £1,250,000 to endow research in the medical school, and then, on learning that it would not be enough, promptly increased the figure to £2,000,000. Other beneficiaries in these years included St. Thomas's Hospital, Guy's Hospital, the Wingfield-Morris Orthopaedic Hospital, the Radcliffe Infirmary, the Hospital for Sick Children, Great Ormond Street, and organizations for the care of cripples and the blind. In addition many other hospitals up and down the country had their financial anxieties suddenly dispelled by a donor whose generosity matched his apparently illimitable purse. To Oxford University he gave a further £1,000,000 for the foundation of Nuffield College, and within the last ten years the Royal Colleges of Surgeons and of Obstetricians and Gynaecologists have also felt the touch of his wand.

Two projects of a different character, yet both with the authentic Nuffield stamp on them, are the Nuffield Provincial Hospitals Trust and the Nuffield Foundation. The first of these was founded in 1939 with about £1,250,000 to finance the co-ordination of hospital services in the provinces, a task already carried out for London by the King Edward's Hospital Fund. Lord Nuffield had shown himself keen to encourage hospitals to preserve their individuality and develop along their own lines, but he felt too that co-operation between them needed fostering. To help all this the Trust has sponsored a number of valuable surveys. The second of these projects, the Nuffield Foundation, started life in 1943 with a nest-egg of £10,000,000. It has financed a remarkable range of researches, most of a medical character, and the perennial youth of Lord Nuffield himself is surely reflected in this

exposition of its aims, taken from the twelfth report, published last week:

"The kind of research inquiry about which the Foundation is likely to become enthusiastic is the inquiry which seems to be not only promising and well planned but also to be one whose originator is imbued with so keen and urgent a desire to carry it out that he is ready to struggle along on a shoe-string if misguided grant-giving bodies fail to appreciate his worth."

If Lord Nuffield's energy and originality have brought him such wealth as to suggest the magic of a Midas touch, we may be thankful too that he has been singularly gifted with a touch that brings light and learning. He is the greatest benefactor to medicine that Great Britain has had. Now to his fine accomplishments and generous heart have been added the blessing of a long life. Members of the medical profession are foremost among his admirers who will wish him and Lady Nuffield many more years of happiness.

PATENT DUCTUS ARTERIOSUS

Before birth the ductus arteriosus is as big as the aorta or pulmonary artery, and, being short, it takes a large flow of blood from the pulmonary artery into the aorta, thus allowing the collapsed and functionless lungs to be bypassed. At this stage the pulmonary resistance is so high that almost all the blood flowing into the pulmonary artery is shunted right to left through the ductus. The high pulmonary resistance is partly due to the collapsed state of the lung and partly to the foetal state of the pulmonary arteries and arterioles, which have thick muscular medial layers and narrow lumina.¹ Thus in the foetus the pressures in the pulmonary artery, ductus, and aorta are almost identical. G. S. Dawes and his colleagues² in their work with lambs have recently reinvestigated the changes in the circulation at birth and filled some gaps in knowledge. They found that a reversal of flow takes place through the ductus after the first few minutes of ventilation. This left-to-right shunt is due

to a fall in pulmonary resistance after expansion of the lungs and to a rise in systemic resistance from tying of the umbilical cord. According to their findings, the oxygen saturation in the pulmonary artery is greater than in the right ventricle, there is a fall of pressure and flow in the pulmonary artery with a rise of that in the aorta if the duct is temporarily tied, and "thorotrast" injected into the aorta goes immediately into the pulmonary artery. Ten minutes after birth probably about half the flow of blood in the pulmonary artery has come from the duct. They believe this left-to-right shunt to be beneficial, since the recirculation through the lungs raises the oxygen saturation at a stage when ventilation is inefficient.³

In infants the ductus remains patent for some hours or days after birth, but there is some evidence that the direction of the shunt is, at least partially, right to left. Intravenous angiocardigrams in infants have shown a shunt of radio-opaque material from the pulmonary artery into the aorta.⁴ This has been criticized because of the artificial rise in pressure in the pulmonary artery from the rapid injection of the radio-opaque material. However, in the first few hours of life capillary blood from the hand shows a higher oxygen saturation than that from the foot, suggesting that there is a shunt of venous blood into the descending aorta.⁵ That the main shunt is from left to right has now been shown conclusively by cardiac catheterization in healthy infants,⁶ but the resistance offered by the lung to blood flow was greater than in adults, and the pulmonary pressures were only a little below those in the aorta, perhaps owing to the relatively thick walls of the pulmonary arteries. Thus conditions exist for persistence of the patent ductus arteriosus usually with a left-to-right shunt, but occasionally with a right-to-left shunt if the pulmonary resistance should remain high. In newborn lambs the increase in arterial oxygen saturation after ventilation has a powerful constrictive effect on the ductus. Presumably the constriction is followed later by fibrotic changes. It is tempting to suggest that anoxia at birth may be responsible for continuing patency of the ductus: foetal distress has commonly been recorded in the history of patients with patent ductus arteriosus,⁷ and V. Alzamora and his co-workers⁸ claim to have found a raised incidence of patent ductus at high altitudes. But, in contrast to this view, Dawes has shown that asphyxia also constricts the ductus as a result of the release of sympathetic amines.

In most cases of patent ductus arteriosus pulmonary resistance is normal and low, the shunt is therefore from left to right, and any increase in pulmonary artery pressure can be attributed to the greatly increased volume of the flow. The large flow through

the left side of the heart and lungs produces the characteristic physical signs. The pulse has a water-hammer quality, the left ventricle is hyperdynamic, and the electrocardiogram usually shows the changes of diastolic overload.^{9,10} When the left-to-right shunt is large, x-ray examination shows increase in the size of the main pulmonary artery, pulmonary plethora, and enlargement of the left atrium and left ventricle. There is a big pressure difference between the aorta and pulmonary artery during both systole and diastole so that the flow and murmur are continuous. In recent studies in the newborn lamb Dawes and his colleagues¹¹ found the continuous murmur was not heard at birth but appeared 10 or 15 minutes later and then gradually disappeared over the next few hours as the duct constricted. Even large flows through the ductus from left to right produced no murmur if there was no constriction. The onset of the murmur was related to the onset of constriction, which increased the pressure difference between aorta and pulmonary artery and thus the velocity of blood flowing between these points. These authors explained the relative softness of the continuous murmur in early systole by the arrival of the pressure pulse from the pulmonary artery at the duct before the aortic pressure pulse had arrived at the other end by its longer route. It is well known that a typical continuous murmur is rare in infants with patent ductus arteriosus, and this may be attributed to the wide lumen of the duct and to the relative pulmonary hypertension. As the months go by the duct presumably becomes narrower in relation to the increasing size of the aorta and pulmonary artery, and the pulmonary resistance drops, giving a bigger pressure difference across the duct. The phonocardiogram is useful when there is doubt between a continuous murmur and a pulmonary or aortic ejection systolic murmur associated with a regurgitant diastolic murmur, since the ejection murmur finishes before the second heart sound at the point where a continuous murmur is maximal. In some infants and children the duct murmur is confined to systole, even in the presence of a big left-to-right shunt. The murmur is pansystolic and thus still easily distinguishable from aortic and pulmonary ejection murmurs, and may be explained by a bigger pressure difference in systole than in diastole between the aorta and pulmonary artery.¹² The greatly increased flow across the mitral valve often produces a mitral diastolic murmur.

If there is doubt about the diagnosis, cardiac catheterization shows increased oxygen saturation in the pulmonary artery. In a few patients the pulmonary resistance is very high owing to changes in the pulmonary arterioles. Pressures in the aorta and

pulmonary artery are identical and the shunt is bidirectional or reversed. These patients present as cases of pulmonary hypertension with or without a little central cyanosis. P. Wood¹³ recognized the similarity between all these cases with a raised pulmonary resistance and a patent ductus or a ventricular or atrial septal defect and grouped them together as Eisenmenger's syndrome, emphasizing the difficulty in differential diagnosis from primary pulmonary hypertension. The peripheral pulse is small. The venous pulse may show a large A wave, the right ventricle is hypertrophied, and the second sound at the base is palpable. On auscultation there may be a short ejection systolic murmur in the pulmonary area related to the dilated pulmonary artery and preceded by a pulmonary early systolic ejection sound.¹⁴ Often there is a Graham Steell murmur of pulmonary regurgitation. Any right-to-left shunt affects the legs more than the arms and head, causing differential cyanosis. There have been many reports on these cases.¹⁵⁻¹⁸ Some of them are believed to have had a high pulmonary resistance persisting from birth, while in others the pulmonary resistance has risen over the years, turning a left-to-right shunt eventually into a right-to-left shunt.¹⁹ In all these patients the ductus is very large, and if there is appreciable reversal of the shunt operation is contraindicated. In fact these patients fare better than those with primary pulmonary hypertension—probably because the duct acts as a safety valve delaying defeat of the right ventricle by the extremely high pulmonary resistance. There is an intermediate group of patients with moderate increase of pulmonary resistance: if the left-to-right shunt is the dominant one they should be helped by surgery. In a suitable case for ligation, left ventricular hypertrophy should dominate over right, and pressure in the pulmonary artery should drop with temporary occlusion of the duct. But the risk of operation is increased in all patients with raised pulmonary resistance.

The treatment of patent ductus arteriosus with left-to-right shunt is ligation and division of the duct, the latter in order to prevent recanalization. The mortality in R. E. Gross's²⁰ series of 525 patients was 2%; this included some patients in congestive failure and twelve with bacterial endocarditis. In those with only minor symptoms the mortality was 0.5%. The arguments in favour of closure in all cases are that the patient is likely to deteriorate in the third or fourth decade of life,¹⁹ that bacterial endocarditis is a continuing danger, and that operation invariably improves those with symptoms. Another large group apparently without symptoms also improves after ligation, and it is only then appreciated for the first time that they

were not in good health before the operation.¹⁰ Perhaps the only patients with left-to-right shunt who should not be operated on are those who have reached middle-age without appreciable symptoms, without much left ventricular hypertrophy, and without the development of some pulmonary hypertension. If such a patient has calcification in the region of the duct it is probably best left alone, since there is some danger of rupture of the great vessels at operation.

PHARMACOLOGY OF SALICYLATE

Synthetic salicylates have been used in clinical medicine for over eighty years, but most of their actions have remained obscure until recently, and much still remains to be elucidated. Interest has concentrated especially on the mechanism of the hyperpnoea which is such a notable feature of heavy salicylate dosage and on the metabolic effects. The relationship of one to the other is now becoming clearer.

J. Reid and his colleagues,¹ of the Medical Research Council's clinical chemotherapeutic unit at Glasgow, have found a progressive rise in output of urinary nitrogen due to increased catabolism of protein, and a respiratory alkalosis. J. B. Cochran^{2,3} has described the metabolic stimulating action of salicylate in normal and rheumatic subjects, and D. H. Sproull⁴ has localized this action at a cellular level. The hyperventilation has been ascribed to a direct stimulation of the respiratory centre^{5,6} and to a stimulant action on afferent vagal nerve endings.⁷ The latter explanation has been denied,⁸ probably correctly. The evidence for the former explanation, direct stimulation of the respiratory centre, is said to be based on inconclusive evidence⁹; moreover, the effects of salicylate can be accounted for without invoking it. Reid⁹ holds that salicylate is a "primary metabolic stimulant." It causes increased protein catabolism, which is accompanied by an increase in requirement of oxygen and a relative drop in production of carbon dioxide (lower R.Q.). The increased need for oxygen has to be satisfied by an increase in pulmonary ventilation. The result of this is a loss of carbon dioxide, leading to a "respiratory alkalosis of metabolic origin," which differs from the alkalosis following overbreathing, hysterical or voluntary, in which the consumption of oxygen is not raised. The old belief that salicylates cause hyperventilation by inducing an acidosis receives no support. In cases of poisoning any acidosis which may occur is probably due to starvation, which is hastened by the metabolic stimulant effect. Reid's view has the merit of fitting the observed facts with maximum economy. He draws attention to the "apparent paradox" of a metabolic stimulant being also an antipyretic, and suggests that the rapid defervescence so often seen is due to the profuse sweating which occurs with salicylates and which overcomes the metabolic stimulant effect. If sweating fails to occur, as in cases of electrolyte depletion, hyperpyrexia may result, and it may be that some

cases of what has been described as "cerebral rheumatism" are examples of this. Reid found that rabbits, unable to sweat and so to lose heat rapidly, die in hyperpyrexia after high doses of salicylate. Pyrexia and sweating are also features of salicylate poisoning in man. W. D. Alexander and K. W. M. Johnson¹⁰ have performed the feat of successfully raising the metabolic rate in myxoedematous patients with about 8 g. of aspirin a day.

The mechanism of the antirheumatic effect of salicylate is still largely obscure. Reid and colleagues¹ consider that simultaneous relief of pain and swelling of joints in acute rheumatism may be due to a decrease in cell water resulting from the lowered content of protein in the cells owing to catabolism. The water passes into the interstitial space and then into the plasma. It is then removed by sweating and diuresis, mainly by the latter. The erythrocyte sedimentation rate falls to normal when the water has been disposed of. Thus the symptomatic relief of acute rheumatism may be due to the primary metabolic stimulating effect of salicylate and so quite unrelated to the cause of the disease. This would explain why cardiac complications and recurrences are not prevented.

G. Ungar¹¹ finds that salicylate and some other anti-inflammatory substances have an antifibrinolytic effect, and that corticotrophin and cortisone cause the serum antifibrinolytic activity to increase. He suggests that this common action may account for the similarities in the response of inflammation to cortisone and to salicylate. It seems likely that, even if salicylate increases adrenocortical activity by an action on the anterior pituitary, as has been claimed by J. Roskam and colleagues,¹² suggested by J. B. Cochran and colleagues,¹³ and denied for therapeutic doses by R. I. S. Bayliss and A. W. Steinbeck,¹⁴ this action cannot account for all the therapeutic effects of salicylate.

It has been known for thirteen years that sodium bicarbonate reduces the toxicity of salicylate not because of any local action in the stomach but because it increases the rate at which salicylate is excreted in the urine.^{15,16} Its continued administration as a routine ingredient in salicylate mixtures is therefore irrational, as it simply produces the effects of lower salicylate dosage. In some cases of salicylate poisoning sodium bicarbonate may be given to hasten excretion, though respiratory alkalosis would make this a dangerous and perhaps an unnecessary procedure. It should therefore be done only if full and recent study of the blood chemistry indicates that it is safe and will not unduly raise the blood pH and cause tetany.

VITAMIN-D INTOXICATION

Vitamin-D intoxication, particularly in adults, is occasionally reported as a result of over-prescribing or injudicious self-medication with the vitamin, both of which are possible with the highly potent preparations which are available. There is also a chance that children may be overdosed with vitamin D by misguided but well-meaning mothers. Although the daily requirements of this vitamin are measured in hundreds of units, capsules and liquid preparations providing doses of 50,000 units can be obtained without prescription. A patient may thus take 300,000 units daily for a long time and run the risk of suffering from the toxic effects of gross overdosage. The vitamin has been used for about 25 years for the treatment of a wide variety of conditions including arthritis, allergic diseases such as asthma and pollinosis, acne, sarcoid, and lupus and other forms of tuberculosis. It is now generally considered that other and more effective remedies exist.

The common manifestations of vitamin-D intoxication are loss of appetite, fatigue, nausea, vomiting, constipation or diarrhoea, abdominal pain, polyuria, and nocturia. Headache, depression, and paraesthesiae may also be present, and abnormal calcification occurs in the larger arteries, kidneys, lungs, and soft tissues. The urine is loaded with calcium and phosphorus, the blood levels of which are also high, and renal function is generally impaired, the kidney being one of the most vulnerable organs in this form of intoxication. These toxic manifestations may occur in adults consuming 50,000 to 150,000 units of vitamin D daily over long periods, though the amount of the vitamin and the time necessary for toxic effects to appear are variable. The shortest period reported was 12 days at a dosage of 750,000 units daily.¹ A high calcium intake potentiates the toxicity of vitamin D. The repeated administration of large doses to infants and young children has resulted in fatalities.² W. B. Scharfman and S. Propp³ report anaemia as a sign of vitamin-D intoxication. This was present in four of their patients and was of the normochromic and normocytic type. These workers state that a review of the literature reveals that anaemia is present in varying degree in nearly all patients with vitamin-D intoxication who have renal involvement. There are two possible explanations of this anaemia—a toxic effect on the bone marrow, or, what is more likely, a result of the azotaemia that accompanies reduced renal function. A normocytic normochromic type of anaemia is common in uraemia. I. R. Callen and L. R. Limarzi⁴ state that when the non-protein nitrogen reaches high levels in this condition erythrocytic hypoplasia of the bone marrow occurs. In the differential diagnosis of vitamin-D intoxication the anaemia, azotaemia, and abnormalities of calcium metabolism may suggest other diseases, such as multiple myeloma, primary hyperparathyroidism, and the syndrome of hypercalcaemia and alkalosis caused by the excessive intake of milk and alkali by dyspeptic patients. The diagnosis of vitamin-D intoxication depends upon

careful questioning of the patient, and estimation of the probable intake. It is now recommended that the daily intake for a child need not exceed 400 units.⁵

RESPIRATORY VIRUS VACCINES

Viruses causing respiratory diseases are at present the subject of intense research. This is partly owing to the application of tissue-culture methods to the study of respiratory diseases. Several new viruses have recently been characterized and associated with a variety of clinical conditions, which are gradually removed from the group of undifferentiated respiratory diseases. The propagation of such new viruses in the laboratory leads naturally to hopes of the vaccine control of the corresponding diseases. Such hopes, raised over 20 years ago in the case of influenza, have unfortunately not yet been wholly fulfilled, as Professor C. H. Stuart-Harris points out in a stimulating discussion published in the opening pages of the *Journal* this week. One of the main difficulties is the antigenic instability of influenza A viruses and the requirement of a strictly specific vaccine for successful protection.^{1,2} This imposes the need to watch constantly throughout the world for the earliest possible indications for the emergence of new antigenic virus types. The importance of such a task, performed by the W.H.O. World Influenza Centre and associated laboratories, is strikingly brought out by the present pandemic, predicted soon after a new antigenic type of influenza A virus made its appearance in the Far East. The indication for a vaccination programme against such a new strain became immediately apparent, especially in view of the possibility, unlikely as it might be, of the recurrence of conditions prevalent in previous pandemics. But the problem of preparing sufficient vaccine for general use remains unsolved, imposing great care in the allocation of available resources. The degree of protection conferred by the vaccine now being made has yet to be determined, and the indications are that the current strain stimulates rather poor antibody responses. Consequently two doses of vaccine are recommended, and Professor Robert Cruickshank suggests in a letter at page 821 that a single booster dose is worth giving to priority staff who had clinical influenza before there was time to vaccinate them.

The discovery and propagation of new respiratory viruses have been closely followed by the use of new vaccines. Adenovirus (A.P.C.-R.I.) vaccines have been developed.³⁻⁵ Their value in reducing the incidence of adenovirus infections in institutional outbreaks has been established, but indications for a general use of the vaccine must await further knowledge of the importance of adenoviruses as a cause of disease in the general population. A report on the development of a vaccine

against the common cold has recently appeared in the lay press.⁶ The work was carried out by W. H. Price of Johns Hopkins University, and the report includes the full text of a paper to be published in the *Proceedings of the National Academy of Sciences*. The vaccine consists of a formalin-killed preparation of the J.H. (after Johns Hopkins) virus, which causes cytopathic effects in cultures of human and monkey tissues. Use of the vaccine in an institutional outbreak of a cold-like disease among children reduced the attack rate by eight times. This agent was isolated from patients with minor respiratory illnesses by Price,⁷ and independently by W. Pelon and colleagues.⁸ Both groups of workers are cautious in proposing an aetiological relationship between J.H. virus and the common cold, and evidence is presented that a number of cases diagnosed as common cold are unrelated to the new virus.

Certain findings obtained with the J.H. virus are not in full agreement with results from studies on the common cold by other workers. The good antibody response obtained with the J.H. virus is, for instance, in contrast with the lack of immunity following common-cold infections in volunteers studied by the Commission on Acute Respiratory Disease.⁹ It might also be pertinent to mention the report¹⁰ by the group working at the Common Cold Research Unit in Salisbury on the propagation of a strain of common-cold virus through ten passages in cultures of embryonic human lung, without evidence of cytopathic effect. It may be expected that studies on similar lines will result in breaking up the clinical entity at present known as the common cold into a group of diseases caused by different viruses.

"WORLD MEDICAL PERIODICALS"

The impetus for publishing an international list of medico-biological periodicals, together with their abbreviated titles compiled according to the code of rules used by the *World List of Scientific Periodicals*, came from a Unesco committee—the Co-ordinating Committee on Abstracting and Indexing in the Medical and Biological Sciences. This committee felt that little headway would be made in the co-ordinating of abstracting activities unless the various agencies could agree on the standardization of certain details of the work. Thus it would obviously be helpful if the same abbreviations for the titles of periodicals could be used throughout the world, and so the committee set to work to prepare a list of titles and approved abbreviations. This list, under the title of *World Medical Periodicals*, was first published in 1953 under the joint sponsorship of Unesco and W.H.O. The titles included in the list amounted to about 4,000. During the last four years there have been numerous changes to record and many new journals have been published; thus the need for a revised list has been apparent for some time. By agreement with Unesco and W.H.O. responsibility for the second edition of *World Medical Periodicals* was assumed by the World Medical Association, and the new volume

was published last week.¹ The list, like the earlier one, was compiled by Mr. L. T. Morton, information officer of the *British Medical Journal*, under the guidance of the Joint Committee on Medical Documentation of the World Medical Association and of the International Union of the Medical Press. The field of work of the joint committee is a fairly narrow one, but the results of its labours will be none the less useful to medical workers everywhere, but more particularly to medical editors, librarians, and publishers. In addition to the title of the periodical, and the abbreviation based on the code of rules used by the *World List* (as modified by the recommendations of the International Standards Organization), the name and address of the publisher is now given. The preface, headings, and explanatory text are printed in English, French, Spanish, and German. Lists of the principal international abstracting journals and indexes are included as appendixes, and the index of periodicals by subjects is usefully subdivided into countries: thus it is easy to see at a glance where, for instance, journals on allergy are published. The World Medical Association is to be congratulated for sponsoring this useful work.

NEW SCHOLARSHIP FOR DOCTORS' SONS

The medical profession in Britain has many reasons to be grateful to the Medical Insurance Agency, whose jubilee was celebrated last week (see p. 819). Earlier this year we described² the foundation and rapid growth of the M.I.A., to the consequent benefit of the Royal Medical Benevolent Fund and the Royal Medical Foundation of Epsom College. Readers of this *Journal* need no reminder of Epsom's close links with the medical profession: since its foundation 102 years ago about one-third of the 7,000 or so boys educated there have become doctors, and many hundreds of boys from medical families in necessitous circumstances have been accepted as foundation scholars. The council of Epsom College, thanks to the generosity of the Medical Insurance Agency, have now announced for competition early in June, 1958, a scholarship of £250 per annum open solely to the sons of registered medical practitioners. The award will be made on the results of an examination, without any means test whatever. Further scholarships of like amounts will be available in subsequent years; they will be called "Henry Robinson Scholarships" and will thus commemorate the work of Dr. Henry Robinson, who as honorary secretary of the Medical Insurance Agency for the past twenty years has been one of the powers behind its phenomenal progress. Further details of the scholarships are given at p. 835.

The essence of this new development by the Foundation of Epsom College is that the qualification for a scholarship is not financial distress but intellectual ability. Coupled with the new buildings, already three-fourths erected, and the reconstruction of the kitchens and dining-halls, shortly to be undertaken, this jubilee-year scheme for rewarding the talented sons of doctors still further increases the usefulness of Epsom College to medical parents.

VISIT TO MOSCOW

We print below a final-year medical student's impressions of her visit to the recent Youth Festival at Moscow. Photographs are by the author.

At the end of July I went to Moscow with the British delegation of the World Youth Festival. Eighteen hundred people went from Great Britain. Of these under a quarter were communists. The others went as individuals or with artistic, sports, Christian, miners', or trade-unionist groups. There were 400 students from Oxford, Cambridge, and London. A few of them were students of Russian. Most of them went to try to get a glimpse of Russian life. I myself never thought we should be really free to move around Moscow and talk openly with people; but, fortunately, I was wrong. Things were made easier by the fact that I speak some Russian and went round with a friend whose Russian was fluent.

The Journey There

We left Victoria station at 7.30 a.m. on Tuesday, July 23, and arrived in Moscow at 9 a.m. Russian time (two hours' difference) on Friday, July 26. We went by train across Belgium, West Germany, East Germany, Poland, and White Russia, changing at the East-West German border and at the Russian-Polish border. The countryside is completely flat the whole way. To us in the train White Russia was a country of wide stretches of marshy land with birch and pine woods and occasional clumps of wooden houses and some towns. We very rarely saw a road. Once behind the iron curtain the train stopped for about half an hour at intervals of two hours, and we talked to people on the different station platforms, and we talked to people on the different station platforms. The East Germans seemed sad and reserved. The Poles were very friendly and open, and were all, it appeared, overjoyed by the fact that Gomulka is now in power.

We arrived in Russia at 10.30 a.m. on Thursday, July 25, and changed into trains with couchettes, which was a relief after the hard seats of the other trains. Russian trains run on wider rails, which makes them move much more smoothly. At the Russian stations the welcome was overwhelming. Apart from the organized reception groups people had come from miles to see people from the West, to look at them, and to ask them questions. They were so excited, as it was their first chance in years to meet so many from other countries. At a few stations the authorities had not been able to control people from rushing on to the platform, and the crowds were so dense that we were not able to get out of the trains. Everywhere they bombarded us with questions: "Where do you come from?" "Were you chosen?" "Were you frightened to come?" "Do you live well in England?" "Can you get our books and papers in London?" The more official people one met at stations—e.g., teachers and engineers—would always start telling you how much they wanted peace and how much they had suffered during the last war, and asked why we wrote "bad things" about them in our papers. Every time we had to explain that we also wanted peace, had also suffered during the war, and had had bombs on London.

The City of Moscow

On arrival in Moscow we were again met by enormous crowds. We were taken to the Tourist Hostel near the permanent agricultural exhibition, 45 minutes by bus from the centre of Moscow. The hostel, which had been built about one year ago, looks like the many blocks of flats going up all over Moscow—dull square buildings which are quite adequate but badly finished. Inside there were long corridors with rooms either side with four or five beds in each one. Everything was nice and clean and we were well looked after; but the doors did not shut properly, there was already a hole in our wall, and one wondered how long the building would last. We ate in a marquee next to the hostel, and were extremely well fed. Many of us avoided the official trips and meetings and went round Moscow in ones, twos, and threes. We were given free travel on all

the buses and in the metro, and were free to do what we wanted. Those who could not speak Russian could usually find someone in a crowd who spoke English and who was not an official interpreter. The English of the official interpreters was not always good, but they were evidently politically "safe."

Moscow has a population of seven million. The buildings are a complete hotch-potch: new flats; old wooden houses and shacks, many of which are completely falling to pieces; lovely old Moscow houses (Fig. 1), some of which had been

FIG. 1.—A typical side-street in Moscow near the Tretyakov art gallery (largest gallery in Moscow with only Russian paintings). The house on the left is a pre-revolution wooden one. There are still many left in Moscow, but some are in very bad repair.

newly painted for the festival; two or three skyscraper type of buildings which looked rather out of place; and dilapidated churches, all of which have people living in them. Their life seems very hard. They work and work, especially the women, who seem to do every type of job, even building and street-sweeping. At the same time they have to look after their families, which are usually small, and have to join enormous queues to do their shopping. They are often helped by their own parents. Food seems expensive. To have a tiny flat of two rooms for a family is almost a luxury, and it is apparently not uncommon for two or three families to live in one room. The streets and the famous Moscow metro are spotlessly clean. I was struck by the almost complete absence of dogs; I think I saw only three while I was there. There was also a welcome absence of advertisements: there were a few for the films being shown at the festival, and they had been hand-painted on canvas. Most people travel by metro, bus, trolley-bus, or tram. There are a few private cars, taxis, and official black chauffeur-driven cars. I often saw lorries full of people, but few on bicycles. The main streets are wide and the cars that there are go rather fast: I saw three accidents during my 17 days in Moscow.

Thirst for Information

What struck us, and has evidently struck many other observers, was the active and enthusiastic part the Russian people took in the festival (Fig. 2). They had been told about it for the whole of the past year, on the wireless and on television. They had been taught short sentences in different languages, and had been told to be good hosts. But I do not think anybody, including the Russian authorities, knew that they would walk the streets day and night trying to find even one out of the 30,000 foreign students to talk to. They seemed to be so desperately eager to meet us, to pour out questions and to hear what we had to say (Fig. 3). It is impossible really to describe in words this great and insatiable thirst for information, for news of the West, for interchange of views on Dickens and Dostoevsky, and, in the next breath, on the cost and standard of living—all this from ordinary

¹ *World Medical Periodicals*, 1957. Published by the World Medical Association. New York. Price \$6.00. Also obtainable from booksellers or from the Publishing Manager, British Medical Association, Price 30s. (by post 31s. 6d.).

workers in the street crowds. A friend of mine (whose Russian is fluent) was held up in a taxi one day because of the crowds, and a man, seeing that he was agitated, came up to him and said: "Forgive us, forgive us—but this is the first time that our people have met any of yours. We could not give them a proper welcome. It is not long since we have been freed."

FIG. 2.—Group of Soviet girls from Azerbaijan. They were in national costume for the opening of the festival at the Lenin Stadium.

Each day we set out to see an art gallery or an old church or monastery, but more often than not we landed up in someone's rooms or in some other part of Moscow, because whenever we stopped for a moment we were surrounded by crowds of people questioning us and then inviting us to do things with them (Fig. 4). Was there, we were asked, freedom of thought, speech, and religion in

England? And the ever-recurring question: "You live better than we do, don't you?" The ordinary people seemed to accept the fact that their papers did not give them a clear picture of the West. Many said that the latest top-level Government changes were a "shady affair," and would sometimes ask us what was written in our papers about it. As I find it very difficult to argue about politics, especially in Russian, whenever anybody asked me, "What about Suez?" I would ask them, "And what about Hungary?" They always seemed to understand and quickly changed the subject. Those who were prepared to talk about Hungary admitted that it was a genuine rising of the people, and apparently quite a number of Moscow students protested at the time of the rising and were arrested.

One incident that happened to my friend and myself gives some idea of the intense curiosity of the people for news and views of what goes on outside Russia, of their feeling of isolation. We went one morning to the Bolshoi Theatre in the centre of Moscow to try to get some tickets for the ballet, but when we got out we could not get any further because of the crowd. So we stood on the top steps of the theatre and answered questions from ten o'clock in the morning till half-past three in the afternoon—five hours non-stop. They all seemed so delighted to talk with us, and discussed everything under the sun—politics, Russian and English literature, religion, freedom, the difference between London and Moscow, and all the details of our own lives: What did we do? How many brothers and sisters had we? What did our parents do? They were so friendly, kind, and direct. From time to time they asked if we were not too tired answering questions. They made us paper hats when the sun got rather hot; they bought us ice-creams and bunches of flowers. Occasionally a slightly unpleasant person would join the crowd and ask us what we were doing and why we were not with our official delegation: then the conversation would become more superficial until the person moved away. I had been told by one Russian that there were, of course, many plain-clothes policemen in Moscow during the festival, but in the vast crowds they became too diluted to be much of a hindrance. People in Moscow seemed to smoke much less than in England, and it was very rare to see a woman smoking. But there were rather a lot of drunk people about despite the fact that the sale of vodka was reduced during the festival. All the drunks we saw were carefully shepherd by friends.

The Kremlin

The Kremlin has been open to the public only for the past two years. Contrary to popular expectations the Kremlin is not a grim and forbidding place. It is amazingly beautiful (Fig. 5). When I walked among the palaces and the churches I had a curious feeling of being in a sleeping-beauty kind of fairy-tale. Around us were visitors from all over Russia—members of the party; men and women bowing and crossing themselves, and praying in front of all the churches and inside them, though no services are held there now; a few soldiers and policemen watching them with what appeared friendly curiosity; and then from time to time large black official cars coming in or out of the Kremlin.

All the Moscow churches we went to were crammed full of people. There are only forty in use now and they are all well kept. The frescoes and icons in the churches are very beautiful. Quite a number of people told me that it is very difficult for young people from the ages of 8 to 20 to attend church, but that as soon as you become older nobody bothers you. The official line is, "Whoever wants to go to church is welcome, but most of us only go to churches as to museums." This sentence was always said in exactly the same tone of voice and with exactly the same wording in a rather irritating and unconvincing way. The type of person who gave this answer also would talk to you as if the Russians were the only people who wanted peace and would try to persuade you that they live well now.

FIG. 3.—Group of Moscow schoolchildren (about 14 years old) asking questions about England, discussing Russian literature, and telling us about their lives. We were outside the Lenin Stadium just before they gave a massed gym display at the opening ceremony.

FIG. 4.—Group of people in the Kremlin asking questions about England. The man on the left was getting excited about Suez and the others seemed worried in case we should quarrel.

A Medical Institute

I went for a short while to the medical meeting at the 1st Moscow Medical Institute and looked over the museums and teaching hospital. Their museum of hygiene is very large, and I gather that students spend a lot of time studying hygiene and public health, because of the great need in Russia generally for public health services. The hospital was, I thought, well laid out. The main building was constructed at the end of last century and has been added to since then. The patients walk around in their striped pyjamas in the corridors and on the outside along the drive and among the flower-beds. In the surgical department the patients who have just been operated on are put into small recovery wards for a few hours or longer before they go back to the ordinary wards. All the dressings are done in a special room. Patients who are well

FIG. 5.—A courtyard inside the walls of the Kremlin with the Cathedral of the Assumption on the right. The Kremlin has three cathedrals and several palaces, in one of which the Supreme Soviet meet.

enough to get up eat in a separate dining-room. The doctors, nurses, and sisters all wear the same white overalls and hats, so it is impossible to tell who is who. The length of the medical course is six years, but so far as I could gather the sixth year is really more like our pre-registration year. The students have examinations every six months and specialize in much earlier than we do. Most of the students live in hostels, and I spent a most enjoyable evening with a group of them. They did not seem very politically minded, one of them. They did not seem to learn about Lenin and although, of course, they have to learn about Lenin and Marx all through their course. In the hostel they have a television and tape-recorder which seemed to play nothing but jazz and songs of Yves Montand. Yves Montand is a French communist who visited Moscow not very long ago, so they all know his songs. When I said I liked Russian folk music they thought I was just being polite. They were interested in what I did in my free time and by the fact that we are able to travel abroad so easily and freely during the holidays. They wanted to know everything that

I liked and disliked about their country. And so the talk went on. In our all-too-short stay of 17 days we had so many new and unexpected adventures and encounters that it has not been easy to sort them all out. Altogether it was an unforgettable experience. One day, I expect, many of us who were in Moscow in August this year will go back, and I wonder what changes we shall find.

NEW ACADEMIC YEAR

KING'S COLLEGE HOSPITAL MEDICAL SCHOOL

The Fergusson Tradition

Sir GORDON GORDON-TAYLOR took as the subject for his inaugural address at King's College Hospital Medical School on September 27 "The Fergusson Tradition."

Sir Gordon Gordon-Taylor recalled that Sir William Fergusson was one of the outstanding surgical figures in the story of King's. He was one of the two original surgeons at the old hospital—the former workhouse of St. Clement Danes. One of the most brilliant figures of all times, his prowess in surgical dexterity and skill had never been surpassed; it was rivalled only by Robert Liston, the professor of surgery in what was once called the "Godless institution" of University College. Fergusson's successor at King's was Lord Lister. In no sense was one the forerunner of the other, except in dates. On the one side Sir William was the supreme surgical operator, the "surgical flamingo." On the other hand, Lister was the laboratory worker, all humility, bringing the work of the laboratory to the operating theatre, the man who pushed back death, and who, as Lord Moynihan said, saved more lives than all the wars in all the ages had thrown away.

In a few months from now 150 years would have passed since Fergusson first saw the light of day and 117 since he first came to King's. After first assaying the law, he had become at the age of 22 demonstrator to Dr. Robert Knox, the great Edinburgh anatomist. Fergusson regarded the dissecting-room as the avenue to surgery and was only 23 when he acquired fame through this approach. At that age he tied the subclavian artery. It was only the third time that the operation had been performed in Scotland, it having previously been done by Fergusson's teacher, Liston, and by Wishart; it had not been accomplished at all in England. Fergusson was essentially an operating surgeon. His name was associated especially with the cleft-palate operation. Whilst in Knox's anatomy rooms he dissected the palate of an elderly woman and studied the muscular apparatus, and he operated on one case whilst in Edinburgh. By 1870, when he wrote the fifth edition of his *System of Practical Surgery*, he had operated on 300 with only six failures. It was a curious thing that he stated in this work that he preferred operating on the cleft palate without anaesthesia. He felt that the movement of the mouth of the unfortunate patient helped him. Loyal to the Scottish tradition, he used chloroform as an anaesthetic.

Lateral lithotomy was a yardstick of the surgeon in those days. Fergusson never had the experience of the famous old St. Thomas's surgeon, Cheselden, who published 128 cases but also operated at St. George's and the Royal Hospital, Chelsea, and in private practice, and so must have performed 300 to 400 lateral lithotomies. But Sir Gordon thought there was no doubt that Fergusson did as many, and might have done more, than his Norwich colleagues. Amputation was the other great yardstick of the surgeon's skill, and Sir Gordon doubted whether Fergusson in his amputations at the hip-joint took much more than 2-14 seconds. Richard Charles, of Ipswich, and himself, Sir Gordon supposed, were the only surgeons to-day who had amputated using transfixation flaps; he commended the method to those surgeons who would have to deal with large numbers of amputations in the next war.

There was another side to Fergusson apart from his surgical artistry. He was a kind-hearted man. He ignored

He was born in Glasgow on October 2, 1857, his mother being a cousin of David Livingstone. Like his famous relative, he worked for many years before studying medicine and he did not graduate M.B., C.M. until 1882. He then studied in London, Paris, and Vienna, and made a voyage to India as a ship surgeon. His first interest was in otorhinolaryngology, and this was his main career specialty. He was appointed to this specialty in the Royal Infirmary of Glasgow in 1893 and later to a lectureship in Glasgow University. He became president of the British Laryngological, Rhinological and Otolological Association in 1893 and again in 1900. For many years he was proprietor and editor of the *Journal of Laryngology*. In this capacity he met most of the stage figures of his day, and, as recorded by Neil Munro in *The Brave Days*, he experimented with early phonographic recordings of their voices. These phonograms

now lamentably destroyed, included recordings of Tetrassini, Melba, Paderewski, Irving, and most other singers and actors of the day.

John Macintyre's fame, however, must rest on his hobby of electrical engineering. He was consulted on the equipment of a new electrical department of the Royal Infirmary in 1887 and much enlarged it in 1894. In December, 1895, Röntgen published his classic paper on the properties of x rays. He sent a copy of this paper to Lord Kelvin, who, being ill at this time, passed it to his brother-in-law, Dr. J. T. Bottomley. Bottomley was associated with Lord Blythwood and John Macintyre in electrical experiments, and these three gave the first demonstration of x rays in Glasgow on February 5, 1896, to the Philosophical Society. It appears that a previous demonstration had been given to graduates and students in the university, but this is undocumented. A. A. C. Swinton has claimed to have produced the first radiograph of the human hand (his own) in Britain on January 13, 1896.

It was reproduced in the *B.M.J.* of January 25. Sydney Rowland gave a demonstration to the Medical Society of London on February 24, 1896. It seems probable, therefore, that Macintyre was among the first if not the first to produce radiographs in Britain. Among his other "firsts" were the first radiograph of spine, the first "instantaneous" radiographs, the first radiographs of soft

tissues of thorax and abdomen, the first location of a bullet by x rays, the first radiograph of a tuberculous hip, the first radiograph of a coin in the oesophagus, and the first radiograph of a stone in the kidney. The most astonishing feat of all was the production of a cineradiogram of a frog's leg in 1896. This film is now in the library of the Royal Faculty of Physicians and Surgeons.

Silvanus Thompson, first president of the Röntgen Society, in his presidential address in 1897 referred to the early workers in radiology. He then said: "To particularize might be invidious but none will object to my mention of the name of Dr. Macintyre of Glasgow . . . who was one of the earliest and most successful practitioners of the new art. His cinematography to show the actual motions of bone in a living creature is of singular interest." Later Macintyre became interested in the therapeutic effects of x rays and published several papers on the treatment of neoplasms. He had experienced their destructive effects in 1896, when he suffered from dermatitis of his hands, and thereafter he insisted on stringent protective measures in his department.

During his lifetime Macintyre received many honours. He was president of the Röntgen Society, member of numerous British and foreign medical societies, a Deputy Lieutenant of Glasgow, and LL.D. of its university. He was a Knight of Grace of the Order of St. John. Early in his career he was elected a Fellow of the Royal Society of Edinburgh. Macintyre's contributions to the literature of radiology and otorhinolaryngology were numerous and widespread; he even had a paper published in Japan. His influence on the early development of radiology was great and his position as a radiological pioneer is assured. He died on October 29, 1928.

Motoring News

AUTOMATIC TRANSMISSION

Much has been said recently in motoring circles on the merits and demerits of automatic transmission for cars. Whenever a step forward is taken in engineering, science, or any other field, there are always some people who condemn the revolutionary and stick to the obsolescent. Apart from these, some drivers prefer to be active and use manual controls, while others are content to sit back and let the machinery do its work. To some extent this is a matter of temperament, but it also depends on how much driving one has to do and under what conditions. The pleasure motorist covering a small annual mileage is unlikely to be as worried about driving fatigue as is the doctor who spends many hours behind the wheel. Automatic transmission has been popular in America for many years and became available on British models some few years after the war; its application was restricted to large expensive models in the luxury range at first, but this year it has reached the 8 h.p. economy car, and is available as an optional extra at comparatively low cost on certain models. The same has occurred on the Continent, for even the diminutive 2CV Citroen is now available with simple automatic transmission working on the centrifugal force principle.

The automatic clutch is of two main types—namely, the centrifugal and the electrical. The former works on the principle of cones or sectors which fly outwards when the engine speed is increased, thus gripping a flywheel which encloses them and causing it to revolve. The latter method uses an electrical power unit which comes into operation as soon as the gear lever is depressed or moved into any particular gear. Fully automatic transmission is a much more complicated affair. It usually consists of a hydraulic torque converter and two epicyclic gear sets in series, giving three forward speeds and a reverse. A manually operated selector obtains neutral, low, drive, and reverse, and, once the required position has been selected, only accelerator and brake are required for driving.

Many of the popular cars now offer some form of alternative to the hitherto orthodox transmission, as can be seen from the list below. The cost of fitting naturally varies with the type of car and the amount of automation required, whether it be simply a power-operated clutch or a fully automatic system, but in any form it is an asset for the motorist who spends much time driving. Many doctors would find it worth while. The automatic clutch is the least expensive and perhaps the most useful of all these innovations, for the process of pressing the clutch is tiring, especially in heavy traffic or after a long day's drive. Moreover, the use of a gear lever sometimes adds interest to driving, while fully automatic transmission is somewhat soulless and on certain units the gears occasionally change at inopportune moments. Fully automatic transmission is expensive and tends to absorb power. It is now available on the medium-priced cars. Only in the luxury range is fully automatic transmission provided as standard equipment.

A further aid that is now becoming more and more popular is the overdrive. Once again there are units available to suit the majority of the popular cars on the road; they can be fitted either on a new car or to some of the older models for quite modest prices. There is no doubt that an overdrive can be a worth-while asset, for not only does it save wear and tear on the car and on the driver's nerves but it also helps considerably in lowering petrol consumption. Indeed, phenomenal figures have been recorded with light cars on long journeys. But the short "stop and start" runs that make up many doctors' motoring do not make the best use of an overdrive, and in this case there is no point in fitting one.

The small Standards set the ball rolling in the low-price field of British models by offering automatic clutch opera-

tion, followed by the Austin A55 and Morris Oxford and Hillman de luxe models. In the medium-price range the Morris Isis is the cheapest car to have an entirely automatic system. All these are optional extras. Laycock overdrives are available for Rootes and B.M.C. vehicles, and Fords can be fitted with Handa overdrive or underdrive units, the latter being designed for the caravan user. Morris Oxford and Cowley likewise will accommodate Handa units. Cars of low and medium price fitted with these automatic devices are given below.

Low-price Models with Automatic Clutch.—Austin A55 Saloon. Citroen 2CV. Hillman Minx Saloon and Convertible. Morris Oxford Saloon. Renault 750 and Dauphine. Standard Eight and Ten.

Medium-price Models with Automatic Clutch.—Armstrong-Siddeley Sapphire 236. M.G. Magnette. Morris Oxford Traveller. Wolseley Fifteen-Fifty.

Medium-price Models with Fully Automatic Systems.—Austin A95 Countryman. Austin A105. Daimler Century Mk. II Saloon. Ford Zephyr and Zodiac. Humber Hawk. Morris Isis. Wolseley Six-Ninety.

Vaccination Against Influenza

SIR,—Now that limited supplies of the new influenza virus vaccine are being distributed to priority groups, it may be opportune to comment on a frequently quoted statement that vaccination may be expected to reduce the incidence of influenza by some 30-40% among the inoculated community. This figure is based on earlier controlled trials with one injection of different influenza virus vaccines, mainly among industrial groups where, in the absence of a high epidemic incidence, the clinical picture of virus influenza may be blurred by admixture with other acute respiratory infections.

Because the new Far Eastern strain of influenza A is so distinct antigenically from earlier A strains and because a single injection of the new vaccine evokes rather a poor anti-body response in inoculated volunteers, it was decided to recommend two doses of the vaccine in order to obtain the secondary antibody response that is known to occur with other prophylactic agents. We shall not know for some time what degree of protection this course of immunization will give, but it is worth quoting the recent experience at Wellington College, where in a sharp outbreak of virus A influenza (confirmed by many isolations of the virus) the attack rate among uninoculated boys was 20%, while among those given two doses of vaccine at one year's interval it was only 2%.¹

The present influenza epidemic has invaded many areas and before any prophylactic vaccination was possible, and medical and nursing staff may feel that there is little to be gained by being vaccinated after the event. However, the present epidemic wave is occurring in the autumn, whereas the most recent epidemics in this country have occurred in the late winter. Again, in the 1918-19 pandemic the summer wave was followed by a much more severe winter wave and second attacks often occurred in the same person. It may, therefore, be prudent to recommend the full two-dose course for priority staff who have escaped infection in affected areas and to give to those who have already had clinical influenza a single booster dose. This procedure might reasonably be expected to give a high degree of protection against first or further attacks of influenza during the current epidemic.—I am, etc.,

ROBERT CRUICKSHANK.

London, W.2.

Influenza in Sheffield

SIR,—It may interest general practitioners in the south to know in advance what calls are likely to be made on their services if the influenza epidemic takes the same pattern there as in this district. My practice is in a well-situated residential area where there is no overcrowding by ordinary standards. There are 3,500 patients on my list. The period under survey is September 8 to 28. During that time 240 calls were received to new 'flu cases. Approximately 290 new cases were seen in their homes, the difference of 50 being made where two or more cases were seen at the same house at the same time. Of these 290 cases, 213 were children under 16. There was only one patient over 70 and only two over 60. A large number of adults were teachers. The worst week was September 16 to 22, when 161 new cases were visited. During the period under survey only 56 new cases attended at surgery and of these none subsequently applied for a home visit. Two hundred and five patients required only one visit, 54 required two visits, 28 required three visits, and 3 required five or more.

The cases can be divided into five main groups. (1) Influenza without respiratory symptoms: the main features were headache, prostration, dizziness, nausea, fever, and sweats lasting for 24 to 48 hours. (2) Influenza with pharyngitis: all the above symptoms with the addition of sore throat and a harsh cough lasting two or three days. (3) Influenza with pharyngitis and tracheitis: all the above symptoms with sore throat and substernal soreness and persistent harsh dry cough. This type lasted five or six days with pyrexia for the first three days. (4) Influenza with enteritis symptoms: here there was headache, fever, prostration, with a small amount of vomiting and diarrhoea. These cases lasted three or four days. (5) Influenza with complications: these were the cases which developed pneumonia.

Many of the patients in all groups complained of stiff neck, aches and pains in the limbs and body, and many children started the attack by vomiting. Stiff neck was generally associated with mild photophobia. Sweating was often excessive, the night clothes having to be changed three times in one night. Examination revealed few positive findings. Mostly the patients were notably pallid initially, dull or apathetic, with temperatures rising to 104° F. (40° C.) and pulse rates up to 120. Mostly their tongues were furred but moist and the posterior pharyngeal wall inflamed. Tonsillitis was rare. Cervical adenitis was not found. Except in the three pneumonia cases there were no physical signs in the chest. Nuchal stiffness was not found. The complicated cases were as follows: A boy aged 15 who suffered from diabetes and was on insulin—he developed hyperglycaemia; a girl aged 5 years and another aged 14 years who developed left basal pneumonia. Both improved rapidly with sulphadimidine and penicillin V. Three adult patients were expectant mothers all over six months pregnant. Two adult patients had been confined within the past two weeks. Both were breast-feeding. They ran initially high temperatures with prostration, sweating, headache, body pains, but recovered in three days. They were told to wear masks when feeding the babies and to wash their breasts with soap and water beforehand. The babies were not affected. In houses where young babies lived in the midst of infected siblings and parents they seemed the least affected by the disease.

Apart from isolation, rest, fluids, fruit juice, etc., most of the patients received only aspirin or codeine compound tablets. If the initial symptoms were severe and the cough very troublesome and the patient had had pneumonia in the past or recurrent bronchitis, a proprietary tablet of sulphadimidine and penicillin V was given in the recommended dosage. None of the patients on this treatment came to any harm and the coughs cleared rapidly 24 hours after starting the drug. It would appear from newspaper reports that young teenagers are particularly liable to influenzal pneumonia and this is confirmed by the above brief experience.

So far one in ten of my registered patients has required a visit or surgery consultation for influenza in the past three weeks. It is interesting to note that of some 300 registered patients over 70 only one has required a visit for influenza so far. My experiences seem to be very similar to those of my colleagues. All have been impressed by the peak period of September 16 to 22 and the sudden decline of new cases on and about September 25. All have been impressed by the absence of elderly sufferers and the difficulties in spotting the patients who are going to get lung complications after a few days. It is not reasonable to give everyone an umbrella of sulphadimidine or penicillin, but it will have to be offered to some. How to select those patients in good time presents a problem. One imagines that many of the reported deaths could have been prevented if an umbrella had been given early enough. How much drug-swallowing and its accompanying dangers of sensitization is justifiable to prevent the reported disasters? It is hoped that further reports may help to answer this question.—I am, etc.,

Sheffield, 8.

E. C. ATKINSON.

Puerperal Infections

SIR,—The paper by Drs. R. T. Martin, H. E. Reiss, and Shelagh E. Milne (*Journal*, September 21, p. 670) is welcome for commending a simple method. In their obstetric unit, swilling the perineum with the Metropolitan Water Board's chlorinated product has cheaply and safely replaced the old uncomfortable swabbing with liquor chloroxylenolis. They found that puerperal infections were not related to the toilet of the perineum but to the degree of obstetrical trauma. They do not describe the background of hygiene against which their findings might be viewed.

Maternity hospitals are very various. In some, ward practice may at the same time minimize major infection and facilitate cross-infection. "Minor pyrexias" may be given penicillin before they cross 100.4° F. (38° C.) and become notifiable, and such (desirably) prompt treatment may obscure the need to isolate the patient. In this paper the notified pyrexias reported were just over 2%, but the total infections were (Table III) 10.4%. How many had been "treated" out of the notifiable category? The uninfected 89.6% may have had personal resistance to thank as well as good labour ward practice, since opportunities for cross-infection are so frequent in hospitals. For example, the practice of rising early in the puerperium means that communal toilets are used, one person's perineum being dragged over another's discharges on the lavatory seat, and the area may then be dabbed with fingered paper from a roll. Few women have the skill and knowledge to stand on the seat. Then bathing may be encouraged in a bath available to ten or twenty patients, without any supervised disinfection between bathers (the money saved on liquor chloroxylenolis and cotton-wool might pay for shower-baths). Other microbial transport routes like bedding, nurses' noses, and jars (not tubes) of nipple lubricant are well known to the point of *ennui*, but all are relevant to studies of hospital infection since they can bypass any particular item of hygiene under survey and so invalidate comparisons. For example, a dirty bath, or even a douche with a jug of dirty water, will make little statistical difference if patients are already sharing a dirty toilet seat.

I do not suggest that all these hygienic defects apply in any one obstetric unit; but I feel sure they should be considered in any work on cross-infection.—I am, etc.,

London, N.9.

MAIR THOMAS.

The Government Prescribes

SIR,—Your leading article on the above subject (*Journal*, September 21, p. 688), in my opinion, will be well received by the medical profession.

There would appear to me to be a considerable amount of apprehension among doctors concerning the present situation and the increasing number of statements issued by the Government on medical matters. A typical case is the

Government's recent decision to import poliomyelitis vaccine from America, which is a complete change from their considered opinion in June, when they decided against this action. One knows little about who advises the Government on these matters, but, personally, I thought the decision then was most probably influenced by the fact that the Salk vaccine contained the Mahoney strain of virus which it had been thought advisable to leave out of the British vaccine. This appeared a wise decision to me, as it must have done to those concerned in the preparation of the British vaccine. If the Government's decision now to import the American vaccine is due to a change of mind of the medical experts working in this particular field, then, naturally, doctors would agree, but if it is due to public opinion expressed in the national press, which may or may not be a true expression of what the public really thinks, then the solution is a dangerous one.

The Government's interest in the public health of the community is praiseworthy, but care should be taken before any public statements are issued that the medical profession have prior information of this, and an opportunity of considering the matter. After all, they have to deal directly with the people, and it is unwise to put them in an embarrassing position. The constant scares published in the national press concerning health matters are not in the best interests of the health of the people, and in the prevention of this the Government could help the medical profession.

Finally, it is pleasing to find a Government interested in the public health of the community; but a Government prescribing—never.—I am, etc.,

Wellingborough

P. X. BERMINGHAM.

SIR.—Recently in the 9 o'clock news of the B.B.C. Home Service the Ministry of Health was quoted as having issued a statement to the effect that the appropriate course for a patient with Asian influenza to follow was to go to bed and take aspirin (dosage not stated).

While allowing that many doctors would agree with such advice, and recognizing that it was well-intentioned, I wonder whether any other of your readers regretted this entry of the Ministry into clinical practice. I suggest that the Ministry is doing a disservice to both patients and the profession by naming the drug to be used in treatment of a common illness for which no specific cure is known. The principle on which my condemnation is based can of course be stated in much wider terms. As far as the patient is concerned, the Ministry is presuming that he has diagnosed his own condition correctly. This being so, should it not also have advised him, for example, that soluble aspirin was to be preferred as being less likely to upset the stomach? And what about the patient who is sensitive to aspirin? How should he treat himself if stricken by Asian influenza? Then, for the doctor who happens to disagree with the Ministry, difficulties could be created if he does not prescribe the ministerially approved drug (always assuming that any patient has remembered correctly which drug that was).—I am, etc.,

Peaslake, Surrey.

G. I. WATSON.

Fulminating Staphylococcal Pneumonia

STR.—I read with interest the report of Dr. C. S. Darke and his colleagues (*Journal*, September 14, p. 606) of a case of fulminating staphylococcal pneumonia associated with influenza virus C. They state that the condition was recognized on admission to hospital and appropriate treatment was begun immediately to combat the extensive pneumonia and profound toxæmia. Despite the treatment, the patient rapidly passed into a state of profound shock, cyanosis, and dyspnoea, and died twenty hours after admission.

I have been so impressed with the dramatic effect of cortisone combined with the appropriate antibiotics in the treatment of patients who are desperately ill with tuberculous pneumonia, and in one patient who had a suppurative pneumonia associated with bronchial carcinoma, that I suggest cortisone could be substituted for nikethamide and

intravenous noradrenaline as a restorative measure in fulminating staphylococcal pneumonia. It is hardly necessary for me to add that the decision to use cortisone in a patient with pneumonia is as difficult as jobbing backwards is easy. —I am, etc., D. L. SIMON

Bournemouth.

D. J. AP SIMON.

Medical Use of Hypnotism

SIR,—There are many points made by Professor A. Kennedy ("The Medical Use of Hypnotism," *Journal*, June 8, p. 1317) with which I and many others disagree. I think I can do no better than recommend to the notice of Professor Kennedy and those who are interested in the issues he raises Sigmund Freud's twenty-eighth lecture in *Introductory Lectures on Psycho-analysis*.¹ Freud's statement, I think, is relevant to Professor Kennedy's remarks on analysis versus hypnosis in training psychotherapists—e.g., he mentions "the dangers of unquestioning indoctrination." Also, Professor Kennedy imputes "a great deal of suspicion" of hypnosis to "orthodox psycho-analysts." In the same issue of the *B.M.J.* there is a reference in an article on hypnosis to Wolberg, who is an avowed advocate of hypnosis and an "orthodox psycho-analyst." There are many others, including Kubie,² whose "Process of Hypnosis and the Nature of the Hypnotic State" is an attempt at an explanatory hypothesis combining neurophysiological and analytical concepts. There are many examples³⁻⁵ of analyst and non-analyst writing on hypnosis separately and co-operatively in a psycho-analytical or other journal.

Professor Kennedy fairly states that his is an account of his own experience, but I have no doubt that statements backed by his authority, such as "only a minority of patients, however, can be given full surgical anaesthesia at first attempt," will be taken as a dictum of general application. The statement certainly does not apply to fracture cases, and I would hope that Professor Kennedy's statement does not discourage competent anaesthetists with first-class facilities from attempting hypnosis where "full" surgical anaesthesia is required. After all, Esdaile did just that, with patients admittedly "prepared" by the mesmeric passes of his assistants. There are many other instances from the nineteenth century, and I do not believe that patients are so different that a modern hospital and theatre cannot compete in patients' minds with the magnetizers' passes. I believe that hypnosis will be of greatest use in general medicine,¹⁰ surgery,¹¹ and midwifery¹² (note it is routine and commonplace in Soviet midwifery), and of least, though some, use in psychiatry proper.

Pierre Janet followed up 3,500 cases treated by him and could ascribe only 7% of cures to suggestion.¹¹ Whereas Bernheim said that a doctor who could not hypnotize 95% of his patients at the first attempt was a doctor who did not know his business.¹² (He was almost certainly referring to hospital practice. In a conversation with Freud he admitted his lack of success in private practice.¹³) These statements are not contradictory, but support the contention that in fields other than psychiatry hypnosis will be important without being a method on its own of obtaining cures.—

men," with the result that "some men and women undergraduates never receive the help they need and leave the university with unsolved emotional problems. . . ." In my experience the vast majority of undergraduates leave the university infinitely less matured psychologically than if they had spent the equivalent time apprenticed to some trade or craft. Here they would have been in continuous touch with matured minds, from whom they would have absorbed the matured outlook in judgment, sense of values, responsibility, and intellectual and emotional expression and discipline, with all the emotional satisfaction and harmony which this acquisition gives. Apart, therefore, from a sense of frustration and anxiety in undergraduate life, this poor maturation frequently leads to disaster when the graduate faces his worldly responsibilities.

Dr. Davy rightly suggests that skilled help should be made available, and that "tutors, chaplains, wardens, doctors, and others should know each other and co-operate with each other." All this is excellent, but I think much more is needed. I feel that all university authorities should be much more acutely aware of their responsibility for the emotional as well as the intellectual maturation of their students, and that for this reason they should see that every undergraduate remains in intimate contact with matured minds, whose special responsibility it will be to watch the undergraduate's development, to assist this development in every way, and to detect signs of frustration, anxiety, wrong sense of values, poor development of responsibility, or the more obvious ones of neurosis, psychosis, or poor characterological development.

In the same issue there are two other most interesting articles which have a direct bearing on this problem. Dr. Nicolas Malleson's account of pre-examination strain (p. 551) illustrates vividly, I think, the immature, "helpless" mental condition of many undergraduates, and the necessity of expert help and advice, while Dr. R. W. Luxton's delightful article (p. 544) points out the main pathways by which mental, moral, and spiritual maturation are achieved.

Your annotation on "Mental Health of Students" (p. 567) suggests that psychiatry has only a limited contribution to make at present—"psychiatrists should be wary of inviting the crowd in until they have more to offer them." To some extent this is true—the factors which make for a full and satisfactory psychological and emotional maturation are at present little taught and less appreciated—but I think psychiatry can and will meet the challenge, and that psychiatrists, in co-operation with chaplains, tutors, wardens, or specially appointed officers, will bring to the undergraduate all the sympathy, encouragement, guidance, and knowledge of which he is in such vital need.—I am, etc.,

Pinner, Middx.

ROBERT THOMPSON.

Dangers of Cigarette-smoking

SIR.—In a letter (*Journal*, July 27, p. 236) Dr. J. Landon points out the lack of correlation between the incidence of carcinoma of the lung and whether or not the subject inhales. A possible explanation of this was given by Dr. C. N. Davies (*Journal*, August 17, p. 410). Another possible explanation is as follows.

Many people when smoking hold the cigarette between their lips while breathing normally; under these conditions a thin wisp of smoke from the burning end of the cigarette is inspired and, in quiet breathing, may pass into the trachea and bronchi virtually undiluted at a high temperature—vide letter by Dr. G. P. Brown (*Journal*, July 27, p. 236)—and likely to remain there little disturbed in quiet breathing. This smoke is thus different from "inhaled" smoke, which is both cooled and filtered by the tobacco between the burning end of the cigarette and the mouth. Of course, many people inhale as well as "smoke with the cigarette in their mouth," and so both "non-inhalers" and "inhalers" would be subject to this factor. In fact, many people who say they do not inhale probably enjoy smoking just as much as the inhalers do, because they do actually take in a lot of this highly concentrated smoke. This possibility

may be tested in two ways. One is to analyse the two different types of smoke—that at the burning end, and that filtered by the cigarette: such investigations may reveal a higher concentration of one of the known carcinogens in the former smoke. The other is to construct some form of model of the respiratory tree, either in perspex or glass, and to observe the course taken by such a wisp of smoke. It is likely that in quiet breathing the smoke would be inspired more or less undiluted at least to the level of the carina, below which many carcinomas develop.—I am, etc.,

London, S.E.1.

RICHARD B. HUDDY,
Medical Student.

St. Luke's Tide Services

SIR.—I have read with great interest the correspondence relating to St. Luke's Tide Services. Dr. Jane H. Thompson's letter (*Journal*, August 31, p. 528) interests me particularly when she reports: "Some of us in the north are trying to form a clergy-medical association formed of clergy and doctors of all denominations." I am quite sure that regional associations of this type would be very valuable, and many will watch the attempts of Dr. Thompson and her colleagues with great interest. May I ask her through your columns to keep us informed of the progress of their endeavours?—I am, etc.,

Taunton.

P. HUGGILL.

SIR.—I have carefully read Dr. Jane H. Thompson's letter (*Journal*, August 31, p. 528) apropos of my earlier one on this subject (*Journal*, August 10, p. 356). While I am in agreement with much that she writes, I must state a few vital facts. She is probably aware that already organizations exist which cater for all branches of the Protestant Church as far as medicine is concerned, of which the Guild of Health is perhaps the most well known. This is supported by the Anglican and all free Churches. Yet, as an Anglican, I submit there is a very strong case for having a body such as is the Union of St. Luke to link together those like-minded in the established Church and to work in closest harmony with other closely akin Anglican bodies, such as the Guild of St. Raphael. The fact that the union is on a strictly communicant basis is something that must be stressed. The union has a very definite contribution to make to the Anglican Church, and were it to be merged with a wider and perhaps less defined body, such as your correspondent advocates, this would be to its own spiritual detriment. In belonging to a large all-embracing body there is always the danger that vital principles may be sacrificed.—I am, etc.,

Redhill, Surrey.

J. B. GURNEY SMITH.

Cancer Research

SIR.—Much of the recent work on cancer is concerned with the recognition, distribution, and mode of action of carcinogens. This stems from the publication of Percival Pott's views on chimney sweep's cancer set out in his article "Cancer Scroti."¹ I think it untrustworthy and, in the light of what has been done since his time, inaccurate. Yet it has continued immensely to affect subsequent investigation, largely because of the fact that cancer could be produced in animals by the application of some substances externally. I believe it is a fallacy to assume that human creatures will react in the same way as animals living under duress. Inevitably work has been confined to laboratory animals, but these are often wild creatures who have to submit to captivity, with all its abnormalities and gross disturbance of their normal sexual instincts, and periodically to forcible restraint while their skin is painted with the substance being investigated. Little is known of the affective life of laboratory animals, and one is bound to think of them in anthropomorphic ways. But there can be no doubt that they may suffer what we understand by the conception of stress, and it is not inconceivable that, if "the slings and arrows of outrageous fortune" become insupportable, they find a flight into illness, and death is their only defence.

It happens we have a countless number of unsuspecting human guinea-pigs to act as controls. The best-known carcinogen, as might be expected historically, is coal tar and its derivatives. Liquor picis carbonis has been shown to be carcinogenic, and yet it is used as a paint or ointment in countless numbers of patients suffering from certain skin diseases. Most dermatologists have ignored this, as many smokers have disregarded the flesh-creeping warnings about their habits. I do not know of any reported case of cancer following the human use of liq. picis carb. Many will require experimental evidence. If this interpretation is correct I think it can be provided. A large number of mice should be divided into equal groups living under identical conditions. One group is treated with a well-established carcinogen, the other with an inert substance, using a modification of the modern double-check technique. Allowance should be made for spontaneous growths, though this would not be easy. If in the result only a few developed cancer after the inert application this would be immensely significant. Ideally the many mice should run into many scores. In examining a secretion for T.B. a few negative results mean little, while a single positive is conclusive.

But I do not suppose any established research organization will take the suggestion seriously. However, the tobacco manufacturers may take a different view and arrange for some of the research bodies they have set up to "try and see," as John Hunter might have said. They would be much concerned with their own interests, but a large number would be concerned in the removal of "cancer scroti," and all that has flowed from it, from the position it has so long enjoyed.—I am, etc.,

London, S.W.1.

Malignant Change Following Herpes Simplex

SIR.—Dr. R. Wyburn-Mason (*Journal*, September 14, p. 615) describes six cases of squamous carcinoma following herpes simplex. I wonder whether he may not have mistaken the lesions of molluscum sebaceum for epithelioma. The history in the first five cases is very short, one to three months; it would be unusual for an epithelioma to reach the size of 1.5 cm. in three months. Both clinically and histologically it is very difficult to differentiate the two, and all of us have made this mistake before MacCormac¹ drew attention to molluscum sebaceum. The sixth case is different, and followed a minor trauma of the lip in which herpes developed secondarily.

I feel, therefore, without clarification of the above points one cannot accept that herpes predisposes to malignant change.—I am, etc.,

Leeds, 2.

Compulsory Powers over Mental Patients

SIR.—I hope that you will permit me one more letter on this subject before it is too late and before medical attention becomes focused on yet another report. As yet there seems to be no organized opposition to the proposed change in the method of certification. Dr. A. Walk (*Journal*, August 24, p. 467) ties himself into knots trying to defend the Royal Commission's recommendations. To say that the admission and detention of patients depend on a consensus of medical and non-medical opinion—doctors, relatives, mental welfare officers, and, later, hospital management committees and the board of control—to which the justice's order is added just like one more vote, is simply to confuse the issue. One doctor and one magistrate carry out certification; the others are accessories either before or after the fact. Again, when he says that the Commission was not so foolish as to imagine that by eliminating the magistrate they would eradicate the stigma, surely they must at least have imagined that it would alleviate it, otherwise what was the

point of tampering with the existing machinery? Next he virtually admits this by saying that they wanted to take away the judicial authority "whose main function is the punishment of crime." Since when has the law in this country been exclusively concerned with crime and its punishment? Quite clearly it is the feeling of guilt connected with the stigma in the minds of men which is projected on to process of certification and which, if Dr. Walk and his friends have their way, will in future be projected on to the two doctors, one of whom is the psychiatrist. He will then be the guilty man who will be haled before the review tribunal to account for his acts.

I must say that when I came to Dr. Walk's paragraph beginning, "Every certified patient knows . . ." I realized that we were living in different worlds. There is only one thing that every psychotic patient does not know and that is that he is psychotic. Neglect of this fundamental consideration can lead to much ideological and unrealistic thinking.—I am, etc.,

Southall, Middx.

C. R. BIRNIE.

Centipede Bites

SIR.—With reference to Dr. G. T. Haneveld's letter (*Journal*, September 7, p. 592) these elongated arthropods have a poison apparatus in the claw of the first pair of legs. I have seen many victims of the centipede's "bite," but none of them appeared to have been actually bitten; perhaps "stung" would be a preferable description. The point would probably be best appreciated by the victim. Each segment of the centipede's body carries two legs; each leg ends in a very fine sharp curved claw.

Many people sleep "in the raw" on hot nights in the tropics, and a centipede may run across the abdomen of a man (or woman) fast asleep. If the movements of the centipede do not rouse the sleeper, all will be well. If, however, the sleeper wakes and attempts to brush off the creature a neat row of claws may be left embedded in the abdominal skin, where, later, two rows of small pustules will appear and persist until the minute foreign bodies are removed or extruded. Old hands advise the new boy to brush off the centipede in the direction of its travel; by this manoeuvre the tiny claws slide forward with the creature's body, and few or none are left in the person's skin.

The effects of the poison apparatus may be seen in a person who has attempted to pick up a live centipede; the two small marks show a local reaction and may go septic, as Dr. Haneveld writes, but I have not seen any systemic reactions follow. As for the full moon . . . "Think'st thou I'd make a life of jealousy, to follow still the changes of the moon with fresh suspicions?" (*Othello*, Act 3, scene 3, line 177).—I am, etc.,

Epping, Essex.

FRANK MARSH.

Snake-bite

SIR.—I refer to a letter by Sir Philip Manson-Bahr (*Journal*, August 24, p. 468). I spent over two years (1916–18) in a field ambulance in the wilds of Macedonia, and certain areas there were swarming with *Vipera nasicornis*; they bred and lived in scattered areas covered by about 12 in. (30.4 cm.) of scrub-oak; curiously enough, one of these spots was swarming with tortoises, but that is not quite to the point. It was our practice to kill any adult vipers, and even their babies of 9 or 10 in. (22.8 or 25.4 cm.) long, when they were adjacent to our field hospital, and this could only be effected by crushing the snake's head completely. The adult viper was usually not more than 30 or 32 in. (76.2 or 81.3 cm.) long. At least one soldier died from a bite. The precaution taken by Army Order was the issue of a metal tube, rather larger than a thermometer case, one end of which, when pulled out, contained a 4-point scarifier, and the other end a tube containing crystals of pot. permanganate. The treatment prescribed was to apply three ligatures on the afflicted limb, starting at the top and then to the middle of the limb and, say, 1 in. (2.5 cm.) above the snake-bite; then a deep scarification was carried out in the wound and the crystals were rubbed in. All medical stations were

surviving female twin? In this case there must have been virtually complete colonization of the marrow of the female twin by haemopoietic cells, both red and white derived from the male. This hypothesis would explain simultaneously the blood group anomaly and the presence of an ovo-testis. If this is in fact the true explanation it may be that other cases of so-called true hermaphroditism have a similar origin.—I am, etc.,

Maidenhead, Berks.

F. E. T. SCOTT.

Medical Superintendents

SIR,—Dr. G. McCoull's statement that "medical superintendent" has joined the list of English "dirty words" (*Journal*, July 6, p. 44) does not apply to Australia. In many cases a medical superintendent will have facilities and beds for clinical work, perhaps research and teaching. These appointments are strongly competitive in most hospitals, and those who hold them are usually highly regarded both by their colleagues and by the public.—I am, etc.,

Cooma, N.S.W., Australia.

DOUGLAS VANN.

Acute Inversion of Uterus

SIR,—We have read with interest the letter by Dr. Henry FitzGibbon from Ontario, Canada (*Journal*, September 7, p. 589), commenting on our recent article on this subject (*Journal*, May 11, p. 1102). We have no desire to open a correspondence on this very controversial condition, but we would like to make some points.

The main theme of Dr. FitzGibbon's letter appears to be that inversion of the uterus should be immediately replaced by the attendant as soon as the condition is recognized. We find this difficult to understand. In our case an attempt at immediate inversion as he suggests, without any preliminary resuscitation measures, would undoubtedly have killed the patient. She was in the most profound shock either of us had ever seen. As we tried to make clear in our article, however, full resuscitation before replacement of the uterus would equally not succeed in such a case carried out, as it would be, against a steadily deepening shock progression. It is our contention that the patient should be brought as rapidly as possible to the minimum state permitting safe anaesthesia. We are both sure that transfusion is necessary, therefore, before reduction of the inversion. This transfusion perforce must be rapid. We used dextran solution to win us five minutes wherein we could do a rapid cross-match and then replace the dextran with blood. We replaced the uterus as soon as we could detect a systolic blood pressure of 70 mm. mercury, and additionally, and more important, when the patient's general appearance suggested that she could now stand up to the additional degree of manipulative shock which is certain to be produced when the uterus is replaced. The whole procedure, from the detection of the inversion to the replacement of the uterus, took us twenty minutes only; admittedly they were the longest twenty minutes of our lives, but, looking back, we think that any attempt to have shortened that time by immediate replacement would have led to disaster.

We were familiar with the work of Dr. O'Sullivan and the other authors mentioned by Dr. FitzGibbon, but we only had time for one method and there was no place for experiment. Many authors state as their opinion that full resuscitation should be carried through, and our short article was written to illustrate that this may have its dangers in undue delay. No one, fortunately, can build up much practical experience of this condition, but we both firmly feel that we cannot agree with immediate replacement, at least when the patient is as badly shocked as ours was.

Additionally, conditions of obstetric practice in this country have not yet reached the utopian level where the obstetrician can do his little job and then let "someone" else worry about replacement therapy, and we hope they never will.—We are, etc.,

Obituary

RUDOLPH MATAS, M.D., LL.D., Sc.D., Hon.F.R.C.S.
F.A.C.S.

Dr. Rudolph Matas, emeritus professor of surgery in Tulane University, Louisiana, and an Honorary Fellow of the Royal College of Surgeons of England, died in hospital at New Orleans on September 23, aged 97. Though his name will always be associated with advances in vascular surgery, he made many original contributions to other branches of surgery, and his pioneer work was recognized throughout the world by universities and learned societies, including the Royal College of Surgeons of England, which elected him to Honorary Fellowship in 1927.

We are indebted to Sir GORDON GORDON-TAYLOR for the following appreciation:

A few days ago, after he had passed his 97th birthday, death brought to a close the long life of one who has been justly acclaimed the doyen not only of American but of the international world of surgery. To the present generation of surgical workers Rudolph Matas is but a legendary name associated with a technique for dealing with aneurysm, but to those of a more senior vintage he was a very vital figure, dominating surgical conferences—as did that great French surgeon, René Leriche—sure of an enthusiastic reception whenever he ascended a surgical platform, and always listened to with rapt attention and respect, for invariably he actively participated in the programme of a congress. Alton Ochsner, his successor at Tulane, knew no one able to speak extemporarily so fluently or so authoritatively as did Matas. Alas, advancing years had latterly imposed their decree upon the human thrust, and he who had scorned the fatigue of long journeys in the service of surgery was now an absentee from the meetings of the International Society of Surgery at Paris, Lisbon, and Copenhagen.

Rudolph Matas was born on September 1, 1860, the son of an ophthalmologist, at Bonnet-Carre, near New Orleans. He came of good vigorous Spanish stock, for father and mother each belonged to families of nine children: his forebears included farmers, merchants, priests, and municipal office holders. Various circumstances, including the American Civil War, directed his parents' steps to Paris and Spain when the boy was only 2, and Rudolph Matas did not return to the United States till 1868. He was now proficient in French and Spanish, and even in the Catalan dialect, but was "without English." This lack was soon remedied, and by 1877 he won by competition the post of resident intern at the Charity Hospital, New Orleans; in 1894 he was appointed professor of surgery at the University of Tulane, and retained an active association with the hospital till 1927, having served it for fifty years. He resigned the post of chief surgeon to the Touro Infirmary in 1935, when he was 75 years of age, and was succeeded by his loyal friend, Isidore Cohn. Matas retired from active surgery in 1940 at the age of 80.

The list of awards and honours conferred upon him would occupy pages, and it must suffice to mention a few only. His connexion with the American College of Surgeons had been long and honourable, including vice-presidency five times and the presidency (1925-26), and he was elected an Honorary Fellow in 1951. He was president of the American Surgical Association in 1909, the recipient of the Bigelow medal in 1926; he was made an Honorary Fellow of the Royal College of Surgeons of England in 1927 on the same occasion as Leriche. In September, 1938, on the very eve of the Munich crisis, he presided at Brussels over the Eleventh Congress of the International Society of Surgery. Never was his linguistic flair, dating back to the peripatetic character of his childhood years, seen to better

advantage than in the great hall of the Belgian Senate—the very court room in which the nursing-sister martyr, Edith Cavell, was condemned to death by a German court-martial—when he addressed representative surgeons of many countries in classic French. It was a memorable meeting, for the audience included the grand old Burgomaster Max, that heroic figure during the "occupation" of the 1914-18 war, and at that very moment a Nazi leader was once again menacingly rattling his sword. Not for Matas a hasty return across the Atlantic when war clouds threatened ominously: he first visited Spain, whither he had gone on a surgical mission during the civil war when there were war casualties to be treated, victims of Nazi and Italian aircraft pilots who were using the Iberian peninsula as a practice ground for not-far-distant grand-scale attacks on Britain, France, Norway, Holland, Belgium, and Poland.

The surgery of the cardiovascular system has advanced in scintillating fashion since Matas's pioneer exploit in 1888, but an individual total of 620 operations for aneurysm is an impressive one. The first successful operation on an aneurysm of the abdominal aorta in 1923 was hailed as a triumph, although such an event is to-day regarded as a commonplace, and the work of colleagues and pupils in the old master in America and of Rob and Eastcott in Britain must have provided gratifying evidence that the branch of surgery which he did so much to initiate was making stupendous advances.

But Matas made many pioneer contributions to surgery, apart from those dealing with the vascular system: he did original work in the field of local, regional, and spinal anaesthesia (1886), and in the intravenous use of saline solution and other sera for shock and haemorrhage (1885-91). By 1911 he was advocating gastro-duodenal suction for intestinal obstruction, peritonitis, and paralytic ileus; he devised positive pressure methods to prevent collapse of the lung in thoracotomy (1897-98); he advised transpleural thoracotomy for hepatic and subphrenic abscess, gall-bladder intubation to supply fluid and nutrient agents into the duodenum (1909), and early prostatectomy. In 1919 he stressed the value of the continuous intravenous drip with glucose. Many of those whose names are now associated with these therapeutic techniques had scarcely entered medicine when the old pioneer was already advocating their usage, but he never vociferously claimed his own priority. In his early pre-graduation years he served on a yellow-fever commission that went to Cuba, and later worked in several areas in the U.S.A. in an effort to combat the disease. Without the pathological aids of to-day he proved that many of the fevers in New Orleans were not malaria but atypical typhoid. For half a century he took a prominent part in every effort to improve the sanitation and public health of Louisiana.

The number of his surgical acolytes is legion, and the affection of surgical colleagues everywhere showed itself in various tributes paid him from time to time as the decades of his long life rolled past, and one is often left in wonder whether to admire more the beautiful language in which these tributes were couched or the depth of sincerity and affection which prompted these dedicatory offerings. The perfect English in which all the contributions from Matas's own pen are written is an endless source of pleasure to the reader, and his essay "The Soul of a Surgeon" (1926) and the address "The Surgeon: His Science and His Art" (1926) are worthy of comparison with Sir Thomas Browne's *Religio Medici*, while his obituary notices of Sir Arbuthnot Lane and Sir Harold Stiles are charming vignettes of these two British surgeons.

Although he had a good knowledge of literature, art, and music (and even patronized the cinema theatre!) his life may be said to have been wholly consecrated to surgery, and in this respect he reminds me more of George Grey Turner than any other surgeon. For most of those who knew him there will remain the memory of a short, sturdy figure, the white moustache and the "goatee" beard, the quick movements, the restlessness of the Latin, the tireless conversationalist, his friendliness and affability, his encourage-

ment to the young surgeon, his own intense humility, his devotion to surgery and to his patients. Perhaps those words from Guy de Chauliac employed in 1940 by that great friend of English surgeons, the late Elliott Cutler, sum up Rudolph Matas: "Bold, where sure; cautious in danger; kind to the sick; considerate of your fellow workers; uninfluenced by gain."

CHARLES TODD, O.B.E., M.D., F.R.S.

Dr. Charles Todd, a veteran worker and indeed in many respects a pioneer in bacteriology and immunity, died at Croydon on September 23, aged 88. For more than twenty years he rendered great services to public health in Egypt.

Charles Todd was a Cumberland man, born on September 17, 1869, and educated at Carlisle Grammar School. From there he went to Clare College, Cambridge, as a scholar, and took first-class honours in the natural sciences tripos. He won an open scholarship to St. Bartholomew's Hospital, and graduated M.B., B.Ch. in 1894. He returned to Cambridge as house-surgeon at Addenbrooke's Hospital, but the laboratory soon claimed him, and he became assistant bacteriologist at the Lister Institute. In 1896 he took the D.P.H. and proceeded to the M.D. two years later. The experience he gained at the Lister Institute led to his appointment as director of the Serum Institute at Abbassia, Cairo. At that time Cairo was a city of 800,000 people, with no high standards of hygiene, and Todd found abundant material for pursuing his bacteriological studies. His services were highly regarded in Egypt, and he became director of the public health laboratories in Cairo and consultant in the public health department of the Egyptian Government. He was a member of the Egyptian Cattle Plague Commission in 1912 and of the Egyptian Public Health Commission in 1918.

Later, after his return to England in 1926, a wider field of work awaited him as a member of the Colonial Medical Research Commission. Addressing a Colonial Conference in London in 1927, the Secretary of State spoke of a certain unity of problems in the colonial empire, along with a great diversity of administration and structure in the various territories, and he alluded to the need for closer co-operation and more effective interchange in those aspects of administration in which scientific methods and research entered, specifically public health and veterinary science. Charles Todd, from his experience of the Middle East and his work in this country at the Lister Institute and, later, at the National Institute for Medical Research at Hampstead, and his special knowledge of that borderline where human and veterinary medicine meet, was one of the men well qualified to assist towards such unity, and assist he did.

As early as 1902 Todd was working on aerobic spore-bearing bacilli, and in 1904 he was able to show that four to six weeks' cultures of Shiga's bacillus contained a soluble toxin which was highly active in rabbits and horses, but to a much less extent in guinea-pigs, rats, and mice. His work on bacteriophage lasted over many years. In 1927 he reported that most phages within the pH range over which they remained active appeared to carry a negative electric charge, in this way resembling bacteria and filterable viruses, and years later he was still working on the same subject, making observations which are recorded in the textbooks on pathology and immunity. Todd himself was the author of no book, but numerous papers by him are to be found in the *Proceedings of the Royal Society*, which made him a Fellow in 1930, in the *British Journal of Experimental Pathology*, and other publications. He was also the author of articles in *A System of Bacteriology in Relation to Medicine*, volumes published by the Bacteriological Committee of the Medical Research Council in 1929-31. In 1931 he joined the staff of the National Institute for Medical Research and continued to work at Hampstead until 1940.

Dr. Todd was often called into consultation by official and other bodies. He was a member of the Foot and Mouth Disease Research Committee. The Empire Rheumatism Council made him a member of its Research Advisory Com-

mittee. For his services in Egypt he was awarded the 2nd Class Order of the Nile and the 3rd Class Order of the Medjidieh, and in this country his services were recognized by an Officership of the Order of the British Empire.

G. H. C. OVENS, O.B.E., M.B., F.R.C.S.

Professor G. H. C. Ovens, dean of the faculty of medicine and professor of surgery at University College of the West Indies, died suddenly in Jamaica on September 20. He was 49 years of age.

Gerald Hugh Campbell Ovens was born on October 3, 1907, son of the late Brigadier-General G. H. Ovens, C.B. He studied medicine at St. Mary's Hospital Medical School, qualifying in 1932, graduating M.B., B.S. in 1935, and taking the F.R.C.S. in 1936. After holding house appointments at St. Mary's and the post of assistant medical officer at St. James' Hospital, Mr. Ovens became surgical registrar and, later, surgical tutor at St. Mary's, and honorary surgeon to the King Edward's Memorial Hospital, Ealing. During his service in the R.A.M.C. he was adviser in surgery to the Palestine Command from 1946 to 1948—a period which preceded the giving up of the Mandate—and for his work in that capacity he was appointed O.B.E. In September, 1948, he became professor of clinical surgery at the University of Alexandria. Three years later he joined the staff of University College of the West Indies as professor of surgery, and in 1953 he became dean of the medical faculty there.

Mr. R. P. M. MILES writes: Gerald Ovens died at the early age of 49, after two years of serious illness, which, nevertheless, had not prevented him from giving the full benefit of his mature wisdom to the ever-increasing problems of the University College of the West Indies and its medical faculty. Appointed to the chair of surgery there in 1952, he was forced, under medical orders, to give up active surgery after the first two years, but his work as an administrator and as dean of the medical faculty gave him more than full-time employment. He gave these years to the university, and he died working in its service to the end.

Many St. Mary's men will remember Gerald Ovens when surgical registrar (and in those days surgical registrars were not two a penny) as a first-rate teacher whose tutorials were an essential feature of the final year. He absorbed the best of the old teaching hospital tradition and took a delight in clinical and bedside instruction. He epitomized these methods in a most excellently written textbook *An Introduction to Clinical Surgery*, which he published in 1954. With great skill he translated the well-tried London teaching tradition to West Indian students, and his success was shown in the results of the first qualifying examinations, which were the subject of a special commendatory message from London University.

Conservative in outlook, greatly experienced in administration, and possessed of the power of immediately assessing a person's worth, Ovens rapidly spread his influence throughout the new University College. He supervised the final stages of building of the new teaching hospital, and succeeded in having it opened on the scheduled day in spite of many obstacles. His election as dean of the medical faculty was unanimous, and after the first year steps were taken to ensure that his term of office was extended. He held this office until his death. During this time pressing problems connected with expansion of the hospital and university finance taxed his resources to the utmost. The recommended extensions to the teaching hospital entailed an expenditure of one million pounds, and Ovens tackled the allocation of this large sum with the most painstaking thoroughness. He was at his best when presiding over estimates committees, carefully and tactfully keeping the peace between the rival claimants for the money. The project nearest to his heart perhaps was the new medical school. He had conceived and planned this almost entirely on his own, and it is to be hoped that his name will be commemorated suitably when the school is finally built. Gerald

Ovens had a maturity of judgment and a deep fund of wisdom which caused him to become a counsellor of everybody concerned in hospital and university affairs, and his influence will be sadly missed in these circles.

His relaxations were few, but he was always active in supporting student and university functions and societies. He was a man of wide reading and was an authority on medical biography, possessing an outstanding collection of historical medical literature. Gerald was somewhat retiring in nature, and it was not everyone's privilege to be able to penetrate beyond his natural reserve and to appreciate his charm, his delightful sense of humour, his modesty, and—in these last years—his magnificent courage in ignoring the obvious implications of his illness. To those who did, his death leaves a gap which is hard to fill.

Sir ARTHUR DE SILVA, K.C.M.G., C.B.E. F.R.C.S.

Sir Arthur de Silva, consulting surgeon to the General Hospital, Colombo, and consulting aural surgeon to the Victoria Memorial Hospital, died in Colombo on September 22, aged 77.

Arthur Marcellus de Silva was born on November 5, 1879, the son of Mudaliyar William Marcellus de Silva. After receiving his early education at the Royal College, Colombo, he came to England to study medicine at the London Hospital, qualifying in 1903. Three years later he took the F.R.C.S. of England, the first Ceylonese post-graduate to achieve that distinction. On his return to Colombo in 1907 he was appointed surgeon to the General Hospital and lecturer in surgery at Ceylon Medical College, where he was also an examiner. For twenty-two years he also held the post of surgeon for diseases of the ear, nose, and throat at the Victoria Memorial Hospital.

Arthur de Silva built up a large consulting practice and many well-known people were among his patients. For ten years he was senior surgeon at the General Hospital, and just before his retirement from the staff in 1940 he was appointed C.B.E. His professional life meant everything to him, but after he had given up active hospital work he became a most valuable member of the Public Service Commission. Knighted in 1949, he was promoted K.C.M.G. in 1956. His hobby was the culture of orchids, on which he was an authority.

In 1909 he married Laura Elizabeth Dias, and they had one daughter.

J. P. HUBAN, C.S.I., O.B.E., M.B., B.Ch.

Major-General J. P. Huban, I.M.S.(ret.), died suddenly at Church Crookham, Hampshire, on September 4 at the age of 66, as a result of a cerebral vascular lesion.

John Patrick Huban was born on February 13, 1891, the son of Malachy Huban, of Gort, Co. Galway. He was educated at St. Colman's College, Fermoy, and University College, Dublin, graduating M.B., B.Ch. from the National University of Ireland in 1914. Mobilized in the R.A.M.C.(S.R.) soon after the outbreak of the first world war, he was sent to India; and in the three frontier campaigns which immediately followed—the Afghan, Waziristan, and Mahsud campaigns—he served with great distinction, was mentioned three times in dispatches, and appointed O.B.E. in 1920.

J. B. H. writes: Huban was gazetted to a regular commission in the I.M.S. in 1919, and after a period of military duty was selected for civil employment in the Foreign and Political Department of the Government of India. Medical officers of that department served in the North-west Frontier Province, Baluchistan, in the Princely States, and in the neighbouring countries of Persia, Afghanistan, and Nepal. Admission to it was eagerly sought and competition keen. From that cadre also was usually drawn the Civil Surgeon

of India's capital, Delhi. In Jaipur and in the Rajputana States Huban enjoyed a very high reputation. For six years he was Civil Surgeon of Delhi. The occupant of that post is very much in the public eye in India, and Huban was regarded very highly as an all-round doctor of first-class ability. His periods on leave were divided between study in Vienna, gynaecology advanced surgery and orthopaedics in London. Reports by his in Dublin, and public health in London. Reports by his political superiors in the various states in which he served regularly praised not only his outstanding surgical skill and his vigorous handling of epidemics but also his tact in dealing with ruling princes and their families, and his kindly understanding of his subordinates.

In 1940 Huban was called to Delhi as Additional Deputy Director-General of the I.M.S. In 1941 he was promoted to the rank of colonel and appointed Inspector-General of Hospitals and Director of Public Health of the North-west Frontier Province of India. His success in these combined posts led to his promotion in 1944 as Surgeon-General with the Government of Madras. Despite his lack of experience in matters relating to medical education and teaching institutions in general, Huban rapidly overcame this handicap and earned the thanks of the government of Madras for his sound plans for post-war reconstruction. He was appointed the C.S.I. in 1946. From 1944 to 1947 he was president of the South Indian and Madras Branch of the British Medical Association. In view of impending changes, Huban retired from the I.M.S. in 1947 and was appointed chief medical officer of Cable & Wireless Ltd., London.

John Huban was the embodiment of all that is most attractive in the Irish character. Warm-hearted and generous to a fault and with a genius for friendship, he nevertheless had a shrewd common sense which made his advice on lay as well as medical subjects worthy of the closest attention as by those who sought it. He never proffered it unasked; but he would take endless trouble to help if requested. His friends were many, and enemies—so far as I am aware—did not exist. He married in 1916 Aimée, daughter of Frank Willett, who survives him. Their only child—a son who gave every promise of his father's ability and charm—was killed in action in Italy in 1943, a blow from which John Huban never fully recovered. His memory will be cherished by all who knew him, and their sympathy goes out in full measure to his widow.

G. A. D. HARVEY, C.B., C.M.G., L.R.C.P.I. Major-General G. A. D. Harvey, formerly D.D.M.S., Western Command, India, died in the Colchester Military Hospital on September 22 after a long illness. He was 74 years of age.

George Alfred Duncan Harvey was born on October 27, 1882. He and his four brothers were all educated at Ellesmere College, where they distinguished themselves both scholastically and at games. Three of the brothers, including G. A. D. Harvey, played Rugby football for Ireland. From school he went on to study medicine in Dublin, where he qualified in 1904. Joining the R.A.M.C. as a probationer, he went out to the Straits Settlements and later served in the Sudan and with the Egyptian Army. During the first world war he became A.D.M.S., Fifth Army, being mentioned in dispatches and appointed C.M.G. in 1927. From 1926 to 1930 he was assistant director of hygiene at the War Office, and after a period of service at Gibraltar he became A.D.M.S. for the Waziristan District in India. Promoted to major-general in 1935, he was appointed D.D.M.S., Western Command. From 1937 to 1939 he was honorary physician to the King, being appointed C.B. in 1938. Major-General Harvey retired in 1939, but he volunteered for service during the second world war and was captured in May, 1940. Repatriated in 1943, he retired from the Service in the following year.

Major-General Harvey is survived by his widow and one daughter.

JEAN NICOLESCO, M.D.

Professor Jean Nicolesco, professor of histology in the University of Bucharest and well known for his contributions to neurohistology and neuropathology, died on September 6.

We are indebted to Dr. MACDONALD CRITCHLEY for the following tribute: By the sudden death of Professor Jean Nicolesco, of Bucharest, neurology has lost a distinguished and lovable exponent. Born in 1895 in Focschani, Rumania, he lost his father when he was 17 years of age, and thereafter he had to support his family while prosecuting his own professional career under financial duress. Entering the faculty of medicine at Bucharest, he soon became a conspicuous student, being president of the medical society as well as editor of the local magazine. In 1921 he married Mlle. Marie Maniu, who later collaborated with him in numerous publications and researches. His lifelong interests lay in the field of neurohistology, but he also studied clinical neurology under Marinesco and Noica at the Pantelimon, Colteza, and Central Hospitals of Bucharest. Perhaps his most important undertaking was in 1922, when he journeyed to Paris for a two-year postgraduate course of study. First he attached himself to Pierre Marie at the Salpêtrière, but later he worked at the Bicêtre and at Ivry, with Charles Foix. A deep friendship developed, and their scientific association bore fruit in 1925 in the publication of the classic monograph, "Les noyaux gris centraux de la région mésencéphalo-sous-optique," which was accorded the Prix Saintour of the Académie de Médecine de Paris.

On his return to his own country Nicolesco became responsible for a steady output of excellent papers, written in diverse languages, mainly concerned with the minute pathology of the nervous system. In this manner his future medical career became moulded, and he was appointed to the chair of histology in the University of Bucharest, and was made a corresponding member of the Rumanian Academy. Many distinctions followed. This year, 1957, saw the publication of his magnificent *Morfo patologia sistemului nervos*, of which he was the editor, and in the press at this present moment is an *Atlas* in which his work upon the visceral nerve-endings has been synthesized. Nicolesco's contributions to neuropathology have been numerous and significant. His name will occupy a place of permanency in his specialty, but he will also long be remembered as a dignified, simple, and warm-hearted *grand seigneur*. He owed much to France—his culture, his friendships, possibly his happiest recollections. Six weeks before his death he was attending an international congress in Brussels, and it was touching to witness the warmth of his re-encounter with his erstwhile contemporaries and colleagues from Paris.

T. N. PARISH, M.D.

Dr. T. N. Parish, who was in general practice at Cranbrook, Kent, died suddenly at his home on September 7 aged 54.

Thomas Newton Parish was born at Cambridge on June 21, 1903, the elder son of Mr. G. E. Parish. At the age of 11 he obtained a scholarship to Christ's Hospital and was head of the school (Senior Graecian) in 1921. Going on to Downing College, Cambridge, with a major scholarship, he took the natural sciences tripos, and made many friends both in the college, for which he played rugby, and in the university. His clinical work was done at King's College Hospital, where he won the Burney Yeo scholarship. After qualifying in 1928 he served as house-surgeon to the orthopaedic department under Sir Thomas Fairbank and Mr. St. J. D. Buxton and later was house-physician at the Belgrave Hospital for Children. In 1929 he graduated M.B., B.Ch., proceeding M.D. six years later. After completing his resident appointments he became an assistant medical officer at St. Giles' Hospital, Camberwell, but found the regulations tedious there and resigned his appointment in 1936, spending the next year or so as surgeon in a ship

laying cable between Australia and Tasmania. He then joined Dr. Wilfred Gough in practice at Cranbrook. During the second world war he served in the R.A.M.C., being posted to special duties with M.I.5; he remained with this unit for the whole of his service. He was a particularly good choice for this type of work, and during his service he met many interesting people.

Returning to Cranbrook after the war, he worked as a single-handed practitioner in a large, good-class general practice. Medical officer to two large schools, he was particularly interested in this side of his work, contributing articles on the control of epidemics to this and other journals.

J. W. E. C. writes: Tom Parish was an ideal general practitioner, kind and wise and withal extremely well read and conversant with the latest developments in medicine. Equipped as he was with a first-class brain, he shunned everything which was slipshod or second rate. This inevitably led to great demands on his services, which could only be met by long hours of work; from this he gave himself too little respite. Always he gave himself unstintingly to his patients or to his friends who asked his help. Although a lifelong member of the B.M.A. he took little interest in medical politics and shied off committee work so far as he was able.

In the post-war years he had little time for outside relaxation, but preferred his family, his home, and his garden. He was a supporter of local activities and always did well at local horticultural shows. Those of us who knew him best will regret his passing and feel that our world will be much the poorer for his death. He married in 1938 Margaret, daughter of Captain F. W. Keary, R.N., and to his widow and his son and daughter we extend our sincere sympathy.

DOROTHY C. WILLIAMSON, M.B., B.Ch., B.A.O.
Dr. Dorothy C. Williamson, an assistant in general practice in Penistone, Yorkshire, died in the Sheffield Royal Infirmary on September 18 at the age of 26.

Dorothy Constance Williamson was born on December 1, 1930, at Dublin. From Wesley College she went on to study medicine at Trinity College, Dublin, where she graduated M.B., B.Ch., B.A.O. in 1953 at the age of 22. Her house appointments were at Sir Patrick Dun's Hospital and the Derby City Hospital, where she was working as senior house officer when she obtained the D.R.C.O.G. Her first experience in general practice was as an assistant in Cocker-mouth. Later she went to Penistone, where she earned the love and affection of all her patients. During the influenza epidemic she developed bronchopneumonia and died six days later.

Dr. L. B. H. writes: Those with whom she worked have learned of the tragic and untimely death of Dr. Williamson with the deepest regret and dismay. In all the posts she held she earned the high esteem of those who came to know her. Her charming personality and gaiety of spirit, springing as it did from her simple Christian faith and assurance, endeared her to the hearts of all. The tragic suddenness of her departure seems almost unbearable to the multitude of her friends, and it is difficult to believe that so delightful a personality has so soon passed from our midst. We may truly say with Solomon of old: "She, in a short time, fulfilled a long time." Our sympathy goes to her widowed mother and family.

TREVOR GRIFFITHS, M.B., B.Ch., D.M.R.D.
Dr. Trevor Griffiths, consulting radiologist to the Woolwich group of hospitals, was killed in a motor accident at Amiens on September 8, when he and his family were travelling home from a Continental holiday. His daughter Gillian, aged 11, was killed in the same accident, and his wife and small son were seriously injured.

Trevor Griffiths studied medicine at Cardiff, qualifying in 1938. After holding house appointments he worked as medical registrar at the Llandough Hospital, Cardiff. Com-

missioned in the R.A.M.C., T.A., in 1939, he served throughout the war, attaining the rank of major and being mentioned in dispatches for his gallant and distinguished services. After the war he decided to specialize in radiology, taking the D.M.R.D. in 1949 and graduating M.B. B.Ch. in the following year. After holding the post of assistant radiologist at King's College Hospital, he was appointed consultant radiologist to the Woolwich group of hospitals.

Dr. J. R. M. SANGSTER writes: Many of us engaged in general practice in south-east London will sadly miss my friend Dr. Trevor Griffiths. He introduced us to the problems and triumphs of domiciliary radiology and we could not have had a better mentor. He had a wide knowledge of general medicine and was always most helpful in discussing the details of a case. Ever interested in the human side of his specialty, he gave pleasure to our patients at his visits and would often sit down to the discussion of some common interest. He was a good and clever man. I am glad to have had him for a friend. His daughter Gillian, who was also killed in the accident, was a dear child of great promise. Our hearts must go out to his wife and little son at this terrible time.

G. C. MORT, M.D., D.P.H.

Dr. G. C. Mort, who was coroner for the city of Liverpool for a quarter of a century, died recently at the age of 76.

George Cecil Mort was born at Stroud, Gloucestershire, on July 13, 1881, the son of the Rev. Samuel Mort. From Kingswood School, Bath, he entered Owens College, Manchester, as a medical student, graduating M.B., Ch.B. from the Victoria University of Manchester in 1905. Four years later he obtained the Liverpool D.P.H., and in 1915 proceeded to the M.D. In 1911 he was called to the Bar by the Inner Temple. After graduation he held the appointments of assistant resident medical officer at the Barnes Convalescent Hospital, Cheadle, house-surgeon at Manchester Royal Infirmary, and resident medical officer at the Handel Cosham Hospital, Bristol. From 1908 to 1912 he was senior medical officer at the Eastern Dispensary, Liverpool, and in 1913-14 assistant medical officer of health at Burton-on-Trent. He served with the Royal Navy as a surgeon-lieutenant throughout the first world war. Soon after the end of the war he settled in practice at Liverpool. From 1928 to 1953 he was coroner for the city, and in 1929 was appointed a justice of the peace. He was president of the Coroners' Society of England in its centenary year, 1946.

D. T. RICHARDSON, C.B., M.C., M.B., Ch.B., D.P.H.
Major-General D. T. Richardson, formerly director of hygiene at the War Office, died at his home at Gairloch, Ross-shire, on September 14. He was 70 years of age.

David Turnbull Richardson was born on December 21, 1886, and received his medical education at Edinburgh University, where he graduated M.B., Ch.B. in 1910. Two years later he entered the R.A.M.C. as a lieutenant. He served in India and with the Aden Field Force during the first world war, and for his services with the latter Force was awarded the Military Cross in 1919 and mentioned in dispatches. In 1923 he obtained the D.P.H. of the Scottish Royal Colleges, and from 1928 to 1932 was an assistant professor at the Royal Army Medical College, being awarded the Leishman Prize in 1931 for his work in the interests of military hygiene.

In 1934 he was promoted lieutenant-colonel, and from 1935 until his retirement in 1946 he held various appointments at the War Office, with the exception of a brief period in 1940 during the second world war when he was A.D.M.S. to the British Expeditionary Force: from 1935 to 1938 he was assistant director of hygiene; in 1938-9 professor of hygiene; in 1939-40 deputy director of hygiene; and, finally, from 1941 to 1946 director of hygiene. From 1941 until he retired he was an Honorary Surgeon to the King. He was appointed C.B. in 1945, and a commander, with star, of the Royal Order of St. Olaf of Norway in 1948.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending September 14 (No. 37) and corresponding week 1956.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

Vital Statistics

Influenza

Deaths from influenza in the great towns in the week ending September 21 were as follows, with the figures for the previous week in parentheses: England and Wales 121 (47), Scotland 5 (1), Northern Ireland 0 (0), and Eire 0 (0). Towns with more than five deaths from influenza were as follows: Middlesbrough C.B. 6, Bury C.B. 6, Manchester C.B. 12, Oldham C.B. 7, Salford C.B. 6. First supplies of influenza vaccine have now been sent out to hospital medical and nursing staffs and are to be followed by supplies for general practitioners and health staffs of local authorities. Reports from Dublin confirm the identification of the Asian virus in the Irish Republic.

The accompanying graph shows numbers of deaths in the 160 great towns of England and Wales from early September to the latest date for which figures are available.

The regional distribution of deaths from various causes in England and Wales was as follows in the week ending September 21:

Region	All Causes	Influenza	Pneumonia	Bronchitis†
Northern ..	305	13	24	10
E. and W. Riding ..	628	28	64	27
North-western ..	1,008	62	66	61
North Midland ..	368	5	20	12
Midland ..	474	4	20	20
Eastern ..	267	2	12	4
London and S.E. (including Greater London) ..	1,647	3	50	48
Southern ..	225	2	5	5
South-western ..	250	0	5	6
Wales ..	159	3	8	4

The following Table shows the age distribution of deaths from influenza in the 160 great towns of England and Wales:

Week Ending	0-	1-	15-	25-	45-	65+
Sept. 14 ..	1	9	3	4	14	16
.. 21 ..	2	18	8	17	39	37

Infectious Diseases

The largest fluctuations in the trends of infectious diseases in England and Wales, during the week ending September 14, were falls in the notifications of 836 for measles, from 2,073 to 1,237, 242 for whooping-cough, from 1,013 to 771, and 79 for acute poliomyelitis, from 279 to 200, and rises of 127 for acute pneumonia, from 206 to 333, 51 for scarlet fever, from 272 to 323, and 37 for food-poisoning, from 223 to 260.

The largest falls in the number of notifications of measles were 85 in Lancashire, from 241 to 156, 64 in Yorkshire West Riding, from 147 to 83, 58 in Norfolk, from 68 to 10, and 56 in Derbyshire, from 95 to 39. The incidence of whooping-cough is now at the lowest level for 8 years; the

largest declines during the week were 52 in Kent, from 91 to 39, and 52 in Yorkshire West Riding, from 75 to 23. A small rise in the incidence of scarlet fever occurred in every region except the south-western, where notifications were 11 fewer than in the preceding week. 2 cases of diphtheria were notified, being 1 more than in the preceding week. The rise in acute pneumonia was mainly in the north of the country; the largest increases were 45 in Lancashire, from 31 to 76, and 40 in Yorkshire West Riding, from 41 to 81.

9 of the 15 notifications of paratyphoid fever were recorded in Yorkshire East Riding, Haltemprice R.D.

The notifications of dysentery numbered 213 and were 7 fewer than in the preceding week. This is the lowest return for four years. The chief centres of infection during the week were Lancashire 37 (Liverpool C.B. 14), Warwickshire 22 (Birmingham C.B. 15), Yorkshire West Riding 22 (Leeds C.B. 14), London 18, and Durham 17 (Sunderland C.B. 10).

The largest outbreak of food-poisoning during the week was 49 cases in Somersetshire, Yeovil R.D.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases (deaths for influenza) of certain diseases notified weekly in England and Wales (great towns for influenza). Highest and lowest figures reported in each week during the years 1948-56 (influenza, 1952-6) are shown thus - - - - -, the figures for 1957 thus ———. Except for the curves showing notifications in 1957, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Week Ending September 21

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 321, whooping-cough 724, diphtheria 3, measles 1,044, acute pneumonia 702, acute poliomyelitis 198, dysentery 174, paratyphoid fever 19, typhoid fever 6.

Industrial Accidents and Diseases

The number of workpeople (other than seamen) in the United Kingdom whose deaths from accidents in the course of their employment were reported in August was 99, compared with 116 in the previous month and 84 in August, 1956.

The numbers of cases of industrial diseases in the United Kingdom reported during August, 1957, were as follows: Lead poisoning 1, mercurial poisoning 4, aniline poisoning 2, anthrax 1, epitheliomatous ulceration 14, chrome ulceration 25; total 47. There were no deaths.—*Ministry of Labour Gazette*, September, 1957.

Universities and Colleges

UNIVERSITY OF WALES

The following candidates have been approved at the examinations indicated:—

M.D.—L. A. J. Evans, T. Griffiths, J. H. Jones, T. L. Morris.

SOCIETY OF APOTHECARIES OF LONDON

The following candidates, having completed the final examination, have been granted the diploma of L.M.S.S.A.:

G. R. Hatch, R. W. Salmon, E. A. Robinson, A. D. H. Pooler, E. D. Keen, V. C. C. V. Dewhurst, D. H. Bailey, R. E. Tattersall, M. Roberts, V. A. Economides, A. J. Dyer, D. A. Logan, F. W. Yates, M. Parkes, B. L. Copley, T. R. Robinson, H. Sabry.

The following candidates have been awarded the Diploma in Mastery of Midwifery:

P. V. Briffa, R. D. Haigh, M. A. H. Rayman, G. D. Rees.

The following candidates have been awarded the Diploma in Industrial Health:

T. J. Burke, G. S. Dhaliwal, G. D. Forwell, J. Harkness, W. R. Lee, E. R. Steyn, G. Thomas.

Medical News

Henry Robinson Scholarships to Epsom College.—A new scholarship to Epsom College of £250 per annum will be competed for early in June, 1958. This scholarship, for which the funds have come from the Medical Insurance Agency (see annotation at p. 814), is open solely to the sons of registered medical practitioners, men or women, living or deceased, and is not subject to any means test. Further awards will be made in subsequent years. Should two candidates of exceptional merit present themselves, two scholarships of the value stated above may be awarded: should the best candidate be of but moderate ability, a scholarship of less than £250 p.a. may be offered. The "ceiling" of the scholarship in the case of a day-boy will be £150 p.a. Candidates must be under 14 years of age on January 1, 1958, and boys under 13 on that date will have their marks augmented by an appropriate proportion. Full particulars may be obtained on application to the Headmaster, Epsom College, Epsom, Surrey.

Private Secretaries.—The Minister of Health, Mr. DEREK WALKER-SMITH, Q.C., has appointed Mr. P. BENNER as his principal private secretary. The Parliamentary Secretary to the Ministry of Health, Mr. RICHARD THOMPSON, has appointed Mr. J. P. CASHMAN to be his private secretary.

D.M.S., Hong Kong.—The Secretary of State for the Colonies has appointed Dr. D. J. M. MACKENZIE, D.M.S., Northern Nigeria, as Director of Medical and Health Services, Hong Kong. Dr. Mackenzie is expected to arrive in Hong Kong early in the new year.

Appeal for Medical Missions.—On Sunday, October 13, the annual Medical Missions appeal in "The Week's Good Cause" is being broadcast from Scotland for all regions of the B.B.C. at 8.25-8.30 p.m. The Right Reverend Dr. GEORGE F. MACLEOD, Moderator of the General Assembly of the Church of Scotland, will make the appeal. The appeal will be preceded by an evening service broadcast for Scottish listeners only from Broadcasting House, Glasgow, at 7.45-8.25 p.m. The Moderator will conduct the service and preach the sermon. The congregation will be composed of members of the medical and nursing professions, and any members of the medical profession in the Glasgow area who wish to attend should apply, stating the number of entry cards required, to Mr. J. Stanley Pritchard, Broadcasting House, Queen Margaret Drive, Glasgow, W.2.

Cancer Detection Centre.—The Marie Curie Memorial Foundation has decided to acquire a site in London on which to build and equip the first British cancer detection and information centre. The Foundation states that it is not proposed to carry out treatment for cancer at first, but to concentrate on the modern methods of diagnosis and to investigate new techniques for the detection of precancerous conditions and carcinoma in the non-invasive phase. For this work x-ray and pathology services together with other diagnostic facilities will be made available for general practitioners. After investigation the patients will be referred for treatment by their own doctors through the usual channels. In addition, it is said, a complete information and welfare service will be established, designed to relieve people of anxieties and difficulties caused by cancer in the family. This will be linked with the existing services run by the Foundation in their convalescent homes, homes for patients with persistent cancer, and their night nursing service. The teaching of the early symptoms, signs, investigation, and treatment of cancer will be carried out for doctors and others who wish to attend.

Dr. R. F. Whelan, lecturer in physiology at Queen's University, Belfast, has been appointed to the chair of human physiology and pharmacology at Adelaide University, Australia.

Lord Nuffield, G.B.E., F.R.C.S., F.R.S.—Lord Nuffield will be 80 on October 10. Elsewhere in this issue (p. 809) we refer to his munificent gifts to medical, educational, and other institutions: they amount in all to over £27m. By electing Lord Nuffield to honorary membership in 1936 the B.M.A. conferred on him its highest honour.

COMING EVENTS

Alex Simpson Smith Lecture.—Mr. DILLWYN M. E. THOMAS, F.R.C.S., will lecture at 5 p.m. on October 8 at the Hospital for Sick Children, Great Ormond Street, London, W.C.1. His subject will be "Thoracotomy Findings in Primary Tuberculosis." Admission by ticket, from the dean of the Institute of Child Health.

Alex Simpson Smith Memorial Lecture.—Mr. A. L. d'ABREU, F.R.C.S., will lecture at 5.15 p.m. on October 9, at West London Hospital, London, W.6, on "A Decade of Cardiac Surgery."

Leeds University Medical Faculty.—Sir FRANCIS WALSH, F.R.S., will give the inaugural lecture at 3 p.m. on October 10, in the Ripley Smith Hall, University Union. Annual dinner, November 8, 7.30 p.m. at the Griffin Hotel, Boar Lane, Leeds. Details from the secretary, School of Medicine, Leeds 2.

Joseph Strickland Goodall Memorial Lecture.—Dr. MAURICE CAMPBELL will lecture at 5.30 p.m. on October 10 at Apothecaries' Hall, London, on "The Results of Surgical Treatment in Congenital Heart Disease."

St. Cyres Lecture.—Dr. A. RAE GILCHRIST will lecture at 5 p.m. on October 15 at the Royal Society of Medicine, London, on "Clinical Aspects of High Grade Heart Block."

St. Luke's-tide.—A special evensong for doctors, nurses, and others concerned with the care and healing of the sick will be held on October 20 at 3 p.m. at the Cathedral Church of Christ, Canterbury. This St. Luke's-tide the Society for the Propagation of the Gospel appeals for doctors and nurses to join the medical missionary service; large sums of money are also required. A special service for the medical and allied professions will be held on October 20 at 3 p.m. at St. Stephen's Church, Norwich.

London School of Hygiene and Tropical Medicine Association.—The School Association dinner will be held at the Waldorf Hotel, Aldwych, London, W.C.2, on Thursday, November 28 (7 for 7.30 p.m.). Tickets (30s. each exclusive of drinks but including dancing until midnight) obtainable from Miss K. M. SHAW, London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1.

Society of Medical Officers of Health.—Refresher course for county district medical officers, October 25-27, at the

London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1. Details from the secretary of the Society, Tavistock House South, Tavistock Square, London, W.C.1.

Morison Lecture.—Dr. W. RITCHIE RUSSELL will lecture at 5 p.m. on October 25, instead of October 24 as previously announced.

United Hospitals' Choir.—October 31, at 8 p.m., at the Church of St. George-the-Martyr, Queen Square, London, W.C.1, works by Purcell, Schubert, and Handel. Admission by programme, price 3s. 6d., available at the door.

NEW ISSUES

British Journal of Ophthalmology.—The new issue (Vol. 41, No. 9) is now available. The contents include:

EFFECT OF DIENCEPHALIC STIMULATION UPON INTRA-OCULAR PRESSURE. J. Gloster and D. P. Greaves.
FUCH'S EPITHELIAL DYSTROPHY OF THE CORNEA. J. H. Doggart.
A PEDIGREE OF ANOPHTHALMOS. Ruby Joseph.
ACUTE OCULAR ONCHOCERCIASIS AND ITS TREATMENT. F. C. Rodger.
A NEW MEDIUM FOR THE STORAGE OF DONOR EYES FOR CORNEAL GRAFTS. A. Sachs.
RETROPOSITION OF THE CONJUNCTIVA. A NEW APPROACH TO TRACHOMATOUS ENTROPION. A. Kahn and R. Ven.
CHLORPROMAZINE IN OCULAR SURGERY. Lalit P. Agarwal, R. B. L. Gupta, and S. R. K. Malik.
MOORE'S ULCER TREATED BY DIATHERMY COAGULATION. E. J. Somerset.
INTRA-OCULAR FRAGMENT OF ALUMINIUM ALLOY TOLERATED FOR TWELVE YEARS. W. May.
BOOK REVIEW.

Issued monthly; annual subscription £4 4s.; single copy 8s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Sunday, October 6

MANCHESTER UNIVERSITY: FACULTY OF MEDICINE.—At Theatre 1, Clinical Sciences Building, York Place, 11 a.m., in conjunction with North-west England Faculty of College of General Practitioners. Lecture-demonstration for general practitioners. Professor Robert Platt: Hypertension.

Monday, October 7

INSTITUTE OF NEUROLOGY.—5 p.m., Dr. Henry Miller: Neurology in the General Hospital.
LONDON UNIVERSITY.—At University College, 5.30 p.m., special university lecture in psychology by Professor A. R. Luria (Moscow): Role of Speech in Normal and Abnormal Behaviour.
MARLBOROUGH DAY HOSPITAL.—8.15 p.m., Dr. J. Bierer, Dr. Joyce Martin, and Mr. P. Senft will report on the International Congress of Group Psychotherapy and the International Congress of Psychiatry held in Zurich. A discussion will follow.

Tuesday, October 8

CHELSEA CLINICAL SOCIETY.—At Rembrandt Hotel, S.W., 8.30 p.m., discussion to be opened by Mr. Iain Macnab: Getting Pleasure from Paintings (illustrated).
● INSTITUTE OF CHILD HEALTH.—At the Hospital for Sick Children, Great Dillyway M. E. Thomas: Thoracotomy Findings in Primary Tuberculosis.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. J. S. Pegum: Keratinization.
LONDON UNIVERSITY.—At University College, 5.30 p.m., special university lecture in psychology by Professor A. R. Luria (Moscow): Role of Speech in Normal and Abnormal Behaviour.
ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Professor A. Kekwick: Obesity.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Erasmus Wilson: Demonstration by Dr. Basil C. Morson: Spread of Malignant Disease.
SOCIETY FOR ANALYTICAL CHEMISTRY: MIDLANDS SECTION.—At Mason Theatre, The University, Edmund Street, Birmingham, 6.30 p.m., Mr. H. Varley: Analytical Methods in Clinical Biochemistry.
WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Mr. J. Minton: Ocular Manifestations in Clinical Neurology. Part I.

Wednesday, October 9

EUGENICS SOCIETY.—At Royal Society, 5.30 p.m., debate on the Motion—"That the Population of the United Kingdom Should be Stabilized at 40 Millions." Speakers: Proposers, Dr. C. P. Blacker and Mrs. Margaret Pyke; Opposers, Captain R. A. Pilkington, M.P., and Mr. Peter R. Cox, F.I.A., F.S.S.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. H. Haber: Normal Skin. Anatomy and Function of Epidermis.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. F. P. Lee Lander: Eosinophilia and Lung Disease.
INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Mr. Harland Rees: Differential Diagnosis of Frequency of Micturition.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Dr. F. V. Flynn: Electrolytes (I).
ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—4 p.m., Benigne Memorial Award Lecture by Dr. Louis Zizine (Paris): Endocrine Problems of Asthma (illustrated).
ROYAL MEDICO-PSYCHOLOGICAL ASSOCIATION: PSYCHOTHERAPY AND SOCIAL PSYCHIATRY SECTION.—At 11, Chandos Street, W., 8 p.m., Dr. D. H. Clark: Administrative Therapy.
ROYAL SOCIETY OF HEALTH.—At Caxton Hall, Westminster, S.W., Conference on Mental Illness and Mental Deficiency. 10.30 a.m., Dr. J. Greenwood Wilson and Dr. A. Walk: Mental Illness. 2.30 p.m., Dr. D. H. H. Thomas and Dr. C. W. J. Ingham: Mental Deficiency.
WEST LONDON HOSPITAL MEDICAL SCHOOL.—5.15 p.m., 10th Alex Simpson Smith Memorial Lecture by Mr. A. L. d'Abreu: Decade of Cardiac Surgery.

Thursday, October 10

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. M. B. MacKenna: Sebaceous Glandular System.
LEEDS UNIVERSITY: FACULTY OF MEDICINE.—At Riley Smith Hall, University Union, 3 p.m., Inaugural Lecture by Sir Francis Walshe, F.R.S.: Necessary Limitations of Medical Education.
LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.—At Royal Free Hospital School of Medicine, 8.30 p.m., Miss Molly Melanby: Women in Prison.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Cecil Joll Lecture by Professor P. R. Allison: Problem of Bleeding Gastro-oesophageal Varices.
SOCIETY OF APOTHECARIES OF LONDON.—5.30 p.m., Joseph Strickland Goodall Memorial Lecture by Dr. Maurice Campbell: Results of Surgical Treatment in Congenital Heart Disease.

Friday, October 11

● INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. M. S. Thomson: clinical demonstration.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. J. Smart: clinical demonstration.
INSTITUTE OF LARYNGOLOGY AND OTOLARYNGOLOGY.—3.30 p.m., clinical discussion for general practitioners by Mr. K. G. Rotter: Causes and Investigation of Nasal Bleeding.
INSTITUTE OF NEUROLOGY.—5.30 p.m., Professor Mogens Fog (Copenhagen): Unconsciousness—A Clinico-pathological Study.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Mr. W. Gissane: Some Surgical Problems in the Treatment of the Seriously Injured.
4 p.m., Dr. J. N. Morris: Epidemiology of Coronary Heart Disease.

Saturday, October 12

HAEMOPHILIA SOCIETY.—At Hospital for Sick Children, 7 p.m., general meeting. Talk by Mr. A. S. Moore, L.D.S., R.C.S.

APPOINTMENTS

BATTEN, J. C., M.D., M.R.C.P., Part-time Consultant in General Medicine to the St. George's Group of Hospitals.
BUCKLEY, A. R., M.B., B.Chir., M.R.C.P., Senior Medical Officer, East Midlands Gas Board.
ROBERTS, D. P. W., M.B., Ch.B., D.Obst. R.C.O.G., D.P.H., Assistant Medical Officer of Health, City of Chester.
SOUTH-WESTERN REGIONAL HOSPITAL BOARD.—Kathleen Blott, M.B., Ch.B., F.F.A.R.C.S., D.A., Consultant Anaesthetist in Bristol Clinical Area; Lillias Kilpatrick, M.B., Ch.B., D.Obst. R.C.O.G., Registrar in Obstetrics and Gynaecology to Bath Group of Hospitals; A. R. Foster, M.B., Ch.B., Registrar to the Bristol Mental Hospitals; P. Murphy, M.B., Ch.B., D.A., Registrar in Anaesthetics to the Bath Group of Hospitals.
WATSON, J. A. G., M.B., B.S., D.P.H., Deputy Medical Officer of Health and School Medical Officer, Southampton.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Bowen.—On September 19, 1957, at Carmarthen Maternity Hospital, to Dr. M. E. Valerie (formerly Jones), wife of Captain Wyndham Bowen, a daughter—Margaret.
Cox.—On September 27, 1957, at Nuffield House, Guy's Hospital, London, S.E., to Betty, wife of Dr. A. G. C. Cox, a daughter—Anne Patricia.
Inman.—On September 21, 1957, at Peterborough, Northants, to Margaret (formerly Stones), wife of Dr. George Inman, a daughter.
Montell.—On September 24, 1957, at Birmingham Maternity Hospital, to Natalie (formerly Johnston), L.R.C.P., L.R.C.S., D.P.H., and James Montell, a daughter.
Powell.—On September 16, 1957, at 56, Bents Drive, Sheffield, to Elizabeth Jeanne, wife of Dr. Glyn D. Powell, a sister for David, Martin, and Siân—Sara Elizabeth.
Shearer.—On September 21, 1957, in Sydney, Australia, to Rosalind (formerly Castleden), M.B., F.R.C.S.Ed., wife of Charles Shearer, M.B., F.R.C.S.Ed., a daughter—Wendy.

DEATHS

Appleyard.—On September 1, 1957, Cecil Steele Appleyard, M.B., Ch.B., of Colinton House, Bedworth, Warwick, formerly of Edinburgh, aged 61.
Barron.—On August 29, 1957, at Oxted and Limpsfield Cottage Hospital, Surrey, Robert Macpherson Barron, D.S.O., M.R.C.S., L.R.C.P., Lieutenant-Colonel, I.M.S., retired, aged 83.
Barton.—On September 8, 1957, at 232, Stockwell Road, London, S.W., Frederic William Barton, L.M.S.S.A., L.D.S.
Byrne.—On September 11, 1957, Edward Crofton Byrne, L.R.C.P.&S.I., L.M., of Horseshoe Cottage, Needle, near Aylesbury, Bucks, late of Forest Gate, London, E.
Dick.—On September 11, 1957, at his home, Clapperway, Manaton, Devon, Andrew Dick, M.D., D.P.H.
Geddes.—On September 3, 1957, John William Geddes, M.B., C.M., of Worthing, Sussex, formerly of Dumfries, Durham, and Middlesbrough, Yorks, aged 86.
Greiller.—On September 10, 1957, in hospital, Bernard Greiller, M.C., M.R.C.S., L.R.C.P., D.M.R.E., L.D.S., aged 70.
Huban.—On September 4, 1957, at Church Crookham Hotel, Hants, John Patrick Huban, C.S.I., O.B.E., M.B., B.Ch., Major-General, I.M.S., retired, aged 66.
Lumb.—On September 6, 1957, at St. Richard's Hospital, Chichester, Sussex, Norman Peace Lacy Lumb, O.B.E., M.S., F.R.C.S., aged 66.
Parish.—On September 7, 1957, at his home, Bakers Barn, Cranbrook, Kent, Thomas Newton Parish, M.D., aged 54.
Rees.—On August 16, 1957, at Royal Victoria Hospital, Boscombe, Arthur David Rees, L.M.S.S.A., of 10, Irving Road, West Southbourne, Bournemouth, aged 84.
Richardson.—On September 14, 1957, at Aird House, Badachro, Gairloch, Ross-shire, David Turnbull Richardson, C.B., M.C., M.B., Ch.B., D.P.H., Major-General, late R.A.M.C., retired, aged 70.
Richmond.—On September 2, 1957, at his home, East Dene, Sunnyside Avenue, Tunstall, Stoke-on-Trent, James Watson Richmond, M.B., Ch.B., aged 83.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Exsanguinating Cattle after Slaughter

Q.—It has long been the practice to drain the blood from cattle which are slaughtered for human consumption. This would seem a wasteful process in that the blood is not eaten. In many other animals the blood is not drained—e.g., deer, birds, rabbits. Are there any valid scientific reasons for this apparently wasteful practice?

A.—The practice of "bleeding" has a well-authenticated scientific basis. Immediately an animal is killed, bacteria pass through the wall of the gut into the blood stream. If the animal is fatigued or frightened, this may happen before death; and, though it is the aim of the slaughtermen—and their practice—to avoid these conditions, they unfortunately occur by accident in a number of cases. With a large animal, the carcass of which cannot be cooled throughout sufficiently rapidly, the presence of these bacteria is dangerous because they multiply rapidly in the warm flesh and putrefy it. The object of bleeding is to remove the vehicle which will spread these bacteria to all parts of the carcass. The problem is much less serious with small animals, in which the carcass will cool quickly to a temperature at which these bacteria multiply only slowly. In addition, there have been indications recently that with hens the bacteria do not escape through the gut so rapidly when the fowl is killed; the reasons for this difference are still unknown. I have no information about rabbits or deer. The latter are the really interesting case, because they are killed in bad conditions and the carcass is comparatively large. It is of course very seldom that the blood is wasted nowadays. Usually it is at least collected for fertilizer; in some factories it is made into products for human consumption, like blood sausage. The psychological prejudice against eating blood limits the consumption of such products, so that only part of the blood can be used in this way. If people would eat more of such products and pay for them, there is no doubt that more blood would be used for food.

Abrasive Treatment of Acne Scars

Q.—What is the technique of the abrasive treatment of acne scars? How good are the results?

A.—The first abrasive technique to be widely used was rubbing with sandpaper. This had the disadvantage of being a relatively crude method, and also one liable to leave silica granules in the tissues with the danger of granuloma formation later. More recent modifications of sandpaper on resection later, with better adhesion between the silica granules and the paper, have greatly reduced these disadvantages. Most people, however, now prefer to use stainless-steel wire brushes. These can be fitted to a standard dental machine revolving at 2,000–4,000 revolutions per minute. Sometimes much higher speeds are used, but at these higher speeds the brushes may become "loaded," and, instead of a cutting or abrasive effect, a thermal-friction effect is obtained, which is not what is wanted. There are also stainless-steel abrasive drums which are useful for fine work around the eyelids. Often the operation is performed after freezing the tissues with an ethyl chloride spray. But, while this helps by making the tissues more rigid and so perhaps increases the accuracy of the cutting, there is no doubt that the freezing hinders subsequent healing. These abrasive techniques constitute only one of a number of methods available for improving the appearance

after acne scarring, tattooing, and comparable lesions, and the doctor who uses abrasion should be experienced in the other methods, as they may be needed as supplements to abrasion if the best result is to be obtained. It is also very necessary that abrasion should be done only under the full aseptic precautions of an operating theatre. Failure to observe this precaution has led to some disrepute for the method in the past.

Abrasion can offer considerable improvement to a patient with acne scarring. The edges of the pits are bevelled away and the facial skin is given a more uniform surface so that make-up is easier to apply efficiently. The more severely scarred cases need two or three abrasions, and many are also helped if the skin is tightened at the same time by a standard face-lifting procedure.

The complications of abrasion include persistent erythema, milia, and, more rarely, a halo of pigmentation. Inadequate asepsis and inadequate technique in use of the brushes can cause severe keloids and disfigurement. Nevertheless, the psychological benefit in successful cases is very worth while. Provided the appropriate precautions and techniques are adopted, abrasion can give thoroughly useful results, but seldom can produce an entirely normal skin.

Prolonged Use of Mercurial Diuretics

Q.—A middle-aged patient has idiopathic oedema of the legs, controllable by mercurial diuretics. Is there any harm in giving weekly injections indefinitely?

A.—The continuous administration of a mercurial diuretic over long periods even in low and infrequent dosage could give rise to depression of the bone marrow or to dermatitis. The chances of such sensitization effects arising are, however, very small. It might be worth while to stop the injections from time to time so as to assess the severity of the oedema, since it may occasionally remit spontaneously. Restriction of sodium intake will increase the effect of the diuretic.

"Jehovah Complex"

Q.—In what psychotic conditions is the "Jehovah complex" most often found? What is the psychopathology of this type of delusion?

A.—The term "Jehovah complex" is not a technical term and it has no exact meaning. Sometimes the term is used as synonymous with the "God complex," or more usually the "God-Almighty complex," or even the "father complex"; but this use is quite inexact.

This type of complex is found in schizophrenic conditions of a paranoid or paraphrenic type. The psychopathology would vary with the patient and also with the views adopted by the psychiatrist. A follower of Freud would align the complex with repression concerning the patient's father. When the complex reaches the dimensions of a delusion it means that the individual has identified himself with the notion contained in the repressed complex.

A good popular description of the "God complex" is to be found in H. G. Wells's book *Christina Alberta's Father*. In this story a very insignificant and inadequate man develops the delusion that he is the great King Sargon and behaves accordingly.

Extensor Rigidity after Cardiac Surgery

Q.—A patient has developed extensor rigidity of the lower limbs after a successful operation for patent ductus arteriosus. Is this a recognized complication of the operation, and, if so, what is its cause?

A.—This is certainly not a recognized complication of the operation and suggests neurological damage, probably cerebral. An alternative explanation could be damage to the spinal cord if it was found necessary to occlude the aorta during the course of the operation. Elucidation of the cause requires fuller details of the operative procedure.

Clicking Jaw

Q.—A girl of 16 has in the past three months developed a persistent and very audible clicking on the right side of the jaw, which occurs when her mouth is about half open. What treatment is advised and what is the prognosis?

A.—This patient would be well advised not to seek treatment. A clicking jaw can be cured by operative removal of the cartilaginous meniscus of the temporo-mandibular joint, but an operation of this severity is hardly indicated for so trivial a symptom as a click. I gather that there is no limitation of movement of the jaw.

Such patients are sometimes helped by manipulation under an anaesthetic, but if there is no limitation of movement of the joint then manipulation would be only a form of suggestion therapy. The patient should be reassured, told that there is nothing seriously wrong with the joint, and that many people have clicking jaws. It is very likely that the click will disappear in time.

Tough Hymen

Q.—An engaged girl with a tough crescentic hymen which admits only a small finger is apprehensive about her defloration. She refuses surgical defloration. Are there any surface analgesics that could be used to reduce the pain, and, if so, which is recommended?

A.—Hymenectomy is rarely necessary as a preparation for marriage even in cases of very small hymeneal aperture, and the patient is probably wise to refuse surgical defloration. The fact that an anaesthetic is required for the operation suggests to the patient that defloration must be an extremely painful process; this is confirmed by the discomfort after the operation and often gives rise to protracted vaginismus and dyspareunia. Furthermore, a number of cases of failure to consummate the marriage have been encountered even after hymenectomy.

Most girls can undertake the stretching of the hymen themselves in preparation for their marriage. Not only is the patient able by this means to discover that this is quite a painless procedure, but she also learns something about the anatomy of the introitus and the direction of the vagina and how to relax the spasm, which is the result of apprehension. The girl is instructed to wash her hands thoroughly and cut her nails short and then to insert one finger-tip with the aid of a lubricant jelly, exerting steady pressure round the circumference of the hymen. This is usually found to be carried out most easily in the squatting position during, or after, a hot bath. After repeating this frequently for a few days she will find that she can readily insert the tips of two fingers, and finally three, without the least discomfort. The use of an analgesic ointment—5% xylocaine ointment—is required only rarely.

However, if the girl does not wish to undertake the stretching of the hymen, xylocaine ointment may be applied prior to intercourse. It is wise to advise her to allow some minutes to elapse for the action of the analgesic to take place and to remove the ointment before intercourse, unless the husband is using a sheath, otherwise the penis will also be affected. Penetration is facilitated by the use of a lubricant jelly.

Cleido-cranial Dysostosis

Q.—A young child has been diagnosed as suffering from cleido-cranial dysostosis. What disability is this likely to lead to and what is the long-term prognosis? Are there any special hazards against which the child should be guarded, and is there likely to be any associated mental disability?

A.—Cleido-cranial dysostosis is unlikely to lead to any disability, and, it is said, many of the patients are unaware of their deformity. The long-term prognosis is therefore perfectly good. There are no special hazards against which an affected child need be guarded, apart perhaps from the effects of dental abnormality, for which some dental or ortho-

dontic treatment may be necessary. There is unlikely to be any associated mental disability, and intelligence is likely to be normal.

The condition is hereditary, although it may occur for the first time in a family, all the other members being unaffected. Various degrees of the disease may be found; in the simplest cases only absence or partial absence of the clavicles is present. Defective development of the membrane bones of the skull may also occur and lead to enlargement of the head with a bulging forehead and a small face. The supra-orbital ridges are prominent and there may be a slight degree of exophthalmos. The palate has a high arch. Abnormal development of the teeth is very common. The first dentition may be delayed and the permanent teeth may fail to erupt and occasionally remain embedded in the jaws. Other bony deformities have also been described in association with the abnormalities of the clavicles and skull, but these are less usual. However, their presence might influence the otherwise good prognosis.

Treatment of Morphine Addiction

Q.—What is the best treatment for morphine addiction? Has the introduction of nalorphine altered the outlook in any way?

A.—Morphine may be withdrawn from the addict either rapidly or slowly. The best technique is probably to combine relatively rapid withdrawal with the administration of methadone (amidone) in order to relieve symptoms during the period when severe abstinence symptoms develop. The subsequent withdrawal of methadone is accompanied by less severe symptoms than those which result from the withdrawal of morphine. In this method the dose of morphine is reduced until the patient is stabilized on the minimum daily dose which prevents abstinence symptoms. This is usually about 120 mg. (2 gr.) a day. Methadone is then substituted in a dose of 1 mg. of methadone for each 4 mg. of morphine. After a period which may vary from 3 to 7 days according to the severity of the case the methadone is withdrawn by reducing the dose over a period of about a week.

Successful withdrawal must be followed by intensive psychotherapy and constant supervision. Relapse is frequent.

Nalorphine administered to an addict precipitates the abstinence syndrome and has been used in this way to unmask secret addicts. Its administration to addicts is, however, dangerous and should never be attempted without the patient's consent. It has no place in the therapy of addiction.

Correction.—In the summary of the paper on "Treatment of Ophthalmic Zoster with Prednisone," by A. Barham Carter and J. E. Royds (*Journal*, September 28, p. 746), the word "prednisone" in the fourth line should have been "antibiotics."

Collected Articles from the "British Medical Journal"

The following books are available through booksellers or from the Publishing Manager, B.M.A. House. Prices include postage.

Emergencies in General Practice (26s. 9d. inland; 26s. 6d. overseas).

Refresher Course for General Practitioners, Volumes 2 and 3 (26s. 9d. inland each, 26s. 9d. overseas).

Clinical Pathology in General Practice (22s. 3d. inland, 21s. 9d. overseas).

HORMONES AND BEHAVIOUR PATTERN*

BY

S. LEONARD SIMPSON, M.A., M.D., F.R.C.P.

Consultant Endocrinologist to St. Mary's Hospital, London

Endocrinology is at least 100 years old, if we accept as a landmark Addison's discovery of suprarenal disease in 1849, the year in which Berthold studied castration and its reversal in the cockerel. For the last quarter of a century people have speculated on the influence of the endocrines on the psyche—often with unbridled imagination and incomplete knowledge both of endocrinology and of psychology. The invitation of your Society has induced me to return, albeit with some trepidation, to this fertile field of merging fact and fantasy in which I made my first incursion some twenty years ago.

Historically we might go back to the Psalms xxvi, 2, "Try my reins and my heart" and the Sancino editorial commentary, "In the Bible the reins are the seat of the emotions; with the heart they determine character and actions." Reins being archaic English for loins, or kidneys, we approximate to modern knowledge of the adrenals and the emotions.

In a symposium at the Royal Society of Medicine in 1937 I advanced the following thesis: "Apart from the well-defined psychoneuroses, the endocrine balance of an individual, either grossly abnormal, or merely constitutional and familial, or physiological (puberty, pregnancy, or the climacteric), has an important influence on the character, behaviour pattern, and emotional reaction. Such endocrine disturbances are exceedingly common, and if, instead of psychiatric labels, one uses the wider conception of behaviour pattern, or characteristics of conduct, one could not fail to recognize a close association." With more recent knowledge, we will consider this thesis under three headings: (I) Psychoneuroses, psychoses, and behaviour patterns in major endocrine disorders; (II) the evidence for types of endocrine constitution in normal individuals; (III) the applicability of knowledge gained from the endocrinopathies to accepted normality.

I. Major Endocrine Disorders

Gonads

Male eunuchs are usually placid, docile, and apathetic, although they may "flare up" at times, and show sensitivities. Apart from ineffective coitus, they are usually incapable of the warmth or intensity of other relationships between husband and wife. As to the dramatic effect of testosterone, I have recorded (Simpson, 1938, 1948) that "psychological and personality changes after testosterone are remarkable. Shyness and diffidence are lost. Patients become extroverted, creative, energetic, and sometimes aggressive. They develop

*Lecture delivered at the Oxford University Medical Society on February 6, 1957.

O—2

initiative and are capable of assuming responsibility. Depression and apathy disappear and may be replaced by euphoria." I have no experience of males castrated before puberty, but those castrated after puberty have behaviour patterns comparable to those of eunuchs. One male patient, aged 20, was previously an exemplary intellectual and athletic leader at public school, but changed completely in character after bilateral castration at 16, following unusual torsion and strangulation in a fall while sprinting. He slept a great deal during the day; was discharged from every job because of laziness; and failed to get on with other people. During the consultation, as at other times, he cried easily without obvious cause. He was said to have changed to a "female" type and to be like a temperamental "female." He showed considerable charm of manner at times. Another surgical castrate was listless and apathetic, had no initiative, felt like someone dying, and showed lack of application and concentration.

On the other hand, a woman, completely castrated in infancy by an operation on an inguinal hernia containing both ovaries strangulated in the inguinal sac, showed none of the above characteristics. She was a charming and successful woman, of many interests and obvious ability and normal sexual activity, after a minor dilatation of the introitus.

Sexual precocity and pseudo-sexual precocity in the male, associated with relatively high 17-ketosteroids, is often characterized by aggressiveness, physical as well as pseudo-sexual, courage, and enterprise, as well as great physical strength.

The "differences" between the sexes, physiological as well as pathological, are complicated by two considerations. Although the testes contribute roughly one-third of the total androgens, the adrenal androgens in any one woman may be greater than the total adrenal and testicular androgens in any one male. Further, the chromatin sex patterns (skin, mucous membrane) may be the opposite of the somatic sex—for example, in ovarian agenesis and Klinefelter type of male eunuchoidism.

Adrenals

Cushing's syndrome, in which there is excessive secretion of cortisone (used for convenience as a comprehensive term for the various adrenal glucocorticoids) is frequently associated with depressive states, but manic agitation and violence have been recorded (Hertz *et al.*, 1955). Phases of euphoria are less usual, but I have met with this condition in the mixed type of adrenal hyperfunction, in which sufficient androgens are secreted to prevent a negative nitrogen balance. Starr (1952) has made a special study of personality changes in Cushing's syndrome. He writes: "It is the purpose of this paper to record the relevant findings gleaned from a scrutiny of 53 proven cases of Cushing's syndrome and to determine the incidence and nature of the mental and emotional aberrations. Most of these cases have been

5049

reported elsewhere. In the earlier report, however, no specific reference was made to psychotic disturbances except when suicide was the cause of death. It is noteworthy that personality changes were present in 60% of these cases. Severe depression was the most frequent finding. Euphoria, which often occurs with A.C.T.H. therapy, was a rare finding in this series. Thirteen (24.5%) of the patients showed such severe personality disturbances that 8 were institutionalized as insane and 5 others attempted suicide. An additional 19 patients (35.8%) had marked or moderate mental symptoms, but isolation was not necessary. The suicide rate in our series is 1,000 times that of the general population."

Cortisone, or corticotrophin, has been given in large doses for a number of non-endocrine disorders. In the majority of cases euphoria results from cortisone therapy, at least initially, although depressive states may follow. Excitement, restlessness, and insomnia are also met with, and even behaviour approximating to the maniacal. One circumspect, dignified patient of mine, successfully adrenalectomized for Cushing's syndrome, found that moderate doses of cortisone accelerated and intensified his intellectual and emotional reactions, caused him to drive his car very fast and recklessly, and to develop an irrepressible compulsion to join any game of football he might be passing, without the consent of the players, and in a black formal jacket, striped trousers, and a bowler hat. All these features, he found, could be abolished by reducing the dose of cortisone and would reappear on increasing it. Sprague *et al.* (1950), of the Mayo Clinic, record the case of a boy of 2½ with macrogenitosomia who became wildly excited and maniacal after 50 mg. of cortisone, injected daily for some days.

Addison's disease may be regarded as the opposite of Cushing's syndrome, and I have frequently (Simpson, 1948, 1952) drawn attention to the apathy, negativism, and irritability of chronic Addison's disease, and the disorientation and delirium of crises. Desoxycortone and (or) cortical extract both favourably influenced these personality changes, but to a far less extent than cortisone, which restores personality to normal, reversing at the same time abnormal encephalogram patterns. Cleghorn (1952) has met with depressive psychosis and delusions, but these must be regarded as rarities.

Pituitary

Gigantism and mild acromegaly are often associated with great physical strength and energy, restlessness, courage, exploratory drive, and social or economic aggressive persistence. When accompanied with good intellect, the physical presence and booming voice (large laryngeal cords) constitute a formidable combination. With the addition of charm, with or without the subtraction of intellect, we get the typical film male hero. Harvey Cushing pointed out the considerably enlarged adrenals in this condition. In the later phases of severe gigantism and acromegaly, weakness may supervene, and it is many years since I suggested that David defeated Goliath in his "weak" phase, with the added disadvantage of optic atrophy from a pituitary tumour.

Simmonds-Sheehan disease, or panhypopituitarism, may be considered the opposite of acromegaly, and is characterized by the development of weakness, apathy, inertia, lack of social drive and pride, lack of interest in the home, in children, and in personal appearance (Simpson, 1948, 1952). Whereas thyroid and testosterone are helpful, particularly testosterone, the improvement in behaviour pattern is not comparable to the dramatic change produced by cortisone. Depressive states and delusional insanity are also met with in patients where the diagnosis has been missed for some time.

In regard to the controversial problem of adiposity, I wrote in 1938: "A pituitary type of adiposity as typified by the fat girl or woman, with slender limbs, a beautiful and lovable face, good teeth, and a fascinating smile; wide social leanings, loving and loved, perhaps made fun of but extremely popular, a good dancer in spite of corpulence, very

musical and often gifted, a warm quality voice, artistic temperament, romantic nature, with alternating phases of happiness and depression that may recall to mind a lesser grade of maniacal-depressive psychosis." This condition I subsequently called adipose gynism (Simpson, 1950), in so far as the patients are intensely "feminine" in regard to certain physical and mental characteristics. They have some clinical features also met with in Cushing's syndrome, and an excess of adrenal glucocorticoids has been indicated by chromatographic assays (Gray *et al.*, 1956), but, owing to their height being above average, an excess of pituitary growth hormone has also been postulated. A comparable condition in males I termed adipose gynandria, to indicate an admixture of male and "female" physical and mental characteristics; and the behaviour pattern as recorded above is comparable.

In addition to adiposity of the face, buttocks, thighs, breast, and abdomen, true gynaecomastia may be present, puberty and descent of the testes delayed, the voice may break late or persist as a high voice, particularly in excitement, body hair may be absent or late, and facial hair may always remain scanty. The patients are sensitive and loving, and particularly attached to their mother. They may be talented musicians, opera-singers, and artists, and are often sentimental and social. In many, in their late teens, an adrenal androgenic phase may change the physical and behaviour pattern, but residual indications may be detected. Both types are usually valuable and gifted members of the community, and, in so far as the mild forms are so numerous, these are more correctly regarded as varieties of normal than as examples of minor endocrinopathies.

Thyroid

Thyrotoxicosis is frequently associated with anxiety neurosis, but it can be argued that thyrotoxicosis is a complication of an anxiety state in a patient with a labile thyroid gland; and, further, that toxic adenomata do not present the same personality pattern as Graves's disease. However, an excess of thyroid by mouth often produces restlessness, apprehension, and hyperacute sensory and intellectual processes. Prior to the era of controlled thyroidectomy, acute mania, hallucinations, and delusions were frequent complications of severe thyrotoxicosis (Rogers, 1904; Jameison and Wall, 1936). It is of interest that Dunlap and Moersch (1934), of the Mayo Clinic, reporting on the "Psychic Manifestations of Goiter," recorded acute delirium reactions in a high percentage of the cases of hyperfunctioning adenomatous goitre, whereas, in exophthalmic goitre, toxic psychosis was the more frequent complication.

The opposite condition of untreated myxoedema may present as an apathetic mentally slow and dull-witted vegetative hibernating individual, the condition sometimes complicated by dementia or delusions, as recognized by the Clinical Society of London in 1888 and more recently by Asher (1949) in a clinical paper with the dramatic title "Myxoedema Madness." Changes in the electroencephalogram occur both in myxoedema and in thyrotoxicosis.

Parathyroids

Hyperparathyroidism does not appear to be associated with characteristic personality changes, but hypoparathyroidism is often associated with irritability, excitability, irascibility, and explosive reactions, which seem to parallel in the mental field the neuromuscular irritability associated with low serum calcium. Greene and Swanson (1941) reported psychoses, with delusions and hallucinations, in five patients with hypoparathyroidism, and refer to the report of Shannon on eight children with hypoparathyroidism, who suffered from convulsions, depression, irrational speech, night terrors, and acute maniacal excitement with screaming, fighting, and tearing of clothes.

Hyperinsulinism

The disorders of feeling and behaviour associated with overdosage of insulin are well known—apprehension, irrita-

bility, argumentativeness, disorientation, mental confusion, and sometimes aggressive bellicosity. These features are present in minor degree when some normal people are kept from eating, giving rise to the old adage "feed the brute" and the custom of prefacing delicate negotiations with a good meal. Functional endogenous hyperinsulinism is found to be more intense with pre-existing emotional instability and following some types of gastrectomy and gastro-jejunostomy (Skillern and Ryneerson, 1953). Much more severe symptoms are met with in pancreatic islet-cell tumours; these may present in psychiatric clinics as anxiety states, as hysteria, and as psychotic states with mania and delusions. Widespread necrosis of the cerebral cells and multiple minute cerebral haemorrhages have been observed (Richardson and Russell, 1952). The disturbance of cell carbohydrate metabolism, with low blood-sugar concentrations, appears to be the essential disturbing factor, initially, and is also met with in pituitary and adrenal insufficiency. The cerebral changes are apparently reversible in the milder or earlier phases but irreversible later.

II. Constitutional Endocrinology or Endocrine Constitution

The experience gained from psychological and behaviour studies of major endocrinopathies would be of little value to our main thesis if we failed to demonstrate that there was such a thing as endocrine constitution and that its physical expression resulted in the recognition of physical types. The answer by an endocrinologist, in regard to the existence of endocrine constitution, is in my opinion an unequivocal and positive, but let us be less credulous, or more sceptical, and examine the problem from two angles: (a) Do endocrine disorders, in major and minor forms, occur in families, their incidence being genetically determined? (b) Can types of normal physical constitution, as recognized by the anthropologist, be correlated with a preponderance or relative deficiency of one or more hormones?

A. Occurrence of Endocrine Disorders in Families

The adreno-genital syndrome, manifest at puberty or in adult life, is undoubtedly familial in incidence, sometimes transmitted through females and sometimes through hairy males (Simpson, 1948, 1953). To the endocrinologist interested in paediatrics, as well as in adults, indications of the tendency can be found in early childhood. This is not to be confused, however, with congenital virilism (adrenal to be confused, however, with congenital virilism (adrenal pseudohermaphroditism) in females and adrenal pseudohermaphroditism) in males, obvious at birth, or infancy, sexual precocity in families, and apparently due to a genetic inability to convert 17-hydroxyprogesterone into 17-hydroxycorticosterone (Bartter *et al.*, 1951; Jailer, 1953); although a puberty or adrenarche type of adreno-genital syndrome may yet be shown to be due to an inherent metabolic abnormality. Cushing's syndrome, in its classical form, is usually not familial, but mixed types of adrenal hyperfunction, with hypersecretion both of androgens and glucocorticoids, are often familial. In one family, grandfather, father, and two adult sons suffered from this disorder, and steroid diabetes was present in both sons and in the grandfather. In adipose gynism and gynandria, conditions associated with clinical and chromatographic assay evidence of adrenal glucocorticoid hyperfunction, a familial incidence is usually present (Simpson, 1950, 1951).

Diabetes mellitus has been divided by Lawrence (1951) into lipoatrophic and lipoplethoric (adipose), the former being due primarily to insulin deficiency and the latter to an excess of pituitary and (or) adrenal diabetogenic hormones (steroid diabetes). Considering both types, Oakley (1955-6) concludes that "there is general agreement that heredity is the most important single factor in the aetiology of diabetes mellitus."

Atkinson (1932, quoted by Rolleston, 1936) collected 12 examples of hereditary or familial incidence of acromegaly. A sister, 55 years old, of three tall big-boned prognathic normal brothers, was sent to me with classical acromegaly

and a pathologically enlarged sella turcica. Professor Seligman (1931), in a letter to *Nature*, described acromegaly among the old Northmen, and Michael Perkins (1931) followed this with a description of a genealogical tree through several generations of the Egil Norse family, and concluded that "gigantism seems to have become endemic in the Fyrdafjord district of Sogn (Norway)—men more like giants in growth and seeming than mortal men." He incidentally refers also to their "bent of mind, courage and fits of uncontrollable rage." The opposite condition of familial dwarfism, with or without other features of infantilism, is frequently met with, and has a parallel in congenital strains of dwarf mice, with few eosinophil cells in the anterior pituitary.

Some other major endocrine disorders which are not hereditary on a large scale, but which are associated with a genetic familial incidence in a limited way, are cretinism due to a genetic chemical defect with inability to synthesize thyroxine (Hutchison and McGirr, 1956); eunuchoidism in twins (Simpson, 1948; Ellenbogen and Ryan, 1955); familial diabetes insipidus (Levinger and Escamilla, 1955); and familial Addison's disease with spastic paraplegia (Harris-Jones and Nixon, 1955).

B. Types of Physical Constitution

Anthropologists (Sheldon, 1940; Tanner, 1955) divide types of physical constitution into three major groups—endomorphs, mesomorphs, and ectomorphs. Briefly and crudely expressed, the mesomorphs are the muscular athletic type (male and female); the endomorphs the adipose type, with some feminine physical characteristics in the male; and the ectomorphs the thin wiry nervous type. Each individual is classified by three arbitrary figures, indicative of the degree of each component.

There is no difficulty in correlating the mesomorphs with a high-level secretion of pituitary growth hormone and (or) an excess of adrenal androgens. In clinical language, as one aspect of this, a trained observer will not fail to notice square massive lower jaws, with mild prognathism, among a good proportion of men in rugby teams and among boxers of the heavier weights. Height is determined not only by the time phase and the extent of pituitary-growth-hormone secretion, but also by the early or late closure of the epiphyses, which depends upon androgens and (or) oestrogens, as well as thyroxine. A heavyweight boxer under my care was found to be excreting 38 mg. of androgens, measured as 17-ketosteroids, in 24 hours, about twice the average. Surprisingly, according to conventional ideas, I found that a very strong, tall, muscular woman excreted nearly as much as this male—namely, 34 mg.—which means that her adrenals were probably secreting more than the adrenals of the boxer. Neither was ill, and their only complaint was their heavy weight. Another group of powerful athletes, including rugby players and boxers, are of mesomorphic build but somewhat plethoric in facies, often with red or purple lineae distensae, because their adrenals are simultaneously secreting an excess of adrenal glucocorticoids. Sometimes the relatively early closure of their epiphyses renders them stocky and broad rather than tall.

Correlation of endocrinology with endomorphism is equally probable on the background of my endocrine experience and interpretation, but appears more controversial and indefinite to many of my colleagues. Without denying the importance of psychogenic and hypothalamic adiposity, I must content myself with referring briefly to a few of the numerous clinical and experimental observations indicating the role of hormones in adiposity (Simpson, 1948, 1953); to Young (1945, 1951) and Salter and Best (1953) on the protein and fat anabolism of pituitary growth hormone and of insulin, separately or in combination, endogenous or exogenous; to the finding of hyperplasia of the pancreatic islet cells in hereditary obese-hyperglycaemic mice (Wrenshall *et al.*, 1955); to the effect of cortisone in non-endocrine states, coupled with gross obesity in some

patients with Cushing's syndrome, particularly in children, and considered in conjunction with Kendall's (1945) experimental studies of the relative and absolute increase in fat content of the carcass of mice treated with various adrenal glucocorticoid hormones; to the close resemblance between endomorphism in the male and adipose gynandrm; to clinical examples of hyperinsulinism; and to the loss of fat in some women with virilism and its return with removal of an adrenal virilizing tumour. Experiments have shown that augmented appetite is one aspect of this complex metabolic problem; but, again from the pragmatic angle, augmented appetite determined by endogenously secreted hormones is just as important as metabolic abnormalities leading to augmented fat deposition. Further, it is necessary to remember that the relative percentage of fat and protein in the body can be changed dramatically by hormones in the absence of change in body weight (Kendall, 1945).

The possible relationship between the ectomorph type and endocrine constitution is admittedly nebulous, and I shall not attempt to substantiate it on the scanty evidence that might be put forward. It might be more easily explained, if at all, by relative deficiency of some pituitary and adrenal hormones. However, the whole field of minor deficiency of hormones, in accepted normality, is itself a much less obvious and difficult field than that of hormone excess.

III. Applicability of Knowledge Gained from the Endocrinopathies to Accepted Normality

The answer to the question of the validity of correlating endocrinopathy behaviour pattern with varieties of normality depends upon the degree of acceptability of the evidence, deductions, and considerations advanced up to this point, as outlined above in I and II. In so far as I have consistently propounded the thesis, based mainly on clinical observations and interpretations, that endocrine disorders, or syndromes, are met with in varying degrees of intensity and completeness, or rather incompleteness, and are manifested frequently in minor degree in accepted normality, I have no personal difficulty in drawing a positive inference on the applicability of knowledge gained from a study of major endocrinopathies. Absolute proof, if such could be forthcoming, is obviously dependent upon a large and comprehensive investigation by a team of experts, including psychologists, psychiatrists, and anthropologists.

Another aspect of this problem is how far physical constitution and appearance, however determined, influence behaviour pattern. I am not attempting to answer this complex problem with any dogmatism, but if the answer is not a complete negative it is worth while bearing in mind that the endocrine glands determine, or at least considerably influence, physical strength, height, breadth of shoulders and hips, hair and skin in regard to thickness, greasiness, dryness and pigment, plethora or pallor of face, strength and pitch of voice, and some forms of adiposity.

However, the main thesis of this paper deals with the more direct influence of various hormone concentrations, or resulting metabolic changes, on cerebral processes. In attempting to apply the deductions from major endocrine disorders we should also consider the applicability of the following generalizations in regard to an excess or deficiency of specific hormones. An excess of androgens (adrenal or testicular) appears to be associated with positive personalities, with energy, drive, enterprise, restlessness, courage, and positive achievement. A severe deficiency of androgens is usually associated with apathy, passivity, negativism, and lack of enterprise. The associated physical strength, or weakness, probably plays a part in determining these attitudes, which latter, however, are more intense and characteristic than those caused by variations of physical strength due to non-endocrine illness. A deficiency of adrenal glucocorticoids is similarly associated with a negative apathetic personality, and cortisone therapy appears to have a remarkable influence on personality changes and

emotions, both in Addison's disease and in Simmonds's disease. In general, the glucocorticoids appear to be more specifically concerned with the emotions, sensibilities, artistic expressions, and social relations than do the androgens. Cushing's syndrome, with an excess of adrenal glucocorticoids, is paradoxically more often associated with depression than with the excitement or euphoria that follows cortisone therapy, but maniacal excitement and restlessness do occur; and, in the mixed types of adrenal hyperfunction, as well as with mild increases of adrenal glucocorticoids (adipose gynandrm and gynism), euphoria, high spirits, great social activities and successes, artistic creative achievements, and an emotional successful drive are in dramatic contrast to the apathy and withdrawal attitudes associated with deficiency of adrenal glucocorticoids. Since alternative phases of excitement and depression (mild manic-depressive states) are also met with in these states, a varying relative level of adrenal glucocorticoid might be as important as an average concentration above normal.

Deficient thyroid secretion results in a general slowing of mental and physical activities, approximating to a vegetative existence, whereas excessive thyroid secretion is associated with the opposite—namely, rapidity of thought and action, anxiety and apprehension, urgent anticipation, intellectual penetration and awareness, and, in milder degrees, with a dynamic vivacious personality. A deficient secretion of parathormone results in a low blood calcium with resulting well-known irritability of neuromuscular tissue but less well known psychogenic irritability and irascibility, an electrolyte influence on cerebral cells.

An excess of insulin, with resulting hypoglycaemia, leads to disorientation, irrational behaviour, sometimes violent, and ultimate coma—degenerative changes in the cerebral cells and multiple minute cerebral haemorrhages being found in fatal cases. Initial changes in the cerebral cells, associated with low blood sugar, appear reversible, but severe and prolonged effects irreversible. Endogenous compensatory adrenaline secretion plays a part in the more immediate symptomatology.

The pituitary gland manifests its influence on personality by its controlling relationship with the adrenals, thyroid, and sex glands; but in addition the growth hormone is nitrogen-anabolic, as is testosterone, prolactin hormone influences maternal behaviour in animals, and the gonadotrophins in excess appear to be a factor in climacteric disturbance.

It is of interest that abnormal electroencephalograms are found in many major endocrine disorders and that they return to normal with appropriate organic therapy. There is as yet no evidence to indicate detectable aberrations in the encephalograms of normal individuals who might be regarded as having a variety of endocrine constitution.

As regards the psychoses, it is noteworthy, and perhaps challenging to hormone theories, that there is no consistent relationship between the type of psychosis and the type of endocrine disorder. This may suggest that hormones do not determine but only precipitate, or reveal, an underlying psychotic disease or tendency. However, the response to therapy is often convincing from the limited pragmatic angle, not unimportant to the clinician and patient.

Summary

In so far as major endocrine disorders, with a preponderant excess or gross deficiency of one or more hormones, are frequently associated with characteristic behaviour patterns, as well as with psychoneuroses and psychoses, it seems reasonable to conclude that the excess or deficiency of hormones is causative or influential, and not merely coincidental—a view which is further supported by successful organic treatment but which does not necessarily exclude the existence of non-endocrine genetic factors modifying the response of individuals to hormonal stimuli, excessive or deficient.

ENDOCRINE ACTIVITY IN PSYCHIATRIC PATIENTS WITH MENSTRUAL DISORDERS

BY

J. H. REY, M.D.

U. NICHOLSON-BAILEY, B.A.

AND

A. TRAPPL, B.Sc.

From the Institute of Psychiatry, the Maudsley Hospital, London

In so far as major endocrine disorders, particularly those of hyperfunction, are frequently familial and genetically determined, and in so far as many major endocrine disorders have their representation, but with less intensity, in accepted normality, observations in regard to the association of major endocrine disorders with characteristic behaviour patterns are relevant to a consideration of the varieties of normal behaviour pattern among normal individuals.

Classifications of physical build, as used by anthropologists, bear some relationship to classifications of endocrine constitution, and the evidence put forward suggests an endocrine basis for two of the anthropological groups, the muscular mesomorphs and the adipose endomorphs, thus giving further support to the previous two conclusions.

I qualify my conclusions by an unqualified admission of the importance of non-endocrine factors in determining behaviour patterns, and even more so in the case of the psychoneuroses and psychoses, the majority of the latter of which are not due to endocrine disorders.

The hospital waiting-list for cases of tuberculosis in Northern Ireland virtually disappeared in 1956, according to the eleventh Annual Report of the Northern Ireland Tuberculosis Authority. In consequence, when the Waringfield Chest Hospital becomes available for the reception of patients, the chest hospitals at Armagh and Downpatrick will be used for other types of cases. The number of people given B.C.G. vaccination was 32,669. The number of patients examined by the mass radiography service was 124,459; of 10,622 people referred by general practitioners in Belfast, 438 were diagnosed tuberculous.

Though psychiatric literature is full of references to the relationship of mental illness and disorders of the sexual and reproductive systems, few studies have been carried out of gonadal activity in mental disorders. This is partly due to the great difficulties encountered in its proper assessment. The methods available are laborious and time-consuming. This applies both to bioassays and to chemical methods, especially serial investigations.

The need for such studies arises, firstly, because of the high incidence of menstrual abnormality in mental illness (Hause, 1923; Allen and Henry, 1933; Strachan and Skottowe, 1933; Ripley and Papanicolaou, 1942); secondly, because psychological changes are observed during the cycle and certain periodic syndromes and events occur at specific times during the cycle (Cooke, 1945; Reifstein, 1946; Kroger and Freed, 1951; Mackinnon and Mackinnon, 1956); and, thirdly, because of the complexity of the psycho-physiological processes which produce normal and abnormal cycles (Kroger and Freed, 1951).

The Experiment

An experiment was designed to obtain information primarily with regard to gonadal activity in psychiatric patients with menstrual disorders. Information was also obtained with regard to gonadotrophic, thyroid, and adrenal activity.

Material.—Patients were chosen from amongst the in-patient population of the hospital. They suffered from: (1) amenorrhoea (below age 45); (2) irregular periods; (3) menstrual disturbances (above age 45); (4) puerperal amenorrhoea. The only other factor affecting the choice of patients was the willingness to show sufficient co-operation in the collection of biological specimens—for example, urine and vaginal smears.

Definitions.—Arey (1939) has summarized the results of 10 different investigations and has found for the length of the cycle a mean of 28 days, with a standard variation of 4.92. This was adopted as a measure of the normal cycle. Any variation of more than twice the standard deviation each way but less than twice the normal cycle was defined as an irregular cycle. Amenorrhoea was taken to be present when a full cycle had been missed—that is, twice the length of a cycle.

Methods Used for Hormonal Estimations.—(a) Gonadal activity was assessed by the vaginal-smear method (de Allende and Orias, 1950; Pundel, 1952; Wachtel, 1954). Smears can be repeated over a long period of time, and the information obtained from such a procedure is fairly extensive. Oestrogenic activity can be measured quantitatively by the cornification index count, and indications of ovulation and pro-

gesteronic activity are also available. Some information about pituitary activity is implied in the fact that the pituitary must be active if gonadal activity is present, whilst the reverse is not true. Smears were made in duplicate and a count of cornified cells was done on both smears. (b) Thyroid activity was assessed by the radioactive iodine urinary excretion method (Fraser *et al.*, 1953). (c) Follicular stimulating hormone (F.S.H.) was estimated by the Gorbman (1945) ultrafiltration method. (d) 17-Ketosteroids were estimated by the method recommended by the Medical Research Council (1951).

Information Sought.—(1) *Gonads*: Serial examinations of vaginal cytology were carried on for detecting (a) fluctuations in the cornification index; (b) presence of ovulation; (c) signs of progesterone activity; and (d) other characteristics such as general appearance of smears, signs of atrophy, presence of basal cells, leucocytes, etc. (2) The daily morning temperature taken by mouth was recorded in all cases. (3) Estimations of thyroid activity, 17-ketosteroids, and urinary gonadotrophin were done to investigate (a) the marked deviations from the normal; and (b) if within normal limits, whether the values obtained tended towards the upper or lower end of the scale.

Gonadal Activity

The 67 patients investigated for their vaginal cytology have been grouped according to menstrual status (Table I) and according to diagnosis (Table II).

TABLE I		
Menstrual Status	No. of Cases	
Secondary amenorrhoea (below age 45)	22	
Amenorrhoea (puerperal)	20	
Secondary amenorrhoea and irregular bleeding (above age 45)	8	
Irregular bleeding (below age 45)	8	
Regular bleeding	9	

TABLE II			
Diagnosis	No. of Cases	Diagnosis	No. of Cases
Anorexia nervosa	6	Schizophrenia	8
Anxiety hysteria	7	Temporal lobe epilepsy	3
Reactive depression	10	Climacteric	8
Manic-depressive	5	Puerperal psychoses	20

Table III shows the length of time during which gonadal activity was studied and the frequency with which smears were taken.

TABLE III.—Duration of Study of Gonadal Activity		
No. of Cases	No. of Days	Frequency of Smears
20	30	Daily
16	60	"
5	90	"
2	120	"
2	150	"
1	360	"
1	540	"
20	60-120	Every 3rd day approx.

Vaginal Smears Findings (see Charts 1-18 on Figs. 1-4)

Secondary Amenorrhoea (Below Age 45).—(a) In all cases there was absence of ovulation and absence of clearly defined progesterone activity. (b) There were marked differences from patient to patient with regard to oestrogenic activity as reflected in the cornification index (C.I.). The only patients in whom low levels persisted (1-10%) unchanged for any length of time were those suffering from anorexia nervosa. But even these patients after a time showed variations in the C.I., especially when some improvement in the mental and physical states took place. In all other patients a varying degree of oestrogenic activity was present (Figs. 5 and 6). The common feature was the slow and delayed character of the rise in the C.I., the failure to

FIG. 1.—Cornification indices: Charts 1-6 (see text). Legends to Charts 1-18 appear on pp. 849-50.

FIG. 2.—C.I.: Charts 7-10 (see text).

FIG. 3.—C.I.: Charts 11-15 (see text).

FIG. 4.—C.I. and percentage of basal cells in three cases (see text).

FIG. 5.—Urinary gonadotrophins.

FIG. 6.—17-Ketosteroid excretion.

maintain higher levels of cornification and to pass to ovulation and progesterone production as judged by the constant absence from the smears of any characteristic of such activity. (c) Basal cells were present at levels varying between 5 and 10% in the cases of anorexia nervosa, and were also found in the patients with a very low C.I., seldom above 3-4%. (d) The general picture of the smears depended on the level of the C.I.: the lower the C.I. the more "dirty" was the appearance of the smear, showing the presence of small cells, broken cells, and leucocytes. The smears of the patients seldom look like those of healthy patients during the first half of the cycle. There is an absence of large well-developed cells with a clear protoplasm, characteristic of that stage of the cycle.

Irregular Menstruation (Below Age 45).—The main findings are delayed rise of the C.I., delayed or absent ovulation, and lack of well-established progesterone effect. There was also a lack of a definite pattern of rise and fall of the C.I. during these cycles. Thus, apart from the delayed reaction mentioned above, sometimes great daily fluctuations in the C.I. were observed.

Amenorrhoea and Irregular Menstruation (Above Age 45).—The characteristics of the smears seem to depend on the stage reached. In the long-standing cases the usual atrophic smear is found. But in the early stages two types of activity can be seen. Either a low and ill-sustained level of the cornification index and no progesterone activity, or a fairly high C.I. level well maintained but no progesterone activity.

Puerperal Psychoses.—Of the 20 patients studied, all had stopped lactation when the investigation was started. In three cases menstruation was resumed during the first month of the investigation. One patient started with a relatively high C.I., reaching levels of 60 and 70%. The remaining 16 patients had a low C.I. varying between 3 to 4% and 10 to 20%. In some cases it was possible to observe cyclical activity in the course of the investigation. However, after basic data had been obtained for a period of no less than a month these patients were submitted to leptaol treatment or electroplexy, which may have interfered with later findings. (The group of puerperal psychoses will be reported upon separately later on as it forms part of another study.) Basal cells were present in 14 patients. In two cases levels up to 50% were reached and in 12 they were not constantly present, the levels fluctuating between 0 and 10% approximately and at times showing an inverse relationship to the C.I. The smears were generally of the "dirty" type; with smaller cells than normal, broken cells, debris, and leucocytes.

Temperature Curves.—Daily temperature curves failed to show the patterns associated with regular ovular cycles.

Urinary Gonadotrophin (Fig. 5)

Urinary gonadotrophin was estimated in 62 patients with menstrual disorder and 15 psychiatric control patients. In 29 cases repeated estimations were made at intervals varying from 2 to 12 assays. For the sake of comparison between groups the first estimation made in each of the four abnormal groups was compared with estimations made between the 7th and the 15th day of the cycle in a control group of psychiatric patients approximately matched for diagnosis and age.

Loraine (1956). For a long time it was believed, chiefly following the work of D'Amour (1943), that there was a peak of gonadotrophin production at the time of ovulation. Heller (1941) and Heller *et al.* (1944) showed that no such peak could be demonstrated and that in some cycles positive values could be obtained every day while in others gonadotrophin was absent altogether for several days. Albert (1956), using improved methods of bioassay, found positive values in 87% of the estimations carried out throughout the cycle in four young women. Positive values were found at any time, although negative findings occurred with least frequency at mid-cycle but were equally distributed between the follicular and the luteal phase. The same pattern separated itself from subject to subject. Reviewing the findings up to date, Loraine (1956) states: "It is obvious that much work is still required with improved methods of extraction and more accurate bioassay techniques before the pattern of excretion of gonadotrophin during the normal menstrual cycle can be established." The increased gonadotrophin excretion at the menopause is well established, but Albert (1956) has further demonstrated in post-menopausal women that production takes place at rhythmic intervals of three to five days.

A number of studies are available about gonadotrophin excretion in the amenorrhoeas. One of the most extensive is that of Pedersen-Bjergaard and Tonnesen (1951). They examined 221 women suffering from secondary amenorrhoea, 145 with hypo-oligo-amenorrhoea, 77 with other menstrual abnormalities, and 110 with primary amenorrhoea. They estimated gonadotrophin and oestrogen urinary excretions by doing bioassays. Of the 221 women with secondary amenorrhoea, 34% had a normal gonadotrophin and oestrogen excretion, 16% had an increased gonadotrophin excretion, and 50% a non-increased and reduced oestrogen production. In none of them was there an increased oestrogen production. Unfortunately it is not possible from the authors' data to assess the incidence of reduced gonadotrophin production. They used a dividing-line for the upper limits of normal for their gonadotrophin estimations, so that they have two groups, increased and non-increased levels. Of the 50% of cases with non-increased gonadotrophin and reduced oestrogen excretion they say that they may represent cases with ovarian function not so greatly affected that it did call for compensatory gonadotrophin excretion, but "these effects may of course be due to a primary reduced hypophyseal function."

The percentages of normal gonadotrophin and oestrogen excretion in the hypo-oligo-amenorrhoea and the other menstrual anomalies were 67 and 81 respectively, and the diminished oestrogen production 28 and 14 respectively. The authors also lay great stress on the day-to-day fluctuations of gonadotrophin and oestrogen excretion. They have used single determinations, but have followed a few cases serially. Two patients with secondary amenorrhoea showed excretion curves similar to those of normally menstruating women.

Frank *et al.* (1937) examined 21 cases of secondary and six cases of primary amenorrhoea. They showed amongst the 21 cases of secondary amenorrhoea that all levels of oestrogen excretion could be found—low, subnormal, normal, and above normal. They did serial examinations over long periods and compared their findings with those from normally menstruating women. They also investigated the gonadotrophin excretion serially in six cases of secondary amenorrhoea and found abnormally high levels in four and no activity in two. They also state that all levels of oestrogen production could be found whatever were the gonadotrophin values.

In 29 cases in the present series repeated gonadotrophin estimations were done and fluctuations in excretion were found. These fluctuations also usually corresponded with fluctuation in the cornification index. The possibility therefore cannot be discarded that added to the postulated absence of L.H. there is a tendency towards diminished production of F.S.H. as well. It has been suggested by Hubble (1955) that in cases of functional hypopituitarism

there is a definite hierarchy in the dissolution of function of pituitary trophic hormones, the reproductive system being the most sensitive and the first to disappear. It may well be that L.H. may be the most sensitive hormone or the only one to disappear in some cases—for example, hypothalamic amenorrhoea—but that F.S.H. may also follow suit if the process becomes deeper. Such is undoubtedly the case in anorexia nervosa as reported by various authors (Emanuel, 1956), and it appears to be so in the present series in other diagnostic groups as well.

The demonstration of the role of the lutein-stimulating hormone has been a very difficult problem, as no practical and satisfactory method of estimation is available. McArthur *et al.* (1955) have used the weight of the ventral prostate in hypophysectomized male rats. They found qualitatively and quantitatively different patterns of excretion of L.H. from the normal in patients suffering from a number of gynaecological disorders, including psychic amenorrhoea.

Similar difficulties have existed with regard to pregnandiol estimations. Brown (1956) has shown, by using the much more precise method of Klopper *et al.* (1955), that the luteal phase in a menstruating woman could be of a very short and evanescent nature and may thus be easily missed.

17-Ketosteroid Excretion

The results obtained with regard to 17-ketosteroid excretion and thyroid activity seem to indicate that the disturbance may involve other endocrine glands, possibly also via a more general hypopituitarism. The 17-ketosteroid excretion was significantly lower in the amenorrhoeic (non-puerperal) and "irregular" groups than in the psychiatric controls and on the low side of accepted normal values for the age groups. This does not apply to the group of puerperal psychoses.

Reifenstein (1946) states that the 17-ketosteroids are usually below normal in "hypothalamic amenorrhoea." Hubble (1952) suggests that this may be due to the absent stimulation of the adrenals by L.H. according to Albright's hypothesis but that there is no decrease in corticotrophin production. The question of the participation of the ovaries in the production of androgens is therefore of great interest. Some observations made during these studies are given here as they seem relevant to the problem, but they are not thought definite enough to be reported in detail. It has been observed that in some patients there was an increase in 17-ketosteroid excretion as the cornification index rose. Also fluctuations in 17-ketosteroid excretion were found during the cycles, the level rising towards mid-cycle. In one case a chromatographic examination done at the beginning and one done at mid-cycle showed a marked increase in the androsterone and etiocholanolone fractions in the latter chromatogram.

Dingemans and Huis in't Veld (1951) and Huis in't Veld and Dingemans (1952) have demonstrated a difference in the excretion pattern of castrated women, who show an increase in the β -fraction and a decrease in the androsterone and etiocholanolone excretion. Migeon (1955) has shown a fluctuation in the blood dehydroisoandrosterone levels during the menstrual cycle. The question of the relative part played by the adrenals and the ovaries during the menstrual cycle, normal and abnormal, needs further elaboration. Hyperadrenalism as a cause of disturbance in the reproductive system has come much to the fore with the work of Wilkins *et al.* (1955), of Jones (1955), etc. It is now well known that certain forms of mental illnesses in their acute phase can be accompanied by increased adrenal activity both of corticoids and of 17-ketosteroids. Altschule (1953) has suggested that some of the disturbances of the menstrual cycle in psychiatric patients could be due to that cause. In two patients in the present series with a consistently high excretion such a mechanism could have been at work: they both suffered from hirsuties.

The normal, low normal, and low values found in this series do not suggest that this mechanism applies on a large

scale unless the stage of adrenal hyperactivity was missed, or that most patients with menstrual disorders have been investigated in a later phase when hypofunction has followed hyperfunction. Hubble (1952), in his cases, reports normal values for all aspects of adrenal function. In another study in progress a number of patients showed fluctuations in excretion of 17-ketosteroids and corticosteroids during the menstrual cycle, sometimes to abnormally high levels, and the first stage of interference could be suppression of the more sensitive gonadotrophin component—that is, the lutein stimulating hormone. However, it must also be remembered that the reverse process may also be true and that the absence of lutein stimulation and progesterone production could call for adrenal compensation in the face of unbalanced oestrogen activity. The role of the adrenals must wait for further experimental work.

With regard to the part played by undernutrition, this factor was pronounced only in the cases of anorexia nervosa. However, the consensus of opinion is that the menstrual disturbance often precedes the anorexia. But it is probable that the undernutrition increases and maintains the endocrine hypofunction, and improvement in weight is always associated with improvement in other spheres. It is only in the severe cases of anorexia nervosa that near complete absence of gonadal activity was found in the present study.

The problem of undernutrition and 17-ketosteroid excretion in this series has already been dealt with. Clinically there seemed to be a difference between the patients with well-preserved 17-ketosteroid excretion and those with low levels in the anorexia group. The former appear to be much more active and lively than the latter.

The question of the correlation of the mental state to the endocrine changes and the menstrual abnormalities will be considered in another study because of the complicated relationship involved. The subject of the influence of emotions on disturbances of the menstrual cycle has been dealt with by Kroger and Freed (1951); but the remarks of Ripley and Papanicolaou (1942), that in no case did increased abnormality of the vaginal smear occur when improvement in normality of the vaginal smear could be confirmed. Further, the mental state took place, can be confirmed. Further, the observation of Reifstein (1946) with regard to his cases of "hypothalamic amenorrhoea," that in many patients the discussion of their psychological problems and superficial psychotherapy can effect a recovery, has also been noted, though in certain patients the disturbance seems to be much more persistent. The literature on the hypothalamic control of the pituitary has been well summed up by Harris (1955).

Conclusion

It is thought that the findings of the hypotrophic type of smear, the low cornification index, the absence of progesterone activity in the smear, the tendency to lowered F.S.H. production, and a possible tendency to low normal 17-ketosteroid excretion and low normal thyroid uptake point to a functional lowering of pituitary activity in the patients of this group.

The disturbance seems to vary in the degree to which the pituitary functions are affected, the gonadotrophin being the most sensitive. When function returns the follicular activity appears before any progesterone activity, and this may last for long periods or anovular cycles may be observed. This is in agreement with the hypothesis of a hierarchy of pituitary function during phases of dissolution and reconstruction.

The association with mental disturbance also indicates that a brain-pituitary mechanism is involved. A possible pathway is suggested by the hypothalamic control of pituitary activity, with special reference to the reproductive functions.

Summary

Fifty-eight patients with menstrual disorders and nine with normal periods were investigated. Serial vaginal smears were taken over periods varying from 30 to 540

days. Gonadotrophic and thyroid activity and 17-ketosteroid excretion were also assessed and compared with similar measurements in psychiatric control groups. Repeated estimations showed fluctuation in the factors measured.

Gonadotrophin estimations in the amenorrhoeic patients were significantly lower than the values recorded for the control group between the eighth and the fourteenth day of the cycle. Highest values selected from repeated estimations did not differ.

17-Ketosteroid excretion in the amenorrhoeic and "irregular" groups, but not in the puerperal group, was slightly lower than, and differed significantly from, the psychiatric control group.

Thyroid activity did not differ significantly between groups, but showed a significantly greater spread of values in the group with menstrual disorder.

Serial vaginal smears showed that complete absence of gonadal activity is rare, and that great variations in cornification index values exist between patients and in the same patient over a period of time. Protracted phases of low oestrogen activity is a common finding; ovulation and progesterone effects were never detected in the patients with amenorrhoea.

Uterine biopsies done on 10 patients with puerperal psychoses confirmed the absence of the luteal phase.

The general hormonal picture is one which indicates that the main type of amenorrhoea met with in psychiatric patients is one of lowering of pituitary function; gonadal activity is abnormal, the luteal function being the one most constantly altered, combined with protracted low oestrogen levels. Gonadotrophin production can also be diminished, and the tendency of the 17-ketosteroid excretion is to vary from normal to the low side of normal. The thyroid also shows variations from the normal distribution.

The relationship to mental illness and the fluctuations observed in the hormonal balance suggest interference at the brain-pituitary level.

LEGENDS TO CHARTS (Figs. 1-4)

Chart 1.—Represents a normal cycle in an unmarried woman aged 20. There is a gradual rise and fall of the C.I.; no marked daily fluctuations. The highest level reached for the C.I. is in the region of 40%.

Chart 2.—Represents a cycle in a woman aged 25. It also shows a gradual rise and fall of the C.I., but the general level of cornification is below that of the cycle shown in Chart 1.

Chart 3.—From an unmarried woman aged 23 who has suffered from anorexia nervosa and amenorrhoea for three years. The curve shows that there is practically no oestrogenic activity. The C.I. fluctuates between 0 and 3%. The smears show characteristics of atrophic smears and the basal cells are in sufficient number for a count to be made.

Chart 4.—From a woman aged 32 who has been suffering from anorexia and amenorrhoea for 14 years. The curve shows the absence of hormonal stimulation; the C.I. fluctuates between 0 and 3%. The smears show the characteristics of atrophy and the presence of basal cells.

Chart 5.—From the same patient as Chart 4, but taken later on when the patient had been improving. It will be noticed that the C.I. shows great fluctuations but that the normal rhythm of the menstrual cycle is not established, so that this woman is submitted here to a fluctuating stimulation by oestrogens but not to the physiological process of menstruation.

Chart 6.—From a girl aged 20 suffering from feelings of depression and lack of drive interfering with her studies. For some time previous to admission she had suffered from anorexia and loss of weight down to 7 st. 4 lb. (3.3 kg.), and amenorrhoea. However, on admission her weight was 9 st. 1 lb. (4.1 kg.). The C.I. curve shows the low level of oestrogenic activity with fluctuations but no indications of any cycle.

Chart 7.—From an unmarried woman of 24 suffering from temporal lobe epilepsy and with a hysterical personality. Her periods have always been irregular and painful since they started at the age of 13. The C.I. curve shows a gradual rise with fluctuations of the C.I. after a period of months. Once more there is here no regular menstrual cycle. When bleeding occurs it is scanty and does not last more than two or three days.

Chart 8.—From a woman aged 38 suffering from attacks of agitated depression and occasional mania. This curve illustrates a number of points in relationship to the menstrual cycle. In the first two cycles there is extremely little ovarian activity though bleeding still takes place. There is no sign of ovulation or progestational activity in these two cycles, and here one must quite clearly distinguish between periodic bleeding and bleeding in relationship to the normal well-defined physiological process of menstruation. In the third cycle the C.I. is at a somewhat higher level and there is a premenstrual peak just before the bleeding. Nearly 18 cycles were studied in this woman, and they all showed this premenstrual peak and sometimes a menstrual peak. In the following cycle once more the level of the C.I. is somewhat higher than in the previous cycle, and clearly defined premenstrual and menstrual peaks can be seen. Again in these two cycles there is no evidence of ovulation or progestational activity. The next cycle shows a still higher level of activity, premenstrual peak, and marked fluctuations but no progestational activity. The various cycles studied are abnormal in that they show low levels of gonadal activity, no ovulation, and no progestin activity. Nevertheless, bleeding takes place at fairly regular intervals and is presumably due to oestrogen withdrawal. Further, a characteristic of the cycles appears to be the premenstrual rise and fall followed by the bleeding. But perhaps the most interesting fact here is the observation that there is a gradual step-up level of gonadal activity from cycle to cycle, though in the present study not yet leading to a normal cycle. This case has been extensively studied over a long period of time and will be reported separately.

Chart 9.—From a woman of 30 suffering from a schizoaffective disorder. She has had pain associated with her periods, and has related some of her symptoms to phases of the menstrual cycle. In this case it can be seen, in the first cycle studied, that the level of hormones is maintained throughout the cycle at a C.I. between 20 and 30 with daily fluctuations. The second cycle shows the beginning of a rise and fall of the C.I., with the latter being constantly maintained above a level of 20-25 C.I. In these two cycles a premenstrual peak is also present. In the third cycle the picture has altered and two well-defined periods of rise and fall can be observed, with the general level of the C.I. above that of the previous cycle. It was not possible in that cycle to detect any signs of progestational activity. However, the general shape of the curve does suggest that it is possible that ovulation has taken place, but if there has been corpus luteum formation progesterone production was very defective. The last cycle resembles the previous one. The level of the C.I. is at a higher one generally than in the previous cycle, otherwise the same remarks apply. In this woman the cycles studied can be compared with interest to the previous case (Chart 8). In both cases the step-up activity can be observed very clearly, though in Case 9 the general level at the time the study was started was higher than that in the previous case. It also illustrates the differences between the normal physiological cycle and periodic bleeding.

Chart 10.—From an unmarried woman of 25 suffering from periods of depression and elation. The first part of the chart shows a rising and falling C.I., followed by bleeding. As the whole cycle was not studied, it is not possible to make further comments on this part of the curve, but it can be seen that, following the bleeding, the normal cycle was not resumed, and for a period extending over weeks the gonadal activity remained very low. The curve is shown to illustrate a protracted first phase of the cycle. She entered menarche at 15 with periods grossly irregular and often associated with marked mood swings. She was capable of ovulation, as she had had an illegitimate child 18 months before the study.

Chart 11.—From an unmarried woman of 19 who had been suffering from a recurrent mood of depression with a tendency to stuporous and bizarre behaviour. The first cycle shown demonstrates the character of the oestrogen rise occurring very suddenly after a period of low gonadal activity in the first half of the cycle. The patient went into the depression and stupor-like state at this point and refused co-operation. The last bit of the curve in that cycle represents the time when it was possible to resume the cytological studies.

Chart 12.—From an unmarried girl of 19 suffering from manic-depressive swings. The chart shows the sudden and sharp rise and fall of the oestrogen and the abnormal cycle as the rise and fall precedes the bleeding and the sudden change in mood.

Chart 13.—From a married woman aged 47 suffering from a menopausal illness with paranoid ideas and disturbing sexual impulses. Her menstruation had become irregular for some time. It can be seen that during the phase studied here she was constantly under oestrogen stimulation at a fairly high level with no normal cyclical change and no progestational activity.

Chart 14.—From a woman of 47 entering into menopause and showing paraphrenic symptoms. In this case it can be seen that the cycle has also become abnormal and irregular, but, in contrast to the previous case, the level of gonadal activity is quite low, ill-sustained, and unbalanced, for progestational activity is lacking.

Chart 15.—From a woman just entering menopause with paranoid symptoms. There is constant oestrogen stimulation, but no cycle.

Chart 16.—A woman aged 34 who developed a schizophrenic-like illness seven days after giving birth. The investigation started 30 days after the baby was born. The chart shows the very low level of cornification and the presence of basal cells. There are no signs that the gonads are showing any tendency to fluctuating activity. After shock treatment she improved and her periods returned.

Chart 17.—A woman aged 24 who developed a schizophrenic-like illness after delivery of her first child. The investigation started 83 days after the baby was born. The chart shows a much higher level of cornification and fewer basal cells than the previous patient (No. 16) and serves to illustrate the various levels of oestrogenic activity that can be observed during amenorrhoeic periods.

Chart 18.—A woman aged 27 who became depressed during her fifth pregnancy and was admitted to hospital during her sixth month of pregnancy. She settled down fairly well, had her baby, and is chosen as a comparison with the two previous cases (Nos. 16 and 17) suffering from serious illnesses. The investigation was started shortly after birth. The chart shows what appears to be an amenorrhoeic cycle—the first one—and also shows very clearly the inverse relationship of the C.I. and the percentage of basal cells.

We have pleasure in acknowledging that this work was made possible through a grant from the Bethlem Royal Hospital and the Maudsley Hospital Research Fund.

A STUDY IN CARDIAC PROGNOSIS

BY

GEOFFREY BOURNE, M.D., F.R.C.P.

Physician and Officer in charge of Cardiology Department,
St. Bartholomew's Hospital, London

Cardiac prognosis depends upon contemporary statistical knowledge and general experience; also upon the personal experience of the physician himself.

General experience is often a safe guide; for example, subacute bacterial endocarditis invariably used to be fatal, usually within a year, before the discovery of penicillin; and, as another example, a minimal blowing mitral murmur without cardiac enlargement was, and is, regarded as entailing no risk to life or health. But time produces continuous changes in the prognostic scene, and to-day 75% of patients with subacute bacterial endocarditis may look forward to a good recovery and a usefully active life. This transmuting effect of time has already influenced the outlook in mitral stenosis, persistent ductus arteriosus, syphilis of the cardiovascular system, and coronary disease. Further changes may soon be looked for in, for example, hypertensive heart disease and atrial septal defect. It is for this reason that orthodox prognosis, founded upon statistics, is apt to be unreliable when applied to individual cases.

It was therefore thought that a study of patients who had survived for long periods in spite of the presence of diseases usually considered serious might stress the value of prognosis of the individual clinical approach. Each case is dealt with separately, and an attempt is made to analyse from general principles the reason for individual survival or absence of deterioration. Such general principles may help the formation of a more reliable individual prognosis than will obsolete or obsolescent statistical figures.

The cases and their survival years are as follows: mitral stenosis, 14 years; aortic stenosis, 45 years; very severe rheumatic aortic incompetence 49 years; very severe rheumatic pancarditis, 20 years; syphilitic aortitis with aortic regurgitation and angina of effort, 15 years; subacute bacterial endocarditis (aortic), 7½ years; right acute bacterial endocarditis (aortic), 7½ years; angina of effort, due to bundle-branch block, 18 years; angina of effort, due to coronary disease, 26 years; posterior myocardial infarction, 23 years; hypertension 25 years (male), and 11 years (female).

General Principles

Cardiac prognosis will always depend upon the heart being able to maintain a normal pumping efficiency. The factors concerned in this are the physical state of the heart muscle; potential change in the state of the heart muscle; maintenance of an easy balance between the systemic and pulmonary circulations; the presence or absence of mechanical handicaps to the functional activity of the left or right ventricle.

The normal heart muscle can maintain an adequate output at rest, and can increase this sufficiently to enable the individual to maintain his or her daily activities without individual to maintain his or her daily activities without symptoms. A similar result can be attained by a previously diseased but now compensated heart. Two distinct questions have thus to be determined in every case. Is the function of the heart normal? Is the structure of the heart normal? It is true, with few exceptions, that the absence of symptoms suggests absence of failure, and that if there is no enlargement of the heart there is no organic disease. Symptoms, however, may be latent, in the presence of serious disease, if both ventricles are equally impaired in functional efficiency.

Circulatory Balance

The importance of this factor of balance between the two pumping systems, systemic and pulmonary, is often overlooked, but its significance cannot be overemphasized. Most cases of cardiac failure are due either to rheumatism or to coronary disease. In both of these examples the left heart is predominantly affected—in rheumatism by mitral or aortic valvulitis, in coronary disease by left ventricular ischaemia. Both types of lesion cause primary failure of the left auricle or the left ventricle, and resultant but secondary increase in the work of the right ventricle. If either type of lesion develops rapidly pulmonary complications in the shape of congestion, paroxysmal dyspnoea or acute pulmonary oedema will follow.

If, however, an exact mechanical balance persists between the two ventricles and their circulations a diseased heart muscle may retain its functional efficiency to a quite remarkable degree. Examples of exactly balanced left and right ventricular myocardial disease, without valvular or other mechanical complications, are rare, however. Diphtheria and severe anaemia can produce such a result. In the past, before the days of diphtheria immunization and adequate treatment of pernicious anaemia, ambulatory patients collapsed and died suddenly from either disease, their heart muscle being riddled with fatty degeneration, as shown microscopically.

Another dramatic example of this situation was that of a case of cardiac haemochromatosis (Bourne and Cureton, 1953). This man, aged 51, died with evidence of severe myocardial disease. All the usual phenomena of haemochromatosis of the heart were present: a very low voltage electrocardiogram; a low blood pressure (115/85 to 98/80); episodes of auricular fibrillation and flutter; and the rapid development, in a few days, of congestive heart failure, with oedema, ascites, and pleural effusion. Moreover, histological examination of the myocardium later showed widespread and severe cardiac haemochromatosis.

In spite of a myocarditis of this degree, from which he died on August 4, he had played 36 holes of golf on July 26. But the majority of patients with cardiac disease lack this benefit of an equally balanced diminution in the efficiency of both left and right ventricles.

Mitral Stenosis for 14 Years

When first seen Mrs. A. was aged 25. At the age of 40 she still had a loud first sound at the apex, a typical pre-systolic murmur, and a rumbling diastolic murmur filling most of diastole and localized to the apex. Her symptoms fourteen years ago were of the functional "nervous" type, including palpitation, exhaustion, giddiness, and a left chest ache not associated with exercise. She also had a little shortness of breath. She was overweight. The blood pressure was 116/80. The rhythm was regular. Hyperaesthesia was present in the left submammary region. Radiologically the heart was normal in size, measuring 11.0 cm. There was no prominence of the pulmonary conus. The barium swallow showed no evidence of auricular enlargement at any time. The electrocardiogram remained normal from the first to last. Twelve years ago she became pregnant and her condition remained unchanged both during and after the pregnancy. Fourteen years from the date of the first examination the size and shape of the heart remained unchanged. The latest transverse diameter measurement by orthodiagraph was 10.5 cm. She remained free from significant shortness of breath in spite of having been persistently overweight. A little palpitation and a feeling of tiredness, especially if she was worried, were constant throughout.

It is clear that the murmurs of mitral stenosis in her case do not indicate a lesion which has affected the function or the structure of her heart. There has been no sufficient mitral narrowing to interfere with the proper emptying of the pulmonary veins. The signs of pulmonary hypertension, shortness of breath on exertion, orthopnoea, and cough on

exertion have remained absent, as have the physical signs of pulmonary hypertension: accentuation of the pulmonary second sound with perhaps splitting of it; the presence of an opening snap; pulmonary conus pulsation; radiological and electrocardiographic evidence of auricular enlargement and of right ventricular hypertrophy. It is obvious that the prognosis in such cases depends on these latter direct evidences of the valvular narrowing and not on the presence of the typical mitral stenotic murmurs. These only indicate the position of the lesion, and give no guide to its extent.

To apply the general principles formulated above, the heart muscle in her case was normal, no recrudescence of rheumatic infection had occurred in the heart muscle. The normal balance between the systemic and pulmonary circulations remained unaffected by the minimal mitral deformity. This minimal mitral deformity was insufficient to cause any handicap to the functional activity of the right ventricle in the shape of pulmonary hypertension or of the left ventricle in the shape of diminishing output per beat. She may well continue in good health for an indefinite period.

Aortic Stenosis for 45 Years

Dr. B. died at the age of 64. When he was 18 Sir Thomas Lewis diagnosed aortic stenosis. The condition had therefore probably been present for fifty years at the time of his death. His youthful activities were normal. In spite of the murmur he joined the R.A.M.C. in 1916. He practised in Bangkok for twenty-five years, and retired to England, where he did general practice without symptoms until the age of 55. He then began to notice slight shortness of breath when climbing hills and stairs, but ascribed this to a mild degree of chronic bronchitis and emphysema, which indeed he had. At the age of 57 the electrocardiogram showed left ventricular strain. A year later he began to notice very slight angina of effort when hurrying up hills and stairs. This was never sufficient to need glyceryl trinitrate. At the age of 60 he was conscious of feeling older. At this time the typical systolic thrill and murmur of aortic stenosis were well developed. The heart rate was 86, the rhythm was regular, and the blood pressure was 152/102. The electrocardiogram still showed the typical picture of left ventricular strain and left ventricular hypertrophy. Radiologically the transverse diameter of the heart by orthodiagraph was 15 cm. Calcification of the aortic valve was visible radiologically.

During the next three years his shortness of breath increased, and two months before his death signs of congestive failure began to show themselves in the form of peripheral oedema and orthopnoea. Auricular fibrillation was now present. Radiologically the heart had enlarged to a transverse diameter of 17.5 cm. The post-mortem examination showed what was apparently a calcified aortic stenosis of the acquired type.

His attack of early rheumatism appeared to have been restricted to the aortic valve. It caused slow fusion of the cusps with the development of aortic stenosis rather than distortion and destruction, producing aortic regurgitation. The remarkably slow development of the lesion was characteristic, and the heart muscle, which had never been seriously injured by acute rheumatism, remained not only in a state of normal health but able to hypertrophy, at its leisure, to meet the slowly increasing mechanical handicap of the narrowing aortic ring. No deterioration in the heart muscle occurred until evidence of coronary ischaemia began to appear in the form of angina of effort. It is probable that in this case, as in the following one, the cause of the ultimate failure was the fact that the myocardium of a man of 64 was unable to maintain the left ventricular output through an aortic valve whose narrowing had reached a critical diminution. A noticeable point indicating the myocardial failure was the increase in the heart size by orthodiagraph from 15 cm. to 17.5 cm. over the last three years of his life.

Aortic Regurgitation (Rheumatic) for 49 Years

Mr. C. had had aortic regurgitation for more than 49 years. The murmur was heard by the late Sir Maurice Cassidy when the patient was 20 years old. He was aged 66 at the time of my first examination of him. The lesion was almost certainly rheumatic in origin. He had remained symptom-free for 46 years after the diagnosis of his valvular lesion. He played Rugby football up to the age of 41 in spite of it. It was not until the age of 65, after an attack of pneumonia, that he became short of breath on exertion. This rather rapidly increased in severity, and he began to notice some orthopnoea. The physical signs found were as follows: increased arterial pulsation, both visible and palpable; considerable displacement of the apex beat to the left; a rapid regular heart rate of 110; pulsus alternans, with systolic figures of 180 and 190 and diastolic of 90 mm.; the typical murmur of aortic regurgitation, heard at the aortic base and down the left sternal border to the apex beat. Radiologically the heart was very large, the transverse diameter being 20.5 cm., and some pulmonary congestion was visible. The electrocardiogram showed the tall broadened R waves of left ventricular hypertrophy and the inverted T wave of the left ventricular strain in the left ventricular leads. During the next two years he fractured his femur, which was pinned, and later underwent a prostatectomy, from which he made a good recovery.

The noticeable points relative to prognosis were as follows: the state of the heart muscle was obviously remarkably good throughout most of his active life; nor was there any deterioration in the normal state of the muscle, probably because he escaped further attacks of rheumatic carditis. The valvular handicap, although considerable, was not too great for the compensatory power of the healthy and hypertrophied left ventricular muscle, which was able to eject the full systemic requirement, and in addition the amount of the aortic reflux, without suffering any serious mechanical disability. The handicap which was probably responsible for the occurrence of symptoms after his 48 years of normal life was the inevitable one of increasing age.

In many cases of organic heart disease which have remained adequately compensated for decades the passage of years begins to produce deterioration in the arterial system. These changes may affect either the peripheral arterial bed in the heart, as elsewhere in the body, or the elasticity, the health, and the permeability of the larger coronary arteries.

Fulminating Rheumatic Carditis, with Perfect Recovery 20 Years Later

Mr. D. was first seen in 1936, when he was aged 34. He was suffering from a very acute attack of typical rheumatic fever with painful synovitis of wrists, a knee, and an ankle. During the acute stage of the disease he developed pericarditis with a loud friction rub, heart block with failure of auriculo-ventricular conduction at every third or fourth beat, and finally symptoms of acute rheumatic meningitis associated with lymphocytosis and other evidences of inflammation in the cerebrospinal fluid (Bourne, 1936). He was ill for three months, but subsequently made an uninterrupted recovery. After convalescence his heart was clinically normal. The P-R interval was normal. Radiologically the heart was not enlarged. The T wave was upright in lead I and diminished in size in lead II.

He was seen at intervals during the next 19 years, usually for symptoms due to alcoholism. During that time the only cardiological abnormalities were a slight systolic murmur at the apex and a progressive flattening of the T waves in the three standard leads. He suffered from no shortness of breath or chest pain.

In 1953 he began to complain of symptoms suggestive of cirrhosis of the liver. When he was examined in 1954 he was found to have ascites. After paracentesis the typical

hobnail liver was discovered; there was no venous distension in the neck, and no peripheral oedema or other evidence of constrictive pericarditis. He developed active pulmonary tuberculosis during this year and died early in 1956. To the end his heart remained clinically and radiologically normal.

Although the likelihood of permanent cardiac complications in acute rheumatism is 90% or more in children below the age of 10, in adults over the age of 20 the cardiac risk becomes progressively less with advancing years. No more acute example of severe active cardiac rheumatism could have been found, yet, for twenty years neither his cardiac function nor his cardiac physical signs deviated from the normal.

Syphilitic Aortic Regurgitation, and Angina of Effort. Symptomless 15 Years Later

Mrs. E. and her husband were caretakers of a city building. She was first seen in October, 1941, when she was 42 years of age. Since the previous December, following a bad air raid, she had begun to notice shortness of breath on exertion and discomfort across her upper chest, which came on if she hurried or climbed stairs or walked against a wind. She was found to have a well-marked aortic regurgitation. The blood W.R. was strongly positive. The blood pressure during her first treatment in hospital was 170/50, subsiding with rest to 140/44. Treatment was by bismuth injections and neoarsphenamine. The treatment was repeated.

Six years later her physical condition was unchanged, the blood pressure being 180/62. Her shortness of breath and angina of effort had disappeared, and in April, 1948, she was doing her own shopping and household washing, and in fact was leading a full normal life. The aortic diastolic murmur persisted. The heart was only slightly enlarged radiologically, but the left ventricle was somewhat rounded. Three years later the aortic leak remained considerable, the blood pressure being 190/45. When last seen on April 19, 1956, she was still free from shortness of breath or anginal pain. Peripheral arterial pulsation was increased. The pulse pressure remained high (210/60). Radiologically the left ventricle was again seen to be rounded, but measurement of the heart by orthodiagraph still showed no great enlargement. Electrocardiograms during the period of her attendance over the last ten years have shown the gradual development of the left ventricular strain pattern.

She thus remains well fifteen years after the first diagnosis of syphilitic aortic valve incompetence, and of angina of effort from coronary ischaemia due to syphilitic aortitis.

The prognosis in such a case depends entirely upon the state of the heart muscle. The chief cardiovascular targets of syphilitic infection are the aorta and the aortic valve cusps. The aortitis may interfere with coronary flow either during the early stage of active progressive inflammation when obstruction results from the inflammatory swelling or after the active inflammation has been followed by fibrosis and progressive scarring, again producing coronary interference. The inflammatory swelling is amenable to treatment, the fibrous scarring is not.

In this case the left ventricular muscle remained healthy, for syphilis does not directly attack heart muscle. The angina of effort was due to temporary narrowing of the coronary mouths from active inflammation. Successful treatment of this restored the normal passage-way and removed the pain. Healthy heart muscle can always cope with an aortic leak by hypertrophy and compensatory dilatation. The prognosis in syphilitic cases will therefore depend entirely upon the presence or absence of coronary obstruction by the aortitis and upon the stage of aortitis reached by the disease. If the ischaemic lesion is sufficiently early prognosis may be excellent. The aortic valvular distortion due to syphilis is by comparison of relatively little importance.

Subacute Bacterial Endocarditis of the Aortic Valve. Normal Function after 7½ Years

Mr. F. had suffered from rheumatic fever at the age of 6. At the age of 45 a dental extraction was performed under penicillin cover lasting for 24 hours. Three months later he noticed irritability and lassitude, and a month before he was examined, five months from his dental extraction, he began to suffer from severe night sweats and transient pain in the shoulder joints. On examination he looked a little pale. The heart rate was 88, the rhythm was regular, and the blood pressure was 130/54. The murmur of aortic regurgitation was present. No mitral diastolic or systolic murmurs were audible. The spleen was not palpable. Radiologically the heart was slightly enlarged, the transverse diameter being 14.3 cm. by orthodiagraph. This enlargement chiefly involved the left ventricle. Watch was kept on his temperature, and fever was found to be present. *Streptococcus viridans* was isolated from his blood culture. He was treated for six weeks with full doses of penicillin, and made an excellent recovery.

Seven and a half years later he was in good health. He was free from shortness of breath, chest pain, or other symptoms, and was living a normal active life. Over this period of time the blood pressure gradually rose to 176/76.

About 75% of patients with subacute bacterial endocarditis make a perfect recovery except for the inflammatory distortion of the affected valve. The remaining 25% die of gradually increasing renal failure, the result of multiple embolism, of progressive heart failure due to myocardial failure, probably due to embolism similar in type to that causing the renal lesion, the remainder from cerebral or pulmonary thrombo-embolic complications. This patient, who was left with distortion of the aortic valve only, was very little inconvenienced by this, for the disease has no long-term direct effect upon the heart muscle. Fortunately, also, the valvular fibrosis nearly always produces regurgitation and not stenosis, probably because, for some unknown reason, subacute bacterial endocarditis is far more likely to occur in mitral and aortic valves in which regurgitation rather than stenosis was originally present. In this case the healthy left ventricular muscle was able to accommodate, per beat, both the normal diastolic filling from the left auricle and the extra diastolic flow from the aorta due to the aortic valve deformity. Furthermore, the left ventricular muscle was able to eject its double load without distress.

Right Bundle-branch Lesion Present for 18 Years Without Change

Mr. G. had had rheumatic fever in 1930 at the age of 41. He was first seen in August, 1935, when he was 46. He at that time complained of heart consciousness and palpitation, clearly due to premature beats. He was, however, playing tennis and golf and living a normal life. A year later he was re-examined. No physical abnormality was discovered. The blood pressure was 130/72. The three-lead electrocardiogram was normal. There was no cardiac enlargement radiologically. In 1938, at the age of 49, the clinical condition was unchanged, but the electrocardiogram showed a complete right bundle-branch lesion. This has persisted without change for eighteen years.

He remained free from significant symptoms until January, 1954, when he was 65. He then rather suddenly noticed shortness of breath while walking at an ordinary speed, and pain in the left arm, produced by walking and synchronous with the dyspnoea. This disappeared when he rested, and returned when he resumed his walk. Two months later he was seized with severe chest pain radiating to the left arm. Collapse and sweating were both present. On examination he was found to have auricular fibrillation. Although the electrocardiogram was inconclusive there was no doubt clinically that he had had a myocardial infarction. He was treated in the usual way by rest followed by gradual resumption of his normal life, but at a considerably lower level of activity.

The electrocardiogram is highly regarded, rightly, as giving invaluable information in cardiac conditions. By the lay public and by some practitioners it is so highly revered as the final court of appeal that deviations from the normal in it are considered to indicate grave trouble. There is no electrocardiographic picture which shows a greater disturbance of the normal pattern graph than a bundle-branch lesion, left or right. It is important, therefore, to know that such an apparently gross abnormality can be present for years (in this case a period of eighteen years) as the only indication that there is anything wrong. Undue emphasis on an isolated electrocardiographic finding could in such a case induce a state of premature cardiac invalidism long before any real reason for this was present.

The reason for this patient's continued good cardiac health in spite of the presence of the bundle-branch lesion was no doubt the fact that the bundle and its branches occupy a small area of heart muscle tissue. If a pathological lesion happens to be so placed as to interfere with the bundle of His, or with either of its branches, such a lesion need only be very small in extent to produce complete interference either with the bundle or with its right or left subdivision. Such a lesion, although minimal, can distort the electrocardiogram grossly, but, being small, will not interfere with the general efficiency of the pumping power of the heart.

Angina of Effort from Coronary Disease (26 Years)

Mr. H. has had classical angina of effort for 26 years. At the age of 37 he first noticed pain in the chest only during exercise. This disappeared quickly when he rested. At that time the three-lead electrocardiogram showed no abnormality. This exercise pain was first present for a period of two years, after which he recovered so well as to be able to play cricket, tennis, and squash. At the age of 47 he noticed cramp in his left calf, which came on while playing tennis. His foot went white and cold. A year later his angina of effort reappeared. The pain was felt across the upper chest and it radiated to both arms. It was usually induced by walking for a distance of about 50 yards. It was accelerated by hurry and prevented by walking slowly. Stairs and emotion also precipitated it and glyceryl trinitrate relieved it. At this time the only abnormalities were a slightly raised diastolic blood pressure (152/100), and in the electrocardiogram a low T wave and a small Q wave in lead II, and an inverted T wave and larger Q wave in lead III.

He was seen again at the age of 50. The angingal pain was unchanged but he still suffered from intermittent claudication in the left leg after walking 50 yards or so. He was re-examined at the age of 52. His general health was remarkably improved and his angingal pain, though occasionally noticed, was much less severe. He had again suddenly suffered intermittent claudication, this time in the right lower leg. The dorsalis pedis and posterior tibial arteries could not be felt on the right side, but were present on the left.

Four years later he retired from his work as secretary to a hospital. His angina of effort was slight, but the intermittent claudication in the right leg still worried him. His condition remained unchanged until he was re-examined seven years later at the age of 63. His intermittent claudication was still somewhat of a handicap; his angina of effort was not evoked unless by considerable exertion. This time, however, he had recently suffered a thrombosis of the left central retinal vein. His heart was clinically normal, the rhythm regular, and the blood pressure 164/92. Radiologically the heart was bulky but within normal limits for a man of his physique. The electrocardiogram showed a flat T wave in lead I and inversion of the T wave from V4 to V7 inclusive. The T wave was also inverted in leads II, III, and VF, and the Q wave remained increased in size in lead III and was visible in leads II and VF.

He thus had had angina of effort for 26 years. The history from the start was classical, and the electrocardiogram throughout most of this time showed evidence of coronary

disease. In this case it is clear that the amount of coronary arteriosclerosis must have been small and that the coronary vessels remained free from further deterioration. It is also probable that some revascularization of the ischaemic area had developed. He had always been a highly strung sensitive person. It is also therefore likely that his visceral sensations were felt more easily from a less degree of local disease than would have been the case in a more phlegmatic patient. Not only was the coronary disease non-progressive, but the state of the heart muscle as a whole must have remained good, thanks to an adequate blood supply. No hypertensive factor was present to burden the heart.

Posterior Myocardial Infarction (23 Years)

Mr. I., aged 72, had suffered from a myocardial infarction at the age of 49 when he was under the care of Sir John Parkinson. He was in a nursing-home for six weeks. He made a good recovery and remained well for 23 years.

The recent history was that he had had slight shortness of breath for a few days, and considerable swelling of the legs and feet for the same length of time. He had noticed that he had bruised rather easily during the preceding fortnight. His physical state during these 23 years had remained good. His activities were normal and he had been free from shortness of breath and chest pain.

On examination marked pitting oedema of the legs and feet was present. The heart, however, was clinically perfect. The blood pressure was 136/80. Radiologically the transverse diameter by orthodiagraph was 13 cm., which was normal for his age and physique. The urine contained no albumin. The electrocardiogram showed large Q waves and inversion of the T waves in leads II, III, and VF. It was clear that the oedema was not cardiac, since he had had no shortness of breath, nor was it renal, since there was no albuminuria. A tourniquet test was done on his arm and multiple fresh petechiae appeared below the band.

He had thus made a good functional and physical recovery from his posterior myocardial infarction, and this recovery was still persisting when he was seen 23 years later. The reasons for this were that temporary injury to the heart muscle was compensated for by scar formation at the site of the infarct, also, in all probability, by successful collateral circulation from the near-by coronary branches, and by hypertrophy of the healthy heart muscle to such a degree that, on balance and after a period of readjustment, he was left with as good a functioning heart as he had had before. No handicaps in the shape of hypertension or of serious atheroma of the other coronary branches interfered with this perfect recovery.

Hypertension for 25 Years

Mr. J., at the age of 15, was found by a doctor to have a higher blood pressure than normal. Two years later, when he was playing vigorous Rugby football, this discovery was confirmed. Figures were first available from an examination when he was aged 22, the blood pressure in the arms being 240/160 and in the legs, by palpation, 210. This excluded the possibility of coarctation of the aorta, further evidence of which condition remained absent. At the age of 23 the figures were 185/130. When first examined by me he was symptomless, having no shortness of breath on exertion, no chest pain, headaches, or visual defects. The retinal vessels showed an early grade I hypertensive change. The blood pressure was 230/140. The first sound at the apex was reduplicated. The aortic second sound was accentuated. The electrocardiogram was normal. Radiologically the heart was slightly bulky for his build and age, the transverse diameter being 13.2 cm. by orthodiagraph. The left ventricle was a little prominent and the aorta also.

Nine years later, when he was 41, he still felt perfectly well. The blood pressure was 212/136. Radiologically the heart was slightly larger, the transverse diameter being 14.7 cm. The electrocardiogram remained normal as regards the standard leads, but the T wave was a little flat in V5.

At the age of 42 he was re-examined. The blood pressure was 208/126. The retinal vessels showed no change from their previous state. Radiologically the heart was still slightly larger, the transverse diameter being 15.5 cm.

Three months later he was seized with the symptoms of myocardial infarction, from which he died very suddenly.

He had clearly suffered from prolonged severe hypertension. This remained harmless to his health or his life for 25 years, the absence of complications during that time being due to the excellent state of his arteries. The adequate supply to his heart muscle enabled the left ventricle to remain healthy and to support the hypertensive burden without in any way failing. Atheroma, however, supervened towards the end, and a fatal coronary thrombosis caused his death. The increasing heart size over the last few years was ominous, although symptoms were absent until the end.

He was a sensible and helpful patient, and it was a tragedy that his disease terminated shortly before the introduction of effective hypotensive drugs. Sympathectomy was thought of, but its failure in so many similar cases led to its not being tried, especially in a symptomless patient.

Hypertension, Unchanged for 11 Years

Mrs. K. was first seen at the age of 65 for attacks of giddiness. She had incidentally a raised blood pressure. The detailed history of her symptoms suggested that the attacks of giddiness were vestibular in origin, the function of the middle ear being affected by local arteriosclerosis. On examination the heart rate was 90 and the blood pressure 230/126. The heart was normal clinically and radiologically. The orthodiagraph gave a normal transverse diameter of 11.5 cm. The electrocardiogram showed upright T waves in the left ventricular leads and no evidence of left ventricular hypertrophy.

trophy. She was seen eleven years later, when she was 76 years old. Her attacks had continued. Her description of the attacks was now not so clear, and it was difficult to disentangle the possible causes as between vestibular disturbance, vasovagal faintness, and functional or psychogenic influence. On examination she again had a nervous tachycardia of 90; the blood pressure was 220/120. The heart remained clinically normal. Radiologically there was some increase in size, the transverse diameter being 13.7 cm. The electrocardiogram was that of a normal horizontal heart. The unipolar limb leads and the unipolar precordial leads V1 to V6 were all used.

She clearly was a woman in whom there was a static, so-called benign, hypertension. Since the heart becomes more bulky in normal people in the 70's and 80's the increase in the transverse diameter is not so significant as it would have been in a younger individual. The hypertension as such was clearly harmless, and her case was a good example of the fact that the prognosis in elderly women with a raised blood pressure is so frequently extremely good.

Conclusions

It is not claimed that this record of long-term cases can provide any accurate statistical guide to the prognosis in the various conditions mentioned. The purpose is to offer proof that a prolonged period of good health may be expected in individual patients. From this it follows that the clinician must carefully analyse all his cases, as individuals, from the point of view of the state of the heart muscle at the time of examination, the changes of deterioration or improvement in the state of the heart muscle, the absence or the presence of mechanical handicaps which might interfere with cardiac efficiency, and the removability of these by medical or surgical means. He should also, so far as the facts will allow him, emphasize to his patients the possibilities of a good prognosis so that their co-operation in a positive constructive line of life may be obtained. It is only by

so doing that those individuals in whom a good prognosis is possible will be enabled to achieve it to its maximum extent.

BLOOD TRANSFUSION IN OBSTETRIC HAEMORRHAGE

WITH REFERENCE TO VALUE OF ESTIMATIONS OF BLOOD VOLUME

BY

W. G. MacGREGOR, F.R.C.S., M.R.C.O.G.

*Late Lecturer, Department of Obstetrics and Gynaecology,
University of Bristol*

AND

A. D. TOVEY, M.D.

Blood Transfusion Officer, Middlesex Hospital; Late Registrar, South-Western Region Blood Transfusion Centre, Bristol

This paper is concerned with the position of blood transfusion and the value of blood-volume estimations in obstetric shock, mainly in cases of concealed accidental haemorrhage. Grant and Reeve (1951) and Crosby and Howard (1954) have shown that estimations of blood volume are of considerable value in the treatment of shock due to blood loss in battle casualties. This work is being followed up on civilian casualties in the Birmingham Accident Hospital by Clarke, Topley, and Flear (1955) and Clarke and Flear (1956). In view of this, one of us (A. D. T.) estimated the blood volume in a number of cases of obstetric haemorrhage as a guide to the amount of blood to administer. In the treatment of obstetric shock the problem of when and in what quantity to administer blood can be a difficult one. This is especially true of concealed accidental haemorrhage, and there is diversity of opinion regarding the best methods of local and general treatment. Clarke and Fisher (1956) state clearly the difficulties arising from the provision of pint bottles of blood. A bottle of blood contains 100 to 120 ml. of anticoagulant, and in fact we transfuse approximately 400 ml. of the whole blood in a bottle. This explains our stating the amounts of blood transfused in millilitres; thus a transfusion of five bottles approximates to 2 litres of whole blood.

By "severe accidental haemorrhage" we mean cases where the patient is admitted with concealed and/or revealed accidental haemorrhage and in whom the foetal heart cannot be heard. Crichton (1950), in an analysis of 120 cases in Capetown, gave a maternal mortality of 10.9%. Sheehan and Moore (1952) described 700 cases of severe accidental haemorrhage with 75 maternal deaths—a mortality of 10.7%—and their criterion of severity was a dead child *in utero*.

Our views on local treatment in accidental haemorrhage are based on those of the late Professor Marshall Allan (1940), of Melbourne, who taught that artificial rupture of the membranes was advisable. Professor Allan followed this treatment with pituitary extract, but we do not use intramuscular pituitary extract or oxytocin because of the possible association of afibrinogenaemia with excessive uterine action. We are coming more and more to the view that caesarean section has little to offer in this condition except in the mild case associated with

foetal distress. Townsend (1955) states: "At the Royal Women's Hospital, Melbourne, we have adopted a very conservative method of treating accidental haemorrhage. We consider that there is no maternal indication for caesarean section in accidental haemorrhage." He does not mention the use of oxytocin. Some of our cases were complicated by afibrinogenaemia, and if present this was treated with intravenous fibrinogen or concentrated plasma. The whole problem of the place of blood transfusion is emphasized by the following tragic case:

A gravida-1 aged 22 was admitted at 40 weeks with severe revealed and concealed accidental haemorrhage. The blood pressure was 135/80 and the pulse rate 110, and the urine contained albumin. The uterus was tense and tender and the foetal heart was not heard. Low rupture of the membranes was performed, and over the next 20 hours the blood pressure varied between 110/80 and 165/115, but the pulse rate rose and stayed at 150 to 160. During this time 800 ml. of blood and 1,200 ml. of dextrose saline were given. Forceps delivery of a stillborn male infant weighing 3,746 g. was followed by general collapse of the patient and a post-partum haemorrhage of 2,400 ml. of fresh blood and 900 ml. of old clot. No further vaginal blood loss occurred. The pulse rate remained elevated to 160 and the blood pressure fell progressively over the following 12 hours despite transfusion of 1,600 ml. of blood. At the end of this time the patient was pale, sweating, restless, and anxious. Sudden collapse and death occurred.

Clinical assessment of this case on admission gave a false impression of the state of the patient's circulating blood volume, and we are now of the opinion that it would have been much safer if the patient had been transfused more actively. She might then have been fit to withstand the post-partum haemorrhage.

Subsequently, a case of traumatic post-partum haemorrhage was treated successfully by the administration of 13,600 ml. of blood (Lennon and Tovey, 1956), and one of us (MacGregor, 1955) reported two cases of severe accidental haemorrhage transfused with 9,600 ml. and 10,400 ml. of blood respectively. Both these patients had excessive post-partum haemorrhages but no circulatory collapse; the urinary output following delivery was satisfactory.

Haematological Methods

On admission, apart from the clinical assessment of the case, blood samples were taken and the following tests performed:

Haemoglobin.—This was estimated on a heparin sample, using an M.R.C. grey wedge photometer.

Packed Cell Volume.—Duplicate tests were performed, using Wintrobe 10 by 0.25 cm. haematocrit tubes, and the blood was centrifuged at 3,000 r.p.m. for 30 minutes in a standard M.S.E. centrifuge.

Plasma Fibrinogen.—Two methods were used: (1) A "bedside" method which was performed in order to give a quick rough guide to the presence of a fibrinogen deficiency before the result of the longer quantitative method was available. Thus treatment, if required, could be administered quickly. The "fibrindex" method as recommended by Scott (1955) was employed. (2) The micro-Kjeldahl method as described by Harrison (1947).

Blood Group.—If not already known, the patient's blood group was determined and a number of bottles of blood were cross-matched.

Estimation of Blood Volume.—As most of the patients are shocked and need active treatment very quickly, a method must be used which is simple and rapid, and causes as little disturbance to them as possible, thus allowing the treatment to be unhampered by the investigations and in-

vestigations. The direct method, using the dye Evans blue (T.1824) as described by Mollison (1951), was therefore employed, as it proved to be the most satisfactory one for routine use. Occasionally, when a repeat estimation several hours later was required, red cells tagged with ⁵¹Cr were used. It was realized that, especially in obstetric patients, the direct method employing the dye does give a rather larger error than a red-cell-tagging method (Verel, Bury, and Hope, 1956). This is due to the fact that the body/venous haematocrit ratio appears to vary in these cases. In view of this variation no ratio was used. In most cases the changes in blood volume were very large and so the error was minimized. After obtaining a "blank" venous sample with minimal stasis 20 ml. of dye (approximately 15 mg. of the dye in 20 ml. of isotonic saline) was injected through the same needle and a sample taken from another vein after 10–15 minutes' interval. In the early stages samples were taken at 10 and 20 minutes, but as both gave almost identical results only one sample was taken in subsequent cases. The dye concentration was measured in an EEL photometer with 620 m μ filter, and 3-ml. volumes of plasma were used, the anticoagulant being heparin. No sample was haemolysed and no gross lipaemia was found. In one case the plasma was faintly lipaemic, but the standard gave readings identical with the ones obtained in other cases where the plasma was clear. The standard consisted of 0.02 ml. of the dye added by means of an "agla" micrometer syringe to 3 ml. of plasma from the "blank" sample.

In a number of cases admitted to the Obstetric Unit blood-volume estimations were made in order to assess blood requirements. The following six cases are reported.

Case 1

A gravida-1 aged 22 was admitted to hospital at 34 weeks with a diagnosis of concealed and revealed accidental haemorrhage. The patient was moderately shocked, and on abdominal examination the uterus was hard and "woody"; no foetal heart was heard. Her pulse rate was 84 and her blood pressure 130/80. Blood examination revealed a haemoglobin level of 10.4 g. per 100 ml. (70%) and a packed cell volume of 28%. The bedside fibrinogen test gave no firm clot in 30 seconds, and the laboratory test gave a result of 190 mg. of fibrinogen per 100 ml.

The blood volume was found to be 3,300 ml. (47 ml./kg. of body weight), consisting of a plasma volume of 2,500 ml. (36 ml./kg.) and a red-cell volume of 800 ml. (11 ml./kg.). We attempted in all cases to restore the patient's blood volume to 80–90 ml./kg. of body weight, and on this basis calculated that the patient required 2 litres of blood, which was given in two hours. The membranes were ruptured and the patient went into labour. However, in spite of this transfusion, the pulse rate rose to 120, the blood pressure remaining at 120/90. A further 1,200 ml. of blood and 1,200 ml. of plasma was given in the next four hours and the pulse rate fell to 108, the blood pressure remaining unchanged.

Eight hours after admission the patient was delivered, by forceps, of a fresh stillborn female infant. The total estimated loss was 2,100 ml., which included a post-partum haemorrhage of 1,200 ml. A further 400 ml. of blood was given, making a total of 3,600 ml. of blood and 1,200 ml. of plasma. Subsequently the patient progressed well; her post-partum urinary output was adequate. The haemoglobin level on the fourth day was 14.8 g. per 100 ml. (100%).

Comment.—In spite of a normal pulse rate and blood pressure on admission the patient was deficient of about 2 litres of blood. She withstood the post-partum loss well because she had been adequately transfused.

Case 2

A gravida-4 aged 31 was admitted at 31 weeks with a diagnosis of concealed and revealed accidental haemorrhage. She was not shocked, the pulse rate being 70 and the blood

pressure 135/85. The uterus was tense and tender, foetal parts were not palpable and the foetal heart was not heard. The urine contained albumin. The haemoglobin level was 12.4 g. per 100 ml. (84%) and the packed cell volume 34%. Blood taken had not clotted after 10 minutes and when it finally occurred clot retraction was poor.

The blood volume was 3,800 ml. (66 ml./kg.), consisting of a plasma volume of 2,500 ml. (44 ml./kg.) and a red-cell volume of 1,300 ml. (22 ml./kg.). It was estimated that 1,200 ml. of blood was required, and this was given.

Low rupture of the membranes was performed and five hours later she was delivered of a stillborn infant weighing 1,700 g. A post-partum haemorrhage of 600 ml. occurred.

The patient gave no cause for alarm and her convalescence was uneventful. The post-partum urinary output was satisfactory and on no day was the volume less than a litre.

Comment.—This was another case where the blood pressure and pulse rate did not suggest a depleted circulating blood volume (Gibberd, 1948).

Case 3

A gravida-1 aged 18 was admitted at 36 weeks following a mild ante-partum haemorrhage. Clinically she was not shocked, her pulse rate was 92, and blood pressure 150/110. The urine contained albumin, the uterus was enlarged to 36 weeks, foetal parts were palpable, and the foetal heart was heard. The haemoglobin was 14.4 g. per 100 ml. (97%) and the packed cell volume 40%.

The blood volume was found to be 5,100 ml., which was within the normal range for the patient's weight. Labour began four hours after admission, and four hours later a live female infant weighing 4 lb. 8 oz. (2,040 g.) was born; after 11 hours it died of atelectasis and tentorial tears. There was a post-partum haemorrhage of 500 ml., and 800 ml. of blood was transfused. The puerperium was uneventful.

Comment.—In this case estimation of the blood volume confirmed the clinical impression that there was no deficiency of circulating blood volume.

Case 4

A gravida-3 aged 33 was first admitted at 29 weeks following a mild ante-partum haemorrhage, and a provisional diagnosis of placenta praevia was made. She remained in hospital until the 37th week, when the bleeding recommenced. Lower segment caesarean section revealed a central placenta praevia. The blood loss at operation (estimated to be about 3,000 ml.) was excessive and 2,000 ml. of blood was transfused rapidly but the blood pressure did not rise above 90/? and the pulse rate was 124. The patient was restless and shocked. The blood volume was 3,100 ml. (48.5 ml./kg.); the plasma volume 2,100 ml. (33 ml./kg.), and the red-cell volume 1,000 ml. (15.5 ml./kg.). It was estimated from her weight that there was a blood-volume deficiency of 2 litres. In view of this a further 2,000 ml. of blood was administered—800 ml. quickly and the remainder over eight hours. The blood pressure rose to 120/80 and the pulse rate fell to 70.

She progressed uneventfully and her haemoglobin was 14.7 g. per 100 ml. (99%) on the fourth post-partum day. Urinary output following the delivery was satisfactory.

Comment.—The clinical impression that the blood volume had not been sufficiently restored was confirmed by estimation of the blood volume. Although after the transfusion of 2,800 ml. of blood her pulse and blood pressure were within normal limits, she still required a further 1,200 ml.

Case 5

A gravida-7 aged 32 was admitted at 22 weeks with an intrauterine foetal death. The uterus was enlarged only to the size of a 14-weeks cyesis, and she was losing blood per vaginam.

O—4

Evacuation of the uterus was performed because of the persistent loss, and, although after this the uterus contracted well, the blood loss continued. Intrauterine packing did not control the loss, and hysterectomy was performed. By the end of the operation 2,000 ml. of whole blood had been given. The bedside fibrinogen test showed a severe depletion. In view of this, 800 ml. of triple-strength plasma was given with a fibrinogen content of approximately 6 g. This was followed by 6 g. of fibrinogen. Blood transfusion was continued, and 22 hours after operation the patient had received 8,800 ml. of blood and 800 ml. of triple-strength plasma. The blood loss had ceased and the fibrinogen test revealed a normal clotting-time. At this stage the blood pressure was 80/50 and the pulse rate 110. The blood volume was calculated to be 2,600 ml. A further 3,200 ml. of blood was given and the pulse rate fell to 90. The patient progressed well for 16 days and her haemoglobin on the fourth post-partum day was 13.6 g. per 100 ml. (92%). On the 16th day a brisk vaginal haemorrhage occurred, necessitating the transfusion of a further 1,200 ml. of blood. Subsequently her convalescence was uneventful. Altogether she had received 13,200 ml. of blood and 800 ml. of concentrated plasma. Although it appeared that the blood loss had been replaced by massive blood transfusion, the clinical impression of a markedly depleted blood volume was confirmed by laboratory estimation.

Comment.—Barry, Geoghegan, and Shea (1955) believe that afibrinogenaemia rarely develops within eight weeks of intrauterine death, and this case agrees with their findings.

Case 6

A gravida-3 aged 34 was admitted at 30 weeks with a diagnosis of concealed and revealed accidental haemorrhage. She was pale and shocked; the pulse rate was 104, the blood pressure 170/100, and the urine contained albumin. The uterus was enlarged to 36 weeks and was tense and tender. The foetal heart was not heard and blood-stained liquor drained per vaginam. She was given 600 ml. of plasma and 300 ml. of blood. The blood volume was found to be 3,900 ml. (71 ml./kg.), consisting of a plasma volume of 3,100 ml. (56 ml./kg.) and a red-cell volume of 800 ml. (15 ml./kg.). The haemoglobin level was 6.7 g. per 100 ml. (45%). She was regarded as a case of toxæmic accidental haemorrhage superimposed on a chronic anaemia.

The membranes were ruptured and 1,600 ml. of blood was given over a period of eight hours, the haemoglobin level being raised to 10.5 g. per 100 ml. (71%). Because of her long-standing anaemia before admission the plasma volume was not depleted to the same extent as her red-cell mass. In view of this it was decided not to transfuse her any further with whole blood but to use concentrated red cells, and 400 ml. was given. Eighteen hours after induction she was delivered of a live premature infant weighing 2 lb. 6 oz. (1,080 g.), and this was followed by a post-partum haemorrhage of 700 ml. The patient's general condition had improved, the blood pressure being 200/130 and the pulse rate 72. There was no evidence of venous congestion. However, the blood pressure continued to rise and two hours after delivery it was 210/140. Bromethol, 4 ml., was administered per rectum. Five hours after delivery the blood pressure was 200/120. During the next three days it ranged between 200/115 and 225/120, and ominously the urinary output was scanty, being 90 ml. on the first, 120 ml. on the second, and 400 ml. on the third post-partum day. On the fifth day she became distressed and cyanosed, the blood pressure remaining at 225/120. Digoxin, 0.5 mg., and aminophylline, 0.25 g., were given intravenously and a venesection was performed. She did not improve, and died on the seventh post-partum day.

Post-mortem Findings.—Each pleural cavity contained about 300 ml. of yellow fluid, and the lungs had considerable areas of pulmonary oedema. The heart showed slight hypertrophy of the left ventricle. The left kidney

weighed 210 g. and was swollen and pale. The right kidney weighed only 110 g. and showed severe chronic pyelonephritis.

Comment.—Until the patient developed hypertensive cardiac failure on the fifth day of the puerperium there had been no pulmonary congestion or distension of the neck veins to suggest circulatory overloading. If too much blood had been given at the time of delivery she would have developed circulatory failure within 48 hours. In fact, her general condition improved over this period. Bull, Joekes, and Lowe (1955) emphasized that in the case of patients who are pre-eclamptic the prognosis in accidental haemorrhage is more serious, and we suggest that underlying renal disease is prejudicial to the outcome.

Discussion

Grant and Reeve (1951) demonstrated clearly that in some instances a patient could have a circulating blood volume of 70% of normal with no clinical evidence in the form of variations in pulse rate and blood pressure. This appears to be the case in obstetric haemorrhage, and explains Gibberd's (1948) observation that in accidental haemorrhage the initial pulse rate may be slow having regard to the poor general appearance of the patient. If in a shocked patient blood is administered to restore blood pressure and pulse rate to normal, the circulating blood volume may still be greatly depleted, and if a further haemorrhage occurs the outcome may be fatal. A further interesting point is that the blood "lost" may not be completely accounted for. Crosby and Howard (1954) were unable to account for the total blood loss in their cases of severe battle injuries, and this has been shown to be true in obstetric cases (Verel *et al.*, 1956). We have confirmed this observation, as, after careful estimation of the blood loss and replacement of this amount, the patient may be left with a depleted circulating blood volume as in Case 1. It is difficult to believe that the difference between the estimated loss and the true state of the circulation can be due to blood loss into uterine muscle.

In our experience assessment of the amount to be replaced needs to be guided wherever possible not only by the measured blood loss but also by measurements of blood volumes. The transfusion of large volumes of blood guided by estimations of blood volume has not produced any untoward complications. In no case did the patient develop signs of overloading of the circulation. Even when 12,000 ml. of blood was given in a few hours, as in Case 5, the patient not only showed no sign of venous congestion but continued to improve.

Many patients admitted with accidental haemorrhage are initially hypertensive, and the blood pressure on admission is often of very little help and may even be extremely misleading. The disease may be complicated by severe anaemia (Case 6). If estimation of the blood volume reveals a considerable depletion in the presence of an apparently normal or slightly raised blood pressure, the only criteria of response to treatment are a falling pulse rate and the general demeanour of the patient.

If the pulse rate continues to rise, the patient is in need of further transfusion. Our aim in these cases has been to bring the pulse rate down to the region of 100. We have found that where no facilities are available for estimating the blood volume the following scheme of management is of value. If a patient has been seemingly adequately transfused, but clinically the general condition, pulse rate, and possibly the blood pressure are unsatisfactory, an examination is made of the neck veins and the lung bases. If there is no evidence of circulatory overloading 800 ml. of blood is given within 10 minutes, a careful note being made of the blood pressure and pulse rate. A falling pulse rate indicates a previously depleted circulating blood volume, and transfusion should be continued until the pulse rate approaches 100. This therapeutic test has been found to be safe so long as a careful watch is kept for circulatory overloading. In practice we have found that in the large majority of cases where the patient has not responded to an

apparently adequate amount of blood she has been suffering from under-transfusion, and we believe the dangers of over-transfusion have been unduly emphasized. This is in agreement with the views of Clarke and Fisher (1956) in cases of civilian trauma. The ultimate fate of the patient and her pituitary and renal function will be seriously jeopardized if prompt and adequate treatment of the shock due to blood loss is not combated.

Grant and Reeve (1951) say, "The first thing the clinician should learn is that there is hardly one sign of shock which is constant." An important observation is the general demeanour of the patient. The patient who is restless, anxious, pale, and sweating as the result of blood loss may not require sedation with morphine. We believe that intravenous morphine in the severely shocked anaemic patient may well prove fatal, and we have demonstrated in one case that with adequate blood transfusion controlled by estimation of the blood volume the patient with the above symptoms will soon be safely asleep without sedation, even in severe accidental haemorrhage.

Two of the maternal deaths in O'Donel Browne's series (1952) had caesarean section performed, and he commented that early blood transfusion had been neglected.

Where adequate treatment was administered the urinary output remained satisfactory, and the patients had a diuresis in the immediate post-partum period. This latter effect was interpreted as being due to the prevention of prolonged renal anoxia. In Case 6 the urinary output was unsatisfactory, but necropsy revealed underlying renal disease without any evidence of renal cortical necrosis.

Crichton (1950) states: "The ultimate prognosis after accidental haemorrhage is not good. Stroink (1934) found that 51% of patients had developed arteriosclerosis, nephritis, or apoplexy in a follow-up extending from two to twenty years. de Snoo (1936) conducted a similar analysis and found 61% to be hypertensive."

Summary

Estimations of the blood volume are of considerable help in the treatment of severe obstetric haemorrhage and are a guide to the amount of blood to be administered.

In some instances patients may have a circulating blood volume of 70% of normal with no clinical evidence in the form of variations in pulse rate and blood pressure. The blood loss may not be completely accounted for (Case 1).

In severe accidental haemorrhage the blood pressure on admission may mislead because many patients are initially hypertensive. The disease may be complicated by anaemia.

The patient suffering from severe obstetric haemorrhage should have the haemoglobin, packed cell volume, plasma fibrinogen, blood group, and blood volume determined on admission.

When blood is transfused in adequate amounts the immediate complication of renal cortical necrosis is averted because renal anoxia is of short duration and the remote prognosis may be improved. The cases described illustrate this and the value of studies of the blood volume.

The aim of transfusion should be to enable the patient to withstand the subsequent effect of haemorrhage and trauma, and we have attempted to restore the patient's blood volume to 80–90 ml./kg. of body weight.

There is a tendency to under-transfuse cases of obstetric haemorrhage. This can be avoided by estimating the blood volume, and a clinical test is described should facilities for this not be available.

It is emphasized that a bottle of blood contains 400 ml., not a "pint," of blood.

There is no maternal indication for caesarean section in severe accidental haemorrhage.

We are indebted to Professor G. Gordon Lennon and Dr. Geoffrey H. Tovey for their help and advice, and to Dr. F. J. Lewis for the fibrinogen estimations.

"ENDOGRAFIN" AS A MEDIUM FOR HYSTEROSALPINGOGRAPHY

BY

D. K. L. DAVIES, M.B., B.Sc., D.M.R.D.

I. ROCKER, M.B., M.R.C.O.G.

Registrar, Professorial Unit, United Cardiff Hospitals

With the advent of intensive investigation of the problems of infertility, the following report is made of our experience with the use of "endograftin" as a contrast medium in hysterosalpingography.

The continued interest shown in the use of new media for this radiographic examination suggests that no for this radiographic substance has yet been evolved, entirely satisfactory substance has yet been evolved, although it is over 45 years since Rindfleisch (1910) first visualized the outline of the uterine cavity with bismuth paste. The pioneer work of Cary (1914) and of Rubin (1915), who independently introduced collargol, was followed by the use of different solutions containing halogen salts and later by the development of iodized oil, of which "lipiodol" is the best-known representative. Iodized oil was applied to gynaecological problems by Heuser (1925, 1926) and remained almost the sole agent employed for many years. The disadvantages of iodized oil are too well known to warrant detailed repetition. They include the danger of embolic phenomena and of extensive foreign-body reactions within the tubes and in the peritoneal cavity.

Later, the organic iodine-containing compounds were prepared and adopted for salpingography, either in their

original form or in some modified form. The desirable properties expected of these media may be briefly summarized as: (1) the material injected should have no undue likelihood of irritating existing inflammatory conditions and should be absorbed within a few hours, leaving no trace behind in the tubes or in the peritoneal cavity; (2) it should be dense enough to cast a clear shadow; (3) it should be sufficiently viscous so that the outline of the tubal lumen can be accurately visualized to demonstrate strictures or other abnormalities; (4) its consistency should allow it to pass through the uterus and Fallopian tubes slowly enough to be filmed accurately; (5) its consistency should be such that a reasonably watertight seal is obtained in the cervix without resorting to an unnecessarily traumatic cannula; and (6) the agent should give rise to a minimum of pain and discomfort to the patient.

It is generally agreed that aqueous solutions do not generally fulfil these criteria satisfactorily, as their viscosity is too low. Such solutions, however, have the advantage of being relatively non-irritating, but, as with more viscid media, spasm may prevent even watery solutions from demonstrating patency.

In order to increase the viscosity of contrast media several substances have been combined with the organic iodine compounds. Titus *et al.* (1937) investigated dextrose, starch, glycerin, propylene glycol, tragacanth, and acacia combined with methiodal sodium ("skiodan"). The optimum solution was considered to be 40% methiodal sodium in 20% acacia, and this substance has been widely used. Similarly, "rayopaque," which included polyvinyl alcohol, and, more recently, media combined with dextran, carboxymethylcellulose, and polyvinylpyrrolidone (P.V.P.) (widely used as a plasma extender) have been employed. None has been entirely satisfactory. Solutions containing P.V.P. have excellent handling characteristics, have given rise to little pain, and have been technically suitable. Solutions of P.V.P. have been extensively used as plasma extenders, and the excretion of P.V.P. has been extensively studied. Altemeier *et al.* (1954) said that up to 49% of 1,000 ml. of a 3.5% solution of P.V.P. was retained in the body for at least 20 months. It has been suggested that some of this material is retained in the reticulo-endothelial system. Campbell *et al.* (1954) claim that 65–90% of P.V.P. is excreted by the kidneys within 48 hours of the injection. One can safely say that it is not clear what percentage of P.V.P. is retained and what are the consequences, if any, of this retention, though there is no proof of any untoward effect and so far there is certainly no confirmation of the unpublished report of possible carcinogenic action in experimental animals.

Endograftin is an aqueous solution of the methyl glucamine of N:N-adipic-(amino-2:4:6-triiodobenzoic acid). It contains no supplements to increase its viscosity, the latter being determined by the molecular size and the concentration (70% as compared with "biligradin forte" 50%). Viscosity measurements at body temperature are endograftin 18 centipoises, biligradin forte 6 centipoises. Biligradin forte has been used extensively in the investigation of the biliary tract, the incidence of serious reactions in this application having been notably low.

Technique

The technique used by us involved the insertion of a Currie cannula without preliminary analgesia, except in two apprehensive patients who received intravenous pethi-

dine (50 mg.). A watertight seal was readily obtained by the use of this cannula, and no examination failed because of vaginal reflux. Owing to their dubious value no tests of sensitivity to the medium were made, apart from inquiries regarding previous allergic manifestations.

The medium was used at room temperature, its relatively low viscosity allowing ease of manipulation, whilst the extent of uterine filling can be assessed by the degree of resistance. This was also directly observed by briefly screening the pelvis, using the smallest practicable aperture. Films in the postero-anterior and oblique projections were taken as required.

The total amount of contrast used varied from 4 to 6 ml., and an average examination involved three exposures.

Results

Eighty consecutive hysterosalpingograms of 75 patients were taken between March and October, 1956. In 48 of these patients the indication for the investigation was primary infertility. The remaining 27 were investigated for secondary infertility, recurrent miscarriages, suspected uterine and developmental abnormalities, or other tubal or uterine lesions. In 65 of these patients one or more tubal insufflations had been done prior to the radiography. In 60 there was an exact correlation between the findings on hysterosalpingography and on insufflation. Of the remaining five, two showed tubal patency on insufflation but the hysterosalpingogram showed infundibular occlusion, presumably due to spasm. Octyl nitrite was not administered during the course of these salpingograms. In the other three cases insufflation had indicated tubal occlusion, despite the administration of octyl nitrite, but patency was demonstrated by the hysterosalpingogram.

Of the whole group of 75 cases, 17 showed a bilateral tubal occlusion, and in 58 bilateral or unilateral patency was demonstrated by either salpingogram or insufflation, or both.

All the patients were seen one week after the x-ray examination. They were questioned in detail concerning the occurrence of abdominal discomfort, pain, skin rashes, irregular bleeding, or any other abnormal feature. They also underwent pelvic examination.

The complications which follow hysterosalpingography may be considered in two groups: firstly, those inherent to the procedure itself; and, secondly, those which are due to the medium employed. In this series we have been mainly concerned with the complications due to the contrast medium. Indeed, no untoward effects attributable to the instrumentation occurred. Complications following salpingography due to the medium employed have been listed by Marshak *et al.* (1950) as pain, peritonitis, endometritis, allergic phenomena, and emboli.

Pain and Peritonitis

Pain occurred in our series in two groups of cases. In the first group it was noted within 24 hours of the examination, and in the second group it occurred after 24 hours.

Group 1.—In this group 11 patients experienced varying degrees of abdominal pain, and in all of these tubal patency had been demonstrated. A curious feature was that virtually no pain was experienced during the examination. It began sometimes as early as an hour after the examination had been completed, but more usually some two to three hours later, and persisted from 6 to 96 hours, the average duration being about 24 hours. The severity of the pain varied from patient to patient; in only one case of this group was hospital admission necessary. In this patient there was no evidence of pelvic sepsis, the temperature remained normal, and the white blood cell count was not raised. In most of these cases the history of pain was elicited only by direct questioning when the patient attended again. It is interesting to observe that none of the patients were deterred from continuing attendance at the clinic for subsequent investigation.

Group 2.—Pain beginning after an interval of 24 hours occurred in five cases. Two of these patients had bilateral tubal block. In view of the interest of this group of cases they are briefly recounted.

Case 1.—This patient had an acute exacerbation of a previously treated tubo-ovarian abscess. The procedure was undoubtedly undertaken too soon after completion of this treatment (about one month after discharge from hospital), and a pelvic mass was still palpable at this time. Some two months after hysterosalpingography, laparotomy was performed and a right-sided tubo-ovarian abscess was removed. This showed no histological evidence of tuberculosis.

Case 2.—This patient had a low pyrexia (99.8° F.—37.7° C.) and some pelvic pain beginning 24 hours after the examination and persisting for about 24 hours. She was admitted to hospital for observation. The tubercle bacillus was isolated on two occasions by culture of the endometrium.

Case 3.—Tubal patency was established in this patient by hysterosalpingography. About 48 hours after the examination she developed moderately severe lower abdominal pain, which lasted for 48 hours. There was no pyrexia, but a fairly heavy loss occurred, although x-ray examination had been undertaken on the seventh day of an apparently regular menstrual cycle. There was no evidence of any pelvic sepsis, but the patient was noted to be suffering from a monilial vaginitis. The loss ceased after about 48 hours and she had no further complications.

Case 4.—A hysterosalpingogram showed unilateral tubal patency with a closed hydrosalpinx on the other side. Three days after the examination the patient developed lower abdominal pain, which was so severe that she was admitted to hospital and laparotomy was performed, (four days after hysterosalpingography). Torsion of a hydrosalpinx was discovered, and this was removed. The other tube appeared to be quite normal. The histological report from the hospital where the operation was done gave no evidence of tuberculosis in the hydrosalpinx.

Case 5.—Hysterosalpingography was undertaken on the seventh day of an apparently normal 28-day cycle. The patient developed some lower abdominal pain after 32 hours associated with a small amount of vaginal bleeding which persisted for some 24 hours. There was no evidence of pelvic infection.

Other Complications

Endometritis.—We have had little evidence of the occurrence of this complication. In two cases premenstrual endometrial biopsy was performed in the same cycle (one of which had had an early reaction) and no histological abnormality was revealed. It is of interest to note that in three cases endometrial biopsy performed after examination, using a medium containing polyvinyl alcohol, the histology showed exudates and marked round-cell infiltration of the endometrium.

Allergic Phenomena.—In one case angioneurotic oedema developed within one hour of the examination and this was presumed to be due to iodine sensitivity. The patient noted that her voice became husky, and on examination there was swelling of the face, limbs, and eyelids, and a giant urticaria of the trunk and limbs. On admission to hospital she improved after subcutaneous adrenaline and oral antihistamines, but the urticaria did not subside completely for 24 hours. She had no abdominal pain, though tubal patency was present, and there was no evidence of vascular extravasation.

Emboli.—As would be expected with an aqueous medium, no embolic phenomenon occurred, although in four cases vascular filling was observed. In three of these there was bilateral tubal block. Abdominal pain was not noted in this group of patients.

Haemorrhage.—This is thought by Marshak *et al.* to be an inherent risk. In our series seven cases noted bleeding; in six of these it was trivial and mainly associated with an irregular menstrual cycle, so that the timing of salpingography was difficult.

Discussion

Radiographically, endografin shows adequate contrast. Its viscosity allows excellent visualization of the uterus and tubes, permitting selective radiography, yet its dispersal is rapid enough to enable the investigation to be completed in 15–20 minutes, and there is no danger of residue. Films

taken two hours after the injection of the medium have shown complete absorption in normal cases. It is easy to inject, there is no tendency for the substance to crystallize out of solution, and it does not have to be warmed before use. The medium gives rise to no undue tubal spasm and easily penetrates narrow channels and sinuses.

We have had one instance of iodism, but such sensitivity reactions appear to be inherent in all iodine-containing compounds.

We regard pain of early onset (group 1) as being due to peritoneal irritation, and at least two of the five cases in which pain occurred after an interval of 24 hours also appear to be of this type. We have no explanation why there should be a delay between the injection of the material and the onset of pain. The occurrence of this reaction does not seem in any way to interfere with the passage of fertilization of the ovum, since of the 11 patients with early reactions three became pregnant in the same menstrual cycle and one in the subsequent cycle. The patient with the iodine-sensitivity reaction also became pregnant in the subsequent cycle.

In attempting to assess the importance of this pain we should remember that Marshak *et al.* state that some pain and discomfort occurred from 80% of the 2,500 hystero- and salpingographies undertaken, and it is worth restating that the pain did not seem to be severe enough to deter our patients from further investigation at the clinic.

It is possible that the injection of endografin may interfere with pregnancy, since in one patient in whom there was a grossly irregular menstrual cycle it was subsequently stated that she had an early miscarriage. This, however, occurred in another hospital, and we have been unable to obtain confirmatory evidence.

In relation to infection, one exacerbation of a tubo-ovarian abscess did occur; but we do not think that the medium alone could be blamed for this, since the timing medium alone could be blamed for this, since the timing of the investigation was a little premature. Three cases of tuberculous salpingitis were investigated; in only one of these was there a reaction (Case 2), and it was of a very mild nature, so that we feel that there is no undue risk, with this substance, of lighting up pre-existing pelvic infection.

In conclusion, we feel that the occurrence of pain can be kept to a minimum if only the smallest satisfactory amount of the medium is injected. Whilst the production of pain is certainly a great disadvantage, we feel that in view of its other advantages endografin merits an extended trial.

Summary

Hysterosalpingograms were taken in 75 cases, using endografin.

The merits of this contrast medium are discussed and also its disadvantages. Of the latter, the most serious is the occurrence, within 24 hours of the examination, of the lower abdominal pain; this occurred in 11 cases. This pain is regarded as being due to peritoneal irritation.

Pain of later onset is also discussed, and brief notes are given on the five cases in which it occurred.

Our thanks are due to Professor A. S. Duncan and Dr. E. H. Hanson for permission to publish the case reports; to Dr. A. C. Coulthard, who carried out the first 10 hysterosalpingograms, and to Dr. J. Grant for her assistance in the infertility clinic. The earlier supplies of endografin were obtained for us by Mr. G. C. Duncan, of Pharmethicals Ltd., to whom we are grateful.

A NEW METHOD OF TREATING OLD ULCERS OF THE LEGS

BY

KEITH BALL, M.D., M.R.C.P.

Assistant Physician, Central Middlesex Hospital

AND

DAVID PHEAR, M.D., M.R.C.P.

Senior Medical Registrar, Central Middlesex Hospital

With this title Baynton in 1799 described a method of firm compression bandaging of the leg for the healing of leg ulcers. It is now accepted that the keystone of successful treatment is such firm compression, to prevent the venous stasis and oedema that predispose to ulceration and prevent healing (Dickson Wright, 1931). But this principle has not been widely applied. Too often local applications to the ulcers are continued for years without improvement. Healing is achieved by periods of bed rest, only to be followed by relapse on resuming normal activities. When venous drainage has been permanently impaired by previous deep venous thrombosis, compression must be continued indefinitely. Even in the minority with leg ulcers due to varicose veins (Anning, 1954), surgery to the veins should be undertaken only after the ulcer has been healed with compression bandages (Dickson Wright, 1940). We here describe the successful use of stockinet bandaging, a technique first described by Jaeger (1936) and developed by Birger (1947). Our interest in the method was stimulated by a visit to Dr. Birger in Arlöv, Sweden. The results which he obtained in his own general practice were so impressive that we decided to use his technique. The method is cheap and simple, and usually enables the patient to continue at work during treatment.

Method

First, a local dressing is applied to the ulcer and surrounding eczema. The actual application used is of secondary importance. Chlortetracycline powder is helpful in controlling infection. A useful astringent preparation is a 1% aqueous solution of gentian violet. For weeping eczema 1/8,000 potassium permanganate baths are often effective, followed by a dressing of paraffin and acriflavine emulsion or gentian violet as exudation decreases. To limited areas of acute eczema, 1% hydrocortisone ointment may be applied.

Over the local dressing is applied a bandage of cellulose wadding reaching from toes to knee. This material is sold in rolls 12 in. (30 cm.) wide and consisting of approximately sixteen layers. The rolls should be cut lengthways into three strips, each 4 in. (10 cm.) wide, and these should then be divided into two bandages of eight layers' thickness.* The cellulose wadding absorbs secretions and prevents grooving of the skin by the final compression bandage.

The main compression bandage consists of not less than seven yards (6.4 metres) of 4-in. (10-cm.) tubular stockinet, of the type used by orthopaedic surgeons.† Each patient is provided with two bandages to allow for laundering; stockinet should not be ironed. When dry, the stockinet tube is drawn up on to one arm to restore its width and elasticity, and is rolled up tightly before use. The technique of

*Cellulose wadding bandages, prepared to the right width and thickness, are obtainable from Robinson and Sons Ltd., Chesterfield, Derbyshire.

†These bandages are sold by John Bell and Croyden Ltd., Wigmore Street, London, W.1. The cost of the two bandages required for each leg is approximately 10s.

bandaging is of supreme importance, and to achieve success diligent practice is required. Really firm bandaging is essential, and unless some initial discomfort is produced by the bandaging it is unlikely to be effective. Starting from the medial aspect of the leg, a fixing turn is first placed above the ankle (Fig. 1). A turn is then placed round the point of the heel, followed by one around the base of the toes.

FIG. 1.—Stages in the application of the stockinet compression bandage. Reproduced from Dr. I. Birger's paper (1947).

The bandage is usually left for a week unless excessive secretions indicate the need of more frequent dressings at the start of treatment. When the ulcer is healed, only the stockinet bandage is needed. The patient is taught to apply it herself each morning before rising. The more severely affected legs require the compression of stockinet bandages indefinitely. When less support is needed and the ulcer has been firmly healed for some weeks, medium- or heavy-weight elastic stockings may be adequate. Patients are then seen at follow-up visits two or three times each year.

Clinical Material

Until two years ago the treatment of leg ulcers was divided between several clinics. Effective treatment requires time, patience, and enthusiasm—qualities which were rarely forthcoming in such circumstances. Undoubted improvement has resulted from the establishment of a special clinic for these patients, where one or two nurses are specially interested in applying the technique. We here describe the results of treatment in 50 consecutive patients with leg ulcers treated in this clinic. Two patients who were treated for less than two months have been excluded from the series.

The mean age of our patients was 62 years, with a range from 23 to 83. The accompanying Table shows the aetiology

Aetiology of Leg Ulcers in 50 Cases		
Primary varicose veins	..	16 (32%)
Following deep thrombosis:		
Pregnancy	..	10
Trauma	..	4
Others	..	12
No known cause	..	8 (16%)
		26 (52%)

of the ulceration, so far as could be determined. Both legs were affected in 12 of our 50 patients. The initial area of ulceration was larger than 15 sq. cm. in 19 patients, between 15 and 5 sq. cm. in 15, and smaller than 5 sq. cm. in 16.

Results

Of the 50 cases, 42 have healed after a mean treatment period of 3.7 months (standard deviation = 3.1 months). The mean total length of ulcer history in the 50 cases was 11 years. The mean length of the present relapse of ulcer was 5 years.

The following is a typical case history.

A woman aged 39 had developed a post-partum deep venous thrombosis in the left calf after her second pregnancy 10 years previously. Swelling of the leg had persisted since then. Her third pregnancy was uneventful, but during her fourth pregnancy, at the age of 31, ulceration of the left leg developed, followed two years later by ulceration of the right leg. Three periods of in-patient treatment, with a right lumbar sympathectomy and skin grafts, had achieved only temporary healing of the ulcers.

FIG. 2.—Chronic leg ulcer at start of compression bandaging. FIG. 3.—Healing after six months' treatment.

Pain was severe, requiring six or eight aspirin tablets daily, and her husband was in favour of amputation. At her first attendance there was considerable oedema of both shins. The ulcer on the left ankle was healed, but above the right lateral malleolus was an ulcer 76 by 46 mm. in size, with extensive surrounding induration (Fig. 2). Compression bandaging was started. Pain was rapidly relieved, and within six months the ulcer was firmly healed (Fig. 3). She was treated solely as an out-patient.

In only five of the successful cases were periods of treatment in bed required. Of the eight which failed to heal, three showed very marked improvement without complete healing of the ulcer. Surgery has been advised in three; in one, healing has resulted from operation, while two more are awaiting surgery. The remaining two patients defaulted from the clinic. This technique has also been used successfully for 45 patients with oedema and eczema but no ulceration.

Similar results can be obtained by other methods of compression treatment, but this method has several advantages. Skin sensitivity, so often produced by adhesive bandages, does not occur; a stockinet bandage can be used repeatedly over many months, and is therefore much cheaper than an adhesive bandage to be used once only; patients can continue at work during treatment; and the method is easily applied in general practice.

Summary

A cheap and effective method is described for the treatment of leg ulcers due to chronic venous insufficiency. The technique has been used successfully in

general practice. Of 50 patients with leg ulcers, 84% have been healed within a few months.

We thank Dr. Inge Birger for stimulating our interest in this method; Sister Deane and Sister Norman for their enthusiastic treatment of these patients; and Mr. A. Booker for the photographs.

THE RESULTS OF CHEMOTHERAPY IN THE TREATMENT OF TUBERCULOUS PLEURAL EFFUSIONS

BY

ARNOLD PINES, M.D., M.R.C.P.Ed.

Department of Tuberculosis and Diseases of the Respiratory System, University of Edinburgh

The ultimate results of the treatment of tuberculous pleural effusions by chemotherapy are uncertain and have been little investigated (Crofton, 1956). Anti-tuberculosis drugs are used in the hope of abating early symptoms, of hastening the absorption of the effusion, and of preventing later and more serious tuberculous sequelae. Their variable effect upon these early manifestations has often been described (Gerocarni, 1949; Chu, 1949; Moyer, 1949; Danopoulos and Melissinos, 1951; Baue and Vannini, 1951; Stadler, 1951; Emerson, 1955). In contrast, only two studies have been published which have attempted to assess their long-term prophylactic value (Emerson, 1955; Falk and Stead, 1956), although streptomycin and para-aminosalicylic acid have been used in treatment since 1947.

From 20 to 30% of patients who have suffered from primary tuberculous pleural effusions eventually develop fresh pulmonary and extrapulmonary tuberculous lesions (Robson, 1952; Emerson, 1954). Bed-rest at the time of the effusion has generally been ineffective in preventing this (Emerson, 1954), although success has often been claimed (Roper and Waring, 1955). The chief aim of the present study has been to assess the efficacy of post-chemotherapy in preventing this high incidence of post-tuberculosis. The investigation is retrospective: a control trial at the present time would be quite unethical.

Material

Sources.—Full records and radiographs were obtained of all patients with tuberculous pleural effusions who had been treated in the country branch of the London Chest Hospital from 1949 to 1953. They came largely from east and north-eastern London, and had been diagnosed at clinics or hospitals in that area. Some had been treated for short periods in these latter before being transferred.

Diagnosis.—Cases were studied only if the lung fields were clear on radiographs taken during the whole time that the effusion was present. Where a parenchymatous lesion was seen or a non-tuberculous cause was suspected, these cases were discarded. In all, an effusion of varying size was present, the fluid was invariably and predominantly lymphocytic, and the Mantoux test was positive to 1 or 10 international units of old tuberculin. Of the 56 cases finally studied, there was a family or contact history of tuberculosis in 16. Tubercle bacilli were isolated from the pleural fluid, sputum,

or gastric washings in only 15 patients; though not a high proportion, this finding is comparable to those of many other series where laboratory search for tubercle bacilli has not been exhaustive (Thompson, 1946).

Follow-up.—Because the great majority of tuberculous lesions develop during the first two or three years after the effusion (Thompson 1946; Emerson, 1954; Roper and Waring, 1955; Wynn-Williams and Shaw, 1955), only patients who had been observed for at least 2½ years were included. Many patients were still attending at the out-patient departments of the London Chest Hospital or at their original hospital or chest clinic. Those who had not been so observed were recalled to their local chest clinic, were examined, and a chest x-ray film was taken. In addition, most of them answered a letter inquiring for specific details of health since their original treatment. All the original suitable patients were thus traced, except four who eluded all inquiry; none of these last had received chemotherapy. The proportion followed for various periods is given in Table I; the majority have been observed for over five years since their effusion.

TABLE I.—Follow-up

Duration	No. of Cases		
	Chemotherapy	Relatively Untreated	Total
2½–3½ years	6	3	9
3½–4½ "	3	4	7
4½–7 "	15	25	40

TABLE II.—Comparison of Groups

	No. of Cases	
	Chemotherapy	Relatively Untreated
Male	12	9
Female	12	23
Age 16–20 years	7	16
" 21–30 "	15	14
" 31 and over "	2	2
Family or close-contact history	8	8
Size of effusion*		
Up to dome of diaphragm	5	5
" hilum	7	13
Above "	12	14

* There were no bilateral effusions.

Division of Material.—After analysis of the records the cases were divided into two groups according to whether they had received efficient chemotherapy or not. In the first there were 24 patients who had received various forms of effective chemotherapy in addition to bed-rest, while, in the second, 32 had been treated by bed-rest alone. Features of the two groups are compared in Table II. They are not completely matched, but most of the differences are probably not of major importance. So far as the retrospective nature of the study permits, therefore, a comparison may be made between the effects of bed-rest alone and of bed-rest with chemotherapy in these patients. There was concurrence in time of both groups, and the duration of follow-up was proportionately equal in both (see Table I); but there was a tendency for more of the effusions with severe manifestations to be treated with chemotherapy.

Treatment

Both groups were treated initially with strict bed-rest, which lasted for an average of three months. In the chemotherapy group drugs were given for periods ranging from

TABLE III.—Chemotherapy

Type	No. of Cases
Streptomycin 1 g. and para-aminosalicylic acid 15–20 g. daily three times weekly and para-aminosalicylic acid 15 g. daily	17
Streptomycin 1 g. and isoniazid 300 mg. daily	2
Para-aminosalicylic acid 15 g. and isoniazid 300 mg. daily	3
	2

As there was clearly a large amount of foreign material still in the bronchial tree, an emergency bronchoscopy was performed at 3 a.m. on December 4. The airway was cleared of a large quantity of milky, frothy mucous fluid. Although the trachea was markedly deviated to the left there was no obstruction to the passage of the bronchoscope. Following this, her condition improved slightly, although she never regained full consciousness. An endotracheal tube was left *in situ*. Her mouth filled up repeatedly with purulent fluid, which was aspirated at regular intervals. Many attempts to abandon the use of the endotracheal tube were followed after a minute or so by coughing, cyanosis, and a deepening of the level of coma. Relief was obtained immediately by reinsertion of the tube and aspiration of fluid from the trachea. A stomach tube could not be passed, and after repeated attempts it was concluded that virtually complete oesophageal obstruction was present. Throughout the pre-operative period glucose fluids were given intravenously.

Later on December 4 a lumbar puncture was performed; the cerebrospinal fluid was under normal pressure and had normal constituents. Blood biochemistry and counts were also within normal limits.

On December 6 she was still comatose, with no localizing signs in the central nervous system. It was therefore decided to carry out an oesophagoscopy to try to determine the nature of the obstruction. This showed that the upper end of the oesophagus was displaced backwards and to the left. An extrinsic obstruction was encountered just below the level of the cricoid cartilage. Immediate exploration of the neck was carried out.

Operation

The thyroid was exposed by one of us (A. G. E.) through the routine incision. The trachea had been pushed to the left by a large thyroid adenoma occupying most of the right lobe of the gland and extending retrosternally. This was delivered with moderate ease and removed, a small posterior fragment of normal gland being left *in situ*. The trachea, however, remained to the left side, and exploration of the left lobe of the gland showed it to be elongated and flattened, with two nodules about 1½ in. (3.8 cm.) in diameter occupying the lower pole. The inferior nodule had become retro-oesophageal, and appeared to be compressing the oesophagus against the trachea and holding both structures over to the left. After delivery of this lobe the trachea returned immediately to the midline. The lower pole was then removed and the remainder of the lobe sutured to the highest point of the trachea. This was followed by routine closure of the wound with drainage.

Post-operative Course

The patient recovered consciousness while still in the theatre and a few hours later had no difficulty in swallowing. Apart from a mild tracheitis and a small wound haematoma, her convalescence was completely uneventful. She had no further attacks of epilepsy or breathlessness. One month after discharge she had a grand-mal attack which was not associated with breathlessness, stridor, or cyanosis.

Examination of the excised thyroid tissue showed it to consist of degenerating adenomata in a nodular colloid goitre. There was no evidence of malignancy.

Comment

Dysphagia is a decidedly rare feature of simple goitre, occurring in about 0.2% of such cases, although it is more common in association with intrathoracic goitres (Keynes, 1950; Rundle, 1951). Hoffman (1955) has recently found this symptom in 8 out of 32 cases of intrathoracic goitre. Complete obstruction, demonstrated in our case by the collections of fluid in the nasopharynx, with the failure to pass a stomach tube or oesophagoscopy, is very uncommon.

Our patient came into hospital unconscious, and remained so until after the thyroidectomy. The coma deepened when anoxia was produced by removal of the endotracheal tube. Apart from this, the cause of the unconsciousness was not clearly understood. There were many possible factors:

cerebral anoxia, cerebral oedema, and epilepsy may all have played some part. It is possible that there was some reduction in the cerebral blood flow through the carotid and vertebral arteries, but no obvious abnormality in these vessels was detected at operation. There was obstruction to the return of blood through the external jugular vein, and it is possible that there was a similar obstruction of the deep veins. The most severe degree of anoxia followed inhalation of nasopharyngeal secretions accumulating in the short segment of the oesophagus above the obstruction and spilling over into the bronchial tree.

We wish to express our thanks to Dr. Una Ledingham and Miss G. M. Barry for permission to report this case.

ADDENDUM.—In the last year the patient has developed a tremor of the red nuclear type affecting the head and upper limbs.

A NEW EVACUANT SUPPOSITORY

RESULTS IN TREATMENT OF RECTAL DYSCHESIA OF CHRONIC SICK AND GERIATRIC PATIENTS

BY

A. N. G. CLARK, M.D.

Geriatric Unit, St. James's Hospital, Leeds

Recently a new laxative agent has been described (4,4'-diacetoxy-diphenyl)-(pyridyl-2)-methane, "dulcolax," and this has been followed by a number of enthusiastic reports in the German literature. Förtsch (1953) has reported it to be orally effective in gynaecological patients, and when administered as a suppository it has been shown to be a very useful measure in evacuating the colon prior to radiography (Kolshorn, 1954). Although the precise mode of action of the drug is not clear, this is stated to be by means of a surface-contact effect promoting colonic peristalsis. It is reported to be non-toxic by the oral route (Scott, 1956) and not absorbed systemically.

Patients who are confined to bed in hospital for long periods often develop rectal dyschezia. This is particularly seen in geriatric cases and the special younger group of chronic sick. In view of the claims that have been made for this drug it was decided to record its effects on a group of these patients when administered rectally as a suppository containing 10 mg. of the active constituent.

The trial was carried out in two parts. Initially the suppositories were administered in a routine fashion in order to assess their effectiveness, and later they were used in a second series of patients who were considered to require an enema.

Method

The patients were from wards of the Geriatric Unit and a long-stay annexe. The nursing staff kept a careful record of the results. For the first part of the trial patients were chosen who were having regular enemata or who had had no bowel action for three or more days. Most of the patients were receiving a variety of aperients, and these were stopped for the period of the trial. The nursing staff were given instructions to insert one suppository as high as possible into the rectum with the gloved finger, and at the same time a note was made of the rectal contents. Later the patient was placed, whenever possible, on a commode or, more rarely, on a bedpan. The time from insertion of the suppository to bowel action was recorded. The result was assessed as one of four grades. Grade 1, Excellent: the result being as good as a successful enema or normal bowel

action. Grade 2, Moderate: here a result occurred which was satisfactory but not as large as those classed as excellent. Grade 3, Poor: the stools consisting of a small quantity of constipated faecal masses. Grade 4 patients showed no response. The consistency of the stools was recorded as (a) hard, (b) soft yet formed, or (c) loose or unformed. Signs of discomfort, abdominal pain or colic, bleeding or signs of collapse were carefully watched for. Patients who had no result were re-examined rectally to see if faecal matter was present.

The second part of the trial consisted of the administration of the suppositories to patients who required an enema. It was arranged that on four wards of the Geriatric Unit all enemata were to be stopped for a period of one month and the suppositories used in their place. After noting the pre-sense of the contents of the rectum a suppository was inserted and the events thereafter were recorded as in the first trial. If no motion occurred after two hours another suppository was inserted and the results were noted. If this second suppository was not followed by an evacuation a simple senna or agar emulsion aperient was administered that evening with the use of a further suppository the next morning. A record of the results was kept throughout these stages.

Results

In the first trial 289 suppositories were administered to 84 patients. The patients' ages varied from 32 to 92 years; more than three-quarters were over the age of 70, and a little under half were over the age of 80. The majority of the patients were frail and aged. 26 patients required the use of regular enemata, or digital rectal evacuation to be performed by the nursing staff, and most of these patients had been bedfast in hospital for many years.

Table I gives the results in the first series of patients. In 246 (75%) instances the administration of one suppository produced a result which was thought to be as good as a successful enema.

TABLE I.—Results of First Trial

Ward:	A	B	C	D	E	Totals
No. of patients	19	15	17	13	20	84
No. of suppositories given	128	61	47	23	30	289
No. having regular enemata	11	3	—	2	10	26
Results:						
I, Excellent	117	52	17	8	22	216 (75%)
II, Moderate	8	9	13	6	3	39 (13%)
III, Little	3	—	12	6	3	24 (9%)
IV, None	—	—	5	3	2	10 (3%)
No. of bowel actions:						
One	122	60	28	19	27	256 (88%)
Two	6	1	10	1	—	19
Three or more	—	—	4	—	—	4

In 34 (12%) instances the result was classed as being "little" or "none." In 256 (88%) instances the result was a single action of the bowel.

In only 9 out of 263 instances the stools were loose and unformed; in the great majority of cases they were soft and formed. It was concluded that there was little tendency for diarrhoea to occur.

In 10 instances no evacuation followed the use of one suppository in this first series. In one of these the rectum was excessively loaded with faeces; the other nine were considered to have had no result because the rectum and sigmoid colon were thought to be empty.

TABLE II.—Results of Second Trial

Ward:	E	F	G	H	Totals
No. of patients	19	12	9	8	48
Occasions enema required	112	17	12	14	155
No. of good results, one suppository	91	15	12	13	131 (84%)
No. of good results, second suppository	10	2	—	—	12 (8%)
No. of good results, aperient and suppository	11	—	—	1	12 (8%)
Occasions enema given	—	—	—	—	—

The results of the second series are given in Table II. In the four wards during the four-weeks period there were 155 occasions when an enema would have been given. In 131 (84%) instances an excellent result occurred following the use of one suppository only. In a further 12 instances a satisfactory result was obtained after using a second suppository. The remaining 12 occasions produced a satisfactory result after the use of a nocturnal aperient and a suppository next morning. In none of these cases was an enema necessary, and none was given on these wards during the period of these observations.

The incidence of side reactions was negligible. During the administration of 480 suppositories slight abdominal pain was noticed in three patients, a feeling of nausea was present in one, and vomiting occurred during the night in a further patient, although this latter symptom may have been unrelated.

The times taken for the suppository to produce evacuation of the bowel in 100 consecutive administrations are given in Table III. The majority of actions occurred 30–60 minutes

TABLE III.—Time from Suppository to Bowel Action in 100 Patients

	¼ Hour	1 Hour	1½ Hours	2 Hours	2½+ Hours
No. of patients	5	56	15	15	9

after insertion of the suppository. It should be noted that few (5%) occurred before 30 minutes and many (39%) after 60 minutes had elapsed.

Discussion

Experience with this new laxative agent in suppository form has shown it to be effective in the treatment of rectal dyschezia. It can be used in the place of an enema. There are distinct advantages in its use in the aged. Many geriatric patients in the trial had been receiving regular or occasional enemata for years. These were sometimes followed by circulatory collapse requiring stimulants. They are now able to use the commode with no ill effects.

Certain other patients are worthy of mention. In one ward there were three bedfast patients aged 47–54 years suffering from post-encephalitic Parkinsonism. They had all been cared for in hospital for periods exceeding 20 years. As is common in this condition, their appetites were voracious. Twice weekly, for at least six years, they received enemata and often required digital evacuation of a large faecal bolus. They are now managed satisfactorily by the suppository method and have not required an enema for the last four months. It has been found to be most effective when combined with an aperient given during the preceding evening.

The suppositories have been the treatment of choice in the case of two patients with extensive abdominal carcinomatosis in whom the enema or aperient therapy was badly tolerated and produced severe discomfort. The ward sister noted that a better result was obtained if the suppository was retained as long as possible and the foot of the bed was raised after insertion.

Several incontinent and demented senile patients with very dirty habits also benefited from the use of the suppositories. Aperients given to these patients often caused aggravation of the incontinence, and often with looseness of the stools throughout the following day. These patients, on the whole, have had their habits, as they are related to rectal distension, improved by the suppository routine. Several have been re-trained to use the commode after long periods of incontinence.

The simplified management of these patients has also been felt by the nursing staff. On one ward two days weekly were given over to the administration of 7–10 enemata; none of these are now given. There has been a saving of time and unpleasantness both for patients and for nursing staff. The need for changing and sluicing of bed-linen has been greatly reduced.

There were some failures to respond to the suppositories. Some of these were explained by the fact that the lower bowel was empty. It was ineffective in a few patients with a large rectal bolus. Earlier in the trial recourse to the commode or bedpan was at times prematurely made. Some patients express a desire to defaecate soon after the insertion of the suppository, and it may be passed before it has undergone solution. This should be disregarded, and the patient does not require placing on the commode until, at the minimum, 20 minutes have elapsed.

In the eight wards in which the drug has been tried enemata have no longer been necessary. It appears that the suppositories possess advantages for use in domiciliary nursing practice. It is concluded that this drug is a valuable, convenient, and effective method of treating the rectal dyschezia of aged and chronic sick patients.

Summary

A clinical trial of a suppository containing a new laxative agent (4,4'-diacetoxy-diphenyl)-(pyridyl)-2-methane ("dulcolax") is reported.

It appears to be effective in the treatment of rectal dyschezia in a group of chronic sick and aged patients.

It has been shown to be capable of replacing the enema in 84% of instances by the use of one suppository only.

Benefits from the point of view of the patient and management by the nursing staff are stressed.

Side effects so far observed are negligible.

I wish to thank Dr. H. Droller for permission to study patients under his care, and the nursing staff of the geriatric wards at St. James's and St. Mary's Hospitals, Leeds.

Applied Medical Bibliography for Students (Charles C. Thomas, 32s. 6d.) is intended to serve as "a guide to the students who must acquire a knowledge of the literature of their profession." Its author, W. D. Postell, is a professor of medical bibliography at Louisiana State University School of Medicine, and he contends that, "for the students to be able to use the library and its facilities to advantage, formal instruction in applied bibliography is an essential part of their education." Apparently in pursuance of this idea he includes at the end of the book a list of 45 questions on its subject-matter, arranged chapter by chapter. A short history of medical journalism is followed by an account of the different types of medical journal published to-day—general, review, abstracting, and so on—and the author describes the use of encyclopaedias, indexes, and works of reference. He also includes short sections on literary style and composition. The value of the book is much diminished by the author's deliberate exclusion of any reference to journals not written in English.

A number of changes have been made in the 23rd edition of *Dorland's Illustrated Medical Dictionary* (W. B. Saunders Co., Ltd., London, pp. 1,598+ xvii, 87s. 6d.). Formerly known as the *American Illustrated Medical Dictionary*, it has been renamed to commemorate W. A. N. Dorland, who edited the twenty-two previous editions and by whose name the dictionary is already familiarly known. The rapid expansion of the medical vocabulary during recent years is reflected in the dictionary, which has increased its page size to accommodate many new terms. Besides these, thousands of definitions have been scrutinized and many have been rewritten to conform with changing concepts or expanded knowledge. Detailed descriptions of specific techniques (e.g., in staining and many other procedures) have been dropped, and the dosages of specific compounds have been replaced by a table of modern drugs and dosage currently accepted by the American Medical Association. The new type-face used in this edition is a great improvement on the old. The postage-stamp-size portraits familiar in previous editions have been omitted, and the illustrations, though fewer in number, have in many cases been redrawn in keeping with the modern setting and outlook of the dictionary.
